The data from the study of predictive ability were compiled for both the sets of ERL and ERM values (from Long et al. 1995) and the comparable TEL (Threshold Effects Levels) and PEL (Probable Effects Levels) values from MacDonald et al. (1996) to provide a synopsis of the likelihood of significant toxicity in amphipod survival tests (Long and MacDonald 1998). This is an attempt to estimate the likelihood that samples with certain chemical characteristics would be toxic.

Table 4 lists the chemical characteristics that equate to different probabilities of amphipod toxicity based on the data from Long et al. (1998a). Data used to derive **Table 4** were compiled from Long et al. (1998a) in which there were 1086 samples and merged with more recent data from Biscayne Bay (FL) (n=226) and Pearl Harbor (HI) n=219), giving a total data set of 1513 samples. These samples were collected in various studies performed on the Atlantic, Pacific and Gulf of Mexico coasts.

The percent incidence of highly toxic responses and the average survival of the amphipods in all samples within each cateogry are shown in **Table 4**. Four chemical indices calibrated to the SQGs are shown for each of four categories. In category 1, sediments least likely to be toxic were actually toxic in only 8-9% of the samples. Average amphipod survival in these samples was 92-93%, indicating that survival, on average, was not decreased appreciably from what would be expected in clean reference sediments. As the numbers of SQGs exceeded increases and as the mean SQG quotients increase, the incidence of toxicity increases and the average survival rate decreases.

Samples with chemical characteristics equivalent to Category 2 have the most uncertainty as to toxicity. Average survival approximates the critical threshold of 80% of controls, whereas in the other categories, average survival is clearly greater than or less than 80%. In category 3, about 50% of samples were toxic and average survival was about 60-70%. In category 4, about 73-83% of samples were toxic and average survival dropped to about 40%, indicating high probabilities of toxic conditions.

These data may be useful in determining the need for additional testing and analyses of sediments. For example, the probability of incorrectly classifying a site as non-toxic when all chemical concentrations are below all SQGs and either of the mean SQG quotients is less than 0.1 is about 10% and the probability of a site being toxic is about 75% or greater when chemical data match the

characteristics of Category 4 conditions in **Table 4**. However, in sediments classified as Category 2, toxicity or the lack thereof is more uncertain.

Table 4. Percent incidence of highly toxic samples and average percent amphipod survival in marine sediment samples classified according to numerical sediment quality guidelines.

The ERLs and mean ERM quotients for saltwater were more efficient at correctly predicting non-toxicity (100% and 93% correct, respectively) than SEM:AVS ratios (80% correct) based on analyses of data compiled to field-validate the SEM:AVS criteria (Long et al., 1998b). Also, the ERMs and mean ERM quotients were slightly more predictive of toxic conditions (33% and 42% correct, respectively) than the SEM:AVS ratios (26% correct). These data suggest that the predictive abilities of SQGs based on bulk trace metals data are not improved with SEM-to-AVS normalizations (Long et al., 1998b).

Limitations

The SQGs should be used with caution and common sense. There are no SQGs available for many substances that can be highly toxic in sediments. The abilities of the SQGs to correctly predict toxicity of co-varying substances for which there are no SQGs are unknown. The SQGs were derived in units of dry weight sediments; therefore, they do not account for the potential effects of geochemical factors in sediments that may influence contaminant bioavailability. The SQGs were not intended for use in predicting effects in wildlife or humans through bioaccumulation pathways. The SQGs were neither calculated nor intended as toxicological thresholds; therefore, there is no certainty that they will always correctly predict either non-toxicity or toxicity. The SQGs were derived with data from soft sedimentary deposits; they should not be applied to assessments of upland soils, gravel, coarse sand, tar, slag, or metal ore.

The SQGs are best applied when accompanied by measures of effects such as laboratory toxicity tests and/or benthic community analyses and/or bioaccumulation tests, which lead to the preparation of a weight of evidence. Furthermore, they are best applied in a comprehensive assessment framework involving the establishment of clear study objectives, *a priori* methods for data analyses, and well-understood decision points regarding the uses of the data.

ABSTRACT

Sediment quality guidelines (SQGs), based upon empirical analyses of matching chemical and biological data, have been developed for many potentially toxic substances. The predictive abilities and recommended applications of two sets of guidelines, ERLs/ERMs and TELs/PELs, are discussed in this paper. The SQGs were intended as informal (*i.e.*, non-regulatory) benchmarks to aid in the interpretation of chemical data. Low-range values (*i.e.*, ERLs or TELs) were intended as concentrations below which adverse effects upon sediment-dwelling fauna would be expected only infrequently. In contrast, the ERMs and PELs represent chemical concentrations above which adverse effects are likely to occur. Evaluations of the reliability and predictive ability of the SQGs indicate they can be used effectively to assess the quality of soft, aqueous, sedimentary deposits. Specifically, the SQGs can be used to classify sediment samples with regard to their potential for toxicity, to identify contaminants of concern, and to prioritize areas of concern based on the frequency and degree to which guidelines are exceeded. Toxicity and bioaccumulation tests, toxicity identification evaluations, and benthic community assessments provide complimentary information for assessing sediment quality.

INTRODUCTION

Numerical sediment quality guidelines (SQGs) have been developed using a variety of approaches, typically involving statistical comparisons of chemical concentrations and measures of adverse biological effects upon exposure to sediments (see USEPA, 1992a; Adams *et al.*, 1992; Chapman, 1989; Ingersoll *et al.*, 1997 for reviews). For certain substances, equilibrium-partitioning models have been used to develop proposed sediment quality criteria (SQC) (USEPA, 1992b; 1994a, 1994b; Ankley *et al.*, 1997; Swartz *et al.*, 1995). Such SQGs and proposed SQCs were developed to provide effects-based, interpretive tools for assessing the quality of sediments. All values were intended to represent either the chemical concentrations below which adverse biological effects were not expected or levels above which effects, such as acute toxicity, would be expected. Thus far, none of these values have been promulgated and implemented for standards or criteria in the U.S.

All SQGs developed thus far, except for the standards set for marine sediments by the state of Washington (WDOE, 1995) and the five criteria proposed by USEPA (1994a), were intended to provide informal interpretive tools or benchmarks. That is, they were developed to provide a basis for evaluating the risks posed to sediment-dwelling organisms by sediment-associated contaminants. While some agencies have developed their own SQGs, others have elected to adopt guidelines prepared by others. Collectively, we are aware of at least 25 federal and state agencies or programs in North America that have either developed SQGs or adopted those prepared by other organizations.

One set of guidelines — Effects Range-Low (ERL) and Effects Range-Median (ERM) values — was originally calculated to provide a means for interpreting monitoring data collected under the National Status and Trends Program (NSTP) of the National Oceanic and Atmospheric Administration (NOAA) (Long and Morgan, 1990; Long *et al.*, 1995). An anologous set of saltwater values — Threshold Effects Levels (TEL) and Probable Effects Levels (PEL) — was calculated for the state of Florida (MacDonald *et al.*, 1996).

Many scientists and administrators in North America have used available SQGs to rank and/or prioritize chemicals of potential concern in specific regions or hazardous waste sites and/or to rank and prioritize areas for further investigation and/or management action. Other uses of SQGs have included: planning monitoring programs; designing spiked sediment bioassays; interpreting historical data; evaluating the need for further studies; assessing the quality of prospective dredge materials; and conducting remedial investigations and ecological risk assessments of waste sites. Often the ways in which the guidelines have been used were consistent with their original intent. However, we have observed that SQGs have also been used in other ways, occasionally resulting in controversies over their proper use. The objectives of this paper are to: (1) provide a synopsis of the reliability and predictive ability of the two sets of SQGs and (2) provide recommendations on the uses of these SQGs for assessing sediment quality, primarily based upon their ability to correctly classifying sediments as either toxic or non-toxic.

CALCULATIONS OF EMPIRICALLY DERIVED SQGS

This paper focuses upon two sets of saltwater SQGs; ERLs and ERMs (Long *et al.*, 1995) and TELs and PELs (MacDonald *et al.*, 1996). Both sets of SQGs were derived using statistical analyses of matching chemistry and biological data compiled from numerous field, laboratory, and modeling studies performed throughout North America. Sufficient amounts of data were compiled to identify with a weight of evidence the chemical concentrations that were rarely, occasionally, and frequently associated with measures of toxicity. Data were derived from analyses of sediments with different physical and geochemical characteristics and from numerous locations to provide a basis for establishing SQGs that should be widely applicable throughout North America. The majority of the data used to derive the guidelines were from field studies in which mixtures of substances occurred in the samples, thus maximizing the applicability of the SQGs to most real-world situations (*i.e.*, those involving mixtures of contaminants). Data for a variety of toxicological endpoints were gathered from published studies also to broaden the applicability of the resulting SQGs.

ERL and ERM values were derived using only chemical concentrations associated with adverse effects (Long *et al.*, 1995), whereas calculations of the TEL and PEL values incorporated concentrations associated with both effects and no observed effects (MacDonald *et al.*, 1996). The ERL and TEL values represented concentrations below which effects were rarely observed, and, therefore, estimated the low end of the effects range. In contrast, the ERM and PEL values represented chemical concentrations toward the middle of the effects range and above which effects would be likely to occur. However, the ERM and PEL values are not intended to represent effects thresholds above which adverse effects would always be observed (such as with apparent effects thresholds — Barrick *et al.*, 1988). By deriving a lower-range and mid-range values for each substance, we attempted to minimize the incidence of both false negatives and false positives.

RELIABILITY AND PREDICTIVE ABILITY OF EMPIRICALLY DERIVED SQGS

We believe that information on the reliability and predictive ability of numerical SQGs is essential to determining their appropriate uses. A panel of environmental scientists concluded that "field validation is an essential element of the SQGs development process because it provides a basis for assessing their reliability in sediment quality assessments" (Ingersoll *et al.*, 1997). In this context, the term "reliability" is defined as the ability of the SQGs to correctly classify sediments as toxic or non-toxic based upon the data used to derive the guidelines. The degree to which the SQGs correctly classify sediments as either toxic and non-toxic in independent data sets (*i.e.*, not used in the guidelines derivation) is referred to here as "predictive ability". All approaches to the derivation of numerical values have specific strengths and weaknesses (USEPA, 1992a; Ingersoll *et al.*, 1997) that will influence their reliability and predictive

ability. Regardless of how they are derived, SQGs, if they are to be useful, must be shown to correctly classify samples as either non-toxic or toxic under a wide variety of ambient conditions.

Reliability of SQGs.

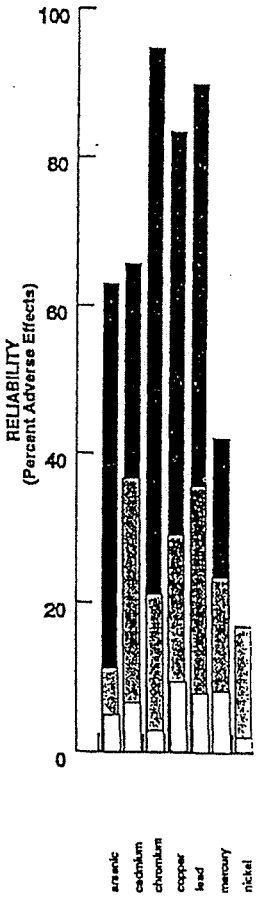
The reliability of both the marine ERL and ERM values (reported by Long *et al.*, 1995) and of marine TEL and PEL values (reported by MacDonald *et al.*, 1996) are summarized in Figures 1 and 2. The percentage of study endpoints showing adverse effects at concentrations less than the marine ERLs ranged from 2% for nickel to 27% for fluorene (Figure 1). For most substances the incidence of effects was less than 15% when concentrations were less than the ERL. The percentages of studies indicating effects with concentrations less than the TEL values were slightly lower than those indicated with the ERL values (Figure 2). For most substances, the incidence of effects ranged from 0% (2-methylnaphthalene) to 16% (total PCBs). An exception was total DDTs; 48% of the studies showed adverse effects at concentrations below the TEL concentrations, and the incidence of effects decreased to 26% at concentrations between the TEL and PEL.

The incidence of study endpoints indicating adverse effects generally increased to 30 to 50% when chemical concentrations were between the ERL and ERM values (Figure 1). For most substances, the incidence of effects increased to 15 to 25% when concentrations exceeded the TELs, but were below the PELs (Figure 2).

Among studies in which chemical concentrations exceeded the ERM values by any amount, the incidence of effects generally ranged from 75 to 100%, indicating relatively high reliability for most substances (Figure 1). When concentrations exceeded the PEL values, adverse effects generally were indicated in 55 to 80% of studies (Figure 2). However, the ERMs and PELs for several substances — notably, chlordane, lindane, nickel, and mercury — were less reliable than those for other substances. Also, the data for total DDT showed relatively high variability.

The percentages of studies indicating adverse effects generally were slightly lower for the TEL and PEL values than for the comparable ERL and ERM values. These small differences were probably attributable to differences in the derivation methods. That is, calculations of TELs and PELs included data from endpoints in which no adverse effects were observed, whereas the derivation of ERLs and ERMs involved the use of effects data only

The saltwater SQGs are comparable to those derived with similar empirical methods, but different data bases, for freshwater sediments (Persaud *et al.*, 1992; Long *et al.*, 1995; Ingersoll *et al.*, 1996). The estimates of the reliability of saltwater SQGs also are similar to those obtained with freshwater SQGs (Smith *et al.*, 1996; Ingersoll *et al.*, 1996). The overall similarity in both the numerical values and the reliability of saltwater and freshwater SQGs suggests that the underlying empirical methods provide a consistent basis for determining chemical concentrations that are likely to be associated with adverse biological effects.



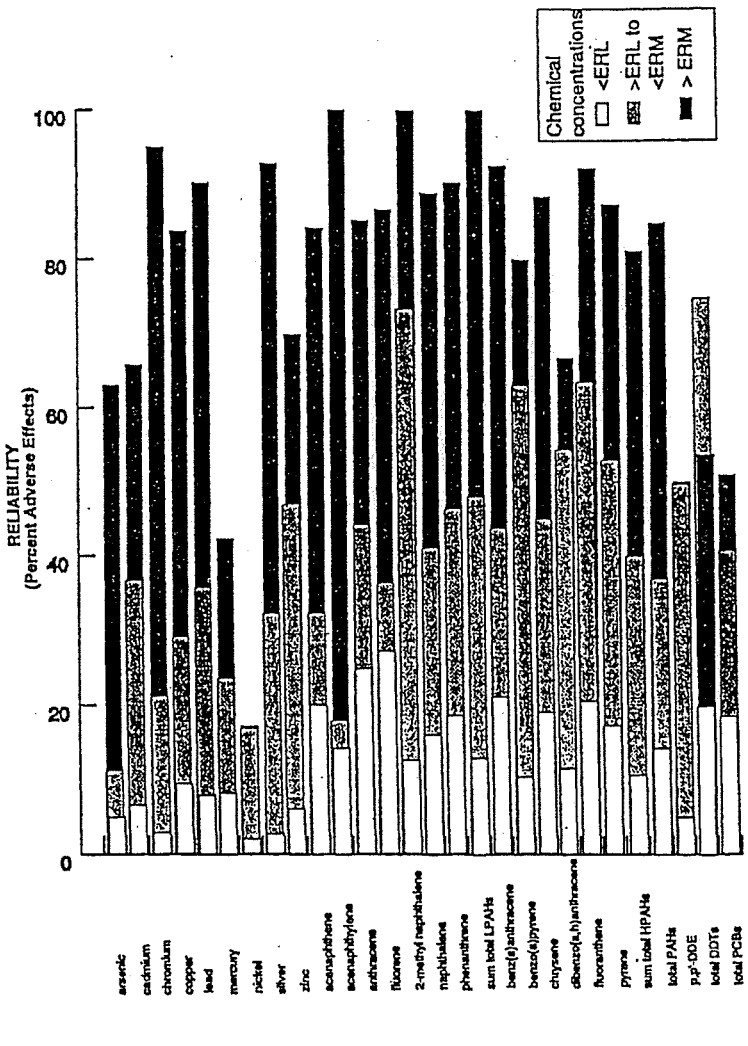


Figure 1. Reliability of marine ERL and ERM values as percentages of study end-points indicating adverse biological effects at concentrations less than the ERLs, equal to or greater than the ERLs but less than the ERMs, and equal to or greater than the ERMs. (From Long *et al.*, 1995.)

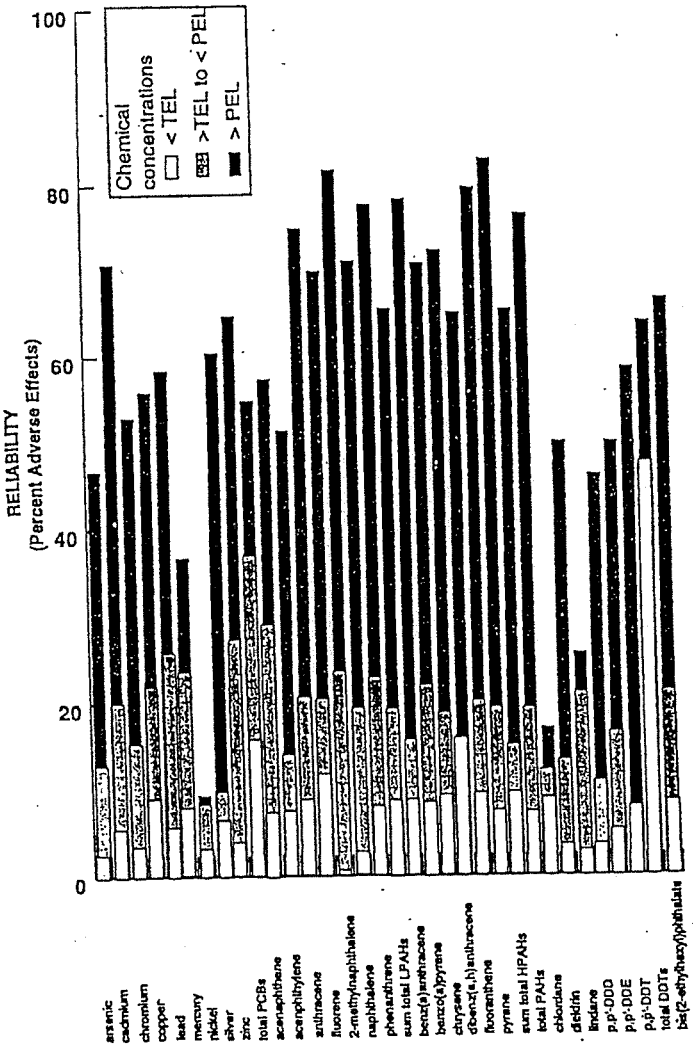

Figure 2. Reliability of marine TEL and PEL values as percentages of study end-points indicating adverse biological effects at concentrations less than the TELs, equal to or greater than the TELs but less than the PELs, and equal to or greater than the PELs (From MacDonald *et al.*, 1996.)

Predictive Ability of SQGs.

Following the analyses of reliability, additional evaluations were conducted to estimate the predictive ability of saltwater SQGs with a large independent data set not used in the guidelines derivation (Long *et al.*, 1998a). Data were compiled from studies performed along portions of the Atlantic, Gulf, and Pacific coasts. The data set was composed of samples in which amphipod survival tests were performed (n = 1068) and in which one to three sublethal bioassays were performed in addition to the amphipod tests (n = 437). Statistical analyses were used to classify samples as either non-toxic ($p > 0.05$), marginally toxic ($p < 0.05$), or highly toxic ($p < 0.05$ and sample means exceed minimum significant differences) relative to controls in the laboratory tests. The predictive abilities of 28 sets of ERLs/ERMs and 33 sets of TELs/PELs were determined.

For most substances, 40 to 60% of samples in which chemical concentrations exceeded individual ERMs or PELs were highly toxic in the amphipod tests (Figures 3 and 4). For example, among the samples in which copper concentrations exceeded the ERM value (n = 25) or the PEL value (n = 179), 52 and 48%, respectively, were highly toxic in the amphipod survival tests. More than 75% of samples were highly toxic in which the ERMs for lead, 2-methylnaphthalene, and acenaphthylene were exceeded. The predictive abilities of the PELs for p,p'-DDE, total PCBs, and lindane were lowest; 33, 39, and 15%, respectively, in amphipod tests. For most substances, an increase in predictive ability of about 20 to 30% occurred when the data from the sublethal tests were included along with the amphipod data. Therefore, for most substances, 80 to 90% of samples were highly toxic in at least one of the tests performed when concentrations exceeded individual ERMs or PELs. For most chemicals, the ERMs and PELs were similar in predictive ability.

To account for the presence of mixtures of chemicals in different concentrations that may have additive toxicity effects, mean ERM and mean PEL quotients were derived as the average of the ratios between the chemical concentrations in the samples and the respective ERM or PEL values (Carr *et al.*, 1996; Long *et al.*, 1998a). The mean ERM quotients corresponded very well with the percentages of the ERMs that were exceeded and with the incidence of toxicity in amphipod tests (Figures 5 and 6). The mean ERM quotients began to exceed 1.0 among samples in which 12 (50%) or more of the 25 ERMs were exceeded (Figure 5). Also, the incidence of highly toxic samples increased to >71% among samples with mean ERM quotients of 1.0 or greater (Long *et al.*, 1998a). The associations between the number of PELs exceeded, the mean PEL quotients, and the incidence of toxicity were similar to those observed for the ERMs (Figure 6); the incidence of toxicity in amphipod tests exceeded 68% among samples with mean PEL quotients of 1.6 or greater (Long *et al.*, 1998a). These data suggest that toxicity increased coincidentally with increases in both the number of guidelines exceeded and with the chemical concentrations of the mixtures of substances in bulk sediments.

MacDonald *et al.*, 1996.)

Figure 3. Predictive ability of 28 ERMs as percentages of samples indicating highly significant toxicity, *i.e.*, $p < 0.05$ and mean survival <80% of controls (data from Long *et al.*, 1998a). Dark bars indicate results from amphipod survival tests performed with either *Ampelisca abdita* or *Rhepoxynius abronius*. Open bars indicate results from any of two to four tests performed, including amphipod tests (see Table 1 for types of other tests). PAH; tPAH = sum of PAHs, DDE = *p,p*-DDE, tDDT = sum of six DDT isomers, tPCB = sum of 26 PCB congeners.

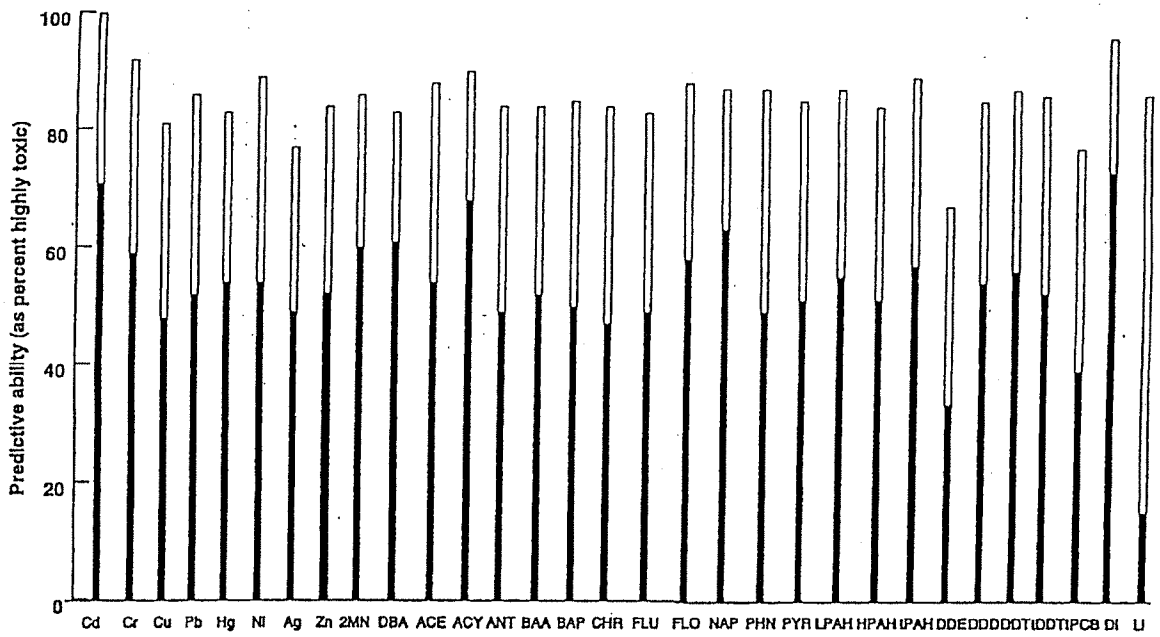

Figure 4. Predictive ability of 32 PELs as percentages of samples indicating highly significant toxicity, *i.e.*, $p < 0.05$ and mean survival <80% of controls (data from Long *et al.*, 1998a). Dark bars indicate results from amphipod survival tests performed with either *Ampelisca abdita* or *Rhepoxynius abronius*. Open bars indicate results from any of two to four tests performed, including amphipod tests (see Table 1 for types of other tests). Chemical abbreviations as in Figure 3, plus: DDD = *p,p'*-DDD; DDT = *p,p'*-DDT; Di = dieldrin; and Li = lindane.

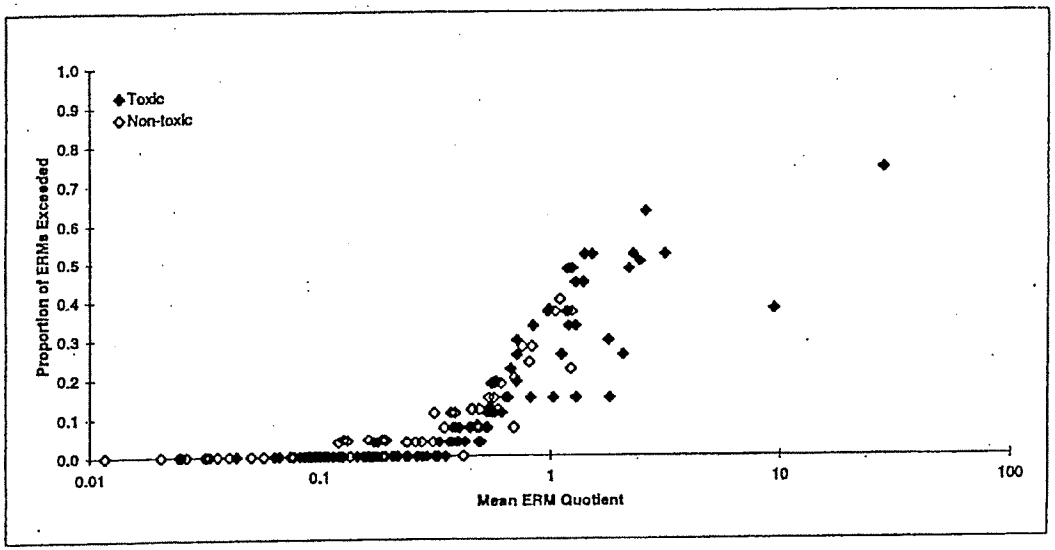

Figure 5. Relationship between the proportion of marine ERMs exceeded and mean ERM quotients. Samples that were toxic in amphipod (*Ampelisca abdita*) survival tests ($p < 0.05$) shown as closed symbols; non-toxic samples ($p > 0.05$) shown as open symbols (n = 212).

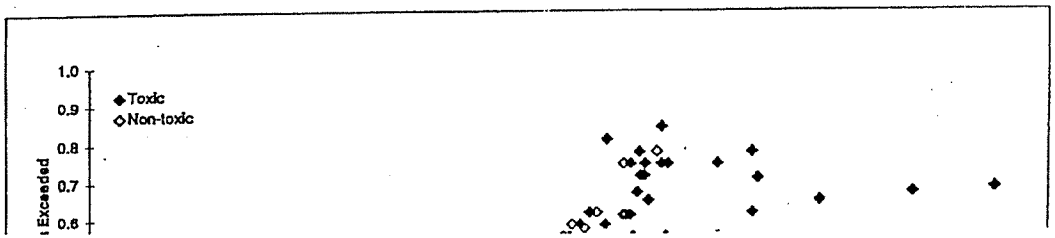

Figure 6. Relationship between the proportion of marine PELs exceeded and mean PEL quotients (n = 212). Samples that were toxic in amphipod (*Ampelisca abdita*) survival tests ($p < 0.05$) shown as closed symbols; non-toxic samples ($p > 0.05$) shown as open symbols.

Estimating the Probabilities of Toxicity with SQGs

Among the samples in which chemical concentrations were < all ERLs or < all TELs, 11 and 9%, respectively, were highly toxic in amphipod survival tests (Table 1). The percentages of samples that were highly toxic when mean ERM quotients and mean PEL quotients were <0.1 were similar: 12 and 10%, respectively (Long *et al.*, 1998a). Therefore, sediment samples in which no ERLs or TELs are exceeded and/or in which the mean SQG quotients are less than 0.1 have the lowest probabilties of highly significant toxicity in amphipod survival tests (9 to 12%).

Chemical characteristics that correspond to the lowest probabilities (9 to 12%), medium-low (24 to 32%), medium-high (46 to 53%), and highest probabilities (74 to 88%) of toxicity in amphipod survival tests are listed in Table 2. Data are shown for both the numbers of chemicals exceeding SQGs and for mean SQG quotients. We recommend these data be used to estimate the likelihood of observing acute toxicity in newly collected marine and saltwater sediments.

The ERLs and mean ERM quotients for saltwater were more efficient at correctly predicting non-toxicity (100 and 93% correct, respectively) than SEM:AVS ratios (80% correct) based upon analyses of data compiled to field-validate the SEM:AVS criteria (Long *et al.*, 1998b). Also, the ERMs and mean ERM quotients were slightly more predictive of toxic conditions (33 and 42% correct, respectively) than the SEM:AVS ratios (26% correct). These data suggest that the predictive ability of SQGs based upon bulk trace metals concentrations is not improved with SEM-to-AVS normalizations (Long *et al.*, 1998b).

The large data set evaluated suggests that some variability exists in the relationships between bulk sediment chemical concentrations and measures of toxicity. However, this variability is equivalent to that observed with the predictive ability of the SEM:AVS ratios (Hansen *et al.*, 1996) and may have been, at least partly, attributable to the uneven distribution of the chemistry data (*i.e.*, too few data points in some concentration ranges). Also, large differences in the physical and geochemical properties of the sediments may have contributed to this variability. Therefore, although the SGQs are not perfect (100%) predictors of non-toxicity and toxicity, it appears that they provide reasonable estimates of the likelihood of toxicity. For example, about 50% of samples were either marginally or highly toxic in acute amphipod survival tests when one or more saltwater ERMs or PELs were equalled or exceeded. Also, about 86% of samples with one or more ERMs or PELs exceeded were either marginally or highly toxic in at least one of a battery of two to four tests performed (Table 1).

The probabilties of observing toxicity generally increased with increases in both the numbers of SQGs exceeded and in mean ERM and PEL quotients (Table 2). Therefore, these data suggest that chemical concentrations normalized to dry wt. can be used to estimate the probability of toxicity. Consequently, we believe that empirically derived SQGs can be used to evaluate the potential

Table 1. Summary of predictive ability[a] of marine ERL/ERM and TEL/PEL values in amphipod survival tests only and in any of 2-4 tests performed (expressed as % of samples indicating toxicity).

Toxicity tests categorized as either marginally toxic (p<0.05 and mean response >80% of controls) or highly toxic (p<0.05 and mean response <80% of controls) and total of both. Amphipod tests performed with Ampelisca abdita and Rhepoxynius abronius. Other tests included sea urchin fertilization (Arbacia punctulata, Strongylocentrotus purpuratus) in pore-water and mollusc embryo development (Mulinia lateralis or Haliotis rufescens in pore-water) and microbial bioluminescence (Microtox) in solvent extracts.

Table 2. Chemical characteristics and probabilities of highly significant toxicity in amphipod survival tests among four categories of sediment samples.

Site Categories	Chemical characteristics	Probability (%) of toxicity in amphipod survival tests*
Highest Priority Sites:		
	• mean ERM quotients >1.5	74% (INJURY / LOST SERVICES)
	• mean PEL quotients >2.3	76%
	• >10 ERMs exceeded	85%
	• >21 PELs exceeded	88%
Medium-high Priority Sites:		
	• mean ERM quotients 0.51-1.5	46%
	• mean PEL quotients 1.51-2.3	50%
	• 6-10 ERMs exceeded	52%
	• 6-20 PELs exceeded	53%
Medium-low Priority Sites:		
	• mean ERM quotients 0.11 to 0.5	30%
	• mean PEL quotients 0.11 to 1.5	25%
	• 1-5 ERMs exceeded	32%
	• 1-5 PELs exceeded	24%
Lowest Priority Sites:		
	• mean ERM quotients <0.1	12%
	• mean PEL quotients <0.1	10%
	• no ERLs exceeded	11%
	• no TELs exceeded	9%

* Data from Long et al., 1998a

toxicological significance of bulk sediment chemical concentrations. However, because of the variability observed in the relationships between chemical concentrations and toxicity among samples with intermediate concentrations (*e.g.*, ERLs exceeded but no ERMs exceeded or mean ERM quotients of 0.1 to 1.0), adverse effects should be verified in samples with intermediate probabilities of toxicity by conducting toxicity tests and/or other biological analyses.

RECOMMENDED APPLICATIONS OF EMPIRICALLY DERIVED SQGS

Both sets of guidelines were intended to be used as informal (*i.e.*, non-regulatory) tools to assist in the interpretation of chemical data for sediments. Primarily, both sets of values were intended to be used to evaluate and rank both sites and chemicals of potential concern.

Evaluating Sites of Concern

Recently, a panel of environmental chemists and toxicologists concluded "that there is sufficient certainty associated with SQGs to recommend their use in sediment ecological risk assessments" (Ingersoll *et al.*, 1997). Consistent

with this observation, we recommend that SQGs can be used to evaluate and categorize the relative quality of sediments on both an individual-sample basis as well as within regions within which multiple samples were collected. In addition, they can be used to categorize sites in terms of the relative probabilities of observing toxicity. Data from regional, ambient monitoring programs can be evaluated to identify which sites, if any, have chemical concentrations that exceed the SQGs and the percentage of sites that exceeded them. If ambient monitoring is performed with stratified-random sampling designs, the surficial extent of toxicity (expressed as area and percent of total area) can be calculated. Data from age-dated cores or time-series sampling can be used to identify temporal trends in sediment quality by using the SQGs. The guidelines can be used to compare and rank the average quality of sediments among basins, waterways or other mid- to large-scale geographic regions. The chemical concentrations in sediments influenced by point sources can be compared to the SQGs and to the chemical characteristics of the effluents to determine if source control measures should be considered for protecting and/or restoring sediment quality.

Data from investigations of hazardous waste sites can be compared to the SQGs to aid in ranking and prioritizing sites and to determine the need for further information to support management decisions. The SQGs can be used in ecological risk assessments at these sites to estimate the potential for adverse biological damage. Ecological risk assessments of sediments are most comprehensive when all three components of the sediment quality triad are included in the approach (Chapman, 1996). Tiered analyses of chemical data from areas to be dredged may be aided by use of the SQGs, especially when accompanied by measures of bioavailability and toxicity.

In all of these applications, sediments in which none of the chemicals equal or exceed any low-range SQGs (ERLs or TELs) should be classified as having the lowest potential for adverse effects on sediment-dwelling organisms, and, therefore, as being the least contaminated (Table 2). Also, if these chemical concentrations are within the expected bounds for background sediments based upon ratios to grain size, aluminum, lithium or other geochemical factors (Schropp *et al.*, 1991), there would be further evidence that the samples are among the least contaminated. However, as indicated by the false negative rates of about 9 to 12% in acute toxicity tests for the TELs and ERLs, there remains some possibility of toxicity due to the presence of substances not quantified in chemical analyses and/or for which there are no applicable SQGs. Furthermore, the probabilities of toxicity in any of a battery of sublethal tests remains about 30 to 50% among samples with these characteristics. The absence of toxicity can be absolutely assured only by performing confirmatory toxicity tests and/or other biological analyses. Sampling areas in which all chemical concentrations are lower than SQGs and in which toxicity is not observed could qualify as reference areas (Long and Wilson, 1997).

The reliability of the ERMs and PELs for nickel, mercury, and DDT were relatively low when compared with the other SQGs. However, the predictive

abilities of these values were similar to those for other substances. Nevertheless, we recommend that sediments in which only these SQGs are exceeded should not be viewed as high priority unless confirmed as such with additional studies, such as multiple toxicity tests, toxicity identification evaluations or sediment-spiking experiments. Studies performed on data sets selected to focus specifically upon toxicity attributable to concentrations of total DDTs in sediments suggest that the reliability of an SQG of 7.12 ppm is much higher — over 95% (MacDonald, 1997).

The ERL and TEL values were not intended to be used as tools for predicting adverse biological effects. Therefore, samples in which chemical concentrations exceed low-range guidelines, but none of the mid-range values, should be viewed as medium-low or medium-high in priority (Table 2). Often, chemical concentrations between the ERLs and ERMs and between the TELs and PELs represented ranges in which there was a transition from principally non-toxic conditions to mainly toxic conditions. Actual toxicity may be highly influenced in these concentration ranges by a number of geochemical factors and by the sensitivity of the toxicity tests.

Toxicity cannot be necessarily expected in sediments in which only a single ERM or PEL was exceeded because these SQGs were not intended as toxicity thresholds or absolute predictors of toxicity. Those samples in which, say, one to five ERMs or PELs are exceeded should be viewed as medium-low priority because there is a probability of about 24 to 32% that the samples would be highly toxic in acute amphipod tests. Samples in which 11 or more ERMs or 21 or more PELs are exceeded have 85 to 88% probabilities of being highly toxic to amphipods and, therefore, should be considered as highest priority. We have established that the number of ERMs and PELs exceeded corresponds very well with the mean ERM and PEL quotients, therefore, comparisons among samples and among areas may be based upon either or both of these sets of cumulative indices and used to estimate the probabilities of observing toxicity.

Evaluations of Chemicals of Potential Concern

The SQGs can be used effectively to identify, rank, and prioritize chemicals of potential toxicological concern by, first comparing the chemical concentrations in test samples to the SQGs, and then comparing the numbers of SQGs exceeded and the mean SQG quotients to the probabilities of observing toxicity (Table 2). Those substances that occur at concentrations below the low-range SQGs and remain low in concentrations in both toxic and non-toxic samples should be identified as relatively low-priority chemicals. Those substances whose concentrations exceed the low-range SQGs, but do not equal or exceed the mid-range SQGs should be ranked as chemicals of low-to-moderate concern. Substances that equal the mid-range SQGs or exceed them by a moderate amount (*e.g.*, factors of 1.1 to 9.9) should be viewed as chemicals of high concern. Chemicals that most frequently exceed the mid-range SQGs and by the greatest amount (*e.g.*, factor ≥10) should be viewed as chemicals of

highest concern, especially if they exceed all SQGs in samples that are highly toxic.

If results of toxicity tests are available, those substances that show coincident patterns of high concentrations in the most toxic samples should be identified as chemicals of highest concern. These patterns of concordance can be demonstrated with correlation statistics and regression plots (Carr *et al.*, 1996). Some chemicals may appear ostensibly as high-priority substances (*i.e.*, they occur in concentrations above the ERLs and/or equal to the ERMs), but, unless it can be shown that their concentrations are coincident with toxicity or other adverse effects, they should not be ranked as chemicals of highest concern.

In evaluations of chemicals of concern, users of the SQGs must take into account the relative reliability and predictive ability of individual guidelines. The reliability of the ERMs and PELs for nickel and mercury, for example, were relatively low compared to those for most other substances (Long et al., 1995; MacDonald et al., 1996). In contrast, the probability of observing toxicity in samples with concentrations of, for example, PAHs that exceeded the SQGs would be relatively high. The probabilities of observing toxicity in samples that exceed only the SQGs for nickel would be much lower.

Regardless of the degree to which chemical concentrations exceed any SQGs, there is not 100% certainty that samples in which SQGs are exceeded will actually be toxic. Toxicity and other adverse effects in sediments are functions of the total concentration and bioavailability of the sediment-associated chemicals. Chemical form or speciation (where applicable), sensitivity and appropriateness of the biological assay, and exposure times also are important factors that influence toxicity. It is important to understand that the SQGs do not provide a direct means of determining which substances are responsible for causing toxicity in sediments. However, SQGs can assist in identifying the chemicals that are most likely to contribute to toxicity, particularly when used in conjunction with other tools. Toxicity identification evaluations and sediment spiking experiments can be performed to determine which chemical(s) actually caused or contributed to toxicity. In this application, the SQGs provide a basis for developing a short list of potentially toxic substances and therefore a means of focusing additional confirmatory studies.

A variety of SQGs can be used to rank and prioritize chemicals in samples. The choice of whether to use the ERL/TEL or ERM/PEL values or others should be predicated upon the probability of toxicity (*i.e.*, level of risk) that is considered tolerable or acceptable. If a relatively low level of risk to sediment-dwelling organisms is tolerable, ERL/TEL values should be used. However, they should be used with an understanding that concentrations exceeding these values by minor amounts are likely to be associated with relatively low probabilities of toxicity. If a higher level of risk is tolerable, then the ERM/PEL values should be used to identify chemicals of potential concern. We suggest that users of the SQGs primarily focus upon the mid-range (ERM and PEL) SQGs as benchmarks for effects and the low-range (ERL and TEL) values as benchmarks for no-effects. Because the probabilities of effects are much

higher when concentrations exceed the ERMs and PELs than when they exceed only the ERLs and TELs, the former would be expected to be more indicative of adverse effects than the latter.

Despite the demonstrated reliability and predictive ability of the SQGs, there is still some uncertainty associated with their use. There are no SQGs for many substances that can be toxic in sediments. In addition, the SQGs were intended to be applicable to acute toxicity endpoints; their applicability to toxicological risks to wildlife and humans through bioaccumulation pathways is unknown. Although data assembled to evaluate predictive ability often indicated that many toxicants occurred together and co-varied in concentrations, the SQGs should not be assumed to be applicable to chemicals other than those for which the SQGs were derived.

It is important to apply the guidelines only to soft, aqueous, sedimentary deposits that include fine-grained particles. The SQGs are not intended to be used for assessing upland soils, or atypical sediments such as gravel, cobble, slag, paint chips, or tar. Applications of the SQGs in such circumstances may result in erroneous conclusions.

CONCLUSIONS

The reliability and predictive ability of two sets of SQGs — the ERLs/ERMs and the TELs/PELs — were summarized to support recommendations on the applications of these sediment assessment tools. The results of these evaluations showed that the ERLs and TELs provide reliable and predictive tools for identifying the concentrations of chemicals in sediments that are unlikely to be associated with adverse biological effects. That is, the incidence of highly significant toxicity in amphipod survival tests is about 10% in sediments in which none of the guidelines are exceeded. The ERM and PEL values are the chemical concentrations above which there is a relatively high likelihood of toxicity (predictive ability of 86%) in at least one of a battery of tests conducted with sensitive, sediment-dwelling organisms. Mean ERM — and PEL— quotients provide additional tools for assessing the quality of sediments in which there are complex mixtures of substances. The evaluations of reliability and predictive ability suggest that the guidelines provide a scientifically defensible basis for assessing the quality of soft sediments in marine and estuarine ecosystems.

The SQGs provide an effective basis for ranking or prioritizing areas of concern with respect to sediment contamination. Because the probability of observing toxicity in amphipod survival tests is in the order of 74 to 88% in sediments in which multiple SQGs are exceeded (>10 ERMs or >21 PELs) or in which mean SQG quotients are high (*i.e.*, >1.5 for ERMs or >2.3 for PELs); a high level of priority should be assigned to sediments with such chemical characteristics. Sediments should be assigned the lowest priority when none of the low-range SQGs are exceeded or when mean SQG quotients are lowest (*i.e.*, <0.1 for both ERMs and PELs). Areas with intermediate chemical concentrations can be assigned priorities in accordance with the probabilities of

observing toxicity or other adverse effects based upon the numbers of chemicals exceeding SQGs or the calculated mean SQG quotients. However, the actual toxicity of sediments with intermediate chemical concentrations may be influenced by a variety of factors, such as contaminant bioavailability, presence of un-measured substances, presence of substances for which there are no SQGs, and other confounding variables. Therefore, we recommend that other assessment tools, such as toxicity tests, bioaccumulation analyses, and benthic invertebrate community analyses, be used to further evaluate the quality of these sediments.

The SQGs also provide a means of identifying chemicals of potential concern in marine and estuarine sediments. Those substances that occur at concentrations below the low-range SQGs, either in individual samples or in multiple samples within a study area, should be classified as lowest priority. Those chemicals that occur at concentrations exceeding background concentrations, both the ERMs and PELs, and other relevant SQGs or criteria should be considered as relatively high priority, particularly if the concentrations of these substances are significantly correlated with measures of effects. However, care should be exercised when using the SQGs to identify the contaminants that are actually causing toxicity in sediments with complex mixtures of chemicals. In these cases, we recommend the use of spiked sediment bioassays, and/or toxicity identification evaluations to confirm which chemicals actually warrant the greatest concern.

Although empirically derived SQGs have been shown to be both reliable and predictive of toxicity, we recommend that sediment management decisions be based upon a weight of evidence that reflects the significance and expense of the decisions. Therefore, the SQGs should be used in conjunction with other tools within an integrated framework for assessing sediment quality.

Abstract—Matching synoptically collected chemical and laboratory bioassay data (n = 1,068) were compiled from analyses of surficial sediment samples collected during 1990 to 1993 to evaluate the predictive ability of sediment quality guidelines (SQGs), specifically, effects range—low (ERL), effects range—median (ERM), threshold effects level (TEL), and probable effects level (PEL) values. Data were acquired from surveys of sediment quality performed in estuaries along the Atlantic, Pacific, and Gulf of Mexico coasts. Samples were classified as either nontoxic ($p > 0.05$ relative to controls), marginally toxic ($p < 0.05$ only), or highly toxic ($p < 0.05$ and response greater than minimum significant difference relative to controls). This analysis indicated that, when not exceeded, the ERLs and TELs were highly predictive of nontoxicity. The percentages of samples that were highly toxic generally increased with increasing numbers of guidelines (particularly the ERMs and PELs) that were exceeded. Also, the incidence of toxicity increased with increases in concentrations of mixtures of chemicals normalized to (divided by) the SQGs. The ERMs and PELs indicated high predictive ability in samples in which many substances exceeded these concentrations. Suggestions are provided on the uses of these estimates of the predictive ability of sediment guidelines.

Keywords—Sediment quality guidelines Predictive ability Laboratory toxicity tests

INTRODUCTION

Using similar empirical approaches, sediment quality guidelines (SQGs) were prepared for salt water [1–3] and freshwater [4,5] as informal (nonregulatory) benchmarks to aid in the interpretation of sediment chemistry data. For marine sediments, effects range—low (ERL) and effects range—median (ERM) concentrations for 9 trace metals, 3 chlorinated organics, and 13 polynuclear aromatic hydrocarbons (PAHs) were identified [1]. Threshold effects level (TEL) and probable effects level (PEL) concentrations for 9 trace metals, 8 chlorinated organics, 1 phthalate, and 13 PAHs were published [2]. These guidelines were not based upon experiments in which causality was determined. Rather, both sets of marine guidelines were based upon empirical analyses of data compiled from numerous field and laboratory studies performed in many estuaries and bays of North America. These studies included chemistry data and a variety of different types of biological data for numerous taxa derived from either bioassays of field-collected samples, laboratory toxicity tests of clean sediments spiked with specific toxicants, benthic community analyses, or equilibrium-partitioning models.

The objectives of the ERL and TEL values and of the ERM and PEL values were comparable. The ERLs and TELs were intended to represent chemical concentrations toward the low end of the effects ranges, that is, below which adverse biological effects were rarely observed. The ERMs and PELs were intended to represent concentrations toward the middle of the effects ranges and above which effects were more frequently observed. As estimates of reliability, the incidence of adverse effects within concentration ranges defined by these SQGs were determined using data with which they were derived [1,2]. Generally, adverse effects occurred in less than 10% of studies in which concentrations were below the respective ERL or TEL values and were observed in more than 75% or 50% of studies in which concentrations exceeded the ERMs or PELs, respectively.

Since they were published, the guidelines [1,2] have been used as interpretive tools in many sediment assessments throughout North America and elsewhere. Generally, the ERLs and TELs have been used to identify relatively uncontaminated samples that pose a limited risk of toxicity. The ERMs and PELs have been used to identify those samples and areas in which chemical concentrations were sufficiently elevated to warrant further evaluation. Because these guidelines were based upon analyses of large databases, mostly composed of field-collected data in which mixtures of toxicants were encountered, it was assumed [1,2] that the guidelines would provide relatively accurate tools for classifying newly collected samples as potentially toxic or nontoxic. Thus far, however, the accuracy of the two sets of guidelines in predicting nontoxic and toxic conditions correctly has not been evaluated. Therefore, because of the widespread use of these guidelines, we concluded there was a need for analyses of their predictive ability with data independent of those with which the SQGs were derived.

The objectives of this paper are to quantify the frequency with which ERL/ERM and TEL/PEL guidelines correctly classify samples as either nontoxic or toxic; to quantify the incidence of toxicity among samples in which different numbers of SQGs were exceeded; to determine the incidence of toxicity

to the SQGs; and to compare the relative predictive ability of the two sets of guidelines. The design followed that of a previous study in freshwater [5] in which type I and type II errors were determined for ERL/ERM and TEL/PEL values. Type I errors (false positives) are those in which toxicity was expected (based upon high chemical concentrations), but was not observed. Type II errors (false negatives) are those in which no toxicity was expected (low chemical concentrations), but was actually observed.

METHODS

Matching, synoptically collected, sediment chemistry and bioassay data for 1,068 samples were compiled from studies performed by the National Oceanic and Atmospheric Administration (NOAA) and U.S. Environmental Protection Agency (U.S. EPA) (Table 1). Regional sediment quality assessments were conducted as a part of NOAA's National Status and Trends Program (NS&TP) and included those performed in (all in the USA) the Hudson–Raritan estuary in New York and New Jersey [6], Newark Bay in New Jersey [6], the bays adjoining Long Island Sound in New York and Connecticut [7], Boston Harbor in Massachusetts [8], Tampa Bay in Florida [9], San Diego Bay [10] and San Pedro Bay [11] in southern California, and Charleston Harbor in South Carolina (unpublished). The U.S. EPA data were generated in Environmental Monitoring and Assessment Program (EMAP) studies of the Virginian and Louisianian estuarine provinces [12–14].

All of these data were generated during surveys performed to quantify the spatial extent, patterns, and severity of adverse biological effects attributable to toxic substances. Samples from the upper 2 to 3 cm of the sediments were collected with grab samplers throughout each survey area to characterize surficial sediment contamination and toxicity. Data for these analyses were selected because they were generated with similar protocols, included matching chemistry and toxicity results, indicated a range in toxicity responses, and represented conditions from all three coastlines.

Sample collection and handling methods, toxicity testing methods, chemical analytical protocols, and raw data are included in the respective technical reports. All analytical laboratories followed the performance-based protocols of the NS&TP and EMAP—Estuaries to ensure comparability among

rials [16,17] for the amphipod survival tests, U.S. National Biological Service [18] for the urchin tests, and U.S. EPA [19] and Schiewe et al. [20] for the Microtox® tests (AZUR Environmental, Carlsbad, CA, USA). All bioassay data were expressed as percent of negative, laboratory controls (not reference samples) to account for variability among studies and laboratories in organism viability.

We considered several different approaches to the classification of samples as either nontoxic or toxic. In an interlaboratory comparison of performance, results of amphipod survival tests were classified as either nontoxic (mean survival 96–96.5%), marginally toxic (mean survival 76.5–83%), clearly toxic (mean survival < 76%), highly toxic (mean survival < 20%) [21]. Swartz et al. [22] classified results of amphipod survival tests as either not toxic (<13% mortality), uncertain (13–24% mortality), or toxic (>24% mortality). Statistical tests were recommended [16] to determine if differences in results of tests of field-collected samples and controls are statistically significant. An alternative approach [23], based upon results of power analyses of amphipod survival tests, recommended the use of minimum significant differences (MSDs) from controls as criteria for classifying samples as toxic.

We chose to use a combination of these approaches to classify samples. Following standardized procedures [16], samples in which test results were not statistically different from negative controls (i.e., $p > 0.05$) were classified as nontoxic and samples in which results were significantly different from controls were classified as toxic. However, to further distinguish differences in degrees of toxicity, sample classifications followed the recommendations of Thursby et al [23]. Samples in which test results were significant relative to controls, but were less than MSDs were labeled as marginally toxic and those in which results were both significant and greater than MSDs were labeled as highly toxic. The highly toxic label does not imply that toxicity was severe; rather, it was used to identify those results for which statistical certainty was greatest. The MSD values calculated and published for *Ampelisca abdita* [23] were used for all amphipod test results. The MSD values for Microtox tests [24], *Arbacia punctulata* fertilization tests [25], and and all other tests were determined empirically with power analyses of the frequency distributions of data from each test.

laboratory replicates is very small [23]. However, these samples could not be classified as nontoxic because they were significantly different from controls. Therefore, we chose to classify them separately as neither nontoxic nor highly toxic. Because of the uncertainty associated with marginally toxic results, this evaluation focuses mainly upon the nontoxic and highly toxic categories.

Following the completion of an electronic database, several analyses were performed to determine the predictive ability of the guidelines. In these analyses, the guidelines for nickel were excluded because of the low degree of reliability determined for these values [1,2]. Also, the sums of low- and high-molecular-weight PAHs and total PAHs were excluded to avoid redundancy with the data for individual compounds. In summations of total polychlorinated biphenyls (PCBs), total dichlorodiphenyltrichloroethanes (DDTs), and total PAHs, concentrations of individual compounds were treated as zeroes when they were below method detection limits (MDLs). The MDLs achieved differed slightly among laboratories; therefore, the use of zeroes minimized inconsistencies in data treatments. In any case the use of either one half of the MDL or zeroes had no effect upon classification of samples relative to the SQGs.

Three data analyses were performed. First, the predictive abilities of individual SQGs were determined. Second, the incidence of toxicity was determined among samples in which none of the substances equaled or exceeded the ERL concentrations; in which one or increasing numbers of substances exceeded ERL concentrations, but none exceeded any ERM; and in which one or increasing numbers of substances exceeded ERM concentrations. The same approach was used to evaluate the predictive ability of the TEL/PELs. We scored samples as exceeding SQGs when a chemical concentration either equaled the value or exceeded it by any amount.

In the third analysis, the incidence of toxicity over ranges in mean SQG quotients [5,25] was determined. The concentrations of individual chemicals were divided by their respective ERMs or PELs and the means of these concentration-to-SQG quotients were determined. The means of these quotients were determined to account for differences among studies in the numbers of chemicals for which analyses were performed. Predictive ability was calculated with samples classified as either nontoxic or highly toxic, excluding the marginally toxic results.

Similar to the criteria used to determine guideline reliability [1], we considered the guidelines to be predictive if the incidence of toxicity was less than 25% when all concentrations were less than the ERLs or TELs and greater than 75% when at least one concentration exceeded an ERM or PEL. Therefore, our target level for both false negatives and false positives was ≤25%.

Data are reported for the results of amphipod survival tests alone and for any one of the battery of two to four tests performed. In the latter analyses, samples were classified as marginally or highly toxic if one or more of the bioassays met the criteria for these classifications.

RESULTS

The database

Data were compiled from 1,068 samples analyzed during EMAP and NOAA studies conducted during 1990 to 1993. Roughly one third of the data were obtained from the NOAA from 20 to 121 (Table 1). The EMAP data from the Atlantic and Gulf coasts constituted the remaining two thirds of the database (n = 611).

Amphipod survival was determined for all samples; one to three additional tests were performed on all samples except those collected in the EMAP and Newark Bay studies (n = 437). The data from bioassays performed with mysids by the EMAP were not used because these tests failed to indicate toxicity. Amphipod survival was determined with *A. abdita* in Atlantic and Gulf coast surveys and with *Rhepoxynius abronius* in California surveys. Other tests included bivalve (*Mulinia lateralis*) embryo survival and development with exposures to elutriates; microbial bioluminescence (Microtox) in exposures to organic solvent extracts; and pore-water tests of echinoderm (*A. punctulata*) fertilization in Gulf and Atlantic coast areas, echinoderm (purple urchin, *Strongylocentrotus purpuratus*) embryo development in San Diego Bay, and embryological development of red abalone (*Haliotis rufescens*) embryos in San Pedro Bay. Insufficient numbers of samples were tested in any of these nonamphipod tests to warrant analyses alone; therefore, the results of these tests were combined.

The chemical data from each survey indicated that samples contained mixtures of contaminants, including trace metals, PAHs, and chlorinated hydrocarbons. The numbers of samples analyzed for each chemical ranged from 399 to 1,060 (Table 2). Analyte concentrations exceeded the MDL in a majority of the samples. The concentrations of most trace metals ranged over two to three orders of magnitude, and those of most organic compounds ranged over four to six orders of magnitude. Concentrations of the PAHs were most often less than the MDL.

None of the samples exceeded the ERM value for arsenic and <1.0% exceeded the ERMs for cadmium and chromium (Table 2). Relatively small proportions of the samples had chemical concentrations that exceeded ERM values, indicating that the data were not skewed toward waste sites with unusually high concentrations. Undoubtedly, some samples contained chemicals that were not quantified or for which there were no SQGs.

Among the different tests performed, 15 to 91% of the samples were at least marginally toxic (Table 3). Bioassay results showed a wide range of response, often from 0 to >100% of mean control responses. In the amphipod tests 36 to 52% of the samples were toxic whereas in the tests of pore water 56 to 91% of samples were toxic.

The frequency distributions of the data from most of the tests were similar, that is, responses in most samples were >80% of control responses (Table 3). Many of the EMAP samples were marginally toxic in amphipod tests. The data from embryological tests with the purple urchin (*S. purpuratus*) and red abalone (*H. rufescens*) indicated similar frequency distributions, both suggesting higher sensitivities to the samples than found in the amphipods. Empirically derived MSDs for each bioassay were very similar, ranging from 80 to 87%.

Incidence of toxicity

Concentrations greater than individual SQGs. Table 4 summarizes the percentages of samples that were not toxic, were marginally toxic, and were highly toxic in the amphipod tests alone and in any of the two to four tests performed when the concentrations of substances equaled or exceeded individ-

results occurred in amphipod tests in 40 to 65% of the samples. The percentages of samples that were highly toxic in amphipod tests ranged from 40% for the ERM value for total PCB to 100% for the cadmium and chromium ERMs. The target percent of false positives (≤25% not toxic) was observed for 13 of the ERMs. The ERMs for six substances correctly classified ≥75% of samples as highly toxic in amphipod tests. Marginally toxic samples contributed relatively little (0–20%) to over-

all predictive ability. However, based upon sums of the marginally toxic and highly toxic responses, the number of ERMs that correctly predicted toxicity in ≥75% of samples increased from 6 to 13.

Relative to results of the amphipod tests, predictive ability increased considerably when the results were considered for all of the tests performed: ≥75% for all substances that exceeded the ERM concentrations (Table 4). The target percent of false positives (≤25%) was observed for all ERMs and was ≤10% for 18 substances. As with the amphipod data, the marginally toxic results in all tests performed contributed relatively little to overall predictive ability; that is, the samples often were either nontoxic or highly toxic.

Predictive ability observed with the individual PELs was slightly lower than that of equivalent ERMs (Table 5). The percentages of samples exceeding PELs that were highly toxic in amphipod tests ranged from 15% (lindane) to 73% (dieldrin). For 25 of the 31 PELs, highly toxic conditions in amphipod tests occurred in 40 to 65% of the samples. Predictive ability of ≥75% was observed for none of the PELs with only highly toxic responses and with three PELs (cadmium, acenaphthylene, and dieldrin) with marginally plus highly toxic responses combined. The target percent of false positives (≤25%) was observed for the same three PELs. When the results of any of the tests performed were considered, the percent of false positives for the PELs was ≤25% for all except one substance (p,p′-dichlorodiphenyldichloroethylene [p,p′-DDE]) and was ≤10.0% for 15 PELs. For most substances, marginally toxic results contributed 5 to 10% to overall predictive ability in both the amphipod tests alone and in all tests considered. Predictive ability of ≥75% (with highly toxic responses) was observed in any of the tests performed for all PELs except that for p,p′-DDE.

Concentrations above and below all ERL or TEL concentrations. Among the 329 samples in which none of the chemical concentrations exceeded any ERL values, 68% were not toxic, 21% were marginally toxic, and 11% were highly toxic in the amphipod tests (Table 6). Among samples in which multiple bioassays were performed, 46% were not toxic in all tests and 41% were highly toxic in at least one test when all chemical concentrations were less than the ERLs.

Of the samples tested with amphipods, 448 were found in which one or more of the 24 concentrations were greater than or equal to the ERL, but none of the concentrations were greater than or equal to the ERM values; 63% were nontoxic, 20% were marginally toxic, and 18% were highly toxic. A total of 64% of 173 samples was highly toxic in any test performed when one or more ERLs was exceeded and no ERMs were exceeded. The percent of false positives for one or more ERLs exceeded was 63% for amphipod tests alone and 20% for all tests performed.

Generally, the incidence of toxicity increased with the number of chemicals greater than or equal to the ERL concentrations; however, this pattern was variable and inconsistent (Ta-

ble 6). Because of the relatively small numbers of samples in which many ERLs were exceeded, the incidence of toxicity also was calculated for several combined ERL categories. In the amphipod tests (n = 777), the incidence of highly toxic responses was 9% with only 1 ERL exceeded, 13% with 1 to 4 ERLs exceeded, 22% with 5 to 9 ERLs exceeded, and peaked at 67% with 15 to 19 ERLs exceeded.

The proportion of samples that was highly toxic in any test performed was 67% when only one ERL was exceeded (Table 6). The incidence of highly toxic samples increased quickly with the number of ERLs that were exceeded, reaching ≥89% when 10 to 14 concentrations were greater than or equal to the ERLs. With several exceptions (notably one sample in which 22 ERLs were exceeded), generally the proportions of samples that were marginally toxic decreased with increases in the number of concentrations greater than or equal to the ERLs.

Among the 233 samples in which all concentrations were less than the TELs; 65% were not toxic, 26% were marginally toxic, and 9% were highly toxic in amphipod tests (Table 7). A total of 62% of samples (n = 26) were not toxic in all tests performed when all concentrations were less than the TELs. The incidence of toxicity did not increase consistently in either amphipod tests alone or in any tests with increases in the number of TELs exceeded. Sample sizes in which multiple bioassays were performed were relatively small and, partly as a consequence, results were highly variable.

Concentrations above and below all ERM and PEL concentrations. Among the 1,068 samples included in this analysis, 777 and 683 had chemical concentrations less than all ERMs and less than all PELs, respectively (Tables 8 and 9). In amphipod tests, 15 and 13%, respectively, of these samples were highly toxic (false negatives). The incidence of highly toxic responses when one or more concentrations was greater than or equal to the ERM or greater than or equal to the PEL was 39 and 35%, respectively, in amphipod tests and 78 and 77%, respectively, in any test performed. With both the marginally and highly toxic responses combined, the incidence of toxicity in samples with concentrations greater than or equal to one or more ERMs or PELs increased slightly to 52 and 48%, respectively, in the amphipod tests and 86.2 and 86.1%, respectively, in any test.

In both the amphipod tests and any tests performed, the incidence of highly toxic responses generally increased and the incidence of marginally toxic responses markedly decreased with increases in the numbers of ERMs or PELs that were exceeded (Tables 8 and 9). The incidence of highly toxic responses in amphipod tests increased from 23% with only 1

ERM exceeded to 32% with 1 to 5 ERMs exceeded, to 52% with 6 to 10 ERMs exceeded, and peaked at 85% with ≥11 ERMs exceeded (Table 8). The lowest percent false positives (10%) occurred among samples with 11 to 20 ERMs exceeded. In samples in which multiple bioassays were performed, incidence of highly toxic responses increased from 70% with only 1 ERM exceeded, to 89% with 6 to 10 ERMs exceeded, and peaked at 100% with ≥11 ERMs exceeded. Results were variable among samples with greater than or equal to eight ERMs exceeded because of the small sample sizes.

The predictive ability of the PELs was somewhat lower than that of the ERMs, but, nevertheless, indicated a similar pattern of increasing incidence of highly toxic responses with increasing numbers of PELs exceeded (Table 9). In the amphipod tests, the incidence of highly toxic responses was 14% with 1 PEL exceeded, 24% with 1 to 5 PELs exceeded, 40% with 6 to 10 PELs exceeded, 50% with 11 to 20 PELs exceeded, and 88% with ≥21 PELs exceeded. The lowest percent false positives (17%) occurred among samples with ≥21 PELs exceeded. The proportion of samples showing highly toxic results was much higher when all bioassays were considered, averaging 80% with 6 to 10 PELs exceeded and peaking at 100% with ≥21 PELs exceeded. Percent false positives in any of the tests performed was <25% when one or more PEL was exceeded.

Over ranges in mean SQG quotients. In the preceeding analyses, the methods did not account for the degree to which the chemical concentrations exceeded the different SQGs. That is, samples in which chemical concentrations exceeded SOGs by very different amounts were scored the same. Given similar sediment characteristics and toxicant bioavailability, the probability of toxicity could increase with increasing concentrations. Therefore, to account for both the actual concentrations of individual substances and the combinations of chemicals occurring as mixtures, the predictive abilities of the mean SQG quotients were determined.

The relationships between the incidence of highly toxic responses in the amphipod tests and mean SQG quotients are illustrated in Figures 1 and 2. To clarify these relationships, the chemical concentrations are shown as medians of 39 SQG quotient intervals, each consisting of at least 25 samples. These relationships were considerably more variable when marginally toxic responses were included; therefore, the plots are shown only for highly toxic responses. The incidence of highly toxic responses was most variable and ranged from 0 to 40% among samples with the lowest mean ERM quotients (0.001–0.02) and PEL quotients (0.006–0.05). A gradual, albeit variable, pattern of increasing incidence of toxicity beginning at mean ERM and PEL quotients of 0.04 and 0.07, respectively, was evident. Among samples with mean ERM or PEL quotients ≥1.0 or ≥1.6, respectively, 60 to 80% were highly toxic in the amphipod tests. Percent false positives decreased to <25% with mean ERM or PEL quotients >1.2 or >2.3, respectively.

Some of the samples with the lowest mean ERM and PEL quotients were highly toxic, as indicated in the left tails of the distributions (Figs. 1 and 2). These samples shared very few of the same characteristics. They were scattered among many

of the different NOAA and EMAP study areas. These samples often, but not always, had relatively low organic carbon content (<1.0%) and percent fine-grained materials (<50%) and detectable concentrations of butyl tins, chlorinated pesticides, alkyl-substituted PAHs, ammonia, or other substances not accounted for with the SQGs.

DISCUSSION AND CONCLUSIONS

Sediment quality guidelines [1,2] were based upon empirical analyses of data compiled from many different studies. The SQGs were intended to provide informal (nonregulatory), effects-based benchmarks to aid in the interpretation of sed-

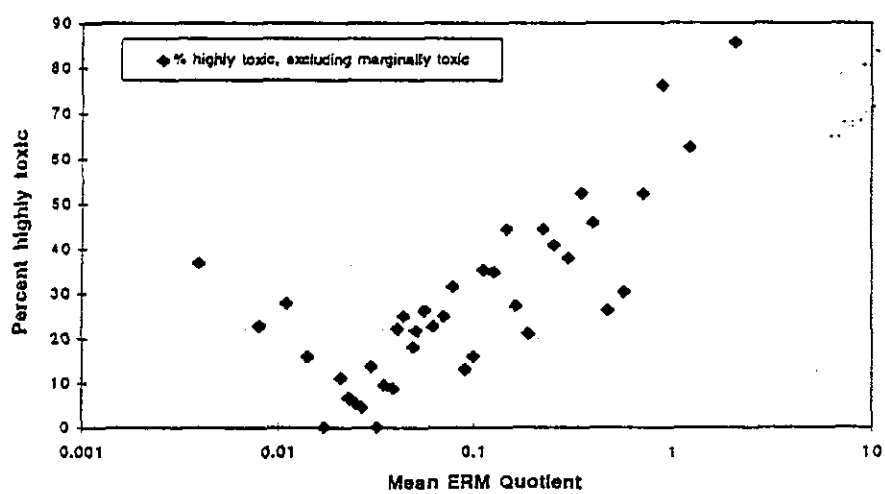

Fig. 1. The relationship between the incidence of toxicity in amphipod survival tests and mean effects range—median (ERM) quotients (plotted as the medians of 39 quotient intervals, each consisting of 25 samples).

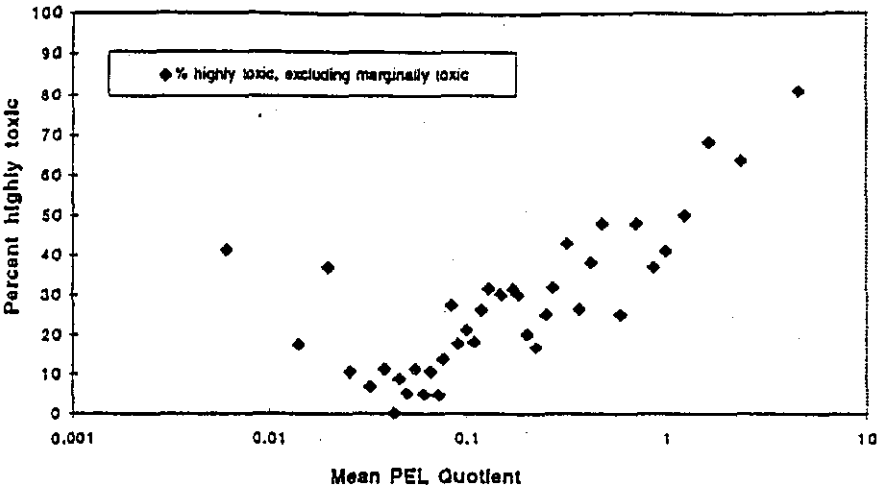

Fig. 2. The relationship between the incidence of toxicity in amphipod survival tests and mean probable effects level (PEL) quotients (plotted as the medians of 39 quotient intervals, each consisting of 25 samples).

iment chemistry data. The ERL and TEL values were intended to represent chemical concentrations below which the probability of toxicity and other effects was minimal. In contrast, the ERM and PEL values were intended to represent mid-range concentrations above which adverse effects were more likely, although not always expected. Intermediate frequencies of effects were expected at chemical concentrations between the ERLs and ERMs and between the TELs and PELs. In this analysis of independent data sets, we attempted to determine if the incidence of toxicity in selected, acute laboratory bioassays would follow the same pattern as observed with multiple measures of effects in the databases used to derive the guidelines.

The majority of the data compiled to develop the guidelines was generated in field studies in which different chemical mixtures were encountered. In these field studies causality could not be determined. The intent of this study was to also use data from surveys of numerous saltwater areas to determine the frequency with which the guidelines correctly predicted nontoxic and toxic conditions.

Unlike SQGs based upon the apparent effects threshold approach [26], the ERL/ERMs and TEL/PELs were not intended to represent concentrations above which adverse effects were always observed. Because the ERLs and TELs were intended to represent conservative concentrations below which toxicity was not frequently expected, we estimated the frequency of false negatives as the incidence of toxicity among samples in which all concentrations were lower than these values. Earlier [1,2], as a measure of reliability, we reported that the frequency of false negatives among the data sets used to derive the guidelines was ≤25% for most chemicals and ≤10% for many chemicals. Specifically, at concentrations below the individual ERL and TEL values for nine trace metals, the incidence of effects ranged from 1.9 to 9.4% and from 2.7 to 9.0%, respectively. For organic compounds, the incidence of effects was more variable, ranging from 5.0 to 27.3% for 19 ERLs and from 0.0 to 47.6% for 25 TELs when concentrations were below these levels.

The same criterion (≤25% false positives) previously used for estimates of reliability was used as the target for estimates of predictive ability in this analysis. Based upon the highly toxic responses, the ERLs and TELs indicated 11 and 9% false negatives (toxicity observed when not expected), respectively, in the tests of amphipod survival, thus bettering the target of ≤25%. The incidence of false negatives also was relatively low (41 and 23% for the ERLs and TELs, respectively) in any one of the two to four tests performed. Based again upon the highly toxic responses, the incidences of false negatives in amphipod tests were, as expected, slightly higher (15 and 13%, respectively) for the ERMs and PELs than for the ERLs and TELs. Therefore, the probabilities of highly toxic responses in amphipod survival tests are relatively low (≤16%) among samples in which all chemical concentrations are lower than both sets of SQGs. However, the incidences of false negatives among any of the tests performed were 60 and 53% (highly toxic responses) for the ERMs and PELs, respectively. These data suggest that there remains a moderate probability of toxicity among samples with all chemical concentrations less than the ERMs or less than the PELs if a battery of relatively sensitive, sublethal bioassays is considered.

In the amphipod tests, the incidences of highly toxic responses and total toxic responses were 18 to 20% and 16 to 19%, respectively, when one or more chemicals exceeded the ERLs and/or TELs. These results agreed well with the original intent of the ERLs and TELs as indicators of the lower end of the possible effects range. These results also agreed very well with the estimates of reliability (calculated with the database used to derive the SQGs) for most ERLs and TELs (30–50% effects) [1,2]. However, when predictive ability was estimated with data from more sensitive sublethal tests, toxicity was observed much more frequently than in the amphipod tests alone.

The ERMs and PELs were derived as mid-range points within the distributions of effects data for each chemical. The ERMs were calculated as the medians (50th percentiles) of chemical concentrations associated with measures of adverse effects. The derivation of the PELs incorporated both the no-effects data along with effects data into the calculations of mid-range concentrations. Neither set of guidelines was intended as a toxicity threshold above which effects were always expected. The incidence of highly significant toxicity in the amphipod survival tests among samples that exceeded individual ERMs and PELs generally agreed with the intent of these values (i.e., as mid-range values). That is, 40 to 65% of

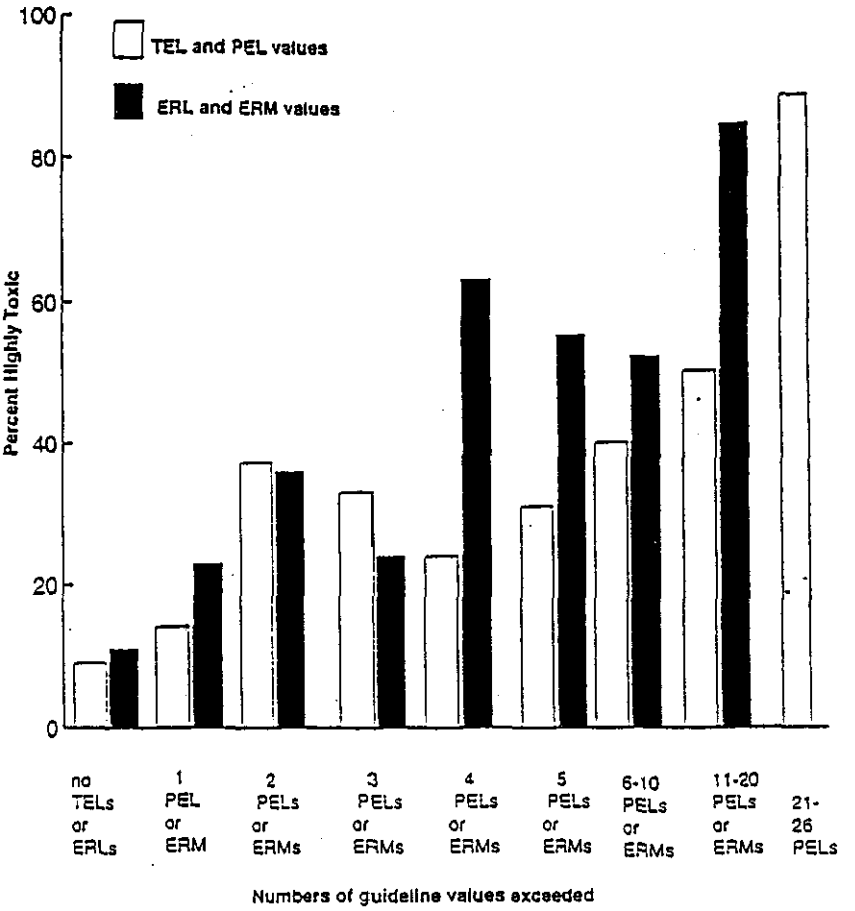

Fig. 3. Summary of the predictive ability of threshold effects level/probable effects level (TEL/PEL) values and effects range—low/effects range—median (ERL/ERM) values in amphipod survival tests (as percent highly toxic among the total numbers of samples).

the samples were highly toxic in amphipod tests at concentrations above most of these individual values. Also, the incidence of total toxicity (marginally + highly toxic) was 52 and 48% when the concentrations of one or more chemicals exceeded ERMs and PELs, respectively. When results from any one of a battery of bioassays were considered, the percentages of samples that were highly toxic increased remarkably to ≥85% for 19 of the ERMs and for 19 of the PELs and to 77 to 78% when one or more ERMs and/or PELs were exceeded.

In all analyses performed on the predictive ability of the SQGs, the percentages of samples demonstrating toxicity were lowest when either no chemicals or the least number of chemicals exceeded the lower range guidelines and increased with increases in the numbers of mid-range guidelines that were exceeded (Fig. 3). Results were variable at intermediate concentrations, but, nevertheless, the data indicated an overall pattern of increasing incidence of toxicity with increasing numbers of ERMs and PELs exceeded. Percent false positives in amphipod tests (no toxicity observed when toxicity was expected) dropped to <25% among samples in which 11 to 20 ERMs (n = 20) and 21 to 26 PELs (n = 17) were exceeded.

Because the two sets of SQGs were derived with slightly different procedures, one objective of this evaluation was to compare their predictive ability. The results indicated that the two sets of SQGs were very similar in predicting toxicity (Fig. 3). The percentages of false negatives for the ERLs and TELs were 11 and 9%, respectively, in the amphipod tests. The incidences of highly toxic responses in amphipod tests were slightly higher for the PELs than for the ERMs among samples in which two or three chemicals exceeded the guideline concentrations. Otherwise, the incidence of toxicity often was higher when chemical concentrations exceeded the ERMs as compared to when the concentrations exceeded the PELs.

Based upon these data, users of the SQGs can identify the probability that their samples would be toxic by comparing the chemical concentrations in their samples to the appropriate SQGs and then to the incidence of toxicity shown in this paper. For example, highly toxic responses would be expected in amphipod survival tests in only approximately 9 to 11% of the samples when all chemical concentrations are below the TELs or ERLs (Fig. 3). Among samples in which only one ERL or TEL value is exceeded and no other chemicals exceeded any other ERL/ERMs or TEL/PELs, toxicity in amphipod tests would be expected in only 9 and 12% of the samples, respectively.

The probability of toxicity in amphipod survival tests is not very high (23 and 14%, respectively) among samples in which only one ERM or only one PEL value is exceeded (Fig. 3). However, the probabilities of toxicity increase with the number of ERMs and PELs exceeded. Based upon the results of this evaluation (n = 1,068), users can expect toxicity in a large majority of samples, that is, in >85% of the samples in amphipod tests (n = 20, n = 17) and in 100% of samples in any one of a battery of sensitive bioassays (n = 9 or 6) when 11 or more ERMs or 21 or more PELs are exceeded. Therefore,

Table 10. Incidence of toxicity in amphipod tests only within three ranges in mean sediment quality guideline quotients

	No. samples	% Not toxic	% Marginally toxic	% Highly toxic
Mean effects range—median quotients				
<0.1	653	67.8	20.5	11.6
0.11 to 1.0	364	51.6	16.5	31.9
>1.0	51	23.5	5.9	70.6
Mean probable effects level quotients				
<0.1	481	67.6	22.0	10.4
0.11 to 1.0	474	58.6	17.1	24.3
>1.0	113	35.4	8.8	55.8

the probability of incorrectly classifying samples as toxic would be 15 and 0%, respectively, in these highly contaminated samples.

The data from the analyses of the mean SQG quotients suggest that the probability of observing toxicity was a function of not only the number of guidelines exceeded but the degree to which they were exceeded. Therefore, the probabilities of highly toxic responses would be relatively low (<12% in amphipod tests) among samples with mean SQG quotients <0.1 (Table 10). The probabilities of toxicity increase to 32 and 24%, respectively, with mean ERM and PEL quotients of 0.11 to 1.0 and increase again to 71 and 56%, respectively, with quotients >1.0.

Despite the selection of high-quality data sets from NS&TP and EMAP—Estuaries studies, the analyses of predictive ability had a number of limitations or potential sources of error. Different results may have been obtained if other data had been used in this evaluation of predictive ability.

The core bioassay upon which these analyses focused was the amphipod survival test. This bioassay has become the most widely applied sediment toxicity test in North America and provides important information for many research, monitoring, and management programs. Amphipod survival tests have been used in both the derivation and field validation of various guidelines [22,26]. However, because different taxa have different sensitivities to toxicants, the use of a battery of toxicity tests is widely accepted and highly recommended in sediment quality assessments [27]. Furthermore, the use of multiple tests increases the number of surrogates of sediment-dwelling taxa. Considerable gains in predictive ability were attained by the addition of data from other tests to those from the amphipod tests. Because only one, two, or three (not, say, 10) tests accompanied the amphipod bioassays, we attribute the gains in predictive ability not to the number of tests performed, but, rather, to the greater sensitivity of the tests to the chemicals in the sediments.

Tests of invertebrate gametes and embryos exposed to pore waters and bioluminescent bacteria exposed to solvent extracts have been used widely in U.S. estuaries [24] and generally are more sensitive than are test with amphipods to the same samples. The large differences in sensitivity between the amphipod survival tests and the other tests performed is reflected in the data that were analyzed. The probabilities of observing toxicity in the more sensitive sublethal tests would be much higher than in the amphipod tests. Users are advised to consider the data from both categories of bioassays when using the guidelines, especially because highly sensitive tests such as those teria [28] have shown strong associations with chemical concentrations.

Sediment quality guidelines were not available for many substances that were measured in the samples. Some substances may have occurred at concentrations above toxicologic thresholds. Other substances that were not measured probably occurred in many or all samples. Also, some samples may have had high concentrations of ammonia and hydrogen sulfide that covaried with anthropogenic substances and contributed to toxicity. Together, the effects of these substances may have contributed to the false negatives observed. However, our nationwide experience indicates that toxicants often covary with each other to a large degree [7,25] and the quantified substances for which SQGs were available should have served as reasonable surrogates for the covariates. Furthermore, our experience in assessments of surficial sediments suggests that ammonia and sulfides occur in either pore water or overlying water in test chambers at toxicologically significant concentrations in <10% of the samples. Nevertheless, the contribution of all potentially toxic substances in the samples could not be accounted for.

Although standardized and widely accepted methods and protocols were used, some interlaboratory and interstudy differences in methods may have occurred. Some variability in results may have been attributable to merging data from different studies and geographic areas. For example, data were compiled from tests performed with two species of amphipods to increase the sample size and to include data from all three coastlines. Differences in sensitivity between these two amphipod species may have contributed to variability in the results. Also, variability may have been increased by merging data from different species of urchins and molluscs along with data from the Microtox tests into one category.

Most of the samples were not collected within hazardous waste sites and most were not highly contaminated (zero to five SQGs exceeded). The relatively small numbers of highly contaminated samples appeared to contribute to variability in results. Additional data from highly contaminated sites would be useful in further clarification of predictive ability.

Despite these potential limitations of this study, the predictive ability estimated with these data often matched their previously reported reliability. Also, the results of this analysis agreed relatively well with the the estimates of reliability reported [5] for freshwater sediment effects concentrations. The results of this analysis [5] determined type I (false positive) and type II (false negative) errors for freshwater ERL/ERM and TEL/PEL values based upon data from individual samples from numerous studies. For most substances, the errors ranged from 5 to 30%. The paired sets of values, however, differed somewhat in absolute concentrations and error rates.

The toxicity/chemistry relationships observed in this study may not apply in all situations, especially in sediments in which contaminants are found in forms such as copper slag [29] or coal pitch in organically enriched mud [30]. The guidelines are most useful when applied to fine-grained, sedimentary deposits such as those sampled during the NOAA and EMAP—Estuaries studies.

In conclusion, the results of these analyses indicate the following: the probabilities of highly toxic responses occurring in amphipod survival tests among samples in which all chemical concentrations are less than ERLs and/or TELs are 9 to 11%; the probabilities of highly toxic responses occurring in

quotients are <0.1 are 10 to 12%; the probabilities of highly toxic responses occurring when one or more ERLs or TELs are exceeded and no ERMs or PELs are exceeded are 16 to 18% in amphipod tests alone and 60 to 64% in any one of a battery of sensitive tests performed; the probabilities of either marginally or highly toxic responses occurring are 48 to 52% in amphipod tests and 86% in any one of a battery of sensitive tests performed when concentrations exceed one or more ERMs or PELs; consistent with their original intent, the ERMs and PELs are considerably better at predicting toxicity than are the ERLs and TELs. Furthermore, the probabilities of toxicity occurring generally increase with increasing numbers of chemicals that exceed the ERM and PEL concentrations; the probabilities of toxicity occurring generally increase with increasing mean SQG quotients; and the incidence of false negatives is slightly lower for the TELs than for the ERLs, but the incidence of false positives is generally higher for the PELs than for the ERMs; however, there is good overall agreement in the predictive ability of the TEL/PELs and the ERL/ERMs.

Based upon these analyses of predictive ability and previous analyses of reliability, it appears that the SQGs provide reasonably accurate estimates of chemical concentrations that are either nontoxic or toxic in laboratory bioassays. However, we urge that all SQGs should be used with caution, because, as observed in this analysis, they are not perfect predictors of toxicity. Especially among samples with intermediate chemical concentrations, the SQGs are most useful when accompanied by data from in situ biological analyses, other toxicologic assays, other interpretive tools such as metals : aluminum ratios, and other guidelines derived either from empirical approaches and/or cause–effects studies.

Received 12 December 1994; accepted 5 May 1995

The weight-of-evidence approach to the development of sediment quality guidelines (SQGs) was modified to support the derivation of biological effects-based SQGs for Florida coastal waters. Numerical SQGs were derived for 34 substances, including nine trace metals, 13 individual polycyclic aromatic hydrocarbons (PAHs), three groups of PAHs, total polychlorinated biphenyls (PCBs), seven pesticides and one phthalate ester. For each substance, a threshold effects level (TEL) and a probable effects level (PEL) was calculated. These two values defined three ranges of chemical concentrations, including those that were (1) rarely, (2) occasionally or (3) frequently associated with adverse effects. The SQGs were then evaluated to determine their degree of agreement with other guidelines (an indicator of comparability) and the percent incidence of adverse effects within each concentration range (an indicator of reliability). The guidelines also were used to classify (using a dichotomous system: toxic, with one or more exceedances of the PELs or non-toxic, with no exceedances of the TELs) sediment samples collected from various locations in Florida and the Gulf of Mexico. The accuracy of these predictions was then evaluated using the results of the biological tests that were performed on the same sediment samples. The resultant SQGs were demonstrated to provide practical, reliable and predictive tools for assessing sediment quality in Florida and elsewhere in the southeastern portion of the United States.

Keywords: sediment quality guidelines; contaminants; biological effects; marine; estuarine.

Introduction

Sediment chemistry data indicate that Florida coastal sediments in several areas are contaminated (Long and Morgan 1990, Delfino *et al.* 1991, FDEP 1994). For example, sediments in Tampa Bay, Pensacola Bay and Biscayne Bay are contaminated with trace metals, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) and certain pesticides. Additionally, Choctawhatchee Bay and St Andrews Bay sediments are contaminated with metals, PAHs and pesticides and elevated levels of PCBs have been

*To whom correspondence should be addressed.

detected in St Andrews Bay, Apalachicola Bay, Charlotte Harbor, Naples Bay, Rookery Bay and the St Johns River (Long and Morgan 1990).

While sediment chemistry data are essential for evaluating sediment quality, they do not provide a comprehensive basis for classifying or managing contaminated sediments (Long *et al.* 1995). Interpretive tools are also required to relate sediment chemistry data to the potential for adverse biological effects. Various toxicity and bioaccumulation tests can be performed to evaluate the biological significance of sediment-associated contaminants (Burton 1992). In addition, numerical sediment quality guidelines (SQGs) can be used to help interpret the significance of chemical concentrations in sediments, identify contaminants of concern and prioritize areas for regulation or restoration (Long and Morgan 1990, Di Toro *et al.* 1991, Persaud *et al.* 1992, MacDonald *et al.* 1992).

A variety of approaches have been developed to support the derivation of numerical SQGs in the United States and Canada (see Chapman 1989, Adams *et al.* 1992, MacDonald *et al.* 1992, USEPA 1992, MacDonald, 1994 for reviews). The procedures used for deriving the SQGs and the philosophy behind their development are approach specific. Consequently, each approach has certain advantages and limitations that affect the applicability of the resultant guidelines. Presently there is little agreement as to which approach provides the most reliable guidelines, therefore, each of the major approaches was evaluated to determine which would best address Florida's unique requirements for SQGs (MacDonald 1994). The results of this evaluation indicated that the weight-of-evidence approach, developed to provide informal guidelines for evaluating data collected under the National Status and Trends Program of the National Oceanic and Atmospheric Administration (NOAA; Long and Morgan 1990, Long 1992), would provide scientifically defensible and broadly applicable guidelines for assessing sediment quality. The evaluation by MacDonald (1994) also indicated that some modifications to the original approach could potentially increase the applicability of the procedure for deriving SQGs for Florida's coastal waters.

The objectives of this study were to (1) describe the modifications made to the weight-of-evidence approach to support the development of SQGs for Florida coastal waters, (2) present the SQGs that were derived and (3) evaluate the applicability of these SQGs for Florida coastal waters. The comparability of the SQGs was assessed by comparing them with those derived using other data or other methods. The reliability of the guidelines was evaluated by determining the percent incidence of adverse effects within each of three ranges of contaminant concentrations. The predictability of the SQGs was assessed using several independent data sets from Florida and the Gulf of Mexico, which contain both sediment chemistry and biological effects data.

Methods

The weight-of-evidence approach to the development of numerical sediment quality guidelines has been described in detail elsewhere (Long and Morgan 1990, Long 1992, Long and MacDonald 1992, Long *et al.* 1995), so only an overview of the approach and the modifications that were adopted in Florida will be presented here. The derivation of numerical guidelines using the weight-of-evidence approach consists of three main steps. First, all of the available information which described associations between contaminant concentrations and adverse biological effects in sediments was collected and evaluated. These data were collated in a biological effects database for sediments (BEDS;

MacDonald *et al.* 1994). Next, two SQGs, a threshold effects level (TEL) and a probable effects level (PEL), were derived for each chemical substance. These guidelines were intended to define three ranges of contaminant concentrations that were rarely, occasionally and frequently associated with adverse biological effects. Finally, the SQGs were evaluated to determine their applicability to Florida coastal waters.

Development of a biological effects database for sediments

The first step in the derivation of SQGs involved the development of a biological effects database for sediments (BEDS) to compile matching chemical and biological data from numerous studies conducted throughout North America. Over 350 reports were reviewed and critically evaluated for this purpose. These reports provided information from equilibrium-partitioning models, laboratory spiked-sediment toxicity tests and field studies used to investigate the toxicity and/or benthic community composition of marine and estuarine sediments. Each record in the database included the citation, type of test and/or biological effects observed or predicted approach that was used, study area, test duration (if applicable and reported), species tested or the benthic community considered, TOC concentrations (if reported) and the concentration(s) of each chemical (expressed on a dry weight basis). More detailed descriptions of the BEDS are provided in Long (1992), Long and MacDonald (1992), CCME (1994), MacDonald (1994), Long *et al.* (1995).

Derivation of sediment quality guidelines

The BEDS was used as the sole source of information about the potential effects of sediment-associated contaminants. Data for each of the chemicals of concern in Florida coastal waters were retrieved from the database, incorporated into data tables and sorted in ascending order of the chemical's concentration. Each ascending data table summarized all available information that related the concentrations of the chemical to effects on aquatic organisms (MacDonald *et al.* 1994). The information in these tables was then sorted into two data sets, including (1) an 'effects data set', which included all of the 'effects' data entries (i.e. those for which an adverse biological effect was observed in association with at least a 2-fold elevation in the chemical concentration above reference conditions; Long *et al.* 1995) and (2) a 'no effects data set', which included all of the 'no effects' data entries (i.e. those for which either no adverse biological effect was observed or an effect was observed but the chemical concentration was not elevated relative to reference conditions; less than a 2-fold elevation). Both a TEL and a PEL were derived for each substance that had at least 20 data entries in both the 'effects' and 'no effects' category.

In this study, the original derivation procedures were modified to develop a TEL and a PEL for each analyte. Originally, the 10th (ER-L) and 50th (ER-M) percentile values in the effects data set were used to establish sediment quality guidelines (Long and Morgan 1990, Long 1992, Long and MacDonald 1992, Long *et al.* 1995). This method was similar to the procedure used by Klapow and Lewis (1979) to establish marine water quality standards in California. These authors reasoned that the use of percentiles of aquatic toxicity data effectively minimized the influence of single (potentially outlier) data points on the resultant assessment values (e.g. Barrick *et al.* 1988). The original procedure did not utilize the information in the no effects data set, however. Nonetheless, data on the concentrations of contaminants that are not associated with

adverse effects may provide additional information for defining the relationships between contaminant exposure and biological effects and was, therefore, used in this investigation.

In the present study, two SQGs were derived for each analyte using the information in both the effects and the no effects data sets, with the distributions of these data sets determined using percentiles (Byrkit 1975). For each analyte, a TEL was derived by calculating the geometric mean of the 15th percentile of the effects data set and the 50th percentile of the no effects data set. Similarly, a PEL was developed for each chemical by determining the geometric mean of the 50th percentile of the effects data set and the 85th percentile of the no effects data set. These arithmetic procedures were established by testing a variety of options using data for cadmium, copper, fluoranthene and phenanthrene and, subsequently, evaluating the resultant guidelines relative to their narrative objective. In this respect, the TEL was intended to estimate the concentration of a chemical below which adverse effects only rarely occurred (i.e. a minimal effects range; Fig. 1). Similarly, the PEL was intended to provide an estimate of the concentration above which adverse effects frequently occurred (i.e. probable effects range). Therefore, the TEL and PEL were intended to define three concentration ranges for a chemical, including those that were rarely, occasionally and frequently associated with adverse effects (Fig. 1). The extent to which the tested options satisfied these narrative objectives was determined by calculating the percent incidence of adverse effects below the TEL and above the PEL (Long *et al.* 1995).

The arithmetic procedures used to derive the SQGs in Florida were similar to those that have been used in other applications. For example, the Canadian Council of Ministers of the Environment (CCME, 1992) calculated the geometric mean of the lowest-observed-effect concentration (LOEC) and the no-observed-effect concentration (NOEC) to establish effects-based soil quality criteria. Similarly, Rand and Petrocelli (1985) calculated maximum acceptable toxicant concentrations (MATCs) from LOECs and NOECs from aquatic toxicity tests. The Canadian Council of Resource and Environment Ministers (CCREM, 1987) established a protocol that utilizes an analogous method for deriving water quality guidelines for the protection of agricultural water uses. In each of these cases, the geometric mean, rather than the arithmetic mean, was calculated due to uncertainty regarding the distributions of the data sets (i.e., the data were not expected to be normally distributed; Sokal and Rohlf 1981). The arithmetic procedures used in this study recently were adopted for deriving national SQGs in Canada (CCME 1994).

Evaluation of sediment quality guidelines

The SQGs developed in this study were evaluated using three procedures. The comparability of the SQGs was evaluated by comparing the TELs and PELs with similar assessment tools that have been derived using different approaches or procedures. The reliability of the SQGs was evaluated by calculating the percent incidence of adverse effects within ranges of contaminant concentrations defined by the TELs and PELs, using the information contained in the BEDS (MacDonald 1994, Long *et al.* 1995). Finally, the predictability of the SQGs was assessed using independent sediment chemistry and biological effects data sets from areas throughout the southeastern portion of the United States (MacDonald 1994).

Comparability. The SQGs were compared to a variety of sediment quality criteria, guidelines, objectives and standards that were developed for use in other applications (Tables 1 and 2). Guidelines developed using different approaches or different procedures were considered to be comparable if they agreed within a factor of three of the SQGs developed in this study (Lorenzato *et al.* 1991).

We interpret the threshold effects levels (TELs) as the concentrations below which adverse biological effects rarely occur. Hence, the TELs are considered to provide a high level of protection for aquatic organisms. A total of four sets of similar guidelines were identified for comparison with the TELs derived in this study, including (1) the NOAA effects range-low values (ER-Ls; Long *et al.* 1995), (2) the screening levels (PSDDA-SL) developed for the Puget Sound Dredged Disposal Analysis Program (USACOE 1988), (3) the USEPA chronic sediment quality criteria (SQC-chronic; Lyman *et al.* 1987, Pavlou 1987, Hansen *et al.* 1993a,b,c,d,e) and (4) the sediment quality objectives SQOs) developed for Burrard Inlet (Swain and Nijman 1991).

We interpret the probable effects level (PELs) as the concentrations above which adverse biological effects frequently occur. Hence, the PELs are considered to provide a lower level of protection for aquatic organisms. The four sets of guidelines that were compared to the PELs included (1) the NOAA effects range-median values (ER-Ms; Long *et al.* 1995), (2) the lowest Puget Sound apparent effects threshold values (LAETs; Barrick *et al.* 1988), (3) the USEPA acute sediment quality criteria (SQC-

*Indicates that the SQGs are within a factor of three of the PEL.

acute; Lyman *et al.* 1987, Pavlou 1987) and (4) the national screening level concentrations (SLCs; Neff *et al.* 1987).

Reliability. The reliability of the SQGs developed in this study was evaluated using the information contained in the ascending data tables. To facilitate this evaluation, a scoring system was devised to integrate information on three distinct attributes of the SQGs, including (1) the incidence of adverse biological effects within the minimal effects range, (2) the incidence of adverse biological effects within the probable effects range and (3) the degree of concordance between the concentrations of sediment-associated contaminants and the incidence of adverse biological effects. Good concordance between these two variables is indicated by marked increases in the incidence of effects over the three ranges of contaminant concentrations (Long *et al.* 1995).

First, a TEL score (TS) was determined for each analyte to quantify incidence of adverse biological effects within the minimal effects range. Specifically, the number of effects data entries and the total number of data entries that were contained within the minimal effects range were determined for each substance. Subsequently, the percent incidence of adverse effects was calculated for each substance by dividing the number of effects data entries by the total number of data entries within the minimal effects range and multiplying this value by 100. A TS of 2, 1 or 0 was assigned if the incidence of adverse biological effects within the minimal effects range was <10%, 10–25%, or >25%, respectively (MacDonald 1994).

Next, a PEL score (PS) was determined for each substance for which SQGs were derived. Consistent with the procedures that were used to determine the TS, the percent incidence of adverse biological effects within the probable effects range was calculated for each substance. A PS of 2, 1 or 0 was subsequently assigned if the incidence of adverse biological effects within the probable effects range was >65%, 50–65% or <50%, respectively (MacDonald 1994).

A concordance score (CS) was determined to assess the degree of agreement between contaminant concentrations and the incidence of adverse biological effects. The CS was calculated by first determining the incidence of adverse biological effects within the possible effects range (i.e. between the TEL and PEL). Next, the percent incidence of adverse biological effects within each of the three ranges of contaminant concentrations were compared. Long *et al.* (1995) indicated that there should be a consistent and marked increase in the incidence of effects within the three concentration ranges. Therefore, the presence of at least a 2-fold increase in the incidence of effects between adjacent ranges of concentrations was used as an indicator of concordance. A CS of 2 was assigned if the percent incidence of adverse biological effects was a factor of 2 or more higher in the probable effects range than in the possible effects range and in the possible effects range compared to the minimal effects range. A CS of 1 was assigned if the factor of 2 difference in the incidence of effects was apparent between only two ranges. A CS of 0 was assigned if there was no apparent concordance between chemical concentrations and the incidence of adverse effects.

Finally, the overall reliability of the guidelines for each substance was evaluated by calculating a total reliability score (TRS; MacDonald 1994). The TRS was determined by calculating the sum of TS, PS and CS for each substance. The guidelines for a substance were considered to have a high degree of reliability if they had a TRS of 6 (i.e. the maximum score). A moderate degree of reliability was assigned when

intermediate scores were obtained for one or two of the parameters or when a low score was obtained for one parameter but high scores were assigned for the other two (i.e. with a TRS of 4 or 5). SQGs with a TRS that was <4 were considered to have a low degree of reliability.

Predictability. The predictability of the TELs and PELs was evaluated separately using independent data from field surveys conducted at sites in Tampa Bay, Pensacola Bay, coastal Gulf of Mexico and offshore Gulf of Mexico. First, the concentration of each substance in each sediment sample was compared to the SQGs. Sediment samples with concentrations of one or more substances that exceeded their respective PELs were predicted to be toxic. Sediment samples were predicted to be non-toxic if the concentrations of all measured substances were below the TELs. Sediment samples with concentrations of one or more contaminants above the TEL but below the PEL (i.e. within the possible effects range) were neither predicted to be toxic nor non-toxic and were not used to evaluate the predictability of the SQGs.

The accuracy of the predictions was then evaluated by comparing them with the results of the biological investigations. The predictability of the PEL was calculated as the ratio of the number of samples that were correctly predicted to be toxic and the number of samples that were originally predicted to be toxic (expressed as a percentage). Similarly, the predictability of the TEL was calculated as the ratio of the number of samples that were correctly predicted to be non-toxic and the number of samples that were originally predicted to be non-toxic (expressed as a percentage). In this assessment, toxic samples were defined as those in which one or more of the measured bioassay end-points were significantly different from control or reference samples.

Results

Numerical SQGs were derived for a total of 34 substances, including nine trace metals, total PCBs, 13 individual PAHs, three groups of PAHs, seven pesticides and bis(2-ethylhexyl)phthalate. The TELs are listed in Table 1 and the PELs are listed in Table 2. Fewer than 20 effects data records were available for a number of additional substances (e.g. tributyltin, pentachlorophenol, dioxins, furans and a suite of pesticides) that are also contaminants of concern in Florida coastal sediments (MacDonald 1994). Therefore, SQGs could not be derived for these substances.

Comparability

The evaluation of the comparability of the SQGs was impaired by the lack of guidelines for certain substances. For example, guidelines from three or more approaches were available for only 19 of the substances for which TELs have been developed and for only 18 of the substances for which PELs had been developed. An adequate number of guidelines were not available for chromium, nickel, silver, bis(2-ethylhexyl)phthalate, several PAHs and most of the pesticides. Nonetheless, the results of this evaluation indicate that many of the SQGs compare favourably to guidelines that were derived for other applications.

The TELs for 17 of the 34 substances were within a factor of three for two or more other guidelines (Table 1). The best agreement was observed for metals and the poorest

agreement was observed for high molecular weight (HMW) PAHs. The TELs were usually lower than values developed using other guidelines, indicating that the TELs could be more protective. The PELs for 14 of the 34 substances were within a factor of three for two or more of the other guidelines listed in Table 2. Once again, greatest agreement among the various guidelines was observed for metals. Relatively poor agreement was observed among the guidelines for pesticides and low molecular weight (LMW) PAHs. As was the case for the TELs, the PELs were generally lower than values developed using guidelines based on other procedures.

Reliability

Using information in the ascending data tables, the reliability of the TELs for 30 substances was found to be relatively high (TS = 2), as indicated by the low incidence of effects (<10%) within the minimal effects range (Tables 3 and 4). This group included the TELs for nine metals, 14 individual PAHs or groups of PAHs, six pesticides and bis(2-ethylhexyl)phthalate. Moderate reliability (TS = 1) was indicated for the TELs for fluorene, dibenz(a,h)anthracene and total PCBs. Low reliability (TS = 0) was indicated for only one substance (total DDT).

The reliability of the PELs generally was lower than that of the TELs. The PELs for 16 substances had a relatively high degree of reliability (PS = 2), as indicated by a high incidence of adverse biological effects (>65%) within the probable effects ranges (Tables 3 and 4). Of the highly reliable PELs, 14 were for individual PAHs or groups of PAHs. The PELs for cadmium and bis(2-ethylhexyl)phthalate were also considered to be highly reliable. A moderate degree of reliability (PS = 1) was indicated for five of the nine metals; a low degree of reliability (PS = 0) was indicated for arsenic, mercury and nickel. The PELs for pesticides and total PCBs had either a moderate or low level of reliability.

A high degree of concordance between contaminant concentrations and the incidence of adverse biological effects was observed for the majority of the SQGs (Tables 3 and 4). The incidence of adverse effects consistently and markedly increased with increasing concentrations for all trace metals except mercury, nickel and silver. Two-fold increases in the incidence of effects between the minimal effects range and possible effects range and the possible effects range and probable effects range were also observed for ten of the 16 individual PAHs and groups of PAHs (Table 4). The concordance scores for three pesticide guidelines were high (CS = 2 for dieldrin, p,p′-DDD and p,p′-DDE), while those for four other pesticides and total PCBs were lower (CS = 0 or 1).

Overall, total reliability scores of 4 or more were calculated for the majority of the guidelines, indicating high or moderate reliability (Table 4). A high degree of reliability (TRS = 6) was indicated for one trace metal (cadmium), ten individual PAHs or groups of PAHs and bis(2-ethylhexyl)phthalate. The SQGs for 16 other substances were moderately reliable (TRS = 4 or 5), including those for six trace metals, five individual PAHs, total HMW-PAHs, dieldrin, p,p′-DDE, p,p′-DDD and p,p′-DDT. The reliability of the guidelines for mercury, nickel, total PCBs, chlordane, lindane and total DDT was lower (TRS < 4).

Predictability

The predictability of the SQGs was evaluated using four independent data sets from the southeastern portion of the United States. In Tampa Bay, Florida, matching sediment

ndependent data sets from the
y, Florida, matching sediment

chemistry and biological effects data were available for 61 sediment samples (Long *et al.* 1994). The analytes in these samples included metals, PAHs, PCBs and a suite of pesticides. Based on a comparison of the sediment chemistry data with the PELs, 46 of these samples were predicted to be toxic (Table 5). A suite of toxicity tests was also conducted on these samples, including a 10 day amphipod (*Ampelisca abdita*) survival test (using bulk sediments) and a 1 hr sea urchin (*Arabacia punctulata*) fertilization test (using undiluted pore water). Based on the results of these toxicity tests, 40 samples were observed to be toxic (i.e. toxicity was observed in one or more tests). Therefore, the predictability of the PELs was 87% (40 out of 46 samples). Only two of the 61 sites were predicted to be non-toxic; the results of the biological tests conducted on these two samples revealed that neither sample was toxic. Thirteen samples were not classified, as the concentrations of all analytes were below the PEL but the concentrations of one or more substances exceeded the TEL (i.e. within the possible effects range).

In Pensacola Bay, data for 20 samples were available for assessing the predictability of the guidelines (E.R. Long, unpublished data). The concentrations of metals, PAHs and a suite of pesticides were measured in each of these samples. Sediment toxicity was assessed using a 10 day amphipod (*A. abdita*) survival test, a sea urchin (*A. punctulata*) fertilization (1 h) and embryo development test (48 h) and a microbial bioluminescence test (Microtox). Based on comparisons of the metals and organics data with the PELs, 12 samples were predicted to be toxic (Table 6). Of these, 11 of the samples were observed to be toxic. Therefore, the predictability of the PELs was 92%. Using the TELs, two samples were predicted to be non-toxic; both of these samples were observed to be toxic. It should be noted that these samples contained elevated levels of one or more substances that could not be identified using a range of analytical techniques and which could have caused or contributed to the toxicity.

As part of the Environmental Monitoring and Assessment Program (EMAP), administered by the US Environmental Protection Agency, matching sediment chemistry and biological effects data were collected from eight areas in the Gulf of Mexico region in 1991 (USEPA, unpublished data). The areas sampled in this survey included Galveston Bay (TX), Matagorda Bay (TX), Mississippi River (LA), Mississippi Sound (LA), Mobile Bay AL), Pensacola Bay (FL), Florida Panhandle (FL) and West Central Florida (FL). Sediment chemistry data were collected on metals, PAHs, PCBs, a suite of pesticides and several additional substances. Sediment toxicity was assessed using acute toxicity (lethality) tests with the amphipod, *A. abdita* (10 days) and the mysid, *Mysidopsis bahia* (4 days). As no statistical evaluation of the toxicity test results were reported, a 20% difference between the survival of test organisms in Gulf of Mexico sediments versus control sediments was assumed to indicate toxicity in this evaluation (USEPA/USACOE 1991, Schimmel *et al.* 1994). Of the 47 samples collected in this survey, three were predicted to be toxic and 16 were predicted to be non-toxic (Table 7). The results of the two toxicity tests indicated that none of the samples that were predicted to be toxic were observed to be toxic (predictability = 0%). In contrast, 15 of the 16 samples that were predicted to be non-toxic were in fact non-toxic (predictability = 94%).

As part of the Minerals Management Services (MMS) Gulf of Mexico Offshore Operators Monitoring Experiment (GOOMEX), sediment chemistry and toxicity data were collected in the vicinity of petroleum exploration and production platforms in the Gulf of Mexico (R.S. Carr, D.C. Chapman, B.J. Prestley, J.M. Biedenbach, L. Robertson

[a]TEL, threshold effect level; PEL, probable effect level.

and S.P. Boothe submitted). Five platforms were sampled during the first cruise and three platforms were sampled during the second cruise. Twenty-five stations were sampled per platform per cruise, with the stations arranged in a radial array around each platform. The sediment chemistry data consisted of a suite of trace metals and petroleum hydrocarbons; however, no chlorinated organic compounds were measured. Both sea urchin (*A. punctulata*) fertilization and embryological development tests were conducted with sediment pore water from the 125 samples from the first cruise, but only the embryological development test was used for the samples collected during the second cruise, as the latter test proved to be more sensitive for assessing the effects of the contaminants present at these platforms.

In the GOOMEX study, 16 of the 200 samples tested were toxic (Kennicutt 1993). Based on comparisons of the sediment chemistry data to the guidelines, 27 of the 200 samples were predicted to be toxic and 50 were predicted to be non-toxic (Table 8). Thirty-seven percent (ten out of 27) of the samples predicted to be toxic (i.e. one or more PELs exceeded) were observed to be toxic. The predictability increased to 58% (seven out of 12) when two or more PELs were exceeded in sediment samples. All of the non-toxic samples with contaminant concentrations that exceeded one or more PELs were predicted to be toxic based on the concentrations of zinc or lead. Ninety-six percent of the 50 samples predicted to be non-toxic were observed to be non-toxic using these very sensitive toxicity tests (Carr and Chapman 1992).

Considering all of the data collected in the Gulf of Mexico region, the results of biological investigations indicated that 59 of the 88 samples that were predicted to be toxic actually were toxic (Table 9). Hence, an overall predictability of 67% was calculated for the PELs. By comparison, 66 of the 70 samples that were predicted to be non-toxic actually were non-toxic to all of the organisms tested. The predictability of the TELs was, therefore, calculated to be 94%. When data from coastal areas of the Gulf of Mexico only were considered, the predictability of the TELs and PELs were 85 and 84%, respectively. It should be noted that slightly more than one-half of the samples collected in these surveys had concentrations of one or more contaminants that fell within the possible effects range; therefore, it was not possible to predict whether or not these samples would be toxic. On average, approximately one-fifth of these samples were observed to be toxic, based on the results of a battery of tests.

Table 8. Predictability of the TELs[a] and PELs[b] in offshore Gulf of Mexico sediments using the sea urchin embryological development test (Carr *et al.* 1995)

Category	Number of samples per category	Number of toxic samples (%)	Predictability (%)
Actual toxicity	200	16 of 200 (11)	–
Not toxic (<TELs)	50	2 (4)	96 (48 of 50)
Possibly toxic (>TELs; <PELs)	123	11 (9)	–
Toxic (one PEL exceeded)	15	3 (20)	20 (3 of 15)
Toxic (two to five PELs exceeded)	12	7 (58)	58 (7 of 12)
Toxic (six to nine PELs exceeded)	0	–	–
Toxic (>10 PELs exceeded)	0	–	–
Toxic (one or more PELs exceeded)	27	10 (37)	37 (10 of 27)
Toxic (two or more PELs exceeded)	12	7 (58)	58 (7 of 12)

[a]TEL, threshold effect level; PEL, probable effect level.

[a]TEL, threshold effect level; PEL, probable effect level.

Table 9. Evaluation of the predictability of the TELs[a] and PELs[a] in southeastern United States sediments

Location	Number of samples correctly predicted as not toxic (%)	Number of samples correctly predicted as toxic (%)

Discussion

The modified weight-of-evidence approach developed here is characterized by a number of attributes that make it attractive for deriving SQGs for Florida coastal waters. Unlike many other approaches to the development of SQGs, the weight-of-evidence approach does not attempt to establish absolute sediment quality assessment values. Instead, the approach delineates ranges of contaminant concentrations that are probably, possibly and not likely to be associated with adverse biological effects. This approach recognizes the uncertainty associated with the prediction of biological effects under a variety of field conditions and relies upon the evidence assembled from numerous independent studies.

One of the more important attributes of the weight-of-evidence approach is its overall practicality. Guidelines for 34 potentially toxic substances were calculated relatively quickly and inexpensively using available data. In addition, by considering matching sediment chemistry and biological effects data from studies conducted in the field, the influence of mixtures of chemicals in sediments is incorporated in the resultant SQGs. This feature increases the degree of environmental realism and, thus, applicability of the guidelines. Furthermore, the information in the BEDS is highly relevant to the guidelines derivation process because it applies to a wide range of biological organisms and end points, incorporates a large number of direct measurements on organisms that are normally associated with bedded sediments and includes many data from various studies conducted in the southeastern United States (including Florida). These attributes are likely to give the SQGs derived using the modified weight-of-evidence approach broad applicability in the southeast, increasing the probability that the guidelines would be appropriate for implementation in Florida.

In addition to the other advantages of the approach, the arithmetic procedures used in this study for calculating SQGs considered the information in both the effects and no effects data sets. Hence, the resultant guidelines were more likely to satisfy narrative objectives. And, in contrast to the apparent effects threshold approach (Barrick *et al.* 1988), the weight-of-evidence procedure does not rely heavily on individual data points. Therefore, outliers do not excessively influence values in the overall guidelines derivation process.

Despite the benefits associated with this approach, a number of limitations were also evident which could restrict application of these guidelines. First, the weight-of-

in the overall guidelines

er of limitations were also
nes. First, the weight-of-

evidence approach does not fully support the quantitative evaluation of cause and effect relationships between contaminant concentrations and biological responses. Although information from spiked-sediment toxicity tests and equilibrium partitioning models is included in the BEDS, the weight-of-evidence approach is still largely based on associations between contaminant concentrations and biological responses. Various factors other than concentrations of the contaminant under consideration could have influenced the actual response observed in any given investigation, including (but not limited to) the additive and synergistic effects of co-occurring contaminants. While the assembly of extensive information from numerous estuarine and marine sites across North America into a single database reduces this limitation, the level of uncertainty associated with the resultant SQGs is still not quantified. We are currently investigating the use of toxic units models to reduce uncertainty (i.e. R.C. Swartz, D.W. Schults, R.J. Ozretich, J.O. Lamberson, F.A. Cole, T.H. DeWitt, M.S. Redmond and S.P. Ferraro submitted).

Application of the recommended approach may also be restricted by other limitations on the available information. Presently, few data exist on the chronic responses of marine and estuarine organisms to contaminated sediments. Furthermore, few data are available for some potentially important contaminants of sediments in Florida, including tributyltin, pentachlorophenol, dioxins and furans and various pesticides. These data gaps impair our ability to evaluate the overall applicability of the approach to Florida.

Sediment-associated contaminants can accumulate in the tissues of aquatic organisms and thus have the potential to adversely affect human and non-human consumers of aquatic biota. However, the guidelines developed in this study do not address either the potential for bioaccumulation or the associated adverse effects of bioaccumulation on higher trophic levels.

One shortcoming of the weight-of-evidence approach is associated with the limitations on the data that describe the potential bioavailability of sediment-associated contaminants (Di Toro *et al.* 1990). Large differences in toxicity of sediment-associated contaminants have been reported for relatively small ranges in concentration for total organic carbon (TOC) and/or acid volatile sulphide (AVS) (Swartz *et al.* 1990, Di Toro *et al.* 1991, Adams *et al.* 1992). However, data on sediment grain size, levels of TOC and concentrations of AVS were not provided in most of the reports reviewed in this study. Thus, it was not possible to express the guidelines in terms of the factors that may influence the bioavailability of these contaminants. While reliance on ranges of concentrations instead of absolute values and consideration of the no effects data set reduces this limitation, sediment quality guidelines are less defensible if they do not account for the factors that control bioavailability (e.g. Di Toro *et al.* 1991). For this reason, the SQGs derived in this study were evaluated to determine their comparability, reliability and predictability. Sediment quality guidelines derived using other approaches and being considered for use in national or regional programs should also be thoroughly evaluated before being implemented.

The results of this evaluation indicate that the SQGs can be used with a high or moderate degree of confidence to assess sediment quality. The SQGs for approximately half of the substances were comparable to other guidelines that have been developed using different approaches or different procedures. Additionally, the SQGs for 28 substances had a moderate or high degree of reliability, as indicated by the data contained in the BEDS. Furthermore, the SQGs for 34 substances, when used

collectively, provided predictive tools for correctly classifying marine and estuarine sediments with respect to adverse biological effects. Overall, the predictability of the dry weight-normalized PELs and TELs was >67 and >94%, respectively, indicating that the potential limitations identified previously do not seriously compromise the applicability of the SQGs. Interestingly, the predictability of the PELs was higher (>80%) for sediment samples that had complex mixtures of contaminants than it was for sediment samples that were contaminated by one or two substances only (predictability = 37%). This increased ability to predict toxicity in sediments with complex mixtures is likely because the database, upon which the guidelines are based, primarily contains information from sites with sediments that contained many chemical substances. Therefore, the guidelines are particularly relevant for assessing sediment quality in areas with multiple contaminant inputs.

A critical consideration in sediment risk assessment is the potential for incorrectly classifying sediments. Based on the results of this assessment, it is apparent that there is an approximately 33% probability of incorrectly classifying non-toxic samples as toxic using the PELs (i.e. false positives). In contrast, there was a relatively low probability of incorrectly classifying toxic samples as non-toxic using the TELs (i.e false negatives). Therefore, the guidelines are considered to be conservative tools for assessing contaminated sediments (i.e. they err on the side of environmental protection; see C.G. Ingersoll, P.S. Haverland, E.L. Brunson, T.J. Canfield, F.J. Dwyer, C.E. Henke, N.E. Kemble, D.R. Mount and R.C. Fox (submitted) for a more comprehensive evaluation of type I and type II errors using SQGs). Together, the evaluations of comparability, reliability and predictability indicate that the SQGs are likely to be appropriate for use in a variety of applications and sites in Florida and, perhaps, elsewhere.

The GOOMEX study, conducted in the vicinity of offshore oil and gas exploration and production platforms in the Gulf of Mexico, provided a unique environment for testing the predictability of the SQGs. The primary contaminants of concern were metals (Cd, Cu, Hg, Pb and Zn) and the sampling design provided a gradient in contaminant concentrations along transects extending from the point source discharge. This situation was unique compared with most urban coastal environments where complex mixtures of organic and inorganic contaminants are usually present due to point and non-point sources of pollutants. Compared with the two studies in coastal areas which used the sea urchin pore water tests, the GOOMEX study had a much lower concordance between predicted and observed toxicity. This may be due to the fact that most of the data used to develop the SQGs was obtained from studies conducted near urbanized coastal areas, where complex mixtures of contaminants are more prevalent. The additive and synergistic effects of these co-occurring chemicals are of necessity incorporated into the SQGs. In this unique study in the Gulf of Mexico, where the numbers and classes of chemicals present were limited compared to urbanized coastal areas, the PELs may be overprotective due to the limited additive or synergistic effects of co-occurring contaminants. Another explanation might be that the particular forms of the metals were insoluble or ligands were present which minimized their bioavailability. The TELs, however, provided accurate predictions of non-toxicity in the GOOMEX study.

The PELs accurately predicted sediment toxicity in two out of three studies used to assess the predictability of the SQGs in coastal areas of the Gulf of Mexico. No

concordance was observed between predicted and observed toxicity in the EMAP study; this disparity might be explained by differences in the types of toxicity tests that were used among studies. The EMAP study utilized whole sediment toxicity tests with adult crustaceans, whereas the GOOMEX study used sea urchin pore water toxicity tests. The sea urchin fertilization and embryo development tests with pore water provide estimates of chronic toxicity and uses, as an end-point, responses of a sensitive life stage of a sensitive species. In contrast, the whole sediment assessments used in the EMAP study involved estimates of acute toxicity to adult crustaceans. The PELs appear to be more predictive of chronic, sublethal effects than the more obvious acute, lethal effects. Likewise, the TELs appear to be protective of chronic, sublethal effects, as demonstrated by the high degree of concordance between the TEL predictions and the observed toxicity with the sea urchin tests. These results emphasize the fact that the organisms used in various toxicity tests differ with respect to their ability to estimate effects of sediment-associated contaminants. Therefore, comprehensive sediment quality assessments should employ a battery of biological tests, at least one of which should be sensitive enough to detect chronic, sublethal effects in sensitive species.

The results of this investigation indicate that the SQGs generally provide reliable and predictive tools for assessing coastal sediment quality in Florida and elsewhere in the southeast. However, the SQGs should not be used as stand-alone sediment quality criteria. The applicability of these guidelines in other coastal areas of the United States has not been fully evaluated. For this reason, the predictability of the guidelines derived using the original (Long and Morgan 1990) and modified (this study) approaches will be compared using independent data sets from throughout the United States and Canada. The results of this comparison, which will be published in a subsequent manuscript, will provide additional guidance in the use and applicability of the respective SQGs.

Acknowledgements

Encouragement, suggestions, and advice were provided by Herb Windom (Skidaway Institute of Oceanography), Steve Schropp (Taylor Engineering Inc.), Gail Sloane and Tom Seal (Florida Department of Environmental Protection), Pam Haverland (National Biological Survey), Sherri Smith (Environment Canada) and Jay Field (National Oceanic and Atmospheric Administration). Technical support was also provided by M.L. Haines, B. Charlish, K. Brydges, B. Moore and M. Popadynec (MacDonald Environmental Sciences Ltd). Initial drafts of this manuscript were reviewed by Sherri Smith, Pam Haverland and Jim Dwyer. Helpful and constructive comments were also provided by two anonymous reviewers.

Review of

Sediment Quality Objectives for Enclosed Bays and Estuaries of California

By

This is a review of the report

Draft Staff Report
Water Quality Control Plan for Enclosed Bays and Estuaries
Part 1. Sediment Quality
State Water Resources Control Board
California Environmental Protection Agency
September 27, 2007

The review is in two parts. The first responds directly to the questions posed in Attachment 2. The second is an Appendix that presents a more complete discussion of the issues and a preliminary analysis of the sediment toxicity data to illustrate the application of mechanistic criteria.

1. Are benthic invertebrates important ecologically relevant receptors to protect from direct exposure to toxic pollutants in sediments within the bays and estuaries of California?

Yes, and the rationale for protecting benthic invertebrates are presented very well in the report.

2. Are multiple lines of evidence appropriate to assess the potential risk to benthic invertebrates from toxic pollutants in sediments within the bays and estuaries of California?

Clearly multiple lines of evidence are required to assess the potential risk to benthic invertebrates from toxic pollutants in sediments. This is the case both within the bays and estuaries of California and for other sites, e.g. streams, rivers and lakes. The report presents the rationale and appropriate citations to the literature supporting this position.

3. Individual lines of Evidence
    a. Are proposed sediment toxicity indicators appropriate for assessing both the potential risk of exposure from toxic pollutants and the biological effects in benthic invertebrates within the bays and estuaries of California?

The analysis of the available toxicity tests and the methodology presented in the report for converting toxicity tests for use in judging the level of toxicity appears to be sound. I find the rejection of the Ampelisca abdita test a little strange since the test is employed widely, but a rationale is presented.

b. Are proposed sediment chemistry indicators appropriate for assessing both the potential risk of exposure from toxic pollutants to benthic invertebrates within the bays and estuaries of California?

The sediment chemistry indicator developed in the report is incomplete. As the report states, there are two general methods available for assessing the potential for toxicity in sediments: empirical and mechanistic. The report embraces the empirical method and dismisses the mechanistic method in a few sentences. In Section 5.5.3.2 "What chemistry indicators should be used?" the reasons are given

> "Mechanistic SQGs based on equilibrium partitioning were not included for several reasons. Data for some of the key parameters needed to apply the mechanistic guidelines (e.g. sediment acid volatile sulfides and simultaneously extracted metals) were not available. In addition chemistry data were not available for all the potential toxicants in the samples, which limited the predictive ability of the guidelines for organics. Previous analyses using Southern California data showed that these limitations significantly affected mechanistic SQG performance; application of a partial suite of mechanistic SQGs for organics resulted in poor predictive ability (Vidal and Bay 2005)."

However *both* empirical and mechanistic methods are incomplete. Neither method can predict with more than a modest degree of certainty the outcome of a toxicity test on a sediment from the field that is contaminated with many, and possibly unknown and unmeasured contaminants. Fig. 1 presents the results of the analysis from "Comparative Sediment Quality Guideline Performance For Predicting Sediment Toxicity In Southern California, USA" by Vidal and Bay 2005.

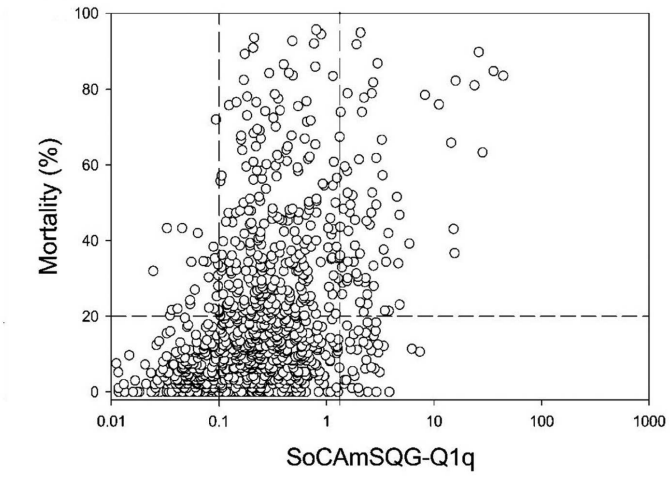

Figure 1

The empirical criteria predicts the lack of toxicity reasonably well (SoCAmSQG-Q1 < 0,1) but fails to discriminate between toxic and non toxic sediments at the same value of SoCAmSQG-

Q1q for the bulk of the data in the range of 0.1 to 1.0. The mechanistic criteria as evaluated by Vidal and Bay appeared to have no predictive ability at all in this data set.

I have prepared an appendix attached to this review that discusses these issues in more detail. It illustrates the applicability of mechanistic criteria to the available data to demonstrate their utility, even if the necessary data for a complete and rigorous application are not available. As demonstrated in the appendix, the role of mechanistic criteria is not to predict toxicity. For the reasons given above and as presented in more detail in the appendix, the role of mechanistic criteria is to determine if the observed toxicity can be explained by known modes of bioavailability and toxic mechanisms.

The results can be used to judge whether the chemical cause of the toxicity for particular sediment is likely to be metals, PAHs and other narcotics, or the pesticides that have been measured. The alternative is that none of these classes of chemicals appear to be the cause of the observed toxicity and the situation is quite uncertain. If the later is the case, then the result of the best professional judgment assessment of the situation would change to be very uncertain, regardless of the level of chemical contamination. Also, in my opinion, more information about the toxic sediment should be collected so that a more secure decision can be made.

Therefore, both mechanistic and empirical criteria should be used to judge the extent of toxicity that is likely due to chemicals, and if the chemical data are consistent with known measures of bioavailability and modes of chemical toxicity. Ignoring mechanistic criteria is not employing the best available science to support regulatory judgments. Mechanistic criteria have been developed and validated from very large datasets. A comprehensive review with citations to the primary literature is available (Di Toro et al., 2005). They are based on quantitative mechanistic models that have been published over the years in the peer reviewed literature, are highly cited, and have been tested by numerous independent investigators. They provide a framework for understanding chemical causes of sediment toxicity, and can be used to discriminate between two important cases: (1) we understand the chemical cause of the observed toxicity; (2) we do not, at our present level of understanding. Empirical criteria cannot provide this important additional information.

c. Are proposed benthic community indicators appropriate for assessing the biological effects through benthic community condition within the bays and estuaries of California?

The report presents the rationale and methodology for selecting the benthic community indicators and they appear to be sound.

4. Is the integration framework appropriate for determining if a station meets the narrative objective?

The integration framework – the quantification of best professional judgment (BPJ) – is to be commended. It produces a specific outcome for the data to be evaluated. The test of the method by experts on a small dataset is a nice demonstration of its utility in quantifying BPJ and making it applicable to specific sediment.

I would suggest one further test. Evaluate the entire dataset for which the necessary triad information is available. What proportion of the tested sediments is in which level of concern? There are a number of arbitrary cutoff levels in the framework, and it is important to know if these choices trigger many highly toxic sediments. A criterion that is too restrictive and triggers too many false positives is not a useful regulatory tool.

5. Is the implementation of the narrative SGO appropriate given the limitations of the individual tools and potential uncertainty associated with sediment quality assessment?

I would strongly recommend the inclusion of the results of an analysis of the data using mechanistic criteria for the purposes of determining the probable cause(s) of toxicity, or whither the cause is unknown. An example application is included in the appendix to this review.

1. Are there any additional scientific issues that are part of the scientific basis of the proposed rule not described above?

I would recommend that a report be prepared that documents the calculations that lead to the LRM in the report so that the analysis can be reproduced, including the analysis leading to Table 2 from Direct Effects Calculation

In order to apply mechanistic criteria without the approximations used in the appendix, certain data are required. Although the historical data may not include the appropriate measurements, all future data collection should include at least: SEM and AVS for a proper assessment of metal toxicity; a complete suite of PAHs including alkylated PAHs and sediment organic carbon to evaluate PAH toxicity. Not requiring such data is not consistent with using the best science.

Section 5.7.4. The staff recommendation is to apply the narrative SQGs to NPDES permits as receiving water limits. Unless mechanistic criteria can successfully identify the chemical causes of the toxicity it is not possible to establish receiving water limits. As discussed above it is the universally agreed that empirical criteria cannot be used to identify the chemical causes of toxicity.

2. Taken as a whole is the scientific portion of the proposed rule based upon sound scientific knowledge methods and practices?

With the exception of the exclusion of mechanistic criteria for judging the possible chemical causes of toxicity – and this is a glaring problem – the implementation is based on sound scientific knowledge methods and practices.

Appendix 1

Empirical and Mechanistic Criteria

To put my review in context, I will quote from the paper "Comparative Sediment Quality Guideline Performance For Predicting Sediment Toxicity In Southern California, USA" (Vidal and Bay, 2005), cited in the report (p76), which examines these issues. First, the nature of the two methods:

> "Sediment quality guidelines can be classified in two main categories based on the approach used to derive their values: empirical and mechanistic. Empirical SQG approaches are based on the statistical analysis of large databases of synoptic sediment chemistry and toxicity data to identify chemical concentrations associated with various levels of biological effects. Examples of this type of SQG include the effects range–low and effects range–median (ERM) values, which are concentrations corresponding to the 10th and 50th percentiles of the distribution observed in toxic samples, respectively [2]. Variations in chemical speciation and bioavailability are not directly addressed in empirical SQGs; such effects are indirectly incorporated into these guidelines through the use of a database containing samples from diverse locations and sediment types. Empirical SQGs have two major practical advantages: they can be calculated for a large number of contaminants, and only routine chemical analysis data are needed for their application. "
>
> "The second principal type of SQG approach includes values based on mechanistic models that incorporate factors that affect the bioavailability of chemicals in the sediment. Mechanistic SQGs may incorporate the effects of sediment organic carbon or sulfides (for metals) on the equilibrium partitioning of contaminants and also use laboratory dose–response models to account for the effects of multiple contaminants [3–5]. Sediment quality guidelines based on equilibrium partitioning (EqP) for organics have been developed for selected pesticides and organics [6–8]. The EqP for organics theory assumes that nonionic chemicals in sediment partition between the organic carbon present in the sediment as well as in the interstitial (pore) water and the benthic organisms living on the sediment. At equilibrium, if a concentration is known in one of the phases (e.g., sediment), then the other ones can be predicted [6]. By accounting for variations in bioavailability and mixture effects, mechanistic SQGs have a greater ability relative to empirical SQGs to determine the specific contaminants responsible for toxicity. Mechanistic SQGs often require more extensive chemical data, and published values are not available for many contaminants, relative to empirical SQGs."

This is a correct characterization of the current understanding of the nature and appropriate use of the two methods. The report embraces the empirical methods and dismisses the mechanistic methods in a few sentences.

> "5.5.3.2 What chemistry indicators should be used? … Mechanistic SQGs based on equilibrium partitioning were not included for several reasons. Data for some of the key parameters needed to apply the mechanistic guidelines (e.g. sediment acid volatile sulfides and simultaneously extracted metals) were not available. In addition chemistry data were not available for all the potential toxicants in the samples, which limited the predictive ability of the guidelines for organics. Previous analyses using Southern California data showed that these limitations significantly affected mechanistic SQG performance; application of a partial suite of mechanistic SQGs for organics resulted in poor predictive ability (Vidal and Bay 2005)."

I regard this dismissal as premature and potentially dangerous. There has been much discussion in the literature and at meetings about the appropriate uses of empirical and mechanistic guides (Wenning and Ingersoll, 2005). The empirical guidelines suggested in this report are based on fitting a logistic probability model to large sets of amphipod mortality data sets collected in California. An equation is developed for each measured potential toxicant in the sediment. Then these probabilities are combined to make predictions of results of these The limitations of such a procedure are well known. To quote from Vidal and Bay, 2005

> "The results of these analyses showed that exceedances of individual empirical chemical guidelines are unreliable indicators of toxicity and do not necessarily indicate the cause of toxicity. For example, the mean SQGQ1q and mean ERMq had similar nontoxicity efficiency and specificity values, yet the mean SQGQ1q uses only nine chemicals in comparison to the 24 used for the mean ERMq. The presence of many contaminants in a sediment sample and the high degree of correlation among them indicates that most empirical SQG values should not be used in isolation but rather be used in combination to provide an overall indication of the potential for adverse effects (e.g., likely to be toxic or nontoxic). The exceedance of an individual empirical SQG value is not an indication that a chemical is toxic to organisms. Other studies have also suggested caution in the use of individual chemical SQG values when assessing sediment quality [14,16]. "

The Regression Model

The California regression model is based on the log logistic equation (page 13 of Appendix A and page 2 of Direct Effects Calculation)

$$p = \exp(b_0 + b_1 \log_{10}(c))/(1+ \exp(b_0 + b_1 \log_{10}(c)) \quad (1)$$

It can be shown that this equation is equivalent to the more intuitive formulation

$$p = 1/(1 + (EC50/c)^{\beta}) \quad (2)$$

where

$$\beta = b_1 /\ln(10) \quad (3)$$

$$EC50 = \exp(-b_0/ \beta) \quad (4)$$

The EC50 is the concentration at which a 50% mortality is predicted and β is the usual slope parameter.

The example in the Direct Effects Calculation can be used to check these equations.
For cadmium: c = 0.15 mg/kg, b_0 = 0.2894, b_1 = 3.1764 and p = 0.09. Using the above equations: β = 1.38, EC50 = 0.81 mg/kg and p = 0.09 as before. Note that the EC50 is approximately 1 mg Cd/kg by visual inspection of Fig. 2 in Direct Effects Calculation, which is consistent with EC50 = 0.81 mg/kg calculated above.The parameters for the other chemicals are listed below

Table 1
(Table 2 from Direct Effects Calculation and EC50 and β)

	units	b_0	b_1	β	EC50
Cd	mg/kg	0.2894	3.1764	1.38	0.81
Cu	mg/kg	-5.5931	2.5885	1.12	144.79
Pb	mg/kg	-4.7228	2.8404	1.23	46.00
Hg	mg/kg	-0.0618	2.6837	1.17	1.05
Zn	mg/kg	-5.1337	2.4205	1.05	132.11
HPAH	ug/kg	-8.1922	1.9995	0.87	12506.17
LPAH	ug/kg	-6.8071	1.8827	0.82	4126.72
Alpha Chlordane	ug/kg	-3.408	4.457	1.94	5.82
Dieldrin	ug/kg	-1.8344	2.589	1.12	5.11
Trans Nonachlor	ug/kg	-4.259	5.3135	2.31	6.33
Total PCBs	ug/kg	-4.4144	1.4837	0.64	944.64
4-4-DDT	ug/kg	-3.5531	3.2621	1.42	12.28

The Basis for the Model

The model parameters (b_0 and b_1, or equivalently EC50 and β) are based on regression fits to the toxicity and chemical data set assembled for this purpose. The report, appendices, and supplementary information do not contain the data and procedures from which these parameters were derived. In an attempt to understand the procedure in more detail, I have attempted to reproduce the fitting procedure. The Access database StatewideSQO_11_17_06.mdb is available on the web. I retrieved the Eohaustorius estuarius (EE) mortality data and the corresponding chemistry. It was not clear what data was used in generating the report values and I did not have the time completely understand this very large database. I restricted the retrieval to "SP" (survival percentage) and "SD_RESULT" (not replicates etc.) which seemed reasonable choices. One of my recommendations is that a report be prepared that documents the calculations that lead to the LRM in the report so that the analysis can be reproduced. Nevertheless the results of this analysis are very instructive.

This analysis will focus on cadmium as an illustration. The Cd data are presented below in Fig. 1.

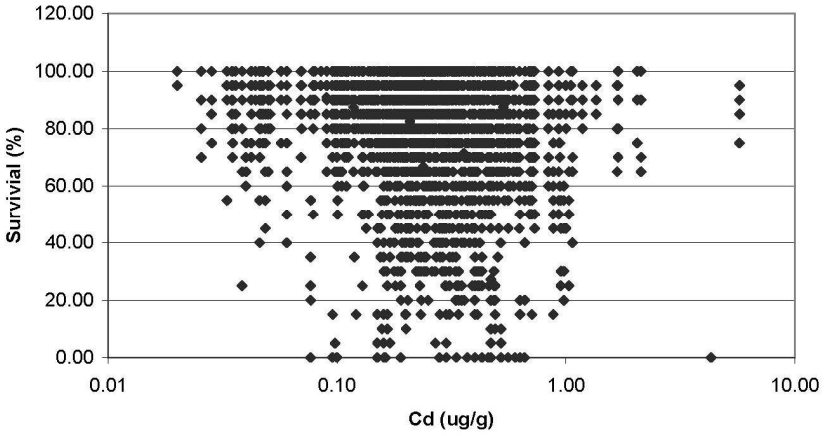

Figure 1

The other metals and PAH data are shown in figures 11 and 12 in the Figure appendix. The data all share a common feature. At low concentrations there is mostly >80% survival indicating no toxicity. At higher concentrations, some samples are not toxic (>80% survival) and others are highly toxic (0% survival). Note that these two extremes can occur *at the same cadmium concentration!* This is the central problem in understanding the toxicity of chemicals in field collected sediments with multiple contaminants. The difficulty is that it is not clear that Cd is causing toxicity in any of these sediments since bioavailability is not accounted for in empirical criteria. It is mechanistic criteria that strive to causally relate a chemical concentration to a toxic response.

This idea behind logistic regression models is to see if it is more probable that as the Cd concentration increases, the survival percentage increases. Fig. 3 presents the results of a fit of the logistic regression equation (2) to the data. The logistic equation using the parameters in Table 1 is also shown. A fit to the data produces an almost flat relationship, indicating that there is virtually no relationship between percent survival and Cd concentration. Yet the logistic equation using the Table 1 parameters seem to indicate a strong relationship.

The reason is, I think, that the data are prescreened before the logistic equation is fit. The procedure is described in Field et al., 2002.

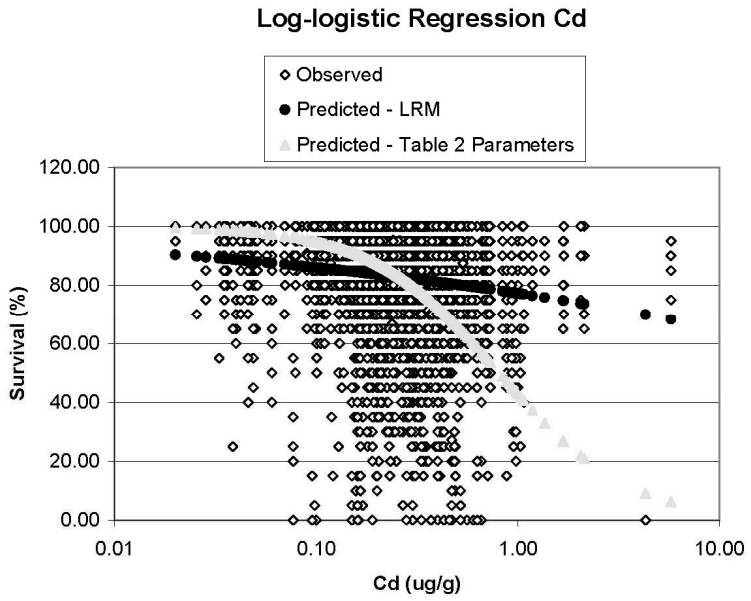

Figure 2

"The presence of multiple contaminants, many of which may be present at very low concentrations, frequently complicates evaluating the relationship between the concentration of an individual contaminant and toxicity in field-collected sediments. Consequently, the data for samples that were identified as toxic in this investigation were further screened before being used to develop the logistic models for each individual contaminant [5]. This screening process excluded toxic samples in which the selected contaminant was unlikely to contribute substantially to the observed toxicity. Following the general screening approach used by Ingersoll et al. [12] and similar to that used by others [1,7,13], the concentration of the selected chemical in each toxic sample was compared with the mean of the concentration of that substance in the nontoxic samples collected in the same study and geographic area. If the concentration of a chemical in an individual toxic sample was less than or equal to the mean concentration of that chemical in the nontoxic samples from that study area, it was considered unlikely that the observed

toxicity could be attributed to that chemical. Therefore, these toxic samples were not included in the screened data set used for developing the logistic model for that chemical. All nontoxic samples were included in these analyses."

An example of the importance of pre-screening the data is shown in Fig. 4 from Field et al, 1999. Before screening, there is virtually no relationship between probability of toxicity and phenanthrene concentration. After prescreening, there is a very nice relationship. Thus the role of pre-screening is critical to the development of LRMs.

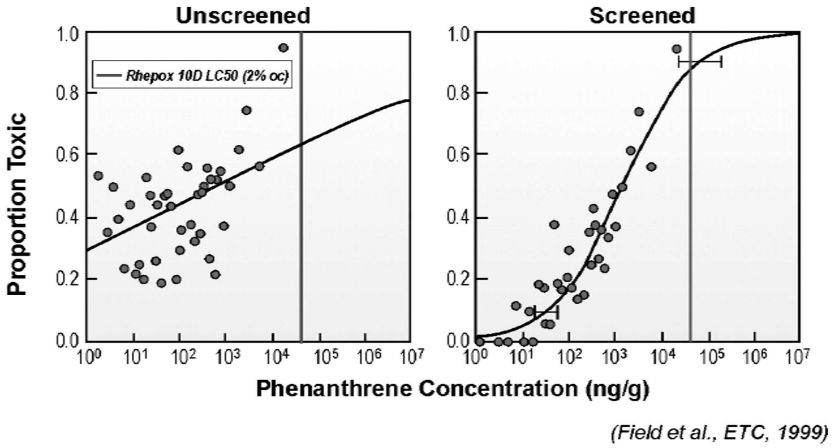

Figure 3

Following this procedure, the median concentration of all nontoxic (survival >80%) samples was found (Cd = 0.26 mg/kg). Then all toxic samples (survival >80%) for which Cd < 0.26 mg/kg were removed. The result is shown in Fig. 5. Since the samples that exhibited toxicity at low Cd concentrations (the samples in the lower left quadrant) have been removed, there is now a relationship between toxicity and Cd concentration. A fit of equation (2) to the screened data is now closer to the result using the Table 1 parameters. Since the methodology used to derive the results in the report are not available, it is not possible to understand why there is still a discrepancy. Nevertheless, it is clear that the pre-screening of the data is a critical part of the analysis.

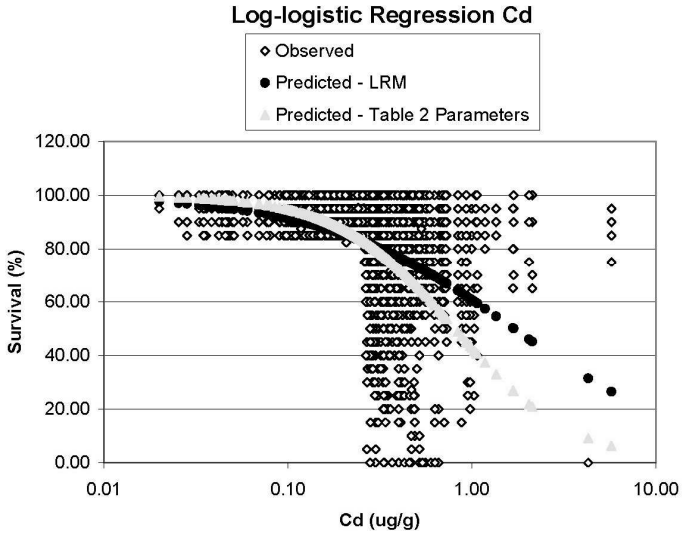

Figure 4

Critique of the Logistic Regression Model (LRM)

Consider the situation when the logistic regression model (LRM) is applied to a new sediment sample. The probability of survival that is computed from the Cd concentration uses the curve derived from the data in Fig. 5. But applying that curve presupposes that the new data comes from the prescreened data set, i.e. it is known a priori that whatever toxicity the sample might exhibit is not due to Cd if the Cd concentration is low. But there is no way of actually knowing that is the case for the new sample at hand. It is, rather, an assumption upon which the method is based. Also note that this result is not peculiar to cadmium. All the toxicity-chemistry data share the same general pattern, and all are pre-screened to produce the LRM.

Another interesting feature of the LRM is that the EC50s for the metals, which are derived from the screened dataset, are comparable to the median concentrations of the metals in the entire dataset. Fig. 6 presents the ratio of the EC50 (Table 1) to the median concentrations computed from the entire data set and also for the non-toxic samples. The ratio ranges from 1 to 4, indicating that the EC50 used in the LRM is a measure of the general level of contamination of the sediments in the dataset. Also the β's are roughly the same. This suggests that for the metals at least, the LRMs are modeling the extent of contamination. They predict low toxicity if the level of metal concentration is well below the median concentration in the datasets.

This is not an unreasonable way to predict *lack* of toxicity for relatively clean, i.e. uncontaminated, sediments. However, it is not much of a guide for predicting the actual toxicity if the level of contamination is larger. The reason the logistic model "fits the data" is that the troublesome data – those showing toxicity at low concentrations – are removed by the pre-screening procedure.

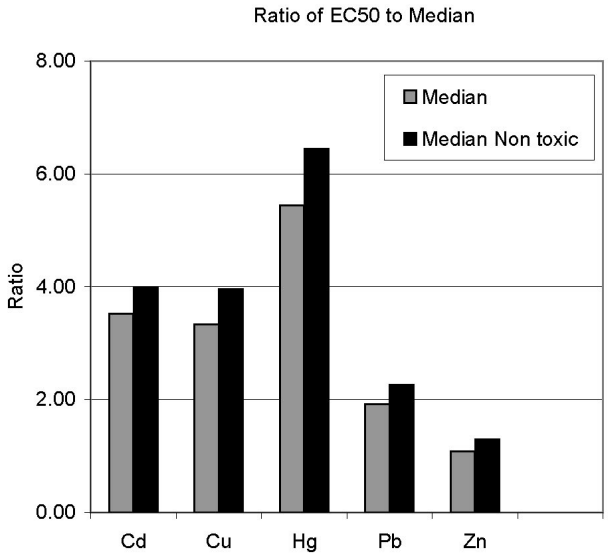

Figure 5

Use of Mechanistic Models

Mechanistic models attempt to relate toxicity to the bioavailable fraction of the chemicals in sediments. The most well developed of there are for mixtures of metals (Ankley et al., 1996, USEPA, 2005) and mixtures of PAHs (Di Toro & McGrath, 2000, USEPA, 2003). They use the Equilibrium Partition Model (Di Toro et al., 1990) as the general framework and apply toxicity mixture and partitioning models to predict the toxicity of single chemicals and chemical mixtures. The models have been validated using spiked sediments (Berry et al., 1996) for which the toxic chemical(s) are not in doubt. Additionally field datasets have been employed that are heavily contaminated with either metals (Hansen et al., 1996) or PAHs (Di Toro & McGrath, 2000) for which the chemicals causing the toxicity can be reasonably assumed to be known.

It has been found that for the large dataset employed for establishing the empirical criteria in this report, the mechanistic criteria do not appear to be as predictive as the empirical criteria. Fig. 7 presents the results of the analysis from Vidal and Bay 2005.

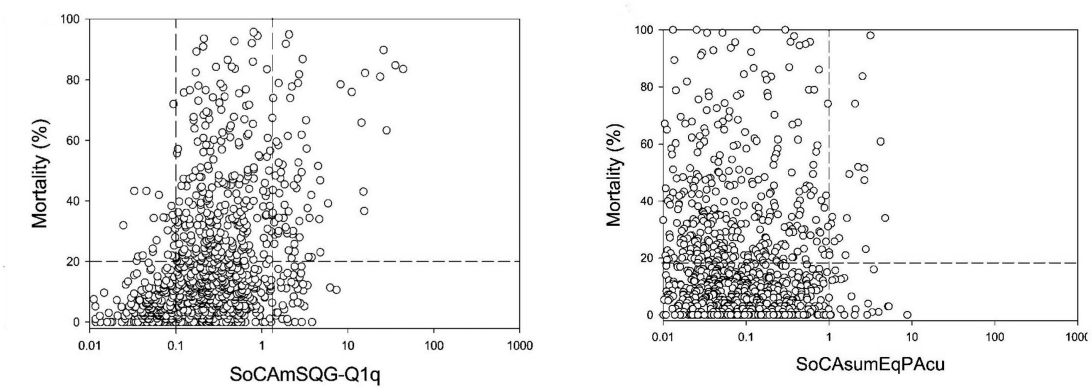

Figure 6 from Vidal and Bay 2005

The SoCAmSQG-Q1q model has very much the same pattern of predictive power as the individual datasets (Fig. 5). For a low level of contamination there is only a control level of mortality. At higher levels of contamination there are both toxic and non-toxic sediments at the same level of contamination (the x-axis). By contrast the EqP comparison shows no discrimination.

There are a number of possible reasons for the failure of the EqP based predictions Certainly one important problem is the lack of the appropriate measure of the critical metal binding parameter acid volatile sulfides (AVS) (Di Toro et al., 1990, 1992) in the majority of sediments in the dataset. The second is the lack of measurements for all the significant PAHs that may be present (McGrath & Di Toro 2000). Finally, and the most vexing problem, is the lack of measurements for other compounds that may be causing toxicity. Nevertheless, the EqP models can be very useful in understanding the possible causes of toxicity.

SEM-AVS Model of Metal Toxicity

For metal toxicity, it has been shown that if the molar sum of the metal concentrations that is simultaneously extracted (∑SEM) with the AVS is less than the AVS concentration, i.e. ∑ SEM – AVS < 0 no toxicity is expected. This has been demonstrated using acute and chronic laboratory spiked and field deployed spiked sediments (Di Toro et al., 2005). SEM data are not available but the molar sum of the total extracted metals (Total Metal = Cd + Cu + Ni + Pb + Zn) are available and inferences can be drawn from these concentrations. Fig.8 presents the data.

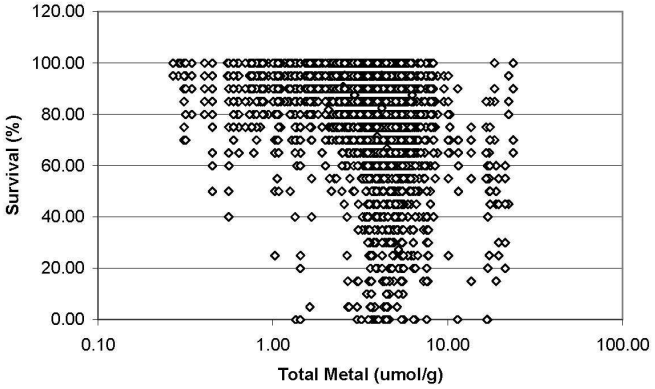

Figure 7

The pattern of the data is not much different from either Cd (fig 2) or the other metals (Figs. 11-12). However the difference is that this distribution can be interpreted in terms concentration of AVS in sediments. For example, little mortality is seen for total metal concentrations < 2 umol/g. If the AVS in all the sediment samples were at least 2 umol/g, not a large amount of AVS for muddy sediments, then the lack of toxicity due to metals would be expected. If AVS concentrations were available for all the data, then metal toxicity could be unambiguously ruled out for those sediment for which Total Metal – AVS < 0, since this would guarantee that $\sum$ SEM – AVS < 0.

There is a small amount of AVS data in the database for which Total Metal – AVS can be calculated and compared to observed mortality. These are shown in Fig. 9. Most of the toxic sediments have AVS concentrations greater than Total Metal, i.e. Total Metal –AVS < 0. Since Total metal > $\sum$ SEM, the data would plot further toward the negative values if $\sum$ SEM were available. This would indicate that in these sediments AVS is greater than $\sum$ SEM and it is unlikely that metals are causing toxicity in this subset of the database. The point is that a judgment can be made about the likely cause of toxicity in these sediments that is not possible using the empirical criteria.

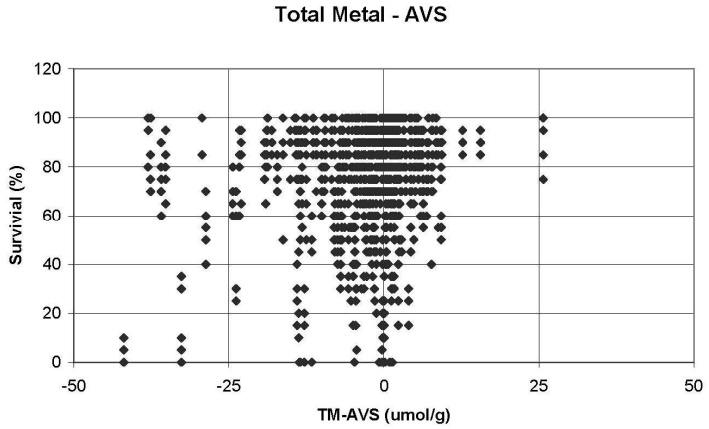

Figure 8

Target Lipid Model of PAH Mixture Toxicity

An EqP model has been developed for mixtures of PAHs is sediments, based on the Target Lipid Model of Narcosis Toxicity (Di Toro et al., 2000). The Criteria corresponding to chronic effects and 10 day Rhepoxynius abronius survival are listed in Table 2. The average and standard deviation of criteria for low (LPAH) and high (HPAH) molecular weight PAH sums as well as total PAH are listed. The toxicity of a mixture is found by summing the toxic units – the ratio of the concentrations to the criteria in Table 2 -- comparing the results to one toxic unit for 50% effect. To a good approximation, the same result is obtained be evaluated by summing the organic carbon normalized molar concentrations of PAHs and comparing the sum to the average criteria. The reason is that the organic carbon normalized sediment criteria for the individual PAHs do not vary very much. For example, the criteria vary from 16.18 to 21.96 umol/gOC for the R. abronius LC50s. An explanation based on the equations for toxic units is available (Di Toro & McGrath, 2000).

Table 2

PAH Sediment Criteria for Chronic Effects and 10 day Rhepoxynius abronius Survival

Chemical	CAS number	MW (g/mol)	Log Kow	Chronic EC50 (umol/gOC)	R. abronius LC50 (umol/gOC)
Acenaphthylene	208968	152.2	3.22	5.03	16.18
Naphthalene	91203	128.19	3.36	5.09	16.38
1-Methylnaphthalene	90120	142.2	3.84	5.31	17.08

Acenaphthene	83329	154.21	4.01	5.39	17.34
Fluorene	86737	166.2	4.21	5.48	17.64
2,6-Dimethylnaphthalene	581420	156.23	4.37	5.56	17.89
Anthracene	120127	178.2	4.53	5.64	18.15
Phenanthrene	85018	178.2	4.57	5.66	18.21
2,3,5-Trimethylnaphthalene	2245387	170.26	4.86	5.8	18.68
LPAH				5.43(0.25)	17.5(0.80)
Pyrene	129000	202.26	4.92	5.83	18.78
1-Methylphenanthrene	832699	192.26	5.04	5.89	18.97
Fluoranthene	206440	202.26	5.08	5.92	19.04
Benzo[a]anthracene	56553	228.29	5.67	6.23	20.05
Chrysene	218019	228.29	5.71	6.25	20.12
Benzo[a]pyrene	50328	252.31	6.11	6.47	20.84
Perylene	198550	252.31	6.14	6.49	20.89
Benzo[e]pyrene	192972	252.32	6.14	6.49	20.89
Benzo[b]fluoranthene	205992	252.32	6.27	6.56	21.13
Benzo[k]fluoranthene	207089	252.32	6.29	6.58	21.17
Benzo[ghi]perylene	191242	276.34	6.51	6.7	21.58
Dibenz[a,h]anthracene	53703	278.35	6.71	6.82	21.96
Indeno[1,2,3-cd]pyrene	193395	276.34	6.72	6.83	21.98
HPAH				6.39(0.34)	20.6(1.1)
TPAH				5.97 (0.57)	19.2(1.84)

The total PAH data in units of umol/gOC is presented in Fig. 10. It is computed from the low (LPAH) and high (HPAH) molecular weight PAH data using average molecular weights for these classes, and the organic carbon concentration of the sediment, which is in the database.

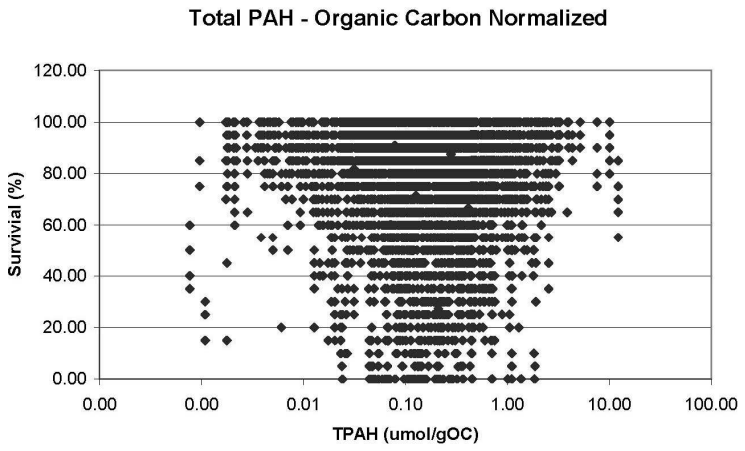

Figure 9

The data has the same shape as the previous chemicals, but as with the metals data, the appropriate toxicity threshold is known. For the 10 day Rhepoxynius abronius survival the average LC50 is 19.2 umol/gOC (TPAH in Table 2). No sediment in Fig. 10 appears to exceed this threshold so it appears that PAHs are not the cause of the toxicity in any of these samples.

There is a significant problem, however, with applying this logic to these data. The criteria apply to the sum of *all* PAHs. But the available data are for only the PAHs in bold face type in Table 2. In particular the alkylated PAHs, which are primarily associated with petroleum contamination, can be a large component of the TPAH and these are not being adequately measured. For these data there is only one representative component 2-methylnaphthalene. Thus it is possible that the total PAH concentration in the sediments could be larger.

The conclusion of this analysis is either that PAHs are not the cause of toxicity in these sediments, or there is large fraction of PAHs that are not being measured, that are contributing to toxicity.

Summary of Empirical and Mechanistic Model Applications

The purpose of this appendix is to examine the utility of empirical and mechanistic models in the evaluation of toxicity of sediment samples. The empirical models estimate the probability of observing toxicity based on the level of contamination. When the sediments have low levels of most contaminants, they predict that the sediment will not be toxic. This conclusion is almost forced by the pre-screening procedure. As levels increase the prediction is that toxicity becomes more likely. But it should be clear from the above analysis that the *cause(s)* of the toxicity cannot be judged from empirical criteria. They are simply responding to the increasing level of overall contamination. The higher the overall level of contamination, the more like it is that toxicity will be found.

The mechanistic criteria can make predictions about which classes of chemicals are possibly involved in the observed toxicity. If the AVS exceeds the total metal concentration, metal toxicity is almost surely not present. If the organic carbon molar sum of the PAHs in the sediment, including the alkylated compounds, is less than the appropriate LC50 for the species being tested, e.g. 19.2 umol/gOC for *Rhepoxynius abronius* survival, then PAHs are almost surely not the cause of toxicity.

If neither metals, nor PAHs are the causes of toxicity, and similar screening calculations can be made for other measured constituents, this information can be included in the next step in the investigation. At least, we know we either know or do not know the causes of toxicity. If the causes are known, we can proceed with confidence. If the cause is unknown, than a completely different approach is warranted. This is crucial information to making judgments about whether sediments are toxic due to chemical contamination, and whether the information at hand is consistent with known chemical modes of toxicity in sediments.

EXECUTIVE SUMMARY

This report summarizes an evaluation of two methods that have been used to establish biological effects thresholds of chemical contamination in sediments; namely, the Apparent Effects Threshold (AET) and the Effects Range-Median (ERM) methods. The work summarized here was initiated by conclusions made in the report entitled *Sediment Injury in the Southern California Bight: Review of the Toxic Effects of DDTs and PCBs in Sediments* (MacDonald, 1997). In that report, threshold concentrations of DDTs and PCBs were derived using the ERM method and then used for predicting toxic and non-toxic responses in Southern California Bight sediments. The implication of findings in the MacDonald report was that derived threshold concentrations could be used to establish sediment quality guidelines that could, in turn, be used to set target remediation levels for selected contaminants, or to establish the basis for injury.

In light of these findings, ENTRIX undertook a study to evaluate the two methods used to establish threshold concentrations for sediment contaminants. This study focused on evaluating the strength of relationships between concentrations of various contaminants in sediments and common measures of toxicity, and evaluating the statistical basis of the AET and ERM methods for establishing threshold concentrations in selected marine sediment data.

There were three overall objectives of this study: 1) to determine the general applicability of AET and ERM methods for evaluating sediment quality: 2) to document limitations in applying AET and ERM methods for evaluating specific contaminants of interest (DDT and PCBs) in the Southern California Bight sediments; and 3) to critique the two methods for their ability to provide ecologically and statistically defensible sediment toxicity guidelines. A summary of major activities and findings of the present study are given below.

- ENTRIX conducted an extensive search for relevant data for use in meeting the project objectives. The search included contacts in Canada, Florida, and State of California agencies,international scientific journals, and professionals in the field of sediment toxicology. A total of 40 data files containing matching (i.e., co-occurring or synoptic) sediment chemistry and toxicity data from marine and freshwater areas were retrieved and electronically stored. We found only ten (10) of these files contained outcomes of statistical comparisons between biological responses in test sediments and controls and, hence, were suitable for evaluation of the AET and ERM methods.

  ENTRIX examined these data sets and associated report documents to ensure that the information was technically defensible and accurate using quality Assurance/ quality control procedures. Approximately 15,000 records of co-occurring measurements were examined and included in the database for analysis.

- We found serious discrepancies in data used in the MacDonald (1997) Southern California Bight report , calling into question the validity of findings and conclusions

related to Los Angeles Harbor sediments as presented in the MacDonald (1997) report. Detailed evaluation of the data used in the MacDonald (1997) report in developing DDT and PCB thresholds is warranted.

- Based on our examination and analysis of the literature , we found that the AET and ERM methods have inherent limitations. We confirmed conclusions previously reached by other investigators which are that neither method can 1) establish cause-and-effect relationships between chemical concentration and biological effects; 2) account for factors important in determining bioavailability of chemicals, and; 3) account for biological effects due to unmeasured concentrations of other chemicals or chemical mixtures.
- An underlying assumption in successfully applying either the ERM or AET method for setting injury levels or sediment clean-up goals is being able to find ecologically and statistically significant relationships between individual biological effects and contaminant concentrations. We could not confirm that any such relationships existed in the MacDonald 1997 report after extensive graphical and statistical analyses.
- For San Diego Harbor sediments (Fairey *et al., 1996)*, we determined that use of either AET- or ERM-based toxicity threshold concentrations of total DDT or total PCB for setting injury or sediment clean-up levels would not be justified since these thresholds failed to distinguish between toxic and non-toxic effects for three toxicological endpoints. Hence, implementing sediment quality guidelines based on these thresholds would not guarantee achieving the intended ecological benefits to natural resources

1.0 INTRODUCTION

Over the past 10-15 years, concerns have arisen over the biological hazards associated with chemical contaminants that have accumulated in both marine and freshwater sediments. These concerns have motivated development of several methods aimed at deriving sediment quality criteria for providing long-term management of contaminated sediments. Two such methods are the Apparent Effects Threshold (AET) and the Effects Range-Median (ERM) methods. The ERM method is based on a modified version of the National Status and Trends Program (NSTP) method (Long and Morgan 1990; Long et al. 1995). ERM values were also used to determine sediment threshold concentrations of DDTs and PCBs in Southern California Bight sediments and to determine if DDT (and various DDT metabolites) and PCBs occur in Southern California Bight sediments at concentrations sufficient to adversely affect sediment-dwelling (benthic) species occurring in the area (MacDonald 1997). The AET method was first developed by Tetra Tech (1986) for assessing adverse biological effects associated with 64 organic and inorganic substances in sediments of Puget Sound WA.

The methods are statistically based, in that they rely on comparing measured biological effect responses in test sediments (either field-collected or chemically spiked) with the same responses in control sediments. A statistical test is then used to determine whether or not these responses are significantly different from one another. The outcomes of these tests are used as partial decision criteria to classify each sediment sample as being either an *effect* (i.e., response is significantly different from the control) or *no-effect* (i.e., response is not significantly different from the control). Once each sample is properly classified, the methods employ quite different techniques in assessing the relationship between biological effect classification and concentration of a contaminant. For the AET method, *effect* and *no-effect* samples are arrayed against the concentration of each chemical of interest and the threshold is chosen as that concentration above which an *effect* is always observed. For the ERM method, a quantile plot of chemical concentration for the *effect* samples is constructed and the threshold (i.e., the effects range-median or ERM) is designated to be the 50^{th} percentile or median of the distribution. A quantile plot is similar in appearance to a cumulative distribution plot; for example, if chemical concentration for the *effect* samples is normally distributed, then the quantile plot should appear S-shaped. Both methods require matching or co-occurrence data (sediment chemistry and toxicity or effects data that have been measured at the same location at the same time) from field and laboratory studies. Biological responses may include mortality in various sediment bioassays and benthic infaunal community structure measurements. These responses are matched with concentration values on a dry-weight basis (Calabrese and Baldwin 1993).

Both methods share an assumption that there is an inherent association between the concentration of a contaminant and a synoptically measured biological effect, implying a cause-and-effect relationship. Furthermore, the methods imply that the magnitude of an

adverse effect would decrease if contaminant levels were to be reduced to less than a threshold concentration. The AET method is generally considered to be site-specific, meaning that derived threshold values for contaminants are not strictly applicable to areas outside of where they were developed. On the other hand, the ERM method employs geographically broad-based co-occurrence data for deriving contaminant thresholds and, therefore, values have typically been applied to sites that are far-removed from one another. Specific assumptions inherent to the ERM method that were originally made by its developers are listed below.

- *"An underlying assumption of the approach is that, if enough data are accumulated, a pattern of increasing incidence of biological effects should emerge with increasing contaminant concentrations"* (Long et al. 1995).
- *The approach assumes that "associations between effects and chemical concentrations would be more credible if based upon data from many different studies than if based upon data from only one approach or experiment"* (Long 1992).
- *"The approach assumes that the use of a large database accounts for interactions between chemicals in complex mixtures, for effects of unknown or unmeasured chemicals or materials, for factors other than measured chemical concentrations that may affect species responses, and that indicators of bioavailability and effects can be determined based on field and/or laboratory data"* (Chapman 1989).

2.0 OBJECTIVES AND DESCRIPTION OF ACTIVITIES

The objectives of this investigation were 1) to determine the general applicability of AET and ERM methods for evaluating sediment quality, 2) to document limitations in applying AET and ERM methods for evaluating specific chemicals in sediments, and 3) to critique the two methods for their ability to provide ecologically and statistically defensible sediment toxicity thresholds. In order to address these objectives, this study consisted of five (5) tasks which provided a means of describing specific advantages and disadvantages of using the methods, the limitations in applying the methods to specific chemicals associated with sediments, and a critical examination of sediment quality predictions. The five tasks are: 1) literature review and database searches; 2) information analysis and database management; 3) statistical analyses; 4) interpretation of literature findings and statistical analyses; and 5) report preparation.

2.1 Literature Review and Database Searches

A literature review was performed and database searches conducted by contacting agencies in Canada, Florida, and California as well as professionals in the field of sediment toxicology. The database searches focused on obtaining relevant toxicological and chemical concentration information for marine sediments both within and outside of Southern California and for freshwater areas. One of the primary sources for information obtained for Southern California was found in the report entitled *Sediment Injury in the Southern California Bight: Review of the Toxic Effects of DDTs and PCBs in Sediments* (MacDonald 1997). These data included co-occurrence measurements for Sum DDT, DDE, and DDD, total DDT, Aroclor 1254, and total PCBs.

Other data for Southern California were obtained by performing a chain-of-citation search of MacDonald's (1997) report. The two most frequently cited documents in this report were (Fairey et al. 1996; Sapudar et al. 1994) and these authors were contacted directly. This resulted in the retrieval of two documents that contained co-occurrence data on sediments collected in Southern California. The study by Fairey et al (1996) was found to be suitable for evaluations intended for the present investigation and was also available electronically. The report by Sapudar et al (1994) contained relatively few co-occurrence data and was not available electronically and therefore not used in the current study. However, both studies were used to perform QA/QC audits on the MacDonald (1997) report.

The report by Fairey et al. (1996) was the only document found other than that by MacDonald (1997) that could be immediately used as a source of co-occurrence data for Southern California. A total of 350 stations were sampled from San Diego Harbor as part of an ongoing Bay Protection and Toxic Cleanup Program designed to assess the relative degree of chemical contamination and associated biological effects in California's bays and harbors. The study involved chemical analysis of sediments, benthic community analysis, and toxicity

testing of sediments and sediment pore water. Co-occurrence data were available and used for Sum DDT, DDE, and DDD, and total DDT, total PCBs, lead, mercury, and zinc.

Co-occurrence data from outside of the Southern California region were obtained from MacDonald (1994). This report contained extensive co-occurrence data that did not duplicate data found in MacDonald (1997). The 1994 report contained co-occurrence data for total DDT, total PCBs, lead, mercury, and zinc for the southeastern US as well as data for other marine and estuarine areas from throughout the US and Canada. These data were not available electronically and were, therefore, manually entered into the project database.

Freshwater sediment data were also obtained from Environment Canada which has developed an extensive co-occurrence database. Data were obtained for Sum DDT, DDE, and DDD (Environment Canada 1998), total PCB (Environment Canada 1997a), lead (Environment Canada 1997b), mercury (Environment Canada 1997c), and zinc (Environment Canada 1997d) for areas throughout the US and Canada. These data were not available electronically and were manually entered into the project database.

2.2 Information Analysis and Database Management

After receiving each document, it was necessary to review the report, extract those data relevant to this project, and manually transfer these data into a useable electronic format suitable for database management and statistical analysis. Data already available in electronic format (i.e., Fairey et al. 1996) were incorporated directly into the project database. A total of 40 data files containing matching sediment chemistry and toxicity measurements from marine and freshwater areas were retrieved and electronically stored for this work. We found only 10 of these files contained outcomes of statistical comparisons between biological responses in test sediments and controls and, hence, were suitable for evaluation of the AET and ERM methods.

A major component of this task was to ensure that data collected and used in our study were both technically defensible and accurate. The following activities were implemented as part of this task: 1) development of a centralized data management system to facilitate the transfer, update, and maintenance of data collected during the project; 2) standardization of scales of measurement of collected data; 3) implementation of a data tracking system; and 4) implementation of database QA/QC audits.

The project database consists of information obtained from four sources: MacDonald (1997), MacDonald (1994), Fairey et al. (1996), and Environment Canada (1997a-d; 1998). Only data from these sources were used to evaluate the AET and ERM methods in our study evaluation. At this time, the database consists of approximately 15,000 records of co-occurring measurements. Definitions of the nine (9) variables in the database are given below.

1. Chemical concentrations were reported in units of mg/kg dry-weight sediment for metals and µg/kg dry-weight sediment for organic constituents;
2. Code indicating whether or not the data were used to calculate a threshold value;
3. Description of biological endpoint;
4. Value of endpoint measurement;
5. Taxon associated with the endpoint;
6. Taxonomic Code;
7. Life stage of taxon (i.e., adult, subadult, juvenile, larvae, embryo, gamete, variable);
8. Total organic carbon (TOC, %);
9. Code for source of sediment (marine or freshwater).

Endpoint and taxonomic codes are defined in Tables 1 and 2. Data were placed in a Microsoft Excel (Version 6.0) spreadsheet and were updated as new information was received or when revisions were required. Individual data files comprising the database were given descriptive names.

Quality Assurance/Quality Control (QA/QC) audits were performed on data used in this study. In particular, reports by MacDonald (1994, 1997) were audited to ensure that the data matched raw data from cited documents. To accomplish this, the most frequently cited documents in the MacDonald (1997) report were identified and obtained (Fairey et al. 1996; Sapudar et al. 1994; Bay et al. 1994). Several reports cited by MacDonald (1994) were also obtained (Espy, Huston & Associates, 1983a,b; 1985a,b). Data that were manually entered into the project database were also audited in their entirety to ensure accuracy.

2.3 Statistical Analyses

The two objectives of these analyses were to determine the strength of association of different toxicity and biological community endpoint measurements with concentrations of different contaminants and to evaluate statistical limitations in developing AET- and ERM-based marine sediment quality thresholds. For the first objective, linear (Pearson) correlations were determined for endpoint responses and co-occurring measurements of the concentration of lead, mercury, zinc, total PCB, total DDT, Sum DDT, Sum DDD, and Sum DDE.

Table 1. Biological endpoints and associated codes used in the project database.

Endpoint	Code	Endpoint	Code

Sand Worm	N	Nemerteans	W
Shrimp	S	Protista	G
Polychaete	P		

In addition, for marine sediment measurements encompassing areas both within and outside of Southern California, separate t-tests were conducted to determine whether or not areas were significantly different from one another on the basis of both contaminant concentration and toxicity response. Similarly, if more than one data source was available for an area, tests were also conducted to determine whether or not data sources were significantly different with respect to the measured variables. For all statistical tests, the nominal significance level was $\alpha = 0.05$. In order to reasonably limit the number of analyses made for marine sediment data, evaluations were restricted to data subsets containing ≥30 total observations in any (area × endpoint × taxonomic code) combination for each chemical. A similar rule was also applied to the freshwater sediment data, whereby the number of analyses were restricted to data subsets containing ≥30 total observations in any (endpoint × taxonomic code) combination.

For the second objective, AET and ERM determinations and related analyses were restricted to data from San Diego Harbor (Fairey et al 1996) that had co-occurring measurements of sediment toxicity (amphipod mortality, sea urchin development, and sea urchin fertilization laboratory bioassays) and concentrations of total DDT and total PCB. Endpoint data for urchin development and fertilization were further restricted to bioassay results using 100% pore water from sediment samples. No attempt was made here to derive AET or ERM sediment criteria for the remaining contaminants. For these data, toxicity responses were determined using sediment collected from a number of stations within the harbor. Laboratory control toxicity was also determined and the test and control responses were statistically compared. A sample sediment was first tentatively considered to be toxic if the response was significantly different from the control. For a sample found to be significantly different, a final determination of toxicity was made on the basis of whether or not toxicity was less than 80% of the control. Using these approaches, the authors stated that "there was no absolute value below which all samples could be considered toxic, although survival below a range of 72-80% was generally considered toxic". For each endpoint, a sample was designated as either an *effect*, meaning that the endpoint response indicated toxicity, or *no-effect*, meaning that the endpoint response did not indicate toxicity. Associated with these endpoint responses and effects designations were synoptic measurements of concentrations of the contaminants.

The first analyses conducted using these data were to determine if statistically significant differences existed between endpoint-specific *effect* and *no-effect* stations with respect to each of the two contaminants. The comparisons between stations grouped in this way were made using separate t-tests and a nominal significance level of $\alpha=0.05$.

Determinations of AET values were then made for total DDT and total PCB using each of the three endpoint responses by arraying the *effect* and *no-effect* stations against the concentration of a contaminant. The concentration above which only *effect* stations were located in the array was then determined and this value was designated as the AET for that endpoint and contaminant. ERM values were also found by determining the concentration of

a contaminant corresponding to the median (i.e., 50th percentile) of the *effect* stations (Long et al 1995). Once this value was determined, it was used to determine the effects incidence which is defined as the ratio of [*effect* stations > ERM] to the combined total of [*effect* + *no-effect* stations > ERM].

Prior to any analyses, data were appropriately transformed to achieve normally or near-normally distributed values in the variables being evaluated. Original bulk sediment concentrations of contaminants, C, were transformed to ln(C, weight/g total Organic Carbon) and endpoint measurements consisting of proportionate counts (e.g., mortality, development, fertilization) were arcsin-square root transformed. For some endpoint measurements, no transformation was required; for example, benthic invertebrate species diversity for freshwater sediments. Checks on the success of data transformations were made by examining distribution and probability plots of the transformed variables.

3.0 RESULTS AND DISCUSSION

3.1 QA/QC DATA AUDITS

The QA/QC audit indicated disparities existed between original data reported by Fairey et al. (1996) and the same data reported by MacDonald (1997). All values of total PCB and total DDT used by MacDonald failed to correspond (as they should have) to the original values of Fairey. The QA/QC audit also indicated that some of the original Sapudar et al. (1994) data cited in MacDonald (1997) did not match. Roughly 50% of all data reported in MacDonald (1997) were inconsistent with the original Sapudar data. Thus, the results presented in the MacDonald (1997) report were in error and the conclusions incorrect. We analyzed the corrected data sets and used these data in our study.

3.2 ADVANTAGES OF THE METHODS

There are a number of strengths or advantages of using an AET or ERM approach to evaluate sediment quality which are inherent to most approaches utilizing co-occurrence data.

1. *The ERM approach is supported by a comprehensive co-occurrence database.* Co-occurrence databases have been recently used in a number of investigations to assess sediment quality. An extensive co-occurrence database on the biological effects of sediment associated chemicals called biological effects database for sediments (BEDS) and similar databases have been used, based on existing data (MacDonald 1994; 1997; Long et al. 1995; Smith et al. 1996a). This large database can be interpreted and used as a tool for evaluating the potential for adverse biological effects at various chemical concentrations and can provide a degree of confidence on the resultant guidelines (MacDonald 1994).
2. *In general, both approaches are practical to develop.* The approaches are considered to be practical because data can be used to generate numerical thresholds for a variety of chemicals, many of which typically accumulate in sediments. Generation of thresholds can be accomplished relatively quickly. The influence of chemical mixtures is incorporated into the data when field data are used. They apply to a wide range of benthic species and endpoints, and incorporate direct measurements taken *in situ*. As such, these attributes are considered to give the approaches broad applicability.
3. *The approaches consider both effects and no-effects data to generate thresholds.* In contrast to the AET method, the ERM approach does not rely heavily on single data points, hence outliers carry less weight in calculating guidelines. By including both effects and no-effects data, detailed tables can be constructed to evaluate the potential biological significance of co-occurrence data (MacDonald 1994).
4. *The database used for deriving ERM values provides a basis for evaluating thresholds.* The co-occurrence database is arranged in ascending order of chemical concentration in a tabular format. This format permits expansion of the database, calculation of the

distribution of *effects* and *no-effects* entries surrounding the guideline, and determination of the reliability (or degree of confidence) of each threshold (MacDonald 1994). These thresholds could then be used within a risk assessment framework for assessing contaminated sediments.

5. *The ERM method has undergone extensive peer review.* The method has been published in the peer reviewed literature (e.g., Long 1992; Long et al. 1995; Smith et al. 1996a). It has received support from a wide variety of user groups and has been adopted by Canada (Smith et al. 1996a) as part of sediment guideline derivation processes. According to MacDonald (1994), the favorable reviews that have been received emphasize the importance and utility of the method in deriving numerical guidelines.
6. *The methods implicitly consider bioavailability and chemical mixture effects.* Since co-occurrence field data are used to generate guidelines, various factors such as organic carbon that may influence bioavailability as well as the effects of mixtures of chemicals are implicitly considered.

3.3 DISADVANTAGES OF THE METHODS

There are a number of inherent limitations or disadvantages in using the AET or ERM methods for evaluating sediment quality. Those listed below apply specifically to the ERM method and, more generally, to the AET method.

1. *The ERM method does not establish cause-and-effect relationships.* The method assumes associations between chemical concentrations and biological effects rather than supporting development of cause-and-effect relationships (MacDonald 1994; Calabrese and Baldwin 1993). Any number of variables such as unmeasured chemicals, ammonia, hydrogen sulfide, and dissolved oxygen content in sediments could affect sediment toxicity and species responses (Chapman 1989; MacDonald 1994).
2. *The ERM method does not account for factors affecting chemical bioavailability.* The method may not account for other factors affecting chemical bioavailability such as grain size and acid volatile sulfide (AVS) content of sediment-sorbed materials (e.g., Nebeker et al. 1989; DiToro et al. 1990). These data are infrequently reported in the open literature and often precludes their use in deriving threshold values. This results in the development of thresholds that may be both under- and over-protective of benthic species (MacDonald 1994).
3. *The method attempts to establish absolute sediment guidelines.* The ERM method typically delineates ranges of chemical concentrations that are probably, possibly, and not likely to be associated with adverse biological effects (MacDonald 1994; Long et al. 1995; Smith et al. 1996a). The method typically recognizes the uncertainty associated with the prediction of adverse effects from sediment-associated chemical measurements and such recognition is believed to enhance defensibility of the guidelines (CCME 1995). However, delineation of ranges was all but ignored by MacDonald (1997) and hence, the

inherent uncertainty surrounding thresholds for the Southern California Bight was ignored, substantially reducing what limited utility they may possess.

4. *Values developed using the method may not reflect chronic responses.* Chronic data are often sparse or absent for a given chemical and hence, the guidelines generated will not reflect chronic responses of benthic species (Chapman 1989; MacDonald 1994).

5. *Guidelines developed by the method may not be applicable for sediments with atypical levels of TOC or other factors.* Care should be exercised when applying the guidelines at a given site because they do not account for factors affecting bioavailability. For example, if sediments in an area contain relatively high or low TOC content, then the thresholds generated may not be applicable (MacDonald 1994). This is because the ameliorating effects of TOC may reduce the bioavailability of organic chemicals thus rendering them over-protective.

6. *The method does not explicitly consider effects as a result of bioaccumulation* The method does not account for potential bioaccumulation of chemicals in benthic organism tissues nor does it account for potential adverse effects on species that may ingest these benthic species (MacDonald 1994; Smith et al. 1996a). However, it has been stated by proponents of the method that because the expression of adverse effects includes effects due to bioaccumulation, then the method indirectly considers bioaccumulative effects (Smith et al. 1996a).

7. *The method requires relatively large co-occurrence databases.* In particular, the ERM method requires at least 20 co-occurring observations associated with an *effect* response (e.g., toxicity significantly different than a control) and an additional 20 co-occurrences of a *no effect* response (CCME 1995). In addition, the concentration of each chemical of interest should vary by at least 10-fold among sampling sites. Finally, statistical procedures used should be presented in detail and test methodology must follow standard protocols (CCME 1995).

8. *The method does not account for effects due to mixtures of chemicals, only a single chemical.* The reliance of the method on co-occurrence data precludes the possibility of separating individual chemical effects from samples where multiple chemicals exist (Adams et al. 1992; Chapman 1989). This limitation is highly relevant to the Southern California Bight, as several chemicals including DDTs and PCBs are present in sediments.

3.4 CORRELATION AND ANALYSES OF VARIANCE

The AET and ERM methods assume that there is a strong association between endpoint response and contaminant concentration. In particular, the ERM method claims that if enough data are examined, a direct relationship should be evident between adverse effect and increasing concentration. In order to examine this assumption, various endpoints and contaminants were selected (refer to selection rule above) for correlation analysis. In those instances where data were from different sources or encompassed areas within and outside of

Southern California, analyses of variance were also conducted to determine whether sources or areas were significantly different from one another. Where significant differences were found, an examination of the overall pattern of relationship between effect and concentration was conducted. No models were derived and tested (via regression analysis) for their adequacy in predicting biological response from co-occurring chemical concentration data. Hence, conventional R^2 values (i.e., the coefficient of determination reflecting the amount of total variation in the response explained by a model) are not reported. The reason that no modeling analyses were conducted is that a particular biological response in natural sediments is a function of many biotic and abiotic factors including concentrations of chemical contaminants. Therefore, it would be inappropriate and misleading to model (i.e., attempt to predict) the magnitude of a biological response using only the corresponding magnitude in concentration of a single chemical.

Linear (Pearson) correlation coefficients between transformed endpoint measurements and chemical concentrations that were obtained for marine and freshwater sediment data are presented in Table 3. Cells in the table having entries $n<30$ indicate that there were insufficient data for analysis according to the criteria defined above. Notice in the table that because of insufficient data, some contaminants of interest were not analyzed; namely, zinc, Sum DDT, and total DDT in freshwater sediments and Sum DDD and Sum DDE for marine sediments. In the following sections, results of analyses that were conducted are discussed in greater detail. All figures associated with these analyses are given in Appendix B.

Lead in Marine Sediments. Comparisons between reference data for lead content in Southern California area sediments having co-occurring amphipod mortality measurements are presented in Figures 1 and 2. It was found that the data reported by MacDonald (1994) had significantly greater concentrations of lead ($P=0.00382$) than did data reported by Fairey et al (1996). However, it was also found that amphipod mortality was significantly greater for the Fairey et al (1996) data ($P=0.00022$). Scatter plots of the Fairey et al (1996) and MacDonald (1994) data are given in Figures 3 and 4 which show the associations between mortality and sedimentary lead content. For the Fairey et al (1996) data in Figure 3, the linear correlation between variables is $r=-0.154$ and for the MacDonald (1994) data in Figure 4, $r=0.278$. In neither case, is there a strong association between mortality and lead concentration.

Comparisons were also made using MacDonald (1994) data for sedimentary lead content in areas within and outside of Southern California having co-occurring measurements of amphipod mortality (Figures 5 and 6). No statistically significant differences were found among the areas for lead content or mortality ($P=0.07646$ and $P=0.15921$, respectively). A scatter plot of mortality against lead content for the combined data is shown in Figure 7 which yielded a linear correlation coefficient of $r=0.226$.

Table 3. Linear (Pearson) correlations between different endpoint measurements and concentrations of chemicals for marine and freshwater sediments. All coefficients were determined using transformed variable values (see text).

Sediment Type	Sediment Location	Endpoint	Chemical Constituent							
			Lead	Mercury	Zinc	Total PCB	Total DDT	Sum DDT	Sum DDD	Sum DDE
Marine	Southern CA	Amphipod Mortality	-0.154 (a) 0.278 (b)	-0.061 (b)	-0.153 (b)	0.574 (a) -0.060 (b)	0.090 (a) -0.084 (b)	-0.196 (b)	n<30	n<30
Marine	Southern CA	Sea Urchin Development	0.226 (b)	0.123 (b)	0.171 (b)	0.052 (b)	n<30	-0.061 (b)	n<30	n<30
Marine	Southern CA	Sea Urchin Fertilization	-0.147 (b)	-0.064	-0.143 (b)	-0.043 (b)	-0.328 (a, b)	-0.288 (b)	n<30	n<30
Marine	Outside Southern CA	Amphipod Mortality	0.226 (a)	0.263 (a)	0.266 (a)	n<30	n<30	n<30	n<30	n<30
	Outside Southern CA	Sea Urchin Development	n<30	0.254 (a)	0.189 (a)	n<30	n<30	n<30	n<30	n<30

(a) MacDonald 1994
(b) Fairey et al 1996
ND Not Determined

Two additional scatter plots are presented in Figures 8 and 9 showing the association between lead content in Southern California area sediments and sea urchin development and fertilization toxicity, respectively. For the development endpoint, the correlation with lead content is r=0.226 and for fertilization ρ=-0.147. Neither of these coefficients indicate a strong association between toxicity endpoints and sedimentary lead content.

Lead in Freshwater Sediments. Scatter plots of benthic invertebrate (infaunal) density, species diversity, and mollusca density against the concentration of lead are presented in Figures 10-12. Provided that sedimentary lead content exerts a singular influence on the values of these variables, then we would expect to observe a monotonically decreasing association in each of these cases. No such trends are evident in Figures 10 and 11 for density or diversity (ρ=0.041 and ρ=0.126, respectively). For mollusca density, the trend is correct (ρ=-0.348), but it is clearly not monotonic.

Mercury in Marine Sediments. Comparisons between areas within (Fairey et al 1996) and outside (MacDonald 1994) of Southern California for sedimentary mercury having co-occurring amphipod mortality measurements are presented in Figures 13 and 14. These comparisons revealed that both the concentration of mercury and mortality are significantly lower for sediments outside of the Southern California area (P=0.00331 and P=<0.00001, respectively). Scatter plots of mortality against mercury content are presented in Figures 15 and 16. No meaningful linear association is apparent between the variables (r=-0.061 and r=0.263, respectively).

Comparisons of areas were also conducted for sedimentary mercury having co-occurring measurements of sea urchin development. These comparisons are presented in Figures 17 and 18. Mercury content was found to be significantly lower in sediments outside of Southern California (P=0.01176). In contrast, areas did not differ significantly in development toxicity (P=0.07656), although this conclusion must be viewed as tentative given the level of the P-value. Scatter plots of mercury content against development toxicity are presented in Figures 19 and 20 which show no meaningful evidence of a linear association between the variables (r=0.254 and r=0.123, respectively).

One additional scatter plot of sea urchin fertilization against mercury content for Southern California area sediments is presented in Figure 21. There is no apparent linear association between the variables (r=-0.064).

Mercury in Freshwater Sediments. Associations between sedimentary mercury and benthic invertebrate (infaunal) density (r=0.052), species diversity (r=-0.263), amphipod density (r=-0.045), and mollusca density (r=0.011) are shown in Figures 22-25, respectively. It is clear from these figures that no linear association can be claimed between the different endpoint measurements and concentration of mercury in sediments.

Zinc in Marine Sediments. Comparisons between areas within (Fairey et al 1996) and outside (MacDonald 1994) of Southern California for sedimentary zinc having co-occurring amphipod mortality measurements are presented in Figures 26 and 27. These comparisons revealed that the concentration of zinc was not significantly different for these sediments (P=0.05582) but that mortality was very significantly lower in sediments outside of the southern California area (P=<0.00001). Scatter plots of mortality against zinc content are presented in Figures 28 and 29. There is no linear association apparent between the variables, evidenced by the correlation for areas within (r=-0.153) and outside (r=0.266) of Southern California.

Comparisons of areas within (Fairey et al 1996) and outside (MacDonald 1994) of Southern California for sedimentary zinc having co-occurring sea urchin development measurements are presented in Figures 30 and 31. It was found that areas differed significantly in zinc content (P=0.00504) and that sediments outside of Southern California contained lesser concentrations of zinc. However, it was also found that areas probably did not differ significantly in development (P=0.07492). Scatter plots of zinc content against development are presented in Figures 32 and 33. In neither case, is there a meaningful linear association between the variables; the correlation between variables for sediments within the Southern California area is r=0.171 and r=0.189 for sediments outside of Southern California.

One additional scatter plot is presented in Figure 34 showing the association between zinc content and sea urchin fertilization toxicity in Southern California area sediments. Again, no apparent linear relationship between the variables is evident (r=-0.143).

Total PCB in Marine Sediments. Comparisons between the Fairey et al (1996) and MacDonald (1994) data for total PCB content having co-occurring amphipod mortality measurements in Southern California area sediments are presented in Figures 35 and 36. It was found that concentrations of total PCB were not significantly different in the two data sets (P=0.42892) but that the Fairey et al (1996) data exhibited significantly greater mortality (P=<0.00001). A scatter plot of total PCB against mortality for the MacDonald (1994) data is presented in Figure 37 which yielded a linear correlation coefficient of r=0.574. A similar scatter plot of these data in the original (non-transformed) space is shown in Figure 38 which suggests that mortality is an increasing exponential function of the concentration of sedimentary total PCB concentration. There is an outlying observation in these data occurring at a concentration of approximately 5 μg total PCB/g TOC and associated mortality of 95%. If that one observation were to be neglected, for example, on the basis of poor laboratory testing procedures for either toxicity testing or chemical concentration determination, then the linear correlation between the variables would be improved considerably. It would, however, not be ecologically reasonable to attempt to model mortality solely as a (exponential) function of concentration. There were undoubtedly other relevant environmental variables that also affected mortality which were not measured and, therefore, could not be included in the model. Neglecting these other unknown variables would lead to a misleading model that only total PCB content in these sediments determines

amphipod mortality. A scatter plot of the Fairey et al (1996) data is presented in Figure 39 which shows that, in contrast to the MacDonald data, there is little linear association between amphipod mortality and total PCB concentration (r=-0.060).

Comparisons between the Fairey et al (1996) and MacDonald (1994) data for total PCB content having co-occurring sea urchin fertilization measurements in Southern California area sediments are presented in Figures 40 and 41. It was found that these data sources did not differ significantly for either total PCB content or urchin fertilization (P=0.18614 and P=0.80104, respectively). A scatter plot for the combined data (Figure 42) shows that there is no apparent linear association between the variables as evidenced by a correlation coefficient of r=-0.043.

One additional scatter plot of sea urchin development toxicity against total PCB content in Southern California area sediments is presented in Figure 43. The linear correlation between these variables is r=0.052, indicating very little association among values.

Total PCB in Freshwater Sediments. A scatter plot of benthic invertebrate density against sedimentary PCB content is presented in Figure 44. The linear correlation between these variables is r=0.042, indicating very little association among values.

Sum DDT in Marine Sediments. Scatter plots of the toxicity endpoints amphipod mortality, sea urchin development, and sea urchin fertilization against Sum DDT content in Southern California area sediments (Fairey et al 1996) are given in Figures 45-47. As shown in Figures 45 and 46, there is no apparent linear association between endpoints and Sum DDT content (r=-0.196 and r=-0.061, respectively). Fertilization toxicity (Figure 47) does show a trend in accordance with expectation (that is, lower fertilization with higher concentration), having a linear correlation coefficient of r=-0.288. However, this apparent trend is largely influenced by several toxicity measurements at concentration values above approximately 2.7 μg Sum DDT/g TOC.

Sum DDD in Freshwater Sediments. Scatter plots of benthic invertebrate density and species diversity against Sum DDD content are presented in Figures 48 and 49. For both endpoint measurements, there is little linear association with concentration (r=-0.183 and r=-0.052, respectively).

Sum DDE in Freshwater Sediments. Scatter plots of benthic invertebrate density and species diversity against Sum DDE content are presented in Figures 50 and 51. For both endpoint measurements, there is little linear association with concentration (r=-0.187 and r=0.032, respectively).

Total DDT in Marine Sediments. Comparisons between the Fairey et al (1996) and MacDonald (1994) data for total DDT content having co-occurring amphipod mortality measurements in Southern California area sediments are presented in Figures 52 and 53. It

was found that these data sources did not differ significantly for total DDT content (P=0.29759). However, data reported by Fairey et al (1996) data exhibited significantly greater mortality (P=0.02490). Scatter plots of these data are shown in Figures 54 and 55. The Fairey et al (1996) data (Figure 54) yielded a correlation coefficient of r=-0.084 while the data reported by MacDonald (1994) yielded r=0.090. In neither case, is there a strong association between mortality and total DDT concentration.

Comparisons between the Fairey et al (1996) and MacDonald (1994) data for total DDT content having co-occurring sea urchin fertilization measurements in Southern California area sediments are presented in Figures 56 and 57. It was found that these data sources did not differ significantly for total DDT content or development toxicity (P=0.80104 and P=0.63995, respectively). A scatter plot of the combined data is shown in Figure 58. While the overall trend in association appears to be in accordance with expectation (i.e., lower fertilization at higher concentration), the association is largely influenced by a single toxicity observation at approximately 67 µg total DDT/g TOC. In addition, no strong linear correlation between the variables is evident (r=-0.323).

In general, the analyses reported above fail to demonstrate the existence of any meaningful correlation between selected endpoint responses and contaminant concentrations in either marine or freshwater sediments. Furthermore, there were instances in which statistically significant differences were found in the magnitude of an endpoint response among areas or among data sources within an area, yet no significant differences were found with respect to the co-occurring concentration of a contaminant. Such inconsistencies immediately call into question the validity of assuming an inherent direct relationship between the magnitude of contamination and the magnitude adverse biological effects using field observations. While this assumption is typically valid for carefully controlled laboratory dose-response tests using a single contaminant, it is rarely satisfied from field observation where samples are often taken across multiple gradients in critical environmental variables other than contaminant levels. Furthermore, the magnitude of field-based responses for a single endpoint is often a function of a complex mixture of contaminants and perhaps other variables, and it is not ecologically or statistically reasonable to ignore such complexity. The combination of effects due to environmental gradients and complex contaminant mixtures precludes simply applying the assumption of cause-and-effect (dose-response) to field observations. Neglecting such effects in the establishment of sediment quality guidelines or clean-up levels for contaminants would, therefore, not be justifiable.

3.5 AET AND ERM DETERMINATIONS: Examples of Misleading Estimates

In our analyses of the data, it is demonstrated that AET- and ERM-based thresholds derived for establishing sediment quality criteria using selected field observations lead to values that have no toxicological or statistical meaning. We used PCB and DDT data reported by Fairey *et al.* (1996) to illustrate that the methods for determining AET and ERM values can lead to sediment quality thresholds which do not achieve their intended toxicological and

ecological relevance. We emphasize that the results presented below follow from the fact that no relationships between toxicity responses and contaminant levels exist in these data and therefore lead to inaccurate estimates of sediment quality criteria.

Comparisons between *effect* and *no-effect* station groups for total DDT and total PCB using the endpoints amphipod mortality, sea urchin development, and sea urchin fertilization are presented in Figures 59-64. Mean concentrations of both contaminants for each endpoint and also the results of t-tests that were conducted to assess whether or not these means were significantly different from one another are presented in Table 4. It can be seen that only the single test comparing total PCB sediment content for sea urchin development was statistically significant (P=0.0043). Results of all other tests were not statistically significant, leading to the conclusion that *effect* stations cannot be distinguished from *no-effect* stations on the basis of the concentration of total DDT or total PCB. In the single instance where *effect* and *no-effect* stations were significantly different, the mean concentration of total PCB in the *no-effect* group was actually greater than in the *effect* group. This result is, of course, contrary to what would otherwise be expected if DDT content in sediment were exerting a negative impact on sea urchin developmental toxicity. In general, these results do not support using the concentration of total DDT or total PCB taken alone, to explain the different toxicity designations in the endpoints considered. These results also demonstrate the inability of being able to predict sediment toxicity response with any acceptable degree of statistical confidence on the basis of arbitrarily chosen levels of contaminant concentration.

Despite these results, both AET and ERM values were determined for each contaminant using each of the biological endpoint measurements. These determinations were made in order to demonstrate differences in potential sediment quality criteria that could result using these two approaches. However, it should be clear from the results presented above that neither method is capable of yielding a criterion having any meaningful statistical or toxicological relevance for contaminated sediments.

AET for Total DDT. AET determinations for total DDT were made using amphipod mortality, sea urchin development, and sea urchin fertilization. These determinations are reflected in Figures 65-67. For amphipod mortality, there were eight stations exhibiting a consistent *effect* greater than the threshold concentration of approximately 2.2 µg/g TOC (Figure 65a). The relationship between mortality and concentration is shown in Figure 65b which yielded a linear correlation of r=0.160. Considering only the eight *effect* stations, the correlation is r=0.630 which is not statistically significant (P=0.0944). It was not possible to determine an AET using urchin development since there were no *effect* stations observed at concentrations greater than that observed for the *no-effect* stations (Figure 66a). The relationship between development and concentration is shown in Figure 66b (r=0.094). For urchin fertilization, there were only two stations exhibiting a consistent *effect* above a threshold concentration of approximately 4.3 µg/g TOC (Figure 67a). The overall linear relationship between fertilization and concentration is shown in Figure 67b which yielded a correlation of r=-0.322.

Table 4. Comparisons of mean concentrations of contaminants for *effect* and *no effect* station groups using different biological endpoints measurements. The P-values result from separate t-Tests conducted for each endpoint × contaminant combination where unequal variances were assumed. Data used in determining these values were from San Diego Harbor marine sediments (Fairey et al 1996).

Biological Endpoint	Mean Total DDT (µg/g TOC)		P-Value (df) Total DDT	Mean Total PCB (µg/g TOC)		P-Value (df) Total PCB
	Effect	No Effect		Effect	No Effect	
Amphipod Mortality	0.75	0.76	0.8922 (76.3)	4.24	5.70	0.0862 (87.0)
Sea Urchin Development	0.74	0.81	0.6706 (24.5)	4.32	7.44	0.0043 (39.1)
Sea Urchin Fertilization	0.82	0.64	0.0849 (84.4)	4.58	5.39	0.3346 (81.5)

AET for Total PCB. AET determinations for total PCB were made using the same three endpoint toxicity response measurements employed for total DDT and are reflected in Figures 68-70. For mortality, there were only two stations exhibiting a consistent *effect* above the threshold of approximately 36.3 µg/g TOC (Figure 68a). The linear relationship between mortality and concentration is presented in Figure 68b which has a corresponding correlation of r=0.029. For sea urchin development, there were four *effect* stations above the threshold concentration of approximately 24.0 µg/g TOC (Figure 69a). Overall, the relationship between this endpoint and concentration appears to be contrary to expectation, having a linear correlation of r=0.296 (Figure 69b). In contrast, the correlation between variables considering just the four *effect* stations above the threshold is r=-0.877. However, the magnitude of this correlation is heavily influenced by the fact that three out of these four *effect* stations had development values of zero. For the sea urchin fertilization endpoint, there were three stations exhibiting a consistent *effect* above the threshold of approximately 25.6 µg/g TOC (Figure 70a). The overall correlation between fertilization and concentration is r=-0.046 while the correlation between the variables considering just the three stations above the threshold is r=-0.862 (Figure 70b).

ERM Determinations. ERM values were determined for total DDT and total PCB using each of the toxicity endpoint measures and the quantile plots reflecting these determinations are shown in Figures 71-76. In addition, associated *effect* incidence values were also determined for each combination of endpoint and contaminant.

A comparison of the various AET and ERM values is given in Table 5. It is immediately apparent that the ERMs are considerably less than the corresponding AETs; on average, ERMs are approximately 83% less than the corresponding AETs. The lesser ERM values are not surprising considering that they are defined to be the median (i.e., 50th percentile) concentrations associated with the *effect* stations whereas the AETs are more equivalent to a much higher quantile (e.g., 90th percentile) of the same *effect* stations. However, in neither case, do the values represent toxicologically meaningful values since they do not provide a statistically significant distinction between *effect* and *no-effect* toxicity responses with respect to concentration of contaminants. Hence, it is not possible to conclude for either contaminant that a concentration above the ERM or AET would consistently exhibit toxicity. Similarly, it is not possible to conclude that concentrations below the ERM or AET would consistently exhibit no toxicity. Results of these analyses show that toxicity response categories are not distinguishable on the basis of contaminant concentration.

The magnitude of an effects incidence value (Table 5) has been used to judge reliability of a derived threshold in predicting an adverse biological response such as sediment toxicity. MacDonald (1994) arbitrarily chose a value ≥80% to indicate acceptable reliability and used this cutoff in deciding whether or not to designate the associated ERM as a sediment quality guideline. Based on analyses of the Fairey *et al.* (1996) data, it is evident that magnitude of effects incidence has virtually no predictive value unless there is a statistically significant difference in contaminant concentration among the *effect* and *no-effect* groups.

Table 5. Comparison of Apparent Effects Threshold (AET) and Effects Range - Median (ERM) for Total DDT and Total PCB using different biological endpoints. Data used in deriving these values were from San Diego Harbor marine sediments (Fairey et al 1996).

Contaminant/Threshold	Biological Endpoint		
	Amphipod Mortality	Sea Urchin Development	Sea Urchin Fertilization
Total DDT			
AET (µg/g TOC)	2.2	(a)	4.3
ERM (µg/g TOC)	0.6	0.7	0.7
Effects Incidence[b] (%)	46	80	70
Total PCB			
AET (µg/g TOC)	36.3	24.0	25.6
ERM (µg/g TOC)	3.8	4.1	4.3
Effects Incidence (%)	42	69	100

(a) Not Defined

(b) The Effects Incidence is variously referred to as the "Incidence of Adverse Effects" (Long et al 1995) or as "Predictability" (MacDonald 1994) for ERM-based thresholds and is determined as follows:

$$\text{Effects Incidence, \%} = \left[\frac{\text{No. Effect Stations} > \text{ERM}}{\text{Total Stations} > \text{ERM}}\right] \times 100$$

4.0 CONCLUSIONS

- The MacDonald (1997) report stated that the thresholds derived for DDTs and PCBs for Southern California Bight sediments "may be used as a scientific basis for establishing target clean-up levels for DDTs and PCBs in bed sediments..." The report further stated that DDT and PCB concentrations were in excess of the derived thresholds and hence, were "sufficient to cause injury to sediment-dwelling organisms". These conclusions may not be rigorously supported if the statistical limitations identified here apply equally to development of thresholds for the Southern California Bight. A detailed evaluation of all data used in the MacDonald (1997) report in developing these DDT and PCB thresholds is warranted. However, it must be noted that proponents of the ERM method (identified below) have stated that derived thresholds should never be used in the manner proposed by MacDonald (1997).

- Based on the statistical evaluations and rationales described herein, the AET and ERM methods have severe limitations in establishing sediment quality guidelines. Methods that rely on a co-occurrence database can be used to examine associations between levels of contamination and biological effects but do not support claims of cause-and-effect. As a result, these methods might only be appropriate as screening tools to identify sediments in areas that may require more detailed evaluation. The evaluations presented in this report suggest that neither method can support the specification of site-specific sediment cleanup goals or estimate injury in sediments containing PCB, DDT, lead, mercury, or zinc.

- Proponents of the ERM method recognized certain disadvantages that limit its use in establishing sediment quality guidelines. They indicated that 1) guidelines generated in this manner should not be used alone in deriving site-specific cleanup goals and 2) other sources of information and data should be obtained before developing site-specific sediment quality objectives. Guidelines developed under this methodology are designed to be used as generic or informal screening tools for assessing sediment quality applied over broad geographic areas (Long et al. 1995; CCME 1995; Smith et al. 1996b). These authors emphasized that the guidelines should be used with other sources of information such as background concentrations of chemicals, further biological assessment (e.g., toxicity test using field-collected sediments, benthic diversity and abundance analyses), and site management considerations before reaching any conclusions regarding sediment quality (Long et al. 1995; CCME 1995; Smith et al. 1996a,b).

- The limitations of such approaches were recently noted by O'Connor *et al.* (1998) who stated that "...ERM exceedance should only be taken to indicate that further analysis is in order. They should never be taken, by themselves, to mean that sediment is exerting a toxic effect upon the environment or that there would be any benefit to decreasing its

chemical content". These statements are clearly supported and substantiated by findings in the present report.

- MacDonald (1994) and Long et al. (1995) previously concluded that the guidelines developed for total DDT, p,p'-DDE, total PCB, and mercury were not "reliable". Reliability refers to the ability of the guidelines to correctly classify toxic and non-toxic sediments in the area of interest. MacDonald (1994) and Long et al. (1995) reached this conclusion based on sediment quality guidelines that were generated to be protective of marine and estuarine sediments on Florida's coasts and of sediments in all areas of the US and Canada, respectively. Our demonstration of deriving misleading (i.e. unreliable) AET and ERM values supports this conclusion.

EXECUTIVE SUMMARY

The following report describes and evaluates chemical and biological data collected from San Diego Bay and its historical tributaries between October, 1992 and May, 1994. The study was conducted as part of the ongoing Bay Protection and Toxic Cleanup Program, a legislatively mandated program designed to assess the degree of chemical pollution and associated biological effects in California's bays and harbors. The workplan for this study resulted from a cooperative agreement between the State Water Resources Control Board and the National Oceanic and Atmospheric Administration (NOAA). Monitoring and reporting aspects of the study were conducted by the Environmental Services Division, of the California Department of Fish and Game, and its subcontractors.

The study objectives were:

1. Determine presence or absence of adverse biological effects in representative areas of the San Diego Bay Region;

2. Determine relative degree or severity of adverse effects, and distinguish more severely impacted sediments from less severely impacted sediments;

3. Determine relative spatial extent of toxicant-associated effects in the San Diego Bay Region;

4. Determine relationships between toxicants and measures of effects in the San Diego Bay Region.

The research involved chemical analysis of sediments, benthic community analysis and toxicity testing of sediments and sediment pore water. Chemical analyses and bioassays were performed using aliquots of homogenized sediment samples collected synoptically at each station. Analysis of the benthic community structure was made on a subset of the total number of stations sampled.

Three hundred and fifty stations were sampled between October, 1992 and May, 1994. Areas sampled included San Diego Bay, Mission Bay, the San Diego River Estuary and the Tijuana River Estuary and are collectively termed "the San Diego Bay Region" in the following document. Two types of sampling designs were utilized: direct point sampling and stratified random sampling.

Chemical pollution was demonstrated by using comparisons to established sediment quality guidelines. Two sets of guidelines were used: the Effects Range-Low (ERL)/Effects Range-Median (ERM) guidelines developed by NOAA (Long and Morgan, 1990; Long *et al.*, 1995) and the Threshold Effects Level (TEL)/Probable Effects Level (PEL) guidelines used in Florida (McDonald, 1993; McDonald, 1994). Copper, mercury, zinc, total chlordane, total PCBs and the PAHs were most often found to exceed critical ERM or PEL values

and were considered the major chemicals or chemical groups of concern in the San Diego Bay Region. ERM and PEL summary quotients were used to develop chemical indices for addressing the pollution of sediments with multiple chemicals. An ERM summary quotient >0.85 or a PEL summary quotient >1.29 was indicative of stations where multiple chemicals were significantly elevated. Stations with any chemical concentration >4 times its respective ERM or >5.9 times its respective PEL were considered to exhibit elevated chemistry. Summary quotients and magnitude of sediment quality guideline exceedances were used as additional information to help prioritize stations of concern for Regional Water Quality Control Board staff.

Identification of degraded and undegraded habitat (as determined by macrobenthic community structure) was conducted using a cumulative, weight-of-evidence approach. Analyses were performed to identify relationships between community structure within and between each station or site (*e.g.,* diversity/evenness indices, analyses of habitat and species composition, construction of dissimilarity matrices for pattern testing, assessment of indicator species, and development of a benthic index, cluster analyses, and ordination analyses).

Analyses of the 75 stations sampled for benthic community structure identified 23 undegraded stations, 43 degraded and 9 transitional stations. All sampled stations with an ERM summary quotient >0.85 were found to have degraded communities. All sampled stations with P450 Reporter Gene System responses above 60 μg/g BaPEq. were similarly found to have degraded benthic communities.

The statistical significance of toxicity test results was determined using two approaches: the reference envelope approach and laboratory control comparison approach used by the United States Environmental Protection Agency- Environmental Monitoring and Assessment Program and NOAA- National Status and Trends programs. The reference envelope approach indicated that toxicity for the *Rhepoxynius* (amphipod) sediment test was significant when survival was less than 48% in samples tested. No reference envelope was calculated for the urchin fertilization or development tests due to high variability in pore water data from reference stations.

The laboratory control comparison approach was used to compare test sediment samples against laboratory controls for determination of statistically significant differences in test organism response. Criteria for toxicity in this approach were 1) survival less than 80% of the control value and 2) significant difference between test samples and controls, as determined using a t-test. Using this approach, there was no absolute value below which all samples could be considered toxic, although survival below a range of 72-80% was generally considered toxic.

Using the EMAP definition of toxicity, 56% of the total area sampled was toxic to *Rhepoxynius*. For the *Strongylocentrotus* larval development test, percent of total area toxic was 29%, 54%, and 72% respectively for 25%, 50%, and undiluted pore water concentrations. Samples representing 14%, 27%, or 36% of the study area were toxic to both *Strongylocentrotus* in pore water (25%, 50%, or undiluted, respectively) and *Rhepoxynius* in solid phase sediment.

Linear regression analyses failed to reveal strong correlations between amphipod survival and chemical concentration. It is suspected instead of a linear response to chemical pollutants, most organisms are tolerant of pollutants until a threshold is exceeded. Comparisons to established sediment quality guideline thresholds demonstrate an increased incidence of toxicity for San Diego Bay Region samples with chemical concentrations exceeding the ERM or PEL values. It is further suspected toxicity in urban bays is caused by exposure to complex mixtures of chemicals. Comparisons to ERM summary quotients (multiple chemical indicators) demonstrate that the highest incidence of toxicity (>78%) is found in samples with elevated ERM summary quotients (>0.85).

Statistical analyses of the P450 Reporter Gene System responses versus the PAHs in sediment extracts demonstrated that this biological response indicator was significantly correlated ($r^2 = 0.86$) with sediment PAH (total and high molecular weight) concentration.

Stations requiring further investigation were prioritized based on existing evidence. Each station receiving a high, moderate or low priority ranking meets one or more of the criteria under evaluation for determining hot spot status in the Bay Protection and Toxic Cleanup Program. Those meeting all criteria were given the highest priority for further action. A ranking scheme was developed to evaluate stations of lower priority.

Seven stations (representing four sites) were given a high priority ranking, 43 stations were given a moderate priority ranking, and 57 stations were given a low priority ranking. The seven stations receiving the high priority ranking were in the Seventh Street channel area, two naval shipyard areas near the Coronado Bridge, and the Downtown Anchorage area west of the airport. The majority of stations given moderate rankings were associated with commercial areas and naval shipyard areas in the vicinity of the Coronado Bridge. Low priority stations were interspersed throughout the San Diego Bay Region.

A review of historical data supports the conclusions of the current research. Recommendations are made for complementary investigations which could provide additional evidence for further characterizing stations of concern.

Purpose

In 1992, the State Water Resources Control Board (SWRCB) and the National Oceanic and Atmospheric Administration (NOAA) entered into a three-year cooperative agreement to assess potential adverse biological effects from sediments in coastal bays and harbors of Southern California (SWRCB and NOAA, 1991, 1992, 1993). The study area for the three-year cooperative agreement extended south of the Palos Verdes Peninsula to the USA/Mexico border. The majority of work focused on selected coastal bays, harbors and lagoons where depth ranged from approximately 60 meters to the upper limit of the tidal range. In the first phase of the study, data were collected, analyzed, and reported from the Los Angeles/Long Beach areas (SWRCB and NOAA, 1994).

This report presents results from data collected in the San Diego Bay area during the second and third years of the cooperative agreement. The study was performed in San Diego Bay, Mission Bay, San Diego River Estuary, and Tijuana River Estuary in southern California (Figure 1).

The purposes of the present study were:

1. Determine presence or absence of statistically significant toxicity effects in representative areas of the San Diego Bay Region;

2. Determine relative degree or severity of observed effects, and distinguish more severely impacted sediments from less severely impacted sediments;

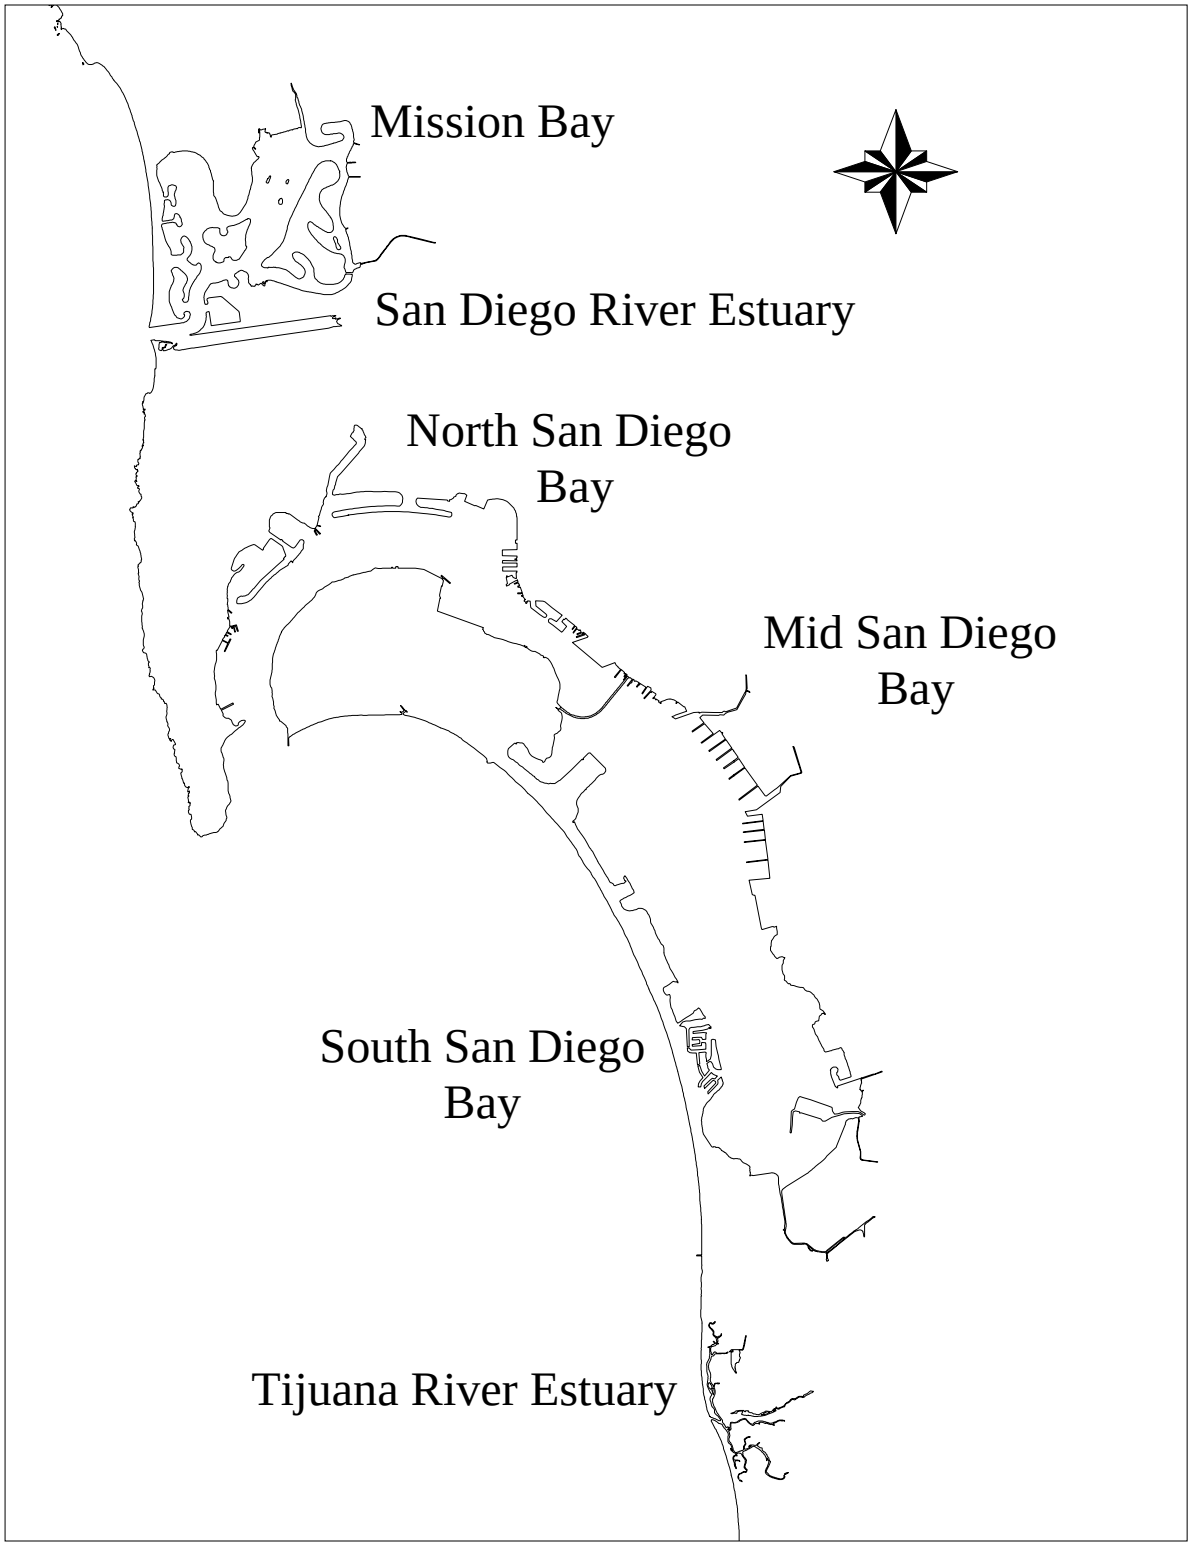
3. Determine relative areal extent of significant toxicity in the San Diego Bay Region;

4. Determine relationships between pollutants and measures of effects in these bays.

Programmatic Background and Needs

Due to the long history of human activity in San Diego Bay and its surrounding waters, there is a need to assess any environmentally detrimental effects which have been associated with those activities. The cooperative agreement between NOAA and SWRCB was designed to investigate these environmental effects by evaluating the biological and chemical state of San Diego Bay sediments. The methods used to assess environmental impacts include sediment and interstitial water bioassays, sediment chemistry analysis, and benthic community analysis. The study areas included San Diego Bay, Mission Bay, Tijuana River Estuary, and the San Diego River. Although these water bodies are separated physically, and are quite different in character, for simplicity they will often be referred to collectively as the "San Diego Bay Region" in this report (Figure 1). The SWRCB and NOAA have common programmatic needs for this research, however, some differences exist. NOAA is mandated by Congress to conduct a

Figure 1
San Diego Bay Region Study Area



program of research and monitoring on marine pollution. Much of this research is conducted through the National Status and Trends (NS&T) Program and the Coastal Ocean Program. The NS&T Program performs intensive regional studies on the magnitude and extent of toxicant-associated bioeffects in selected coastal embayments and estuaries. Areas chosen for these regional studies were those in which pollutant concentrations indicate the greatest potential for biological effect. These biological studies augment regular chemical monitoring activities of the NS&T Program, and provide a means for estimating the extent of toxicity associated with measured concentrations of sediment pollutants.

The California Water Code, Division 7, Chapter 5.6, Section 13390 mandates the State Water Resources Control Board and the Regional Water Quality Control Boards to provide the maximum protection of existing and future beneficial uses of bays and estuarine waters and to plan for remedial actions at those identified toxic hot spots where the beneficial uses are being threatened by toxic pollutants.

A cooperative agreement between NOAA and SWRCB has been implemented through the Bay Protection and Toxic Cleanup Program (BPTCP). Sediment characterization approaches currently used by the BPTCP range from chemical or toxicity monitoring only, to monitoring designs which attempt to generally correlate the presence of pollutants with toxicity or benthic community degradation. Studies were designed, managed, and coordinated by the SWRCB's Bays and Estuaries Unit as a cooperative effort with NOAA's Bioeffects Assessment Branch, and the California Department of Fish and Game's (CDFG) Marine Pollution Studies Laboratory. Funding was provided by the SWRCB and NOAA's Coastal Ocean Program.

Research for the San Diego Bay Region involved toxicity testing and chemical analysis of sediments and sediment pore water. Toxicity tests and chemical analysis were performed using aliquots of homogenized sediment samples collected synoptically from each station, resulting in paired data. Analyses of benthic community structure and P450 enzyme induction were also made on a subset of the total number of stations sampled.

Field and laboratory work was accomplished under interagency agreement with, and under the direction of, the CDFG. Sample collections were performed by staff of the San Jose State University Foundation at the Moss Landing Marine Laboratories, Moss Landing, CA (MLML). Trace metals analyses were performed by CDFG personnel at the trace metal facility at Moss Landing Marine Laboratories. Synthetic organic pesticides, polycyclic aromatic hydrocarbons (PAHs), and polychlorinated biphenyls (PCBs) were analyzed at the UCSC trace organics analytical facility at Long Marine Laboratory in Santa Cruz, California. MLML staff also performed total organic carbon (TOC) and grain size analyses, as well as benthic community analyses. Toxicity testing was conducted by the University of California at Santa Cruz (UCSC) staff at the CDFG toxicity testing laboratory at Granite Canyon,

California. P450 Reporter Gene System analyses were conducted by Columbia Analytical Services in Carlsbad, CA.

Study Area

San Diego Bay

San Diego Bay is the southern-most embayment on the west coast of the United States. It is located within the Southern California Bight and is the largest embayment along the 1450 kilometer stretch of coastline between San Francisco and Central Baja California. Located 16 kilometers northwest of the Mexico border, it is considered one of the finest natural harbors in the world. This reputation is due mainly to its deep entrance and protection from weather it provides ships. San Diego Bay lies entirely in the county of San Diego, extending from the entrance at Point Loma southward to the mouth of the Otay River.

San Diego Bay is a natural, nearly-enclosed, crescent-shaped estuary that encompasses approximately 52 square kilometers. It is approximately 24 kilometers (km) in length and varies from 0.4 km to 5.8 km in width. Depths in the Bay vary from 18 meters near the mouth to less than 1 meter in the southern part of the bay, with the average depth for the entire bay being slightly more than 12 meters. The Bay is much deeper and narrower than it was historically, due mainly to dredging of channels and filling of nearshore areas.

San Diego Bay opens to the Pacific Ocean and is classified as an estuarine system due to its fresh water dilution. The diversion of the San Diego River to Mission Bay by the U.S. Army Corps of Engineers in 1857 was the first major reduction of freshwater input into the bay (Smith, 1977). Sweetwater River and the Otay River were also main sources of freshwater for San Diego Bay, although these sources have been greatly reduced over the years as a result of dam construction, extensive ground water use, and limited rainfall in recent years. Freshwater input is now limited to periodic surface drainage from the metropolitan area and intermittent flow from several rivers and creeks during periods of rainfall. Because of the dry Mediterranean-like climate that characterizes San Diego Bay, average annual rainfall in the Bay is usually between 10 and 13 inches, the majority of which falls between November and February.

Tides in San Diego Bay demonstrate marked variation between the heights of two high tides and two low tides that occur daily, classifying them as diurnal. The range between mean higher high water (MHHW) and mean lower low water (MLLW) is 1.6 meters and the extreme range of tides within the Bay is approximately 2.9 meters (Browning and Speth, 1973). Tidal currents are strongest in the northern part of the Bay where surface velocities reach 2.9 knots on ebb tide and 2.2 knots on flood tide (U.S. Army Corps of Engineers, 1973). Tidal currents are reduced considerably in the shallower central and south bay areas. Average tidal flushing for San Diego Bay is about 30% of the

entire Bay water volume exchanged per tidal cycle (12.5 hours). This volume of water is referred to as the tidal prism and in San Diego Bay represents approximately 74,000,000 cubic meters. Tidal flushing rates differ drastically between the Bay entrance and South Bay. Complete tidal flushing for the South Bay requires seven to fourteen days, whereas, the entrance of the Bay may only require one to two days. It has been estimated over the last century, tidal flushing in San Diego Bay has been reduced by 30% due to channel dredging and landfill projects (Browning and Speth, 1973).

San Diego Bay is a sedimentary environment with the bay floor and bay margins characterized by sand, silt and clay deposits (Peeling, 1974). Sand deposits are found near the Bay's mouth and along western margins, while finer silt and clay deposits are located on the eastern margins and at the southern end of the Bay.

An early navigation chart issued by the U.S. Coastal Survey in 1859 shows an undredged Bay fifteen miles long with a channel varying in depth from 22.2 meters decreasing to 3.6 meters. This natural channel stretched for 13 kilometers from the tip of Point Loma to the South Bay. Salt marshes existed at the mouths of seven creeks and river tributaries.

The early residents of the San Diego Bay area were Native Americans, who hunted and fished in the Bay; Spanish, Mexican, and American ranchers, who traded hides and tallow; and the early Yankee whalers who established camps in North Bay. These groups appeared to have little impact on the water quality in the Bay. By 1830 there were 16 American whaling vessels operating out of San Diego Bay. The whaling industry reached its peak in 1871-72 when 55,000 gallons of oil and 200 tons of whalebone were shipped from Point Loma. Americans participating in the New Town land boom of the 1880's settled in the central San Diego Bay area, site of the present downtown San Diego. This settlement soon represented a considerable increase in the population of the area as well as a dramatic threat to water quality in the Bay.

The Cuyamaca Dam and a flume were completed in 1888, diverting freshwater from eastern mountains into what is now Chollas Reservoir. Forty miles of sewers coupled with a sewage reservoir and outfall located in San Diego Bay off Market street were also completed in 1888. This sewage system marked the beginning of the decline in water quality for the Bay. Conditions within the Bay continued to decline because of the increase in population (30,000 in 1901) and acceptance of the Bay as a major harbor for the U.S. Navy and civilian commerce.

During the next four decades communications and aviation stations were added and docking facilities expanded. Naval facilities expanded greatly during World War II as business and industry boomed. In 1940, the population had increased to 200,000 causing a failure of the overloaded sewage collection and treatment facilities. In 1943, raw or minimally treated sewage was being

discharged into the Bay from 15 outfalls. After World War II and the Korean War, San Diego Bay was subject to the dumping of more than 50 million gallons of sewage and industrial waste per day (San Diego Interagency Water Quality Panel, 1989).

In 1950, the population of the San Diego metropolitan area had increased to over 400,000. In an attempt to curtail the flow of raw sewage into the Bay, San Diego and several neighboring communities combined their sewage outfalls into one system. Unfortunately, this new system was constantly operating on overload and discharging directly into the Bay. Simultaneously, the Bay received untreated industrial discharge from five fish canneries, a large rendering operation, a kelp processing plant, four aircraft manufacturing plants, several shipyards, and the Pacific coast's largest naval base, naval air station, and submarine base (San Diego Interagency Water Quality Panel, 1989). The California Regional Water Quality Control Board was established in 1950 (following the passage of the Dickey Act in 1949). Through extensive water sampling it was concluded that the entire Bay had become contaminated, due to heavy loading of domestic and industrial wastes. Dissolved oxygen concentrations in the Bay had declined to about half normal levels and turbidity in the water resulted in a visibility of less than 1 meter. Bait and game fish had virtually disappeared from the Bay. Coliform bacteria were routinely isolated from the Bay at significant levels. In 1955, the State Board of Public Health and the San Diego Department of Public Health declared much of the Bay contaminated, and posted quarantine and warning signs along 10 miles of shoreline. By 1963, sludge deposits from the treatment plant outfall were two meters deep, extended 200 meters seaward, and along 9000 meters of the shoreline.

A report in the early 1950's from the Regional Board and the San Diego Sewerage Survey report indicated sewage discharge into the Bay was becoming a major problem which had to be corrected. In 1960, San Diego voters approved a bond ($42.5 million) which allowed construction to begin on the Metropolitan Sewerage System. In August of 1963, a massive collection, treatment, and ocean disposal system began operation and by February, 1964, domestic sewage disposal had been eliminated from San Diego Bay. Following the completion of the new sewage treatment plant, dissolved oxygen concentrations rose to an average of more than 5 parts per million, visibility increased to 2 meters, and coliform bacteria counts dropped within the federal safety standards. Plankton blooms were scarce and sludge deposits of more than 30 cm were seldom reported. The sewage system currently processes 170 million gallons of waste per day (City of San Diego, 1995)

Routine sampling, beginning in the 1970's, revealed new information regarding the presence of industrial wastes in the Bay. Regulatory standards were developed for the protection of humans and wildlife based on new sampling systems and more refined analytical techniques. The conventional engineering and bacteriological data gathered earlier did not adequately address

the issue of toxic waste in the Bay. During the late 1980's, the press regarded San Diego Bay as being heavily contaminated, particularly for PCBs. Although conditions in the Bay are similar to other urban influenced embayments in the United States, San Diego Bay has serious problems with chemical pollution. A number of toxic hotspots in the Bay have been identified on lists of water quality impairment such as Clean Water Act Section 303(d), Section 319, Section 304(l) and Section 131.11.

Mission Bay

Mission Bay is located 9 kilometers north of Point Loma and encompasses an area of 1860 hectares. It has two main tributaries, Tecolote creek and Rose creek (Dexter, 1983). Originally named False Bay because its entrance was near San Diego Bay and occasionally fooled ship captains, it is now considered a recreational small-craft harbor (United States Coast Pilot, 1994). Prior to the development of Mission Bay park in 1946, Mission Bay was a natural estuary of over 2020 hectares of salt marshes, tidal channels, and a shallow central bay. Between 1946 and 1962 major dredging within the Bay and modifications to the San Diego River flood control channel gave way to its present-day configuration. Today it is a highly modified lagoon which receives freshwater input only during infrequent, heavy rains. The major additions of freshwater into Mission Bay occur at Rose Inlet, in the northeastern portion of the Bay, and Tecolote Creek, in the southeast. Because of this limited amount of freshwater, the salinities throughout the Bay do not change markedly. Mean tidal range is 1.2 meters and the mean diurnal range is 1.7 meters at the Bay entrance (Levin, 1983).

As a result of circulation patterns within Mission Bay, a variety of sediments are found. In the mouth of the Bay and near the main channel, water movement is sufficient to maintain a sandy bottom. In other parts of the Bay, such as Sail Bay and sites located further east, sediments are muddy with a high silt and clay content (Dexter, 1983).

Tecolote and Rose creeks carry urban pollutants such as oil, grease, fertilizers, and high sediment loads into the back bay. Furthermore, sewer lines back up occasionally into the back bay. The lack of water circulation in the back bay allows these pollutants to accumulate and has resulted in quarantines for several months at a time (Marcus, 1989).

Tijuana River Estuary

The Tijuana River Estuary is located 16 kilometers southeast of Point Loma. Although the estuary is situated entirely within the boundaries of San Diego County, three-fourths of its watershed is in Mexico. It is a wetland dominated estuary with no major embayment, however, a series of channels allows for a relatively narrow ocean connection (Herron, 1972). In the classification scheme developed by Prichard (1967), Tijuana Estuary is considered an intermittent coastal plain estuary due to the large

freshwater input during the winter wet season. During most years, the river mouth has been open and tidal flushing has prevailed. The intertidal area supports salt marsh vegetation (*Salicornia virginica*, *Spartina foliosa*), whereas mudflats and sandflats occupy only a small fraction of the estuary (Zedler *et al.*, 1992).

The Tijuana River Estuary has been altered substantially by natural and human disturbances. In the early 1900's, sewage disposal practices led to dredging of the east-west channel in order to connect an adjacent waste collecting lagoon with the estuary. Dikes were then created to subdivide the lagoon into three wastewater receiving ponds, however, these dikes were later removed to increase tidal flow. Gravel extraction for street and dike construction created isolated ponds within the estuary. Long-term dumping and filling altered most of the peripheral topography, while extensive damage to the southern half of the estuary from military, agricultural, and horse-raising activities is evident (Marcus, 1989).

Wastewater flow from Tijuana has been a serious threat to water quality in the estuary. In 1988, approximately 30 million gallons of sewage per day were produced while only 17 million gallons were collected. The remaining 13 million gallons emptied directly into the Tijuana River and estuary (Seamans, 1988). Breaks in the Tijuana sewer line, which carried collected sewage to an ocean outfall, were also common.

Recent U.S. projects have reduced the threat of sewage pollution. An interceptor on the Tijuana River, completed in early October 1991, diverts approximately 15 million gallons of sewage a day to the San Diego wastewater facility (Zedler, 1992). A sewage treatment plant is planned for the U.S. side of the border, and a new ocean outfall is under evaluation.

Sampling Design

Two basic sampling designs were used to meet both SWRCB's and NOAA's goals. A directed point sampling design was required to address SWRCB's need to identify specific toxic hot spots. A stratified random sampling design was required to address NOAA's need to evaluate spatial extent of pollution. This has resulted in a data set of 350 samples collected between October, 1992 and May, 1994. Of the 350 total samples, 229 were collected from directed point sampled stations and 121 were collected from randomly sampled stations.

When directed point sampling design was required, a two step process was used. Areas of interest were identified, by regional and state water board staff, for sampling during an initial "screening phase". Station locations (latitude & longitude) were predetermined by agreement with the SWRCB, NOAA, Regional Water Quality Control Boards, and DFG personnel. Changing of the site location during sediment collection was allowed only under the following conditions:

1. Lack of access to predetermined site,
2. Inadequate or unusable sediment (i.e. rocks or gravel)
3. Unsafe conditions
4. Agreement of appropriate staff

This phase of work was intended to give a broad assessment of toxicity throughout the San Diego Bay area using multiple test species and toxicity endpoints. Fifty-six stations were sampled during the period between October, 1992 and January, 1993. Chemical analysis was performed on selected samples in which toxicity results prompted further analysis. Stations which met certain criteria during the screening phase, or during the random sampling phase, were then selected for a second round of sampling, termed the "confirmation phase". During this phase sampling was replicated and chemical analysis of samples was more extensive. In addition, benthic community analysis was performed on all confirmation stations sampled during the summer of 1993. Evidence from this two step process is used to establish a higher level of certainty for stations which may later be identified as "toxic hot spots".

Stratified random sampling began in March, 1993 and continued through August, 1993, with a total of 121 stations sampled. The San Diego Bay Region was stratified into areas of similar physical characteristics or uses, such as transit channels, anchorages, marinas, commercial shipping or military uses, and designated as 95 blocks of known size (Figures 2a & 2b). Station coordinates were chosen randomly within the boundaries of each sampling block by USEPA Environmental Monitoring and Assessment Program (USEPA-EMAP) personnel using a computer program developed for that purpose. Eight alternate locations were chosen for each block, a maximum of two of which were actually sampled (Weisberg *et al.*, 1993). This stratified random design "forces"

Figure 2a
Sampling Blocks for Random Stations
San Diego Bay

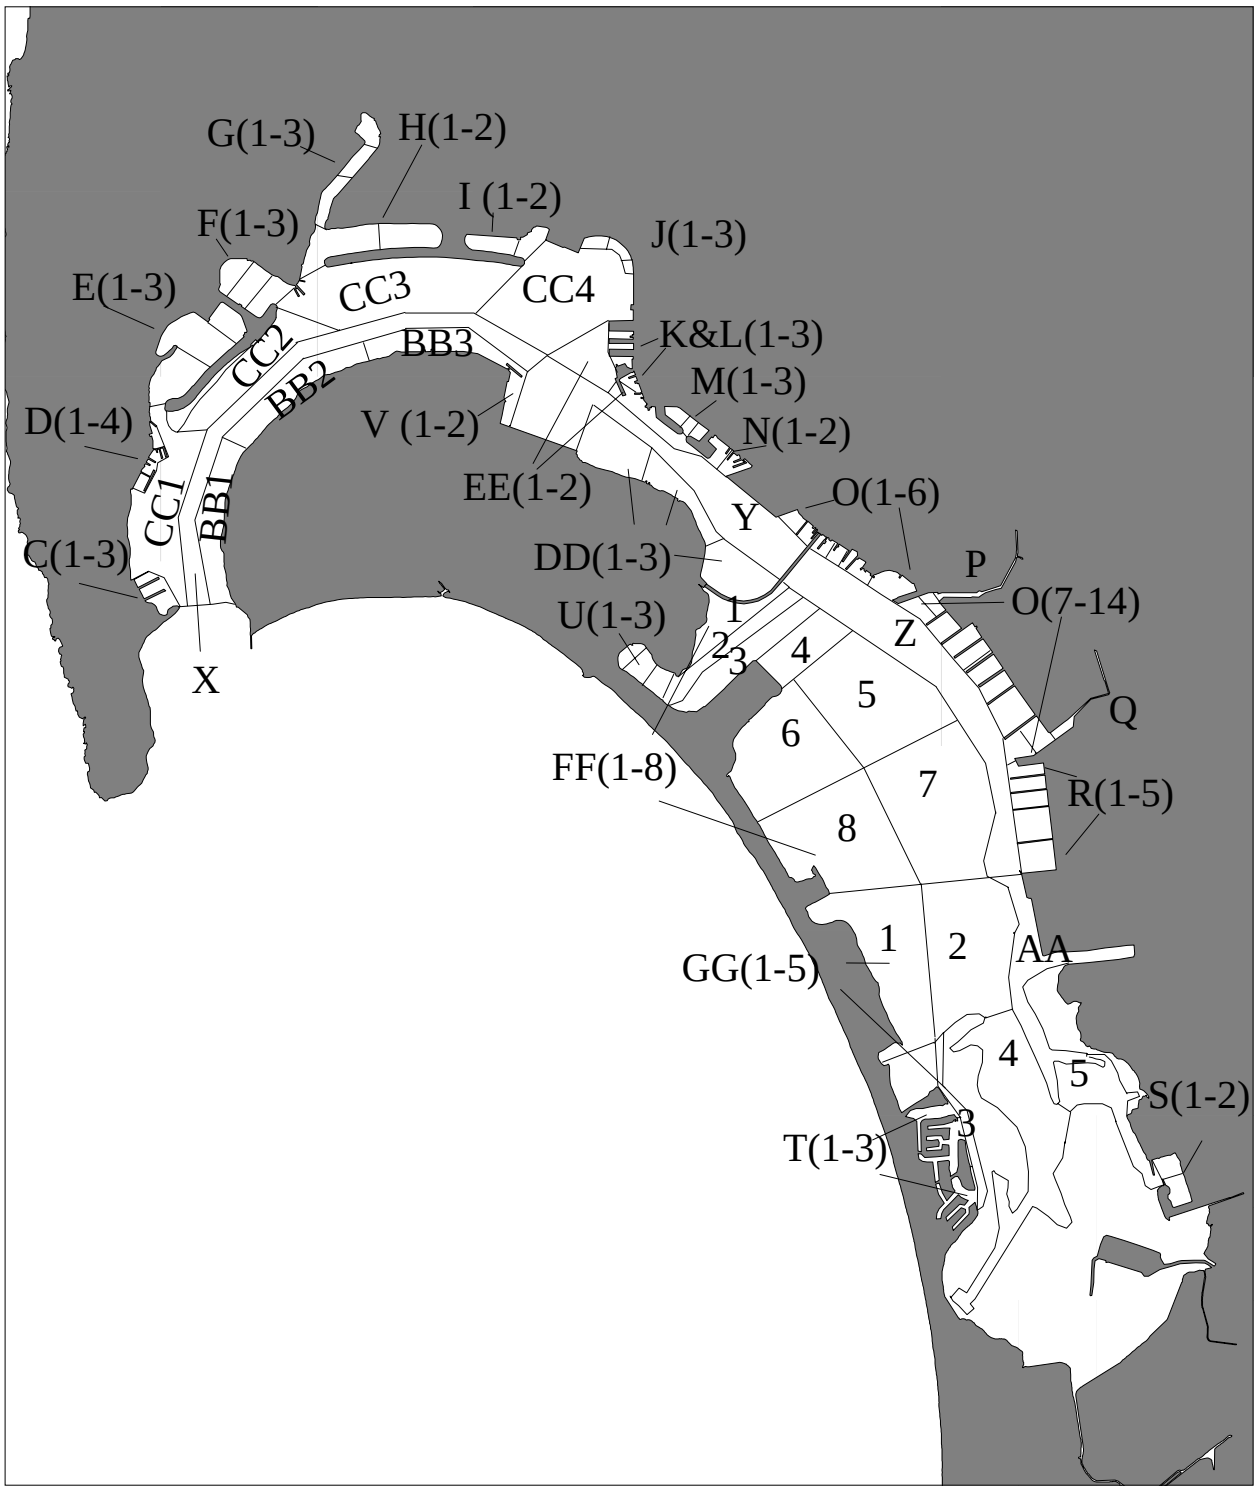


Figure 2b
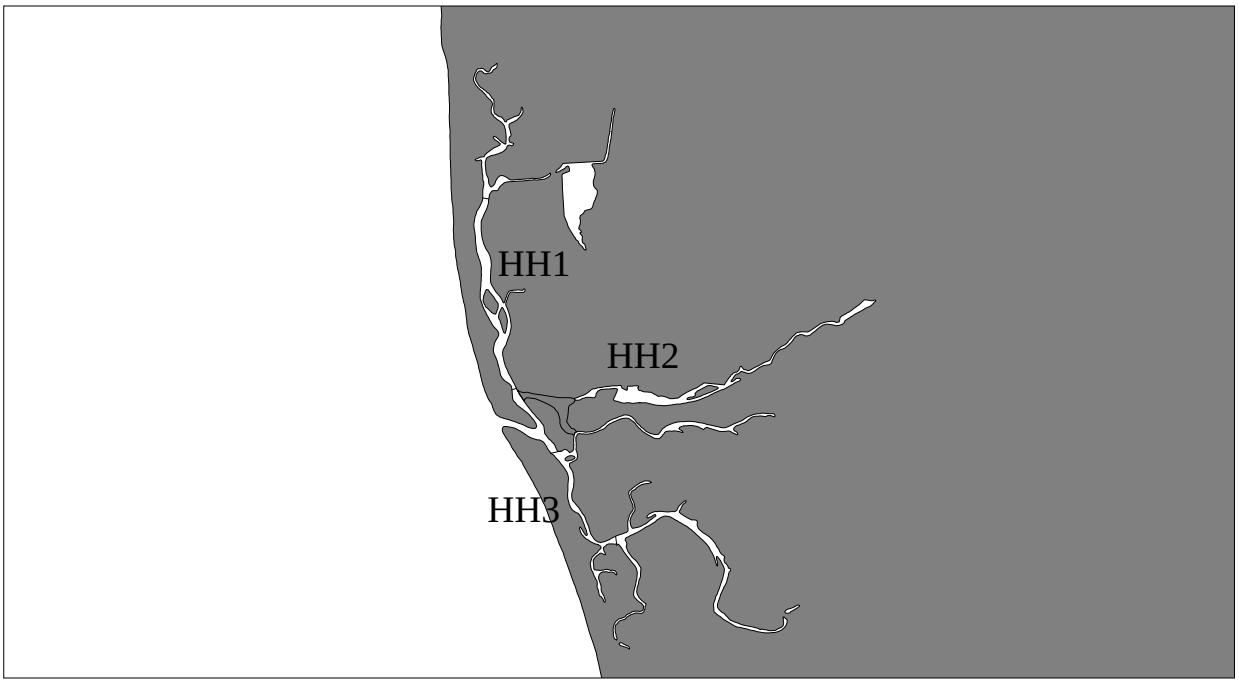
Sampling Blocks for Random Stations
Mission Bay and San Diego River Estuary

Tijuana River Estuary



random samples to cover all areas of the Bay, whereas a pure random design most likely would miss some areas and oversample others. In the field, sampling was attempted at each designated location (x1-x8), beginning with x1, until a sample was retrieved which met sample acceptability criteria. For example, in block FF2, Station number 93124 was sampled at the random location x1 while in block FF3, Station #93172 was sampled at random location x4 because the grain size was too coarse at locations x1, x2 and x3. Of the 121 stations sampled, ≈15% could not be sampled at the random x1 location, due to the location being inaccessible by boat because of obstructions, vessel moorings, piers or shallow depths. Similarly, ≈3% were not sampled because the grain size was too coarse at the x1 location. Samples were collected successfully at alternate locations (x2, x3, x4, ...) for all stations where x1 was not sampled. This sampling design allows data from random stations to be used for calculation of areal extent of toxicity in the San Diego Bay Region. Chemical analyses were only performed on a limited number of random station samples.

From the combined sampling designs, a total of 350 samples were collected from 183 station locations in the San Diego Bay Region (Figure 3(a-d)). Station locations which were sampled more than once were always resampled at the original location using navigational equipment and lineups. Bioassay tests, grain size and total organic carbon analyses were performed on all 350 samples. Trace metal analysis was performed on 217 samples. Trace synthetic organic analysis was performed on 229 samples. Benthic community analysis was performed on 75 samples.

Sample Collection and Processing

Summary of Methods

Specific techniques used for collecting and processing samples are described in this section. Because collection of sediments influences the results of all subsequent laboratory and data analyses, it was important that samples be collected in a consistent and conventionally acceptable manner. Field and laboratory technicians were trained to conduct a wide variety of activities using standardized protocols to ensure comparability in sample collection among crews and across geographic areas. Sampling protocols in the field followed the accepted procedures of EMAP, NS&T, and ASTM and included methods to avoid cross-contamination; methods to avoid contamination by the sampling activities, crew, and vessel; collection of representative samples of the target surficial sediments; careful temperature control, homogenization and subsampling; and chain of custody procedures.

Cleaning Procedures

All sampling equipment (*i.e.*, containers, container liners, scoops, water collection bottles) was made from non-contaminating materials and was precleaned and packaged protectively prior to entering the field. Sample collection gear and samples were handled only by personnel wearing non-contaminating

Figure 3a

Tijuana River Estuary

polyethylene gloves. All sample collection equipment (excluding the sediment grab) was cleaned by using the following sequential process:

> Two-day soak and wash in Micro® detergent, three tap-water rinses, three deionized water rinses, a three-day soak in 10% HCl, three ASTM Type II Milli-Q® water rinses, air dry, three petroleum ether rinses, and air dry.

All cleaning after the Micro® detergent step was performed in a positive pressure "clean" room to prevent airborne contaminants from contacting sample collection equipment. Air supplied to the clean room was filtered.

The sediment grab was cleaned prior to entering the field, and between sampling stations, by utilizing the following sequential steps: a vigorous Micro® detergent wash and scrub, a sea-water rinse, a 10% HCl rinse, and a methanol rinse. The sediment grab was scrubbed with seawater between successive deployments at the same station to remove adhering sediments from contact surfaces possibly originating below the sampled layer.

Sample storage containers were cleaned in accordance with the type of analysis to be performed upon its contents. All containers were cleaned in a positive pressure "clean" room with filtered air to prevent airborne contaminants from contacting sample storage containers.

Plastic containers (HDPE or TFE) for trace metal analysis media (sediment, archive sediment, pore water, and subsurface water) were cleaned by: a two-day Micro® detergent soak, three tap-water rinses, three deionized water rinses, a three-day soak in 10% HCl or HNO_3, three Type II Milli-Q® water rinses, and air dry.

Glass containers for total organic carbon, grain size or synthetic organic analysis media (sediment, archive sediment, pore water, and subsurface water) and additional teflon sheeting cap-liners were cleaned by: a two-day Micro® detergent soak, three tap-water rinses, three deionized water rinses, a three-day soak in 10% HCl or HNO_3, three Type II Milli-Q® water rinses, air dry, three petroleum ether rinses, and air dry.

Sediment Sample Collection

All sampling locations (latitude & longitude), whether altered in the field or predetermined, were verified using a Magellan NAV 5000 Global Positioning System, and recorded in the field logbook. The primary method of sediment collection was by use of a $0.1m^2$ Young-modified Van Veen grab aboard a sampling vessel. Modifications include a non-contaminating Kynar coating which covered the grab's sample box and jaws. After the filled grab sampler was secured on the boat gunnel, the sediment sample was inspected carefully. The following acceptability criteria were met prior to taking sediment samples. If a sample did not meet all the criteria, it was rejected and another sample was collected.

1. Grab sampler was not over-filled (*i.e.*, the sediment surface was not pressed against the top of the grab).
2. Overlying water was present, indicating minimal leakage.
3. Overlying water was not excessively turbid, indicating minimal sample disturbance.
4. Sediment surface was relatively flat, indicating minimal sample disturbance.
5. Sediment sample was not washed out due to an obstruction in the sampler jaws.
6. Desired penetration depth was achieved (*i.e.*, 10 cm).
7. Sample was muddy (>30% fines), not sandy or gravelly.
8. Sample did not include excessive shell, organic or man-made debris.

It was critical that sample contamination be avoided during sample collection. All sampling equipment (*i.e.*, siphon hoses, scoops, containers) was made of non-contaminating material and was cleaned appropriately before use. Samples were not touched with un-gloved fingers. In addition, potential airborne contamination (*e.g.*, from engine exhaust, cigarette smoke) was avoided. Before sub-samples from the grab sampler were taken, the overlying water was removed by slightly opening the sampler, being careful to minimize disturbance or loss of fine-grained surficial sediment. Once overlying water was removed, the top 2 cm of surficial sediment was sub-sampled from the grab. Subsamples were taken using a precleaned flat bottom scoop. This device allowed a relatively large sub-sample to be taken from a consistent depth. When subsampling surficial sediments, unrepresentative material (e.g., large stones or vegetative material) was removed from the sample in the field. Small rocks and other small foreign material remained in the sample. Determination of overall sample quality was determined by the chief scientist in the field. Such removals were noted on the field data sheet. For the sediment sample, the top 2 cm was removed from the grab and placed in a pre-labeled polycarbonate container. Between grabs or cores, the sediment sample in the container was covered with a teflon sheet, and the container covered with a lid and kept cool. When a sufficient amount of sediment was collected, the sample was covered with a teflon sheet assuring no air bubbles. A second, larger teflon sheet was placed over the top of the container to ensure an air tight seal, and nitrogen was vented into the container to purge it of oxygen. If water depth did not permit boat entrance to a site (*e.g.*, <1 meter), divers sampled that site using sediment cores (diver cores). Cores consisted of a 10 cm diameter polycarbonate tube, 30 cm in length, including plastic end caps to aid in transport. Divers entered a study site from one end and sampled in one direction, so as to not disturb the sediment with feet or fins. Cores were taken to a depth of at least 15 cm. Sediment was extruded out of the top end of the core to the prescribed depth of 2-cm, removed with a polycarbonate spatula and deposited into a cleaned polycarbonate tub. Additional samples were taken with the same seawater rinsed core tube until the required total sample volume was attained. Diver core samples were treated the

same as grab samples, with teflon sheets covering the sample and nitrogen purging. All sample acceptability criteria were met as with the grab sampler.

Replicate benthic samples (n=5) were obtained at predetermined sites from separate deployments of the sampler. Three of the replicates were positioned according to the BPTCP sampling protocol (*e.g.*, located by previously assigned lat/long coordinates), while the other two replicates were chosen within the location range of the previous three samples. The coring device was 10 cm in diameter and 14 cm in height, enclosing a 0.0075 m^2 area. Corers were placed into sediment with minimum disruption of the surface sediments, capturing essentially all surface-active fauna as well as species living deeper in the sediment. Corers were pushed about 12 cm into the sediment and retrieved by digging along one side, removing the corer and placing the intact sediment core into a pvc screening device. Sediment cores were sieved through a 0.5 mm screen and residues (*e.g.*, organisms and remaining sediments) were rinsed into pre-labeled storage bags and preserved with a 10% formalin solution. After 3 to 4 days, samples were rinsed and transferred into 70% isopropyl alcohol and stored for future taxonomy and enumeration.

Transport of Samples

Six-liter sample containers were packed (three to an ice chest) with enough ice to keep them cool for 48 hours. Each container was sealed in precleaned, large plastic bags closed with a cable tie to prevent contact with other samples or ice or water. Ice chests were driven back to the laboratory by the sampling crew or flown by air freight within 24 hours of collection.

Homogenization and Aliquoting of Samples

Samples remained in ice chests (on ice, in double-wrapped plastic bags) until the containers were brought back to the laboratory for homogenization. All sample identification information (station numbers, etc.) was recorded on Chain of Custody (COC) and Chain of Record (COR) forms prior to homogenizing and aliquoting. A single container was placed on plastic sheeting while also remaining in original plastic bags. The sample was stirred with a polycarbonate stirring rod until mud appeared homogeneous.

All prelabeled jars were filled using a clean teflon or polycarbonate scoop and stored in freezer/refrigerator (according to media/analysis) until analysis. The sediment sample was aliquoted into appropriate containers for trace metal analysis, organic analysis, pore water extraction, and bioassay testing. Samples were placed in boxes sorted by analysis type and leg number. Sample containers for sediment bioassays were placed in a refrigerator (4^{o}C) while sample containers for sediment chemistry (metals, organics, TOC and grain size) were stored in a freezer (-20^{o}C).

Procedures for the Extraction of Pore Water

The BPTCP primarily used whole core squeezing to extract pore water. The whole core squeezing method, developed by Bender *et*

al. (1987), utilizes low pressure mechanical force to squeeze pore water from interstitial spaces. The following squeezing technique was a modification of the original Bender design with some adaptations based on the work of Fairey (1992), Carr *et al.* (1989), and Long and Buchman (1989). The squeezer's major features consist of an aluminum support framework, 10 cm i.d. acrylic core tubes with sampling ports and a pressure regulated pneumatic ram with air supply valves. Acrylic subcore tubes were filled with approximately 1 liter of homogenized sediment and pressure was applied to the top piston by adjusting the air supply to the pneumatic ram. At no time during squeezing did air pressure exceed 200 psi. A porous prefilter (PPE or TFE) was inserted in the top piston and used to screen large (> 70 microns) sediment particles. Further filtration was accomplished with disposable TFE filters of 5 microns and 0.45 microns in-line with sample effluent. Sample effluent of the required volume was collected in TFE containers under refrigeration. Pore water was subsampled in the volumes and specific containers required for archiving, chemical or toxicological analysis. To avoid contamination, all sample containers, filters and squeezer surfaces in contact with the sample were plastics (acrylic, PVC, and TFE) and cleaned with previously discussed clean techniques.

Chain of Records & Custody

Chain-of-records documents were maintained for each station. Each form was a record of all sub-samples taken from each sample. IDORG (a unique identification number for only that sample), station numbers and station names, leg number (sample collection trip batch number), and date collected were included on each sheet. A Chain-of-Custody form accompanied every sample so that each person releasing or receiving a subsample signed and dated the form.

Authorization/Instructions to Process Samples

Standardized forms entitled "Authorization/Instructions to Process Samples" accompanied the receipt of any samples by any participating laboratory. These forms were completed by DFG personnel, or its authorized designee, and were signed and accepted by both the DFG authorized staff and the staff accepting samples on behalf of the particular laboratory. The forms contain all pertinent information necessary for the laboratory to process the samples, such as the exact type and number of tests to run, number of laboratory replicates, dilutions, exact eligible cost, deliverable products (including hard and soft copy specifications and formats), filenames for soft copy files, expected date of submission of deliverable products to DFG, and other information specific to the lab/analyses being performed.

Trace Metals Analysis of Sediments

Summary of Methods

Trace Metals analyses were conducted at the California Department of Fish and Game's (CDFG) Trace Metals Facility at Moss Landing, CA. Table 1 indicates the trace metals analyzed and lists method detection limits for sediments. These methods were modifications

of those described by Evans and Hanson (1993) as well as those developed by the CDFG (California Department of Fish and Game, 1990). Samples were selected for chemical analyses by SWRCB staff based on results from toxicity tests.

Analytes and Detection Limits

Table 1 - Trace Metal Detection Limits in Sediments (μg/g, dry weight).

Aluminum	1	Antimony	0.1
Arsenic	0.1	Cadmium	0.01
Chromium	0.1	Copper	0.1
Iron	0.1	Lead	0.1
Manganese	0.05	Mercury	0.03
Nickel	0.1	Selenium	0.2
Silver	0.01	Tin	0.02
Tributyltin	0.013	Zinc	0.05

Sediment Digestion Procedures

One gram aliquot of sediment was placed in a pre-weighed Teflon vessel, and one ml concentrated 4:1 nitric:perchloric acid mixture was added. The vessel was capped and heated in a vented oven at 130^0 C for four hours. Three ml Hydrofluoric acid were added to vessel, recapped and returned to oven overnight. Twenty ml of 2.5% boric acid were added to vessel and placed in oven for an additional 8 hours. Weights of vessel and solution were recorded, and solution transfered to 30 ml polyethylene bottles.

Atomic Absorption Methods

Samples were analyzed by furnace AA on a Perkin-Elmer Zeeman 3030 Atomic Absorption Spectrophotometer, with an AS60 auto sampler, or a flame AA Perkin Elmer Model 2280. Samples, blanks, matrix modifiers, and standards were prepared using clean techniques inside a clean laboratory. ASTM Type II water and ultra clean chemicals were used for all standard preparations. All elements were analyzed with platforms for stabilization of temperatures. Matrix modifiers were used when components of the matrix interferes with adsorption. The matrix modifier was used for Sn, Sb and Pb. Continuing calibration check standards (CLC) were analyzed with each furnace sheet, and calibration curves were run with three concentrations after every 10 samples. Blanks and standard reference materials, MESS1, PACS, BCSS1 or 1646 were analyzed with each set of samples for sediments.

Trace Organic Analysis of Sediments (PCBs, Pesticides, and PAHs)

Summary of Methods

Analytical sets of 12 samples were scheduled such that extraction and analysis will occur within a 40 day window. The methods employed by the UCSC-TOF were modifications of those described by Sloan *et al*. (1993). Tables 2 and 3 indicate the pesticides, PCBs, and PAHs currently analyzed and list method detection limits for sediments on a dry weight basis.

Extraction and Analysis
Samples were removed from the freezer and allowed to thaw. A 10 gram sample of sediment was removed for chemical analysis and an independent 10 gram aliquot was removed for dry weight determinations. The dry weight sample was placed into a pre-weighed aluminum pan and dried at 110◦C for 24 hours. The dried sample was reweighed to determine the sample's percent moisture. The analytical sample was extracted 3 times with methylene chloride in a 250-mL amber Boston round bottle on a modified rock tumbler. Prior to rolling, sodium sulfate, copper, and extraction surrogates were added to the bottle. Sodium sulfate dehydrates the sample allowing for efficient sediment extraction. Copper, which was activated with hydrochloric acid, complexes free sulfur in the sediment.

After combining the three extraction aliquots, the extract was divided into two portions, one for chlorinated hydrocarbon (CH) analysis and the other for polycyclic aromatic hydrocarbon (PAH) analysis.

The CH portion was eluted through a silica/alumina column, separating the analytes into two fractions. Fraction 1 (F1) was eluted with 1% methylene chloride in pentane and contains > 90% of p,p'-DDE and < 10% of p,p'-DDT. Fraction 2 (F2) analytes were eluted with 100% methylene chloride. The two fractions were exchanged into hexane and concentrated to 500 µL using a combination of rotary evaporation, controlled boiling on tube heaters, and dry nitrogen blow downs.

F1 and F2 fractions were analyzed on Hewlett-Packard 5890 Series gas chromatographs utilizing capillary columns and electron capture detection (GC/ECD). A single 2 µl splitless injection was directed onto two 60m x 0.25mm i.d. columns of different polarity (DB-17 & DB-5; J&W Scientific) using a glass Y-splitter to provide a two dimensional confirmation of each analyte. Analytes were quantified using internal standard methodologies. The extract's PAH portion was eluted through a silica/alumina column with methylene chloride. It then underwent additional cleanup using size-exclusion high performance liquid chromatography (HPLC/SEC). The collected PAH fraction was exchanged into hexane and concentrated to 250 µL in the same manner as the CH fractions.

Total Organic Carbon Analysis of Sediments

Summary of Methods
Samples were received in the frozen state and allowed to thaw at room temperature. Source samples were gently stirred and sub-samples were removed with a stainless steel spatula and placed in labeled 20 ml polyethylene scintillation vials. Approximately 5 grams equivalent dry weight of the wet sample was sub-sampled.

Sub-samples were treated with two, 5 ml additions of 0.5 N, reagent grade HCl to remove inorganic carbon (CO^{-3}), agitated, and centrifuged to a clear supernate. Some samples were retreated with HCl to remove residual inorganic carbon. The evolution of gas during HCl treatment indicates the direct presence of inorganic carbon (CO^{-3}). After HCl treatment and decanting, samples were washed with approximately 15 ml of deionized-distilled water, agitated, centrifuged to a clear supernate, and decanted. Two sample washings were required to remove weight determination and analysis interferences.

Prepared samples were placed in a 60◦ C convection oven and allowed to come to complete dryness (approx. 48 hrs.). Visual inspection of the dried sample before homogenization was used to ensure complete removal of carbonate containing materials, (shell fragments). Two 61 mm (1/4") stainless steel solid balls were added to the dried sample, capped and agitated in a commercially available ball mill for three minutes to homogenize the dried sample.

A modification of the high temperature combustion method, utilizing a Weatstone bridge current differential was used in a commercially available instrument, (Control Equipment Co., 440 Elemental Analyzer) to determine carbon and nitrogen concentrations. The manufactures suggested procedures were followed. The methods are comparable to the validation study of USEPA method MARPCPN I. Two to three aliquotes of 5-10 mg of dried prepared sub-sample were used to determine carbon and nitrogen weight percent values. Calibration of the instrument was with known standards using Acetanilide or L-Cystine. Detection limits are 0.2 ug/mg, carbon and 0.01 ug/mg nitrogen dry weight.

The above methods and protocols are modifications of several published papers, reference procedures and analytical experimentation experience (Franson, 1981; Froelich, 1980; Hedges and Stern, 1983; MARPCPN I, 1992).

Quality Control/Quality Assurance

Quality control was tested by the analysis of National Research Council of Canada Marine Sediment Reference Material, BCSS-1 at the beginning and end of each sample analysis set (20-30 individual machine analyses). All analyzed values were within suggested criteria of $\pm$ 0.09% carbon (2.19% Average). Nitrogen was not reported on the standard data report, but was accepted at $\pm$ 0.008% nitrogen (0.195% Average) from the EPA study. Quality assurance was monitored by re-calibration of the instrument every twenty samples and by the analysis of a standard as a unknown and comparing known theoretical percentages with resultant analyzed percentages. Acceptable limits of standard unknowns were less than $\pm$ 2%. Duplicate or triplicate sample analysis variance (standard deviation/mean) greater than 7% is not accepted. Samples were re-homogenized and re-analyzed until the variance between individual runs fell below the acceptable limit of 7.0%.

Grain Size Analysis of Sediments

Summary of Methods
The procedure used combined wet and dry sieve techniques to determine particle size of sediment samples. Methods follow those of Folk (1974).

Sample Splitting and Preparation
Samples were thawed and thoroughly homogenized by stirring with a spatula. Spatulas were rinsed of all adhering sediment between samples. Size of the subsample for analysis was determined by the sand/silt ratio of the sample. During splitting, the sand/silt ratio was estimated and an appropriate sample weight was calculated. Subsamples were placed in clean, pre-weighed beakers. Debris was removed and any adhering sediment was washed into the beaker.

Wet Sieve Analysis (separation of coarse and fine fraction)
Beakers were placed in a drying oven and sediments were dried at less than 55◦C until completely dry (approximately three days). Beakers were removed from drying oven and allowed to equilibrate to room temperature for a least a half-hour. Each beaker and its contents were weighed to the nearest .01 g. This weight minus the empty beaker weight was the total sample weight. Sediments in beakers were disaggregated using 100 ml of a dispersant solution in water (such as 50g Calgon/L water) and the sample was stirred until completely mixed and all lumps disappear. The amount and concentration of dispersant used was recorded on the data sheet for each sample. Sample beakers were placed in an ultrasonic cleaner for 15 minutes for disaggregation. Sediment dispersant slurry was poured into a 63 μm (ASTM #230, 4 phi) stainless steel or brass sieve in a large glass funnel suspended over a 1L hydrometer cylinder by a ring stand. All fine sediments were washed through the sieve with water. Fine sediments were captured in a 1L hydrometer cylinder. Coarse sediments remaining in sieve were collected and returned to the original sample beaker for quantification.

Dry Sieve Analysis (coarse fraction)
The coarse fraction was placed into a preweighed beaker, dried at 55-65◦C, allowed to acclimate, and then weighed to 0.01 g. This weight, minus the empty beaker weight, was the coarse fraction weight. The coarse fraction was poured into the top sieve of a stack of ASTM sieves having the following sizes: No. 10 (2.0 mm), 18 (1.0 mm), 45 (0.354 mm), 60 (0.25 mm), 80 (0.177 mm), 120 (0.125 mm), and 170 (0.088 mm). The stack was placed on a mechanical shaker and shaken at medium intensity for 15 minutes. After shaking, each sieve was inverted onto a large piece of paper and tapped 5 times to free stuck particles. The sieve fractions were added cumulatively to a weighing dish, and the cumulative weight after each addition determined to 0.01g. The sample was returned to its original beaker, and saved until sample computations were completed and checked for errors.

Analytical Procedures
Fractional weights and percentages for various particle size fractions were calculated. If only wet sieve analysis was used, weight of fine fraction was computed by subtracting coarse fraction from total sample weight, and percent fine composition was calculated using fine fraction and total sample weights. If dry sieve was employed as well, fractional weights and percentages for the sieve were calculated using custom software on a Macintosh computer. Calibration factors were stored in the computer.

Benthic Community Analysis

Summary of Methods
Each catalogued sample was processed individually in the laboratory to obtain an accurate assessment of species diversity and abundance. All macroinvertebrates were sorted from residues under a dissecting microscope, identified to lowest possible taxon, and counted. Laboratory processing of benthic cores consists of both rough and fine sorting. Initial sorting separates animals into large taxonomic groups such as polychaetes, crustaceans, mollusks and other (*e.g.*, phoronids). Bound laboratory logbooks were maintained and used to record number of samples processed by each technician, as well as results of any sample resorts, if necessary. Sorters were required to sign and date a Milestone Progress Checksheet for each replicate sample processed. Specimens of similar taxonomic groups were placed in vials and labelled internally and externally with project, date collected, site/station information, and IDORG. Samples were selected for benthic community analysis by SWRCB staff based on results from toxicity tests.

In-house senior taxonomists and outside specialists processed and verified the accuracy of species identification and enumeration. An archived voucher specimen collection was established at this time.

Toxicity Testing

Summary of Methods
All toxicity tests were conducted at the California Department of Fish and Game's Marine Pollution Studies Laboratory (MPSL) at Granite Canyon. Toxicity tests were conducted by personnel from the Institute of Marine Sciences, University of California, Santa Cruz.

Pore Water Samples
Once at MPSL, frozen pore water samples were stored in the dark, at -12^{0}C, until required for testing. Experiments performed by the U.S. National Biological Survey have shown no effects of freezing porewater upon the results of toxicity tests (Carr *et al.*, 1995). Samples were thawed on the day of a test, and pH,

temperature, salinity, and dissolved oxygen were measured in all samples to verify water quality criteria were within the limits defined for test protocol. Pore water samples with salinities outside specified ranges for each protocol were adjusted to within the acceptable range. Salinities were increased by the addition of hypersaline brine, 60 to 80 parts per thousand (ppt), drawn from partially frozen seawater. Dilution water consisted of Granite Canyon seawater (32 to 34 ppt). Water quality parameters were measured at the beginning and end of each test. Dissolved oxygen concentrations and pH were measured using an Orion EA940 expandable ion analyzer. Salinity was measured with a refractometer. Temperature of each sample was measured with a mercury thermometer.

Measurement of Ammonia and Hydrogen Sulfide

Total ammonia concentrations were measured using an Orion Model 95-12 Ammonia Electrode. The concentration of unionized ammonia was derived from the concentration of total ammonia using the following equation (from Whitfield 1974, 1978):

$$[NH_3] = [\text{total ammonia}] \times ((1 + \text{antilog}(pK_a^\circ - pH))^{-1}),$$

where pK_a° is the stoichiometric acidic hydrolysis constant for the test temperature and salinity. Values for pK_a°were experimentally derived by Khoo *et al*. (1977). The method detection limit for total ammonia was 0.1 mg/L.

Total sulfide concentrations were measured using an Orion Model 94-16 Silver/Sulfide Electrode, except that samples tested after February, 1994, were measured on a spectrophotometer using a colorimetric method (Phillips et al. in press). The concentration of hydrogen sulfide was derived from the concentration of total sulfide by using the following equation (ASCE 1989):

$$[H_2S] = [S^{2-}] \times (1 - ((1 + \text{antilog}(pK_a^\circ - pH))^{-1})),$$

where temperature and salinity dependent pK_a° values were taken from Savenko (1977). The method detection limit for total sulfide was 0.1 mg/L for the electrode method, and 0.01 mg/L for the colorimetric method. Values and corresponding detection limits for unionized ammonia and hydrogen sulfide were an order of magnitude lower than those for total ammonia and total sulfide, respectively.

Subsurface Water Samples

The subsurface water toxicity tests are water column toxicity tests (abalone development, mussel development, etc..) performed on water collected with the modified Van Veen grab. A water sample bottle on the frame of the grab and a stopper is pulled as the jaws of the grab close for a sediment sample. The water sample is consequently collected approximately 0.5 meters above the bottom. Subsurface water samples were held in the dark at 4^0C until testing. Toxicity tests were initiated within 14 days of

the sample collection date. Water quality parameters, including ammonia and sulfide concentrations, were measured in one replicate test container from each sample in the overlying water as described above. Measurements were taken at the beginning and end of all tests.

Sediment Samples
Bedded sediment samples were held at 4^0C until required for testing. All *Rhepoxynius abronius* and *Neanthes arenaceodentata* solid phase sediment tests were initiated within 14 days of the sample collection date. All sediment samples were processed according to procedures described in ASTM (1992). Water quality parameters, including ammonia and sulfide concentrations, were measured in one replicate test container from each sample in the overlying water as described above. Measurements were taken at the beginning and end of all *Rhepoxynius* and *Neanthes* tests, and during overlying water renewals in the *Neanthes* tests.

Sea Urchin Larval Development Test
The sea urchin (*Strongylocentrotus purpuratus*) larval development test was conducted on all pore water samples. Details of the test protocol were given in Dinnel (1992). A brief description of the method follows.

Sea urchins were collected from the Monterey County coast near Granite Canyon, and held at MPSL at ambient seawater temperature and salinity (approx. 32±2 ppt) until testing. Adult sea urchins were held in complete darkness to preserve gonadal condition. On the day of a test, urchins were induced to spawn in air by injection with 0.5M KCl. Eggs and sperm collected from the urchins were mixed in seawater at a 500 to 1 sperm to egg ratio, and embryos were distributed to test containers within 1 hour of fertilization. Test containers were polyethylene-capped, sea-water leached, 20ml glass scintillation vials containing 5 mls of pore water. Each test container was inoculated with approximately 150 embryos (30/ml). All pore water samples were tested at three concentrations: 100, 50 and 25% pore water, each having three replicates. Pore water samples were diluted when necessary with one micron-filtered Granite Canyon seawater. Laboratory controls were included with each set of samples tested. Controls include a dilution water control consisting of Granite Canyon seawater, a brine control with all samples that require brine adjustment, and in some tests a frozen seawater control consisting of Granite Canyon seawater that has been frozen along with the pore water samples. Tests were conducted at ambient seawater salinity (usually 33±2 ppt). A positive control reference test was conducted concurrently with each pore water test using a dilution series of copper chloride as a reference toxicant.

After an exposure of 72 or 96 hours (no difference in results was detectable between these periods), larvae were fixed in 5% buffered formalin. Approximately 100 larvae in each container were examined under an inverted light microscope at 100x to determine the proportion of normally developed larvae as

described by Dinnel (1992). Visual clues used to identify embryos as normal included development of skeletal rods (spicules) that extend beyond half the length of the larvae and normal development of a three part gut. Slow growing embryos were considered abnormal.

Percent normal development was calculated as:

$$\frac{\text{(Number of normally developed larvae) X 100}}{\text{(Total number of observed larvae + number of abnormal larvae)}}$$

Sea Urchin Fertilization Test
The sea urchin (*Strongylocentrotus purpuratus*) fertilization test was conducted on pore water samples. Details of the test protocol were described in Dinnel *et al*. (1987).

Sea urchins were from the same stock described for the sea urchin larval development test. On the day of a test, urchins were induced to spawn in air by injection with 0.5M KCl. Sperm were exposed in test containers for sixty minutes before approximately 1000 eggs were added. After twenty minutes of fertilization, the test was fixed in a 5% buffered formalin solution. A constant sperm to egg ratio of 500 to 1 was used in all tests. This ratio maintained fertilization in the 70-90% range required by the test protocol. Fertilization was determined by the presence or absence of a fertilization membrane (raised chorion completely surrounding the egg). Test containers were polyethylene-capped, sea-water leached, 20ml glass scintillation vials containing 5 mls of pore water. All pore water samples were tested at three concentrations: 100, 50 and 25% pore water, each having three replicates. Pore water samples were diluted with one micron-filtered Granite Canyon seawater. Laboratory controls were included with each set of samples tested. Controls included a dilution water control consisting of Granite Canyon seawater, a brine control with all samples that require brine adjustment, and in some tests a frozen seawater control consisting of Granite Canyon seawater that has been frozen along with the pore water samples. Tests were conducted at ambient seawater salinity (usually 33±2 ppt). A positive control reference test was conducted concurrently with each pore water test using a dilution series of copper chloride as a reference toxicant. All eggs in each container were examined under an inverted light microscope at 100x, and counted as either fertilized or unfertilized.

Percent fertilization was calculated as:

$$\frac{\text{(Number of fertilized eggs) x 100}}{\text{(Number of fertilized eggs + number of unfertilized eggs)}}$$

Sea Urchin Cytogenetics Test
Analysis of cytogenetic abnormalities using sea urchin embryos followed methods described in Hose (1985). Sea urchin embryos were exposed to pore water for 48 hours then preserved in 5% buffered formalin. Embryos were placed on a clean glass

microscope slide and excess formalin removed with tissue paper. Embryos were then treated with a few drops of aceto-orcein stain (19 parts aceto-orcein:one part propionic acid) for approximately 1 to 3 minutes, and a cover slip was then applied to the darkly stained embryos. Excess stain was removed by blotting, and embryos were compressed into a monolayer by application of direct pressure. Embryo monolayer preparations were observed under oil immersion using either an Olympus BH2 or Tiyoda light microscope at 100x magnification. Cytogenetic abnormalities were observed in mitotic cells in anaphase and telophase. Possible aberrations observed followed those described in Hose (1985), including: stray or lagging chromosomes, accentric or attached chromosome fragments, and translocated or side-arm bridges . Because a majority of the embryos exposed to the 100 and 50% pore water concentrations displayed gross developmental abnormalities, mitotic aberrations were generally assessed using embryos exposed to 25% pore water.

Red Abalone Larval Development Test

The red abalone (*Haliotis rufescens*) larval development test was conducted on all subsurface water samples. Details of the test protocol were described in Anderson *et al*. (1990). The following was a brief description of the method. Adult male and female abalone were induced to spawn separately using a dilute solution of hydrogen peroxide in sea water. Fertilized eggs were distributed to the test containers within 1 hour of fertilization. Test containers were polyethylene-capped, seawater leached scintillation vials containing 10 mls of sample water. Each of five replicate test containers were inoculated with 100 embryos (10/ml).

Positive control reference tests using zinc sulfate as a reference toxicant were conducted concurrently with each batch of samples. A negative sea water control consisting of one micron-filtered Granite Canyon seawater was tested along with sub-surface water samples and zinc concentrations. After 48 hours of exposure, developing larvae were fixed in 5% buffered formalin. Approximately 100 larvae in each container were examined under an inverted light microscope at 100x to determine the proportion of veliger larvae with normal shells as described in Anderson et al. (1990).

Percent normal development was calculated as:

$$\frac{\text{(Number of normally developed larvae)} \times 100}{\text{Total number of observed larvae}}$$

Amphipod Tests

Solid-phase sediment sample toxicity was assessed using the 10-day amphipod survival toxicity test protocol for *Rhepoxynius abronius* (ASTM 1993).

All test organisms were obtained from Northwest Aquatic Sciences in Yaquina Bay, Oregon. Amphipods were separated into groups of approximately 100 each, placed in polyethylene boxes containing

Yaquina Bay collection site sediment, and then shipped on ice via overnight courier. Upon arrival at Granite Canyon, the amphipods were acclimated slowly (<2 ppt per day) to 28 ppt sea water ($T = 15^0C$). Once acclimated to 28 ppt, the animals were held for an additional 48 hours prior to inoculation into the test containers.

Test containers were one liter glass beakers or jars containing two cm of sediment and filled to the 700 ml line with seawater adjusted to 28 ppt using spring water or distilled well water. Test sediments were not sieved for indigenous organisms prior to testing although at the conclusion of the test, the presence of predators was noted and recorded on the data sheet. Test sediment and overlying water were allowed to equilibrate for 24 hours, after which 20 amphipods were placed in each beaker along with 28 ppt seawater to fill test containers to the one liter line. Test chambers were aerated gently and illuminated continuously at ambient laboratory light levels.

Five laboratory replicates of each sample were tested for ten days. A negative sediment control consisting of five lab replicates of Yaquina Bay home sediment was included with each sediment test. After ten days, the sediments were sieved through a 0.5 mm Nytex screen to recover the test animals, and the number of survivors was recorded for each replicate.

Positive control reference tests were conducted concurrently with each sediment test using cadmium chloride as a reference toxicant. For these tests, amphipod survival was recorded in three replicates of four cadmium concentrations after a 96 hour water-only exposure. A negative seawater control consisting of one micron-filtered Granite Canyon sea water, diluted to 28 ppt was compared to all cadmium concentrations.

Amphipod survival for each replicate was calculated as:

$$\frac{\text{(Number of surviving amphipods) X 100}}{\text{(Initial number of amphipods)}}$$

Polychaete Tests

A subset of sediment samples was tested using *Neanthes arenaceodentata*. The protocol follows procedures described by Johns *et al.* (1990). Newly emergent juvenile *Neanthes* (2 to 3 weeks old) were obtained from Dr. Donald Reish in Long Beach, California. Worms were shipped in seawater in plastic bags at ambient temperature via overnight mail. Upon arrival at MPSL, worms were allowed to acclimate gradually to 28 ppt with <2 ppt daily incremental salinity adjustments. Once acclimated, the worms were maintained for at least 48 hours, and no longer than 10 days, before the start of a test.

The test setup was similar to the amphipod test. Test containers were one liter glass beakers or jars, each containing 2 cm of sediment and filled to the 700 ml line with 28 ppt seawater. Seawater was adjusted to the appropriate salinity using spring

water or distilled well water. After test sediment and overlying water were allowed to equilibrate for 24 hours, 5 worms were placed in each of 5 replicate beakers per sample, and 28 ppt seawater was added up to the one liter line. Test chambers were aerated and illuminated continuously during the 20-day test period. Worms were fed TetraMin® every 2 days, and water was renewed every 3 days. At the end of 20 days, samples were sieved through 0.5mm Nitex® screens, and the number of surviving worms recorded. Surviving worms were placed in pre-weighed foil in a drying oven until they reached a constant weight. Worms were weighed to the nearest 0.1mg.

Worm survival for each replicate was calculated as:

$$\frac{\text{(Number of surviving worms)} \times 100}{\text{Initial number of worms}}$$

Mean weight/worm for each replicate was calculated as:

$$\frac{\text{(Total weight) - (foil weight)}}{\text{Number of surviving worms}}$$

Positive control reference tests were conducted using cadmium chloride as a reference toxicant. Worm survival for 10 worms was recorded in three replicates of four cadmium concentrations in seawater after 96 hours of exposure. A negative seawater control consisting of one micron-filtered Granite Canyon seawater was compared to all cadmium concentrations. A negative sediment control consisting of Yaquina Bay amphipod home sediment was also included in each test.

Mussel Development Test

The bay mussel (*Mytilus edulis*) larval development test was conducted on pore water and sub-surface water samples for which salinity was in the range of 0-26 parts per thousand (ppt). Details of the test protocol are given in ASTM (1992). A brief description of the method follows.

Mussels were shipped via overnight courier and held at MPSL at ambient temperature (11-13°C) and salinity (32-34 ppt) until testing. On the day of a test, adult mussels were transferred to 25°C water to induce spawning through heat stress. Sperm and eggs were mixed in 25 ppt water to give a final sperm-to-egg ratio of 15 to 1. After approximately 20 minutes, fertilized eggs were rinsed on a 25 μm screen to remove excess sperm. Embryos were distributed to the test containers after approximately 90% of the embryos exhibited first cell cleavage (approximately 1 hour).

Test containers were polyethylene-capped, sea water-leached, 20 ml glass scintillation vials containing 10 mls of test solution. Each test container was inoculated with approximately 250 embryos (25/ml). Pore water samples were tested at 25 ± 2 ppt. Low salinity samples were adjusted to 25 ppt using frozen seawater brine. Controls consisted of one micron-filtered Granite Canyon sea water adjusted to 25 ppt, and a separate brine control consisting of sea water brine adjusted to 25 ppt with distilled water. A positive control reference test was conducted concurrently with each test using a dilution series of cadmium chloride as a reference toxicant.
After a 48-hour exposure period, larvae were fixed in 5% buffered formalin. All larvae in each container were examined under an inverted light microscope at 100x to determine the proportion of normally developed larvae as described in ASTM (1992). The percentage normally developed larvae was calculated as:

$$\frac{\text{Observed number of live normal larvae} \times 100}{\text{Mean number of live embryos inoculated at start of test}}$$

Statistical Analysis of Toxicity Test Data
A total of three hundred fifty solid-phase sediment samples were tested for toxicity to amphipods (*Rhepoxynius abronius)* as part of this study. A subset of 154 samples of solid-phase sediment samples were tested with the polychaete *Neanthes arenaceodentata*. Two hundred twenty-five pore water samples were tested using the purple sea urchin *(Strongylocentrotus purpuratus*) fertilization test; 196 samples were tested using the sea urchin larval development test; and 65 subsurface water (water column) samples were tested with the red abalone *(Haliotis rufescens)* larval development test. The bivalve mollusc *(Mytilus edulis)* larval development test was used to test eight sub-surface water and three pore water samples that had salinities below the threshold (26 ppt) selected for use of the sea urchin test.

There were three primary objectives for the toxicity testing portion of this study:
(1) Investigate the areal extent of toxicity in the San Diego Bay region by estimating the percent area considered toxic, based on toxicity test data for each individual protocol; (2) Identify those sites which were most toxic to assist in prioritization and designation of "toxic hot spots"; and (3) Evaluate the performance of each toxicity test protocol.

The first objective (investigating the spatial extent of toxicity) was primarily for use of the National Oceanic and Atmospheric Administration (NOAA)- National Status and Trends Program. The second objective (identifying and prioritizing individual sites as "toxic hot spots") was primarily for the California State Water Resources Control Board.

The different objectives required different sampling designs and different statistical approaches. The first objective, determination of the areal extent of toxicity, was accomplished through a process this report will refer to as the "EMAP approach": statistical procedures that compared samples from

randomly selected stations against the test controls. In this approach, classification of a particular test sample as "toxic" was determined by a two step statistical approach comparing test samples to laboratory controls, as described below.

To accomplish the second objective, distinguishing the most toxic stations in the region to assist in the designation and prioritization of "toxic hot spots", a relatively new statistical method was employed, termed the "reference envelope approach". This approach compared organism response (e.g. % survival) from an individual test sample with mean organism response from a group of reference sites presumed to represent optimal ambient conditions in the San Diego Bay region. Optimal ambient conditions are defined as indicative of conditions that can be found within the study area at sites that have relatively low pollutant concentrations and relatively undisturbed benthic communities. This method was intended to refine the definition of sample toxicity in order to identify a subset of toxic sites that were of greatest concern. This method is also described in detail below.

It should be noted that the EMAP approach and the reference envelope approach are distinctly different, yet complementary, statistical methods for determining toxicity. The intent of using two approaches is to identify non-toxic, significantly toxic and highly toxic locations based on multiple analyses of the data, for ranking toxicity results in a tiered approach.

EMAP Approach for Determining Spatial Extent of Toxicity

The "San Diego Bay Region" incorporates three non-connecting water bodies: San Diego Bay, Mission Bay and Tijuana Slough. Ideally these water bodies should be treated as discrete areas and analyzed separately to determine percent area toxic for each. However, the number of samples from Mission Bay and Tijuana Slough were 13 and 6, respectively, and these were considered too few to accurately represent toxicity in a frequency distribution.

Consequently, data from all three water bodies were combined in this report to determine the percentage of total area that was toxic.

In this analysis, sample toxicity was determined using procedures described by Schimmel *et al.* (1991); a method used in the EPA Environmental Monitoring Assessment Program (EMAP) and in similar NOAA studies nationwide (e.g., Long *et al.*, 1994). Using the EMAP approach, samples were defined as toxic if the following two criteria were met: (1) there was a significant difference in mean organism response (e.g. percent survival) between a sample and the control as determined using a t-test, and (2) mean organism response in the toxicity test was less than 80% of the laboratory control value. The t-test generates a t statistic by dividing the difference between control and test sample response by an expression of the variance between laboratory replicates. If the variation between control and test sample is sufficiently greater than the variation among laboratory replicates, the t-test

indicates a significant difference in response. A "separate variance" t-test was used to adjust the degrees of freedom to account for variance heterogeneity among samples (SYSTAT, 1992).

The second criterion, that sample response must be less than 80% of the control value to be considered toxic, is useful in eliminating those samples that were statistically different from controls only because of a very small variance among laboratory replicates. For example, a sample that had 90 ± 2 % *Rhepoxynius* survival would be significantly different from a control with survival of 96 ± 2 %, and would therefore be considered toxic based on a simple t-test even though the biological significance of this response would be negligible. By adding the second criterion, any sample with percent survival exceeding 80% of the controls would be considered non-toxic. The 80% level was established by examination of numerous amphipod toxicity data sets (Thursby and Schlekat, 1993). These researchers found that samples with survival less than 80% relative to controls were significantly different from controls about 90% of the time. Preliminary analyses of *Rhepoxynius* test data from the BPTCP indicate a similar level of statistical sensitivity. Based on this observation, the 80% criterion has been adopted previously (Schimmel *et al.*, 1991; USEPA/USACOE, 1991). Samples identified as toxic according to these criteria were used to estimate the percent of total area toxic within the San Diego Bay region.

Using Cumulative Distribution Frequencies to Characterize Spatial Extent

The stratified random sampling design, allowed 121 of the total 350 samples collected in this study, to be used to estimate the areal extent of toxicity. Samples collected using directed sampling (non-random sampling directed to areas of particular characteristics) were not included in this analysis since they may have been biased toward increased contamination. Directed non-random sampling was designed to address the State and Regional Water Quality Boards objective to identify and prioritize potential toxic hot spots. Samples were collected from randomly selected stations within 95 non-overlapping mapped blocks of known area in the San Diego Bay region (Figure 2). Total area sampled, calculated as the sum of all 95 block areas, was 40.9 km^2. The estimate of spatial toxicity was determined from cumulative distribution frequencies (CDFs) that relate toxicity response to percent of total sampled area. CDF calculations follow procedures used by both EMAP and NS&T.

CDFs were determined using calculated areas of each block normalized to the number of samples per block. Block areas were calculated using a planimeter on NOAA National Ocean Service navigation chart (means of three trials), calibrated to the scale of the charts. Because no more than two samples were collected per block, numbers of toxic samples per block ranged from 0 to 2, representing 0%, 50% or 100% of a given block area. By combining the blocks with their toxicity designations in a cumulative manner, the CDFs indicate the percentage of total area sampled that was toxic. Sample toxicity was determined from comparisons

with laboratory controls as described above in the EMAP approach; each sample with a mean significantly different from, and less than 80% of, the laboratory control mean was considered toxic. Calculations used to derive percent areas determined to be toxic are shown on worksheets in Appendix F. CDFs were generated from toxicity tests using *Rhepoxynius* survival (solid phase) and *Strongylocentrotus* larval development (pore water). There were insufficient data from randomly selected sites to generate CDFs for *Haliotis*, *Mytilus* and *Neanthes* tests.

The Reference Envelope Approach for Determining Toxicity

The second objective of this study was to assist in the identification of "toxic hotspots", where adverse biological impacts are observed in areas with localized concentrations of pollutants. Identification of problem sites was an essential step in prioritizing efforts to improve sediment and water quality through regulation and remediation programs. While it was possible large areas of San Diego Bay may be degraded to some extent, logistical constraints required efforts be focused on localized areas that were significantly more toxic than optimal ambient conditions that exist in the greater portion of the bay. In this study, a "reference envelope" statistical approach was employed (Smith,1995) to identify samples that exhibit significantly greater toxicity than expected in San Diego Bay as a whole.

The reference envelope approach uses data from "reference sites" to characterize the response expected from sites in the absence of localized pollution. Using data from the reference site population, a tolerance limit was calculated for comparison with data from test sites. Samples with toxicity values greater than the tolerance limit were considered toxic relative to the optimal ambient condition of the Bay.

This relative standard established using reference sites was conceptually different from what might be termed the absolute standard of test organism response in laboratory controls. Rather than comparing sample data to control data using t-tests, with laboratory replication used to characterize the variance component (as in the "EMAP approach" described above), the reference envelope approach compared sample data against a percentile of the reference population of data values, using variation among reference sites as the variance component. The reference envelope variance component, therefore, included variation among laboratory replicates, among field replicates, among sites, and among sampling events.

The reference stations were assumed to be a random sample from an underlying population of reference locations that serve as a standard for what we considered relatively non-impacted conditions. The toxicity measured at different reference locations will vary due to the different local conditions that can affect the toxicity results. In order to determine whether sediments from a test location were toxic, bioassay results for the test location were compared with bioassay results from the population of reference locations.

Assuming the bioassay results from the population of reference locations are normally distributed, an estimate of the probability that the test sediment is from the underlying reference station distribution can be made. For example, if the result for a test sediment was at the first percentile of the underlying reference location distribution (in the direction of toxicity), then there would be about a 1% chance that the test sediment was from the distribution of reference locations. The toxicity level at the first percentile of the reference distribution is not known because there were only limited samples from the underlying distribution and only an estimate could be made of where the first percentile lies. If an estimate of the first percentile value was made a large number of times, using different random samples from the reference distribution, a (non-central t) distribution of estimates, with the distribution mode at the actual first percentile would be obtained (Figure 4). In Figure 4, it can be seen from the distribution of estimates that about one half of the time the estimate from the sample was above the actual first percentile. Ideally, identification of an estimated toxicity value would cover the actual first percentile for a large percentage of the estimates (say 95% of the time). Such a value can be obtained from the left tail of the distribution of estimates where 5% of the estimates are less than the chosen value. The definition of p is the percentile of interest, and alpha is the acceptable error probability associated with an estimate of the pth percentile. Thus, in this example, p=1 and alpha = .05.

The toxicity level can be computed that will cover the pth percentile 1 minus alpha proportion of the time as the lower bound (L) of a tolerance interval (Vardeman 1992) as follows.

$$L = X_r - [\, g_{a,p,n} * S_r \,]$$

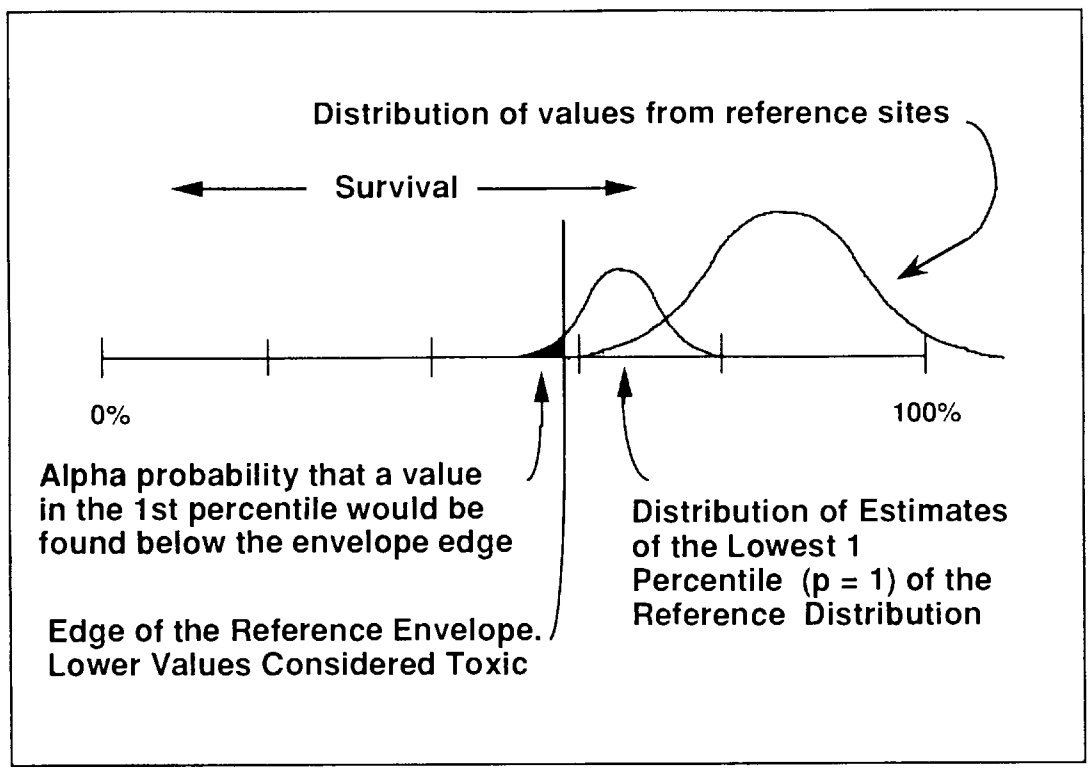
where X_r is the mean of the sample of reference stations, S_r is the standard deviation of the toxicity results among the reference stations, and n is the number of reference stations. The g values, for the given alpha, p, and n values, can be obtained from tables in Hahn and Meeker (1991) or Gilbert (1987). S contains the within- and between-location variability expected among reference locations. If the reference stations are sampled at different times, then S will also incorporate between-time variability. The "edge of the reference envelope" (L) represents a cutoff toxicity level used to distinguish toxic from non-toxic sediments. The value used for p will depend on the level of certainty needed for a particular regulatory situation. In this study a p value equal to 1% was chosen, to distinguish only the most toxic samples, that is, samples having a 95% certainty of being in the most toxic 1%.

Reference Station Selection for Reference Envelope

Reference stations were selected to represent optimal ambient conditions available in San Diego Bay, based on available chemistry and benthic community data. Toxicity data were not

used in the selection process. Stations were selected if both of the following criteria were met: 1) the benthic communities appeared relatively undisturbed (based on indices described in the benthic community analysis section), and 2) sediment chemical concentrations were below Effects Range Median (ERM) levels (Long *et al.*, 1995) and Probable Effects levels (PELs) (McDonald, 1994). Among all stations, both randomly and non-randomly

Figure 4. Schematic illustration of the method for determining the lower tolerance interval bound (edge of the reference envelope) to determine sample toxicity relative to a percentile of the reference site distribution.



selected, a total of 75 samples were analyzed for toxicity, chemistry and benthic ecology in this study. After screening these 75 samples, eleven stations in the San Diego Bay region were selected as reference stations (Table 4). It should be noted these stations were not selected prior to the initiation of the study, but were selected after all of the analyses for the study were completed.

P450 Reporter Gene System

Summary of Methods

A subset of thirty sediment samples was sent to Columbia Analytical Services (CAS) in Kelso, Washington for extraction with methylene chloride. Extracts of 20 g sediment samples were evaporated to 1 ml and placed in small vials for shipment to the Carlsbad, CA laboratory of CAS where 2 μl samples were applied in triplicate to genetically engineered human liver cancer cells (101L cells) developed by Dr. Robert Tukey of the University of California, at San Diego. A previous study partially funded by the State Board (Anderson *et al.*, 1995) had demonstrated that low levels of dioxin, coplanar PCBs and selected PAHs could be detected by the P450-RGS response to the extracts. When this small volume of solvent (with extracted contaminants) is applied to approximately one million cells in 2 ml of medium, induction of the CYP1A1 gene leads to production of the detoxification enzyme, P450, and the luminescent enzyme, luciferase. When the cells are lysed (after 16 hours) and the centrifugate tested with luciferin, the amount of light measured in a luminometer is a function of the concentration and potency of the contaminants on the sediments. When the contents of a single well (containing ≈ one million cells) are centrifuged and placed in the luminometer the resulting measure is in Relative Light Units (RLU). The RLUs of the solvent blank are set to unity and by dividing all RLU readings for the reference toxicant and samples by the RLUs of the blank, the data are converted to Fold Induction (or times background). To make the data more relevant to environmental samples, the data are converted to Equivalents of Benzo(a)pyrene (BaPEq), a ubiquitous PAH compound of environmental concern (U.S. EPA, 1995). To convert mean fold induction to BaPEq in μg/g dry weight, the fold induction values are divided by sixty, which (based on a dose response curve) is the response of the assay to 1μg/ml of Benzo(a)pyrene (BaP). The μg of BaP per volume of extract (e.g. 10 μl) is adjusted to an initial volume of 1 ml and this product divided by the dry grams of sample contained in the 1 ml extract. This method can be used to calculate Equivilants for PAHs, from benz(a)anthracene to benzo(g,h,i)perylene (Table 4), as well as dioxins/furans and coplanar PCBs. Both sediments and tissues (marine mussel) from San Diego Bay have been analyzed for the presence of P450 inducing compounds in previous studies (Anderson *et al.* 1996, in press a). The detailed methods and results of P450-RGS testing with standards and sediment extracts are described in Postlind *et al.* (1994), and Anderson *et al.* (1995). In 1996, three publications will be available describing the specific test methods (ASTM, Standard Methods,and CRC Press).

None of the above samples exhibited any chemical exceedance of an ERM or PEL.
None of the above samples exhibited elevated ammonia or hydrogen sulfide during toxicity testing.
Amphipod Survival value is the mean and standard deviation from 5 laboratory replicates.
Urchin Development values are the mean and standard deviation of 5 replicates in 25% porewater.
ERM and PEL summary quotients are discussed in Appendix B and the report text.

Quality Assurance/Quality Control

Summary of Methods

Summaries of quality assurance and quality control procedures are described under separate cover in the Bay Protection and Toxic Cleanup Program Quality Assurance Project Plan (QAPP). This document describes procedures within the program which ensure data quality and integrity. Quality assurance procedures follow those of the NS&T Program to ensure comparability with other NOAA survey areas nationwide. In addition, individual laboratories prepare quality assurance evaluations of each discrete set of samples analyzed and authorized by task order. These documents were submitted to the California Department of Fish and Game for review, then forwarded to the State Water Resources Control Board for further review.

RESULTS

Tabulated data for all chemical, benthic, toxicological and P450-RGS analyses are presented in Appendices B, C, D and E. The summary data presented in the following results sections were used to demonstrate significant findings from the analysis of the full data set in Appendices B, C, and D.

Distribution of Chemical Pollutants

Chemical Specific Screening Values

There have been several recent studies associating pollutant concentrations with biological responses (Long and Morgan, 1990; MacDonald, 1992). These studies provide guidance for evaluating the degree to which sediment chemical pollutants levels are responsible for effects observed in a toxicity test. Reported values are based on individual chemical pollutants within sediments. Therefore, their application may be confounded when dealing with: biological effects which could be attributed to a synergistic effect of low levels of multiple chemicals, unrecognized chemicals, or physical parameters in the sediment which were not measured.

The National Status and Trends Program has used chemical and toxicological evidence from a number of modeling, field and laboratory studies to determine the ranges of chemical concentrations which are rarely, sometimes, or usually associated with toxicity (Long and Morgan, 1992). Evaluation of available data (Long *et al.*, 1995) has led to identification of three ranges in concentration for each chemical:

1) Minimal Effects Range: The range in concentration over which toxic effects are rarely observed:

2) Possible Effects Range: The range in concentrations over which toxic effects are occasionally observed;

3) Probable-Effects Range: The range in chemical concentrations over which toxic effects are frequently or always observed.

Two slightly different methods were used to determine these chemical ranges. One method developed by NOAA (Long and Morgan, 1990; Long *et al.*, 1995) used chemical data which were associated with a toxic biological effect. These data were used to determine the lower 10th percentile of ranked data where the chemical level was associated with an effect (Effects Range-Low, or ERL). Sediment samples in which all chemical concentrations were below the 25 ERL values were not expected to be toxic. The Effects Range-Median (ERM) reflects the 50th percentile of ranked data and represents the level above which effects are expected to occur. Effects are expected to occur occasionally when chemical concentrations fall between the ERL and ERM. The probability of toxicity was expected to increase with the number and degree of exceedances of the ERM values.

Another method identifies three ranges using chemical concentration data associated with both toxic biological effects and no observed effects (MacDonald, 1992; MacDonald, 1994; MacDonald *et al., In Press*). The ranges are identified as TEL (Threshold Effects Level) and the PEL (Probable Effects Level). TEL values were derived by taking the geometric mean of the 50th percentile of the "no effects" data and the 15th percentile of the "effects" data. The PEL values were derived by taking the geometric mean of the 85th percentile of the "no effects" data and the 50th percentile of the "effects" data. Although different percentiles were used for these two methods, they are in close agreement, usually within a factor of 2. Values reported for both methods are shown in Table 5. Neither of these methods is advocated over the use of the other in this report. Instead, both are used in the following analysis to create a weight of evidence which should help explain toxicity observed from some sediments.

A cautionary note should be included; the degree of confidence which MacDonald (1994) and Long *et al. (*1995) had in their respective guidelines varied considerably among the different chemicals. For example, they express low confidence in the values derived for nickel, mercury, DDTs, chlordane, dieldrin, and endrin. When more data becomes available regarding these chemicals and their potential effects, the guidelines may be revised, probably upward for some substances.

Primary Chemicals of Concern

Figure 5 presents a summary of the chemicals and chemical groups which exceeded ERM or PEL values at the 217 stations where complete chemical analysis was performed. Copper, mercury, zinc, total chlordane, total PCBs and the PAHs were most often found to exceed ERM or PEL values and are considered the six major chemicals or chemical groups of concern in the San Diego Bay

Table 5- Comparison of Sediment Screening Levels
Developed by NOAA and the State of Florida

SUBSTANCE	State of Florida (1) TEL	State of Florida (1) PEL	NOAA (2) ERL	NOAA (2) ERM
Organics (ug/kg- dry weight)				
Total PCBs	21.550	188.79	22.70	180.0

(1) D.D. MacDonald, 1994

(2) Long et al., 1995

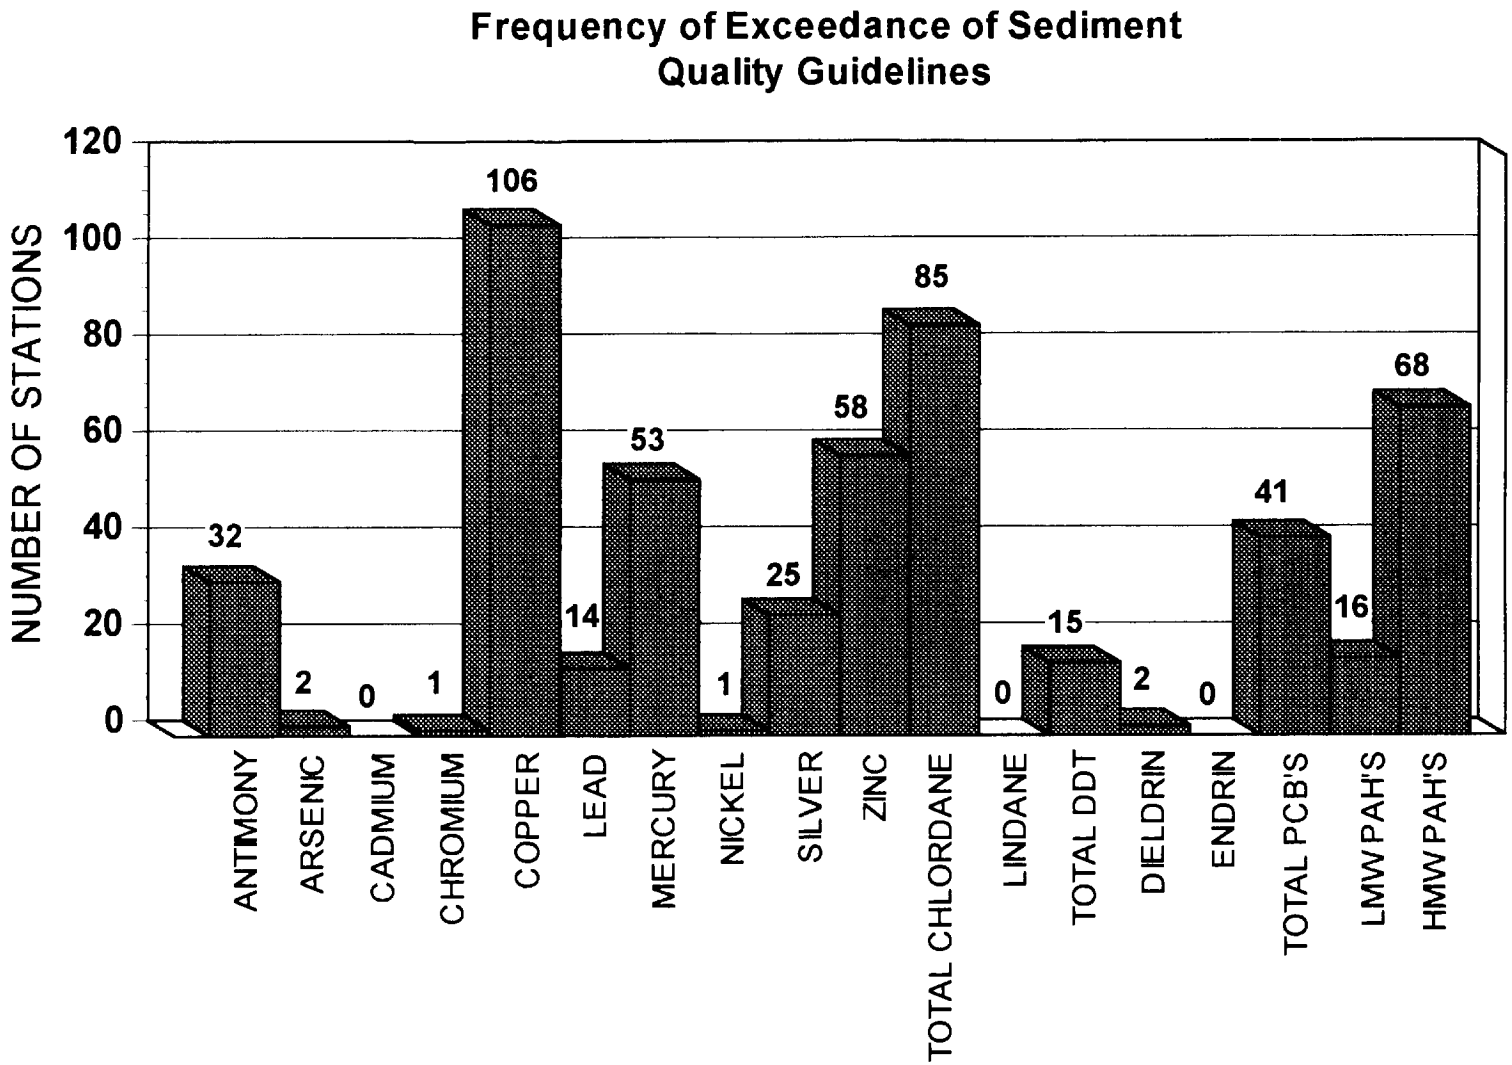

Figure 5. Number of stations which exceeded either the PEL or ERM values.

Region. MacDonald (1994) and Long *et al. (*1995) express relatively high confidence in the ERM and PEL values derived for copper, zinc, total PCBs and PAHs. Figures 6-12 map the geographical distribution of the six chemicals of concern throughout the San Diego Bay Region. Three ranges of chemical concentration are given for each chemical: (1) below the TEL, (2) between the TEL and PEL and (3) above the PEL to the maximum concentration determined.

Copper is a broad spectrum biocide which may be associated with acute and chronic toxicity, reduction in growth, and a wide variety of sublethal effects (Spear and Pierce, 1979). Elevated copper concentrations above the PEL (>108.2 mg/kg) or ERM (>270 mg/kg) were found throughout San Diego Bay (Figure 6(a-d)), with small boat harbors, commercial shipping berths and military berths most often impacted. Considering the historical use of copper based anti-fouling paint in the area, this distribution pattern is expected.

Zinc demonstrates a similar pattern of distribution, although actual exceedances of PEL levels (>271 mg/kg) or ERM levels (>410 mg/kg) only occur in the central portion of the bay, along the naval shipyard waterfront (Figure 7(a-d).

Mercury, particularly methylmercury, is highly toxic to aquatic biota. Although there is variability in sensitivity of different organisms to the substance, bioaccumulation of mercury in aquatic species has significant implications with respect to human health. PEL exceedances (> 0.696 mg/kg) and ERM exceedances (>0.71 mg/kg) of mercury were found in several small boat areas, near commercial shipping operations and predominately near naval shipyard areas (Figure 8(a-d)).

Polycyclic (polynuclear) aromatic hydrocarbons (PAHs) are base/neutral organic compounds with a fused ring structure of two or more benzene rings. They are components of crude and refined petroleum products and are also products of incomplete combustion of organic materials. Exposure to PAHs may result in a wide range of carcinogenic, teratogenic and mutagenic effects to terrestrial and aquatic organisms (Eisler, 1987). Due to their similar modes of toxic action, individual PAHs are often grouped into low and high molecular weight compounds, for concise reporting purposes. Individual PAHs used for the summations of low and high molecular weight PAHs in this report are given in Appendix B -Section VII. PAH pollution, as shown for high molecular weight PAHs in Figure 9(a-d), exceeds the PEL (>6676.14 μg/kg) or ERM (>9600 μg/kg) near commercial shipping operations and naval shipyard areas, as well as the submarine facility near the mouth of the harbor. The pattern for PEL (>1442 μg/kg) or ERM (>3160 μg/kg) exceedances of low molecular weight PAHs is similar to high molecular weight PAHs (Fig. 10(a-d)).

A significant concern is polychlorinated biphenyls (PCBs) levels found in sediments throughout San Diego Bay. PCBs are base/neutral compounds which are formed by direct chlorination of

biphenyl. There are 209 numerically designated individual compounds, called congeners (*i.e.*, PCB #101), based on the possible chlorine substitution patterns. Mixtures of various PCB congeners have been manufactured in the U.S. since 1929 (Phillips, 1987) and are used commercially under the trade name Aroclor. Each PCB mixture has a number designation (*i.e.*, Aroclor 1254) with the last two numbers indicating the percentage of chlorine in the mixture. PCB mixtures were used extensively in the U.S. prior to 1979 for industrial applications which required fluids with thermal stability, fire and oxidation resistance and solubility in organic compounds (Hodges, 1977). PCBs have proven to be extremely persistent in the environment and have demonstrated a variety of adverse carcinogenic and non-carcinogenic effects (USEPA, 1993c). These substances have a high potential to accumulate in the tissues of aquatic organisms and can represent significant hazards to consumers of aquatic species (Moore and Walker, 1991). Total PCB (the sum of 18 congeners, Appendix B - Section VII) pollution is most prominent in sediments along the naval shipyard waterfront (Figure 11(a-d)), although several locations along the downtown waterfront and small boat harbors also show total PCB values in excess of the PEL (>188.79 μg/kg) and ERM (>180 μg/kg).

Chlordane is a multipurpose insecticide which has been used extensively in home and agricultural applications for the control of termites and other insects. Although use of this compound ended in the mid-70s, its persistence in sediments of the region is apparent. Total chlordane is the summation of major constituents of technical grade chlordane and its metabolite (Appendix B - Section VII). Chlordane pollution is extensive along the north shore of San Diego Bay, the San Diego River, and the most northerly station in Mission Bay (Figure 12(a-d)). Areas which receive storm runoff, such as Chollas Creek, Seventh St. Channel, and urban storm drains appear to be the most heavily contaminated (PEL (>4.79 μg/kg) or ERM (>6 μg/kg)).

ERM and PEL Summary Quotients

In this report, comparisons of the data to effects-based numerical guidelines were made to assess how sediment pollution in the San Diego Bay Region compares to sediment pollution on a national scale. Additionally, these guidelines were used to identify chemicals of concern for sediment quality management within the San Diego Bay Region. Rankings and comparisons were made in this report using summary ERM-quotients (ERMQ) and PEL-quotients (PELQ). Summary quotients are summations of chemical concentrations for chemicals listed in Table 5, divided by their respective ERM or PEL value, and then divided by total number of chemicals used. In samples where levels of measured chemicals were below the analytical method detection limit (MDL), a value of one-half the MDL was used for summations. Methods and analytes used for summations and averaging are given in Appendix B-Section VII. This was a simple approach for addressing overall chemical pollution where there were multiple pollutants at a station, and was in addition to the standard chemical by chemical

approach discussed earlier. This approach considered not only the presence of guideline exceedances, but the number and degree of multiple exceedances.

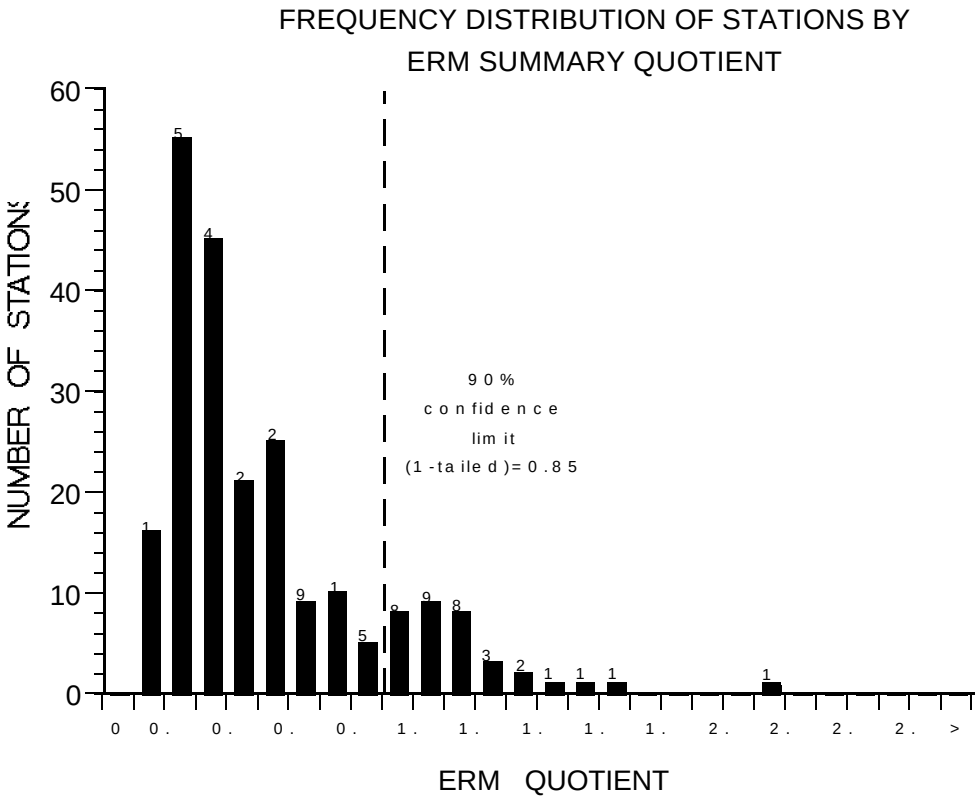
Based upon analyses of the national NS&T and EMAP database, the incidence of toxicity has been shown to increase with increasing summary ERM and PEL quotients (Long, Field and MacDonald, in prep). Synergistic effects are possible, but not implied by the quotient summations, therefore, this method should be recognized only as a ranking scheme meant to better focus management efforts on interpretation of ambient sediment chemistry data.

Interpretations using ERM and PEL summary quotients were limited to statistical analysis within this dataset because the approach has not been formally presented in other reports, therefore, outside comparisons are unavailable at this time. The 90% confidence interval from a 1-tailed t-distribution was chosen as an arbitrary threshold level for evaluating the data set. For the 220 stations on which chemical analysis was performed, stations with an ERMQ>0.85 or a PELQ>1.29 were found to fall above this confidence interval (Figure 13). Although these values of 0.85 and 1.29 cannot be considered threshold levels with proven ecological significance, they can be used for within bay comparative purposes. Forty-one stations exhibited ERM or PEL quotient levels exceeding the confidence interval cutoffs. Of these forty-one stations, twelve received benthic community analysis, all which were determined to have degraded communities in the analysis discussed later (Figure 14). All 41 stations were tested for *Rhepoxynius* toxicity, of which 29% demonstrated significant toxicity, at the 48% limit established by the reference envelope method discussed later. This difference in biological response to pollutants, between benthic community structure and bioassays, may be explained by long term exposure to pollutants in the benthic community relative to short term (10 day) pollutant exposure in bioassay tests. Use of the ERM and PEL quotients appear to give a worthwhile representation of overall chemical pollution and are used later in this report for station rankings and characterizations.

Distribution of Benthic Community Degradation

Data Analyses and Interpretation

The identification of benthic degraded and undegraded habitat (as determined by macrobenthic community structure) was conducted using a cumulative, weight-of-evidence approach. Tests were employed without prior knowledge or integration of results from laboratory exposures or chemical analyses. Analyses were performed to identify relationships between community structure within and between each station or site. This included diversity/evenness indices, analyses of habitat and species composition, construction of dissimilarity matrices for pattern testing, assessment of indicator species and development of a benthic index, cluster and ordination (multidimensional scaling) analyses. Initially, a triangular correlation matrix was produced



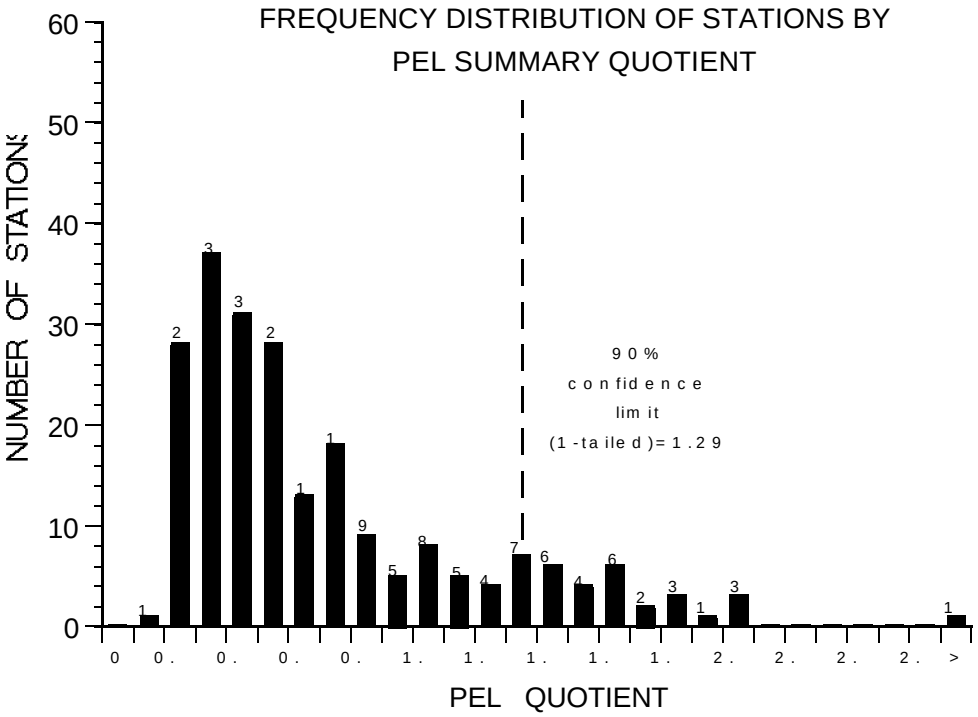


Figure 13. Histogram of the number of stations by ERM or PEL summary quotient group. Vertical dashed line indicates 90% confidence limit of the mean.

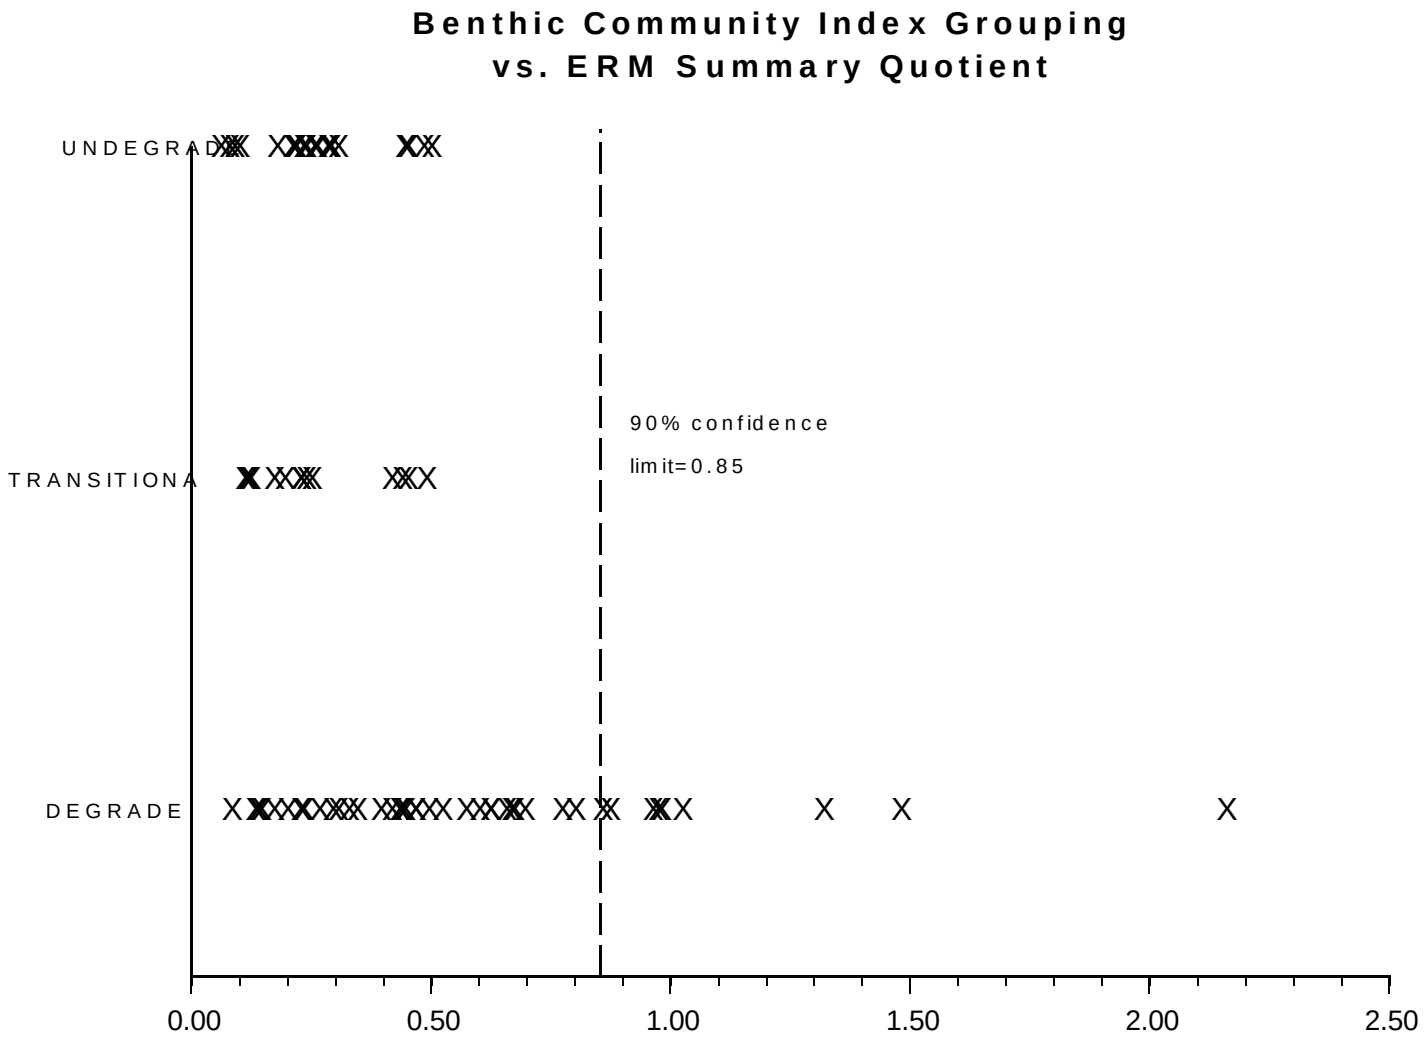

Figure 14. Benthic index grouping vs. ERM summary quotient value. Each data point represents one station (n=75).

from species density data from each site using the Systat® statistical program. From this matrix several tests for association of variables were performed. The tests employed are common in marine and estuarine benthic community analyses and are well-documented in the literature (Field *et al.,* 1982; Pearson *et al* 1983; Swartz *et al.,* 1985; Gray, 1989; Clark and Ainsworth, 1993). Classification analysis was employed to demonstrate site-related community patterns such as species dominance. Cluster analysis is a multivariate procedure for detecting natural groupings in data, and, for our purposes, data were grouped by average similarities in total composition and species abundance (Krebs, 1989). The average-linkage method calculates similarity between a pair of cluster groups as the average similarity among entities in the two groups. Species information is used to compute similarity index values. Grouped stations were clustered at a conservative distance limit of 50-60% similarity, however, this level was purely arbitrary. Because classification analyses have the tendency to force data into artificially distinct groups, another method (*e.g.*, multi-dimensional scaling) was used to confirm the validity of group clusters and site similarity. Ordination analysis was useful because it enables one to see multidimensional gradients in data rather than just groupings (Smith, personal communication).

Multi-dimensional scaling (MDS) is used extensively in the analyses of benthic communities, particularly in estuarine and marine pollution studies. MDS is a procedure for fitting a set of points in space such that the distance between points correspond to a given set of dissimilarities. This technique is more flexible than principal co-ordinate analyses when handling the large number of zero counts generally characteristic of species-samples matrices. Nonmetric MDS analyses were performed using Systat®. For a detailed account of MDS statistical procedures, see Clarke and Ainsworth (1993) and Warwick and Clarke (1993). Inferences from the resultant ordination are also presented. It is important to note that, as with cluster analyses, MDS results are not definitive and must be used in conjunction with additional ecological information. MDS results are based on total species number and numbers of individuals. Inferences from the resultant ordination are also presented.

After classification and ordination patterns were determined, the raw data were reevaluated to assess which species may have influenced the observed patterns. Indicator species were then selected on the basis of a literature review (*i.e.,* distribution, life history strategies and habitat preference), by recommendations from other experienced benthic taxonomists, and review of the raw data. Initially, community analyses were conducted as a per "site" comparison. Later, it was decided analyses also be expanded to a per "station" comparison to produce a more definitive data set for the reference pool. The extended analysis of station variability was performed using the benthic index.

Benthic assemblages have many attributes which make them reliable and sensitive indicators of the ecological condition in estuarine environments. The following procedure summarizes the construction and application of the benthic index used to reliably discriminate between degraded and undegraded conditions at sites in the San Diego Bay Region. Although there are problems with trying to simplify complex biological communities, we attempted to develop a quantitative method which creates a partition between degraded and undegraded areas. Polluted sites can not be conclusively identified using results from benthic community analyses alone, but these analyses impartially describe "environmentally stressed" areas. This benthic index is based on species (indicators), and group (general taxa) information. The index also evaluates community parameters, such as species richness, and abundance or presence of pollution indicators, which identify the extremes of the community characteristics. Sites are ranked according to these extremes and are represented by a single value. In general, decreasing numbers of species, increasing numbers of individuals, and decreasing diversity values are common responses observed near polluted areas. These trends are incorporated into the index. One of the important restrictions with the existing method is it evaluates this limited San Diego Bay benthic data set when dividing groups for categorization. Construction and subsequent validation of this simplified benthic index are loosely based on criteria developed by several agencies, including USEPA-EMAP and SCCWRP. However, the benthic index developed by USEPA-EMAP (Weisberg *et al.*, 1993) included several environmental variables in its construction (*e.g.* dissolved O_2), while the index for San Diego Bay data used only biological parameters. Briefly, the following major steps were followed in constructing and validating this benthic index:

1. Degraded and undegraded (*i.e.,* reference condition) stations were identified on the basis of measured environmental and biological variables.
2. A list of "candidate" parameters was developed using species abundance data. The list included metrics having ecological relevance (*e.g.,* species diversity indices, etc.) which were used to discriminate between degraded and reference areas.
3. A value for each candidate parameter (*i.e.,* diversity, abundance, taxonomic composition) was calculated for each station (*e.g.,* total species per station, total individuals per station, total crustaceans species per station, total number of polychaete individuals, total amphipods per station, etc.).
4. Range of values per metric was determined (lowest to highest value).
5. Quartiles from that range were determined.
6. Ranking within quartiles were assigned: upper quartile=2, lower quartile=0, middle quartile=1. These calculations were applied to the metrics from step 3.

7. The index was defined by values of 0, 1, or 2. A value of 0 defines the degraded (detectable stress) stations(s), and 2 identifies environmentally undegraded stations(s). Stations with an index value of 1 are considered transitional communities, which are neither degraded nor reference stations. Transitional stations have species or other parameters which indicate both degraded and undegraded habitats. These stations are investigated further to determine the cause of ambiguity of the transitional status.

8. Relative abundance of indicator species (both degraded and undegraded habitat indicators) per station is assessed.

A primary concern regarding the benthic index is how well it fulfills the objective of discriminating among degraded and undegraded estuarine conditions. This simplified version forms the basis for ongoing iterative procedures involved in construction of an index. This index will include a variety of indicator values (Bascom *et al.*, 1978; Kerans *et al.*, 1994; EcoAnalysis *et al.*, 1995) for future applications of the assessment of benthic community structure. The following sections report results of benthic community analyses based solely on composition and abundance of macrobenthic species from sediment cores throughout San Diego Bay and its vicinity. Environmental parameters (*e.g.*, total organic carbon levels and sediment grain size range) and other factors capable of influencing benthic composition were examined, but not evaluated in conjunction with the data presented here. Those data are examined later in sections which address correlative analyses.

In this study, bioeffects are required to be demonstrated in relation to properly selected reference sites and to occur in association with significant pollutant levels. The following evidence for undegraded (possible reference) and degraded (possible contaminated) sites was based on benthic community "quality" at each site and station. Benthic community structure was evaluated as an indicator of environmentally degraded or undegraded areas and not as a pollution or contamination indicator. Benthic reference sites were determined predominantly by analyses of specific indicator species and groups (*e.g.*, amphipods). These species are generally not found in polluted or disturbed areas.

The intention of this section is to clearly describe the condition of macrobenthic communities from sampling areas. Definitions of degraded, transitional, and undegraded used in this section are adopted from several papers (Bascom *et al.*, 1978; Pearson and Rosenberg, 1978; Schindler, 1987; Swartz *et al.*, 1985; Underwood and Peterson, 1988). Although the boundaries set in Bascom *et al.* (1978) were based on food supply and not on toxicants, the same general principles apply to this study. In benthic analyses, the term "degraded" does not refer to a

community response to significant levels of toxic chemicals. Degraded areas are those which contain significant numbers of opportunistic species, in the absence of non-opportunistic species, and have relatively low species diversity. Correlations are later used to determine if community profiles are influenced by chemistry or by natural environmental disturbances. Sites and stations which are categorized as "undegraded" have high species diversity, high proportional abundance of amphipods and other crustaceans, while noting there are a few exceptions to this rule (*e.g., Grandidierella japonica*, etc.). Undegraded areas generally contain species which are known to be sensitive to pollutants. Transitional sites and stations are those which are not confidently partitioned into the other two categories. These areas may solicit further study. Overall, an integration of data from laboratory exposures, chemical analyses, and benthic community assessments provide strong complementary evidence of the degree of pollution-induced degradation in aquatic communities. The following data analyses were conducted on a per site basis using sample replicates (n=5) at each sampling location (Table 6). An analysis also was performed using per station data (n=1) and is presented later in this section. Tests included classification and ordination analyses, diversity measurements, construction of a benthic index, and assessment of indicator species. One cautionary note is each of the benthic community and population condition tests are subject to effects of not only the pollutants measured in this study, but many other confounding natural factors, such as depth, salinity, sediment texture, and/or predation.

Abundance and Diversity

There were 7,232 individuals, representing 198 macrobenthic species, collected from 375 benthic cores during sampling legs 20 through 23 of the San Diego Bay confirmation phase (Table 7). Mean number of species was calculated from 5 replicates per site (Table 8). Polychaetes comprised the majority of specimens in samples. Great numbers of mollusks in sites within West Basin, Downtown Piers, and Glorietta Bay were due to the bivalve *Musculista senhousei* which was collected as large aggregates. Echinoderms were found at only 6 of the 25 sites, and were significantly ($p>0.01$) greater at the Mission Bay A3 site (640.0±216.6) and the Mission Bay A8 site (213.3±53.3) compared to all other sites. Holothurians comprised the majority of echinoderms found at these sites, although ophiuroids were also present. Colonial species were not present. Diversity ranged from 9 to 46 benthic species per site in collected samples. Significant differences in species diversity were not as distinct as with other indices and no trends were obvious. Results shown in Table 9 indicate most communities in this study were relatively diverse and even. Simpson's diversity index (D') which emphasizes more common species, and Shannon-Weaver (H') which puts statistical weight on rare species, showed differences in the range of diversity values. Chula Vista Yacht Basin was the only site which showed a moderately high level of dominance as

Table 7. Species list of macroinvertebrates from the San Diego Bay region benthic samples

Acmira catherinae	Gastropoda	*Fabricinuda limicola*	Polychaeta	*Orchomene pacifica*	Gammaridea
Acmira horikoshii	Gastropoda	*Glycera americana*	Polychaeta	*Orchomene sp.*	Gammaridea
Acuminodeutopus heteruropus	Amphipoda	*Glycera nana*	Polychaeta	*Paracerceis sculpta*	Isopoda
Aglaja sp.	Gastropoda	*Gnathia crenulatifrons*	Isopoda	*Paradexamine sp.*	Amphipod
Alpheus californiensis	Decapoda	*Goniada brunnea*	Polychaeta	*Paramage scutata*	Polychaeta
Amaeana occidentalis	Polychaeta	*Goniada sp(p).*	Polychaeta	*Paranthura elegans*	Isopoda
Ampelisca brevisimulata	Gammaridea	*Grandidierella japonica*	Gammaridea	*Paraprionospio pinnata*	Polychaeta
Ampelisca cristata	Gammaridea	*Harmothoe hirsuta*	Polychaeta	*Parasterope barnesi*	Ostracoda
Ampelisca hancocki	Gammaridea	*Harmothoe imbricata*	Polychaeta	*Parougia caeca*	Polychaeta
Ampharete labrops	Polychaeta	*Heptacarpus cf taylori*	Decapoda	*Parvilucina tenuisculpta*	Bivalvia
Amphicteis scaphobranchiata	Polychaeta	*Heptacarpus sp. A*	Decapoda	*Pectinaria californiensis*	Polychaeta
Amphideutopus oculatus	Amphipoda	*Hesperonoe sp(p).*	Polychaeta	*Pennatulacea*	Anthozoa
Amphilochidae	Gammaridea	*Heterophoxus oculatus*	Gammaridea	*Pherusa capulata*	Polychaeta
Ampithoe sp.	Gammaridea	unidentified holothuroid	Holothuroidea	*Pherusa sp(p).*	Polychaeta
unid. anemone	Anthozoa	*Hyale frequens*	Gammaridea	*Pholoe glabra*	Polychaeta
Aphelochaeta monilaris	Polychaeta	*Hydroides pacificus*	Polychaeta	unidentified phoronida	Phoronida
Aphelochaeta multifilis	Polychaeta	*insect larva*	Arthropoda	*Photis sp.*	Gammaridea
Aphelochaeta sp(p).	Polychaeta	*Laevicardium substriatum*	Bivalvia	*Pista alata*	Polychaeta
Apistobranchus sp(p).	Polychaeta	*Laonice cirrata*	Polychaeta	*Pista sp(p).*	Polychaeta
Aporprionospio pygmaea	Polychaeta	*Leitoscoloplos pugettensis*	Polychaeta	*Pleustidae*	Gammaridea
Armandia brevis	Polychaeta	*Lembos sp.*	Gammaridea	*Podarkeopsis glabra*	Polychaeta
Asteropella slatteryi	Ostracoda	*Leptochelia dubia*	Tanaidacea	*Podarkeopsis perkinsi*	Polychaeta
Autolytus sp(p).	Polychaeta	*Leptognathia sp.*	Tanaidacea	*Podocerus cristatus*	Gammaridea
unidentified bivalve	Bivavia	*Levinsenia gracilis*	Polychaeta	*Poecilochaetus johnsoni*	Polychaeta
Brania brevipharyngea	Polyehaeta	*Listriella goleta*	Gammaridea	*Polydora cornuta*	Polychaeta
Bulla sp.	Gastropoda	*Lophopanopeus bellus diegensis*	Decapoda	*Polydora nuchalis*	Polychaeta
Campylaspis rubromaculata	Cumacea	Lumbrineridae, unident.	Polychaeta	*Polydora socialis*	Polychaeta
Capitella capitata complex	Polychaeta	*Lyonsia californica*	Bivalvia	*Polyophthalmus pictus*	Polychaeta
Caprella californica	Caprellida	*Lysippe labiata*	Polychaeta	*Pontogeneia rostrata*	Gammaridea
Caulleriella sp(p).	Polychaeta	*Macoma cf yoldiformis*	Bivalvia	*Praxillella pacifica*	Polychaeta
Chaetozone corona	Polychaeta	*Macoma nausta*	Bivalvia	*Prionospio heterobranchia*	Polychaeta
Chone mollis	Polychaeta	*Macoma sp.*	Bivalvia	*Prionospio lighti*	Polychaeta
Cirratulidae, unident.	Polychaeta	*Mactra californica*	Bivalvia	*Prionospio sp(p).*	Polychaeta
Cirratulus sp(p).	Polychaeta	*Malmgreniella macginitiei*	Polychaeta	*Prionospio steenstrupi*	Polychaeta
Cirriformia luxuriosa	Polychaeta	*Marphysa disjuncta*	Polychaeta	*Pseudopolydora paucibranchiata*	Polychaeta
Collisela depicta	Gastropoda	*Mayerella banksia*	Amphipoda	*Rhynchospio glutaea*	Polychaeta
Compsomyax subdiaphana	Bivalvia	*Mediomastus californiensis*	Polychaeta	*Rudilemboides stenopropodus*	Amphipoda
Cooperella subdiaphana	Bivalvia	*Megalomma pigmentum*	Polychaeta	*Scleroplax granulata*	Decapoda
Corophium acherusicum	Gammaridea	*Melinna oculata*	Polychaeta	*Scolelepis quinquedentata*	Polychaeta
Corophium heteroceratum	Gammaridea	*Metasychis disparidentata*	Polychaeta	*Scoletoma erecta*	Polychaeta
Cossura candida	Polychaeta	*Microjassa litotes*	Gammaridea	*Scoletoma tetraura*	Polychaeta
Crepidula fornicata	Gastropoda	*Monoculodes hartmanae*	Gammaridea	*Scoloplos acmeceps*	Polychaeta
Crucibulum spinosum	Gastropoda	*Monticellina dorsobranchialis*	Polychaeta	*Scyphoproctus sp(p).*	Polychaeta
Cryptomya californica	Bivalvia	*Monticellina sp. C*	Polychaeta	*Serolis carinata*	Isopoda
Cylichnella inculta	Gastropoda	*Monticellina tesselata*	Polychaeta	*Sigambra tentaculata*	Polychaeta
Cylichnella sp.	Gastropoda	*Munnogonium californiensis*	Isopoda	*Siliqua lucida*	Bivalvia
Diastylis sp.	Cumacea	*Musculista senhousei*	Bivalvia	unidentified spionid	Polychaeta
Diopatra sp(p).	Polychaeta	*Myriochele sp. M*	Polychaeta	*Spiophanes berkeleyorum*	Polychaeta
Diopatra tridentata	Polychaeta	*Mysella sp.*	Bivalvia	*Spiophanes missionensis*	Polychaeta
Diplocirrus sp(p).	Polychaeta	unidentified mysid	Mysidacea	*Sthenelais tertiaglabra*	Polychaeta
Dorvillea longicornis	Polychaeta	*Nassarius perpinguis*	Gastropoda	*Sthenelanella uniformis*	Polychaeta
Drilonereis falcata minor	Polychaeta	*Neanthes acuminata*	Polychaeta	*Streblosoma sp. B*	Polychaeta
Elasmopus rapax	Amphipoda	*Neastacilla californica*	Isopoda	*Streblospio benedicti*	Polychaeta
Eranno lagunae	Polychaeta	*nemertean*	Nemertea	*Sulcoretusa xystrum*	Gastropoda
Eteone californica	Polychaeta	*Neotrypaea californiensis*	Decapoda	*Synchelidium rectipalmum*	Gammaridea
Eteone sp(p).	Polychaeta	*Nephtys caecoides*	Polychaeta	*Synchelidium sp.*	Gammaridea
Euchone limnicola	Polychaeta	*Nephtys cornuta*	Polychaeta	*Tagelus subteres*	Bivalvia
Euclymeninae spp. indet.	Polychaeta	Nereididae, unident.	Polychaeta	*Tellina modesta*	Bivalvia
Eudorella pacifica	Cumacea	*Nereis procera*	Polychaeta	*Tenonia priops*	Polychaeta
Euphilomedes carcharodonta	Ostracoda	*Notomastus tenuis*	Polychaeta	Terebellidae, unident.	Polychaeta
Euphilomedes producta	Ostracoda	*Nuculana taphria*	Bivalvia	*Terebellides californica*	Polychaeta
Eupolymnia sp(p).	Polychaeta	*Odontosyllis phosphorea*	Polychaeta	*Theora fragilis*	Bivalvia
Exogone lourei	Polychaeta	*Odostomia sp.*	Gastropoda	*Trachycardium quadragenarium*	Bivalvia
Exogone molesta	Polychaeta	*oligochaeta*	Oligochaeta	*Turbonilla sp.*	Gastropoda
Exogone sp(p)	Polychaeta	*Olivella baetica*	Gastropoda	*Urocaris infraspinis*	Decapoda
Exogone uniformis	Polychaeta	unidentified ophiuroid	Ophioroidea	*Zeuxo normani*	Tanaidacea

shown by the evenness index (J'=0.490). This was due to an abundance of *Mediomastus californiensis* and *Leitoscoloplos pugettensis* polychaetes. Compared to all other sites, Chula Vista had a significantly lower density of crustaceans. The Mission Bay A4 site had moderately high species diversity but comparatively low species abundance.

Cluster and Ordination Analyses

Cluster analyses produced the dendrogram (Figure 15) of station affinities, based on mean root-root transformed abundance of the 198 macrobenthic species, using Pearson's correlation of similarity and group-average sorting. A root-root transformation, reduced the weighting of abundant species (Field *et al.*, 1982). The similarity level, although arbitrary, was designated somewhat conservatively near 50%. The resulting classification of assemblages reflect general patterns of benthic species composition, domination, and evenness (*e.g.*, sites along the 0.00 line would be identical in species composition and abundance). Six major groups were delineated from the hierarchical clusters, which were defined by an overall dominant species. Group I, which included only a single site (32 Swartz, Sweetwater Channel) was co-dominated by the tube-building tanaid *Zuexo normandi* and polychaete worm *Leitoscoloplos pugettensis*. Groups IV, V and VI were all dominated by the polychaete worm species *L. pugettensis*, *Prionospio heterobranchia*, and co-dominants *P. heterobranchia* and oligochaetes, respectively. Amphipods (*Acuminodeutopus heteruropus*) were the most abundant group in cluster II. The seemingly ubiquitous bivalve *Musculista senhousei* was the numerically important species in Group III. When plotted, these biologically-based clusters provide a qualitative assessment of the pattern of physical data and visually demonstrate the relationship of one site to another. To put the relationship of samples into a more general perspective, the level of similarity found between San Diego Bay site samples and those from Los Angeles Harbor was between 5-10% (Figure 16), revealing the benthos of these northerly areas should not be used comparatively, due to differences in habitats and biotic response. Although tidally influenced, the species composition of the San Diego River B1 site was also found to be highly dissimilar to other San Diego Bay samples, presumably due to habitat differences.

In addition to conventional methods, non-metric multi-dimensional scaling (MDS) using a weighted Spearman rank correlation coefficient dissimilarity matrix was used to determine similarity in species composition between stations. Non-metric MDS can handle large numbers of zeros, missing data, and unequal replication. MDS seeks a representation of individuals in a space of low dimensionality where the distances between individuals in ordination space optimally represent their dissimilarities in variable space (Kenkel and Orloci, 1986). Typically, transformed biotic and abiotic data are initially analyzed separately, then combined to assess common MDS spatial patterns. The resulting ordination for biotic variables is demonstrated here.

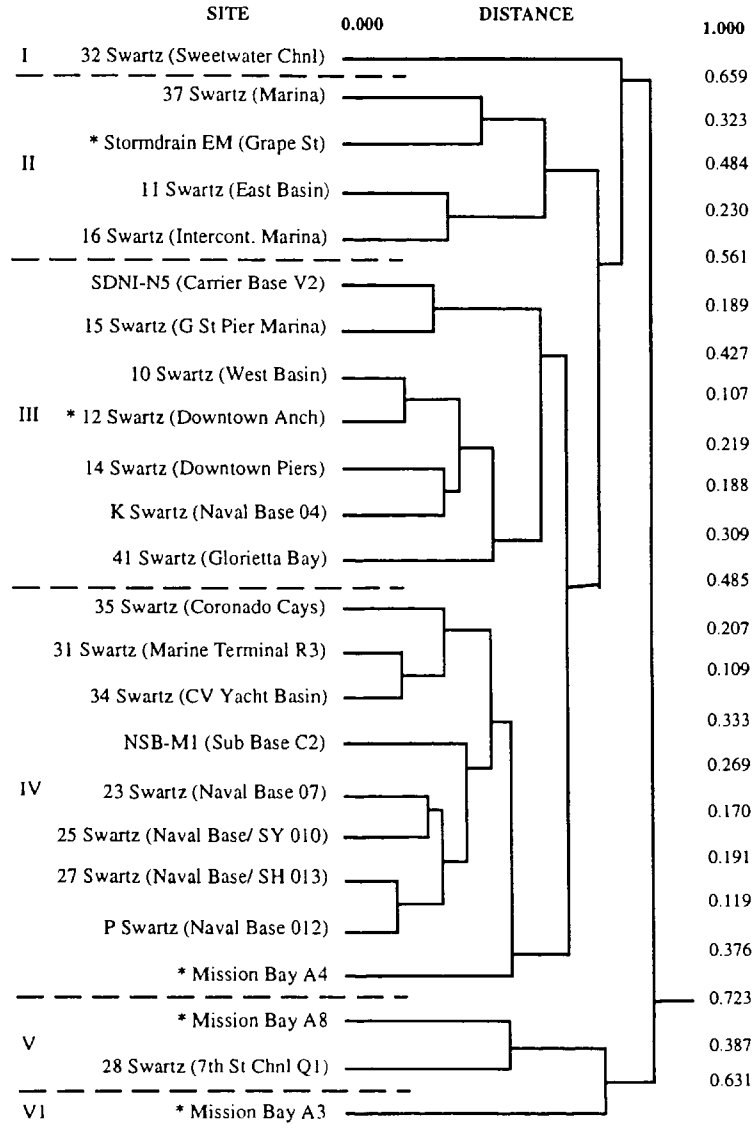

Figure 15. Numerical classification of mean abundance data of 198 macrobenthic species. Clusters are derived from Pearson correlation matrix data and group-average sorting. Six major clusters are shown, each dominated by 1-2 species.

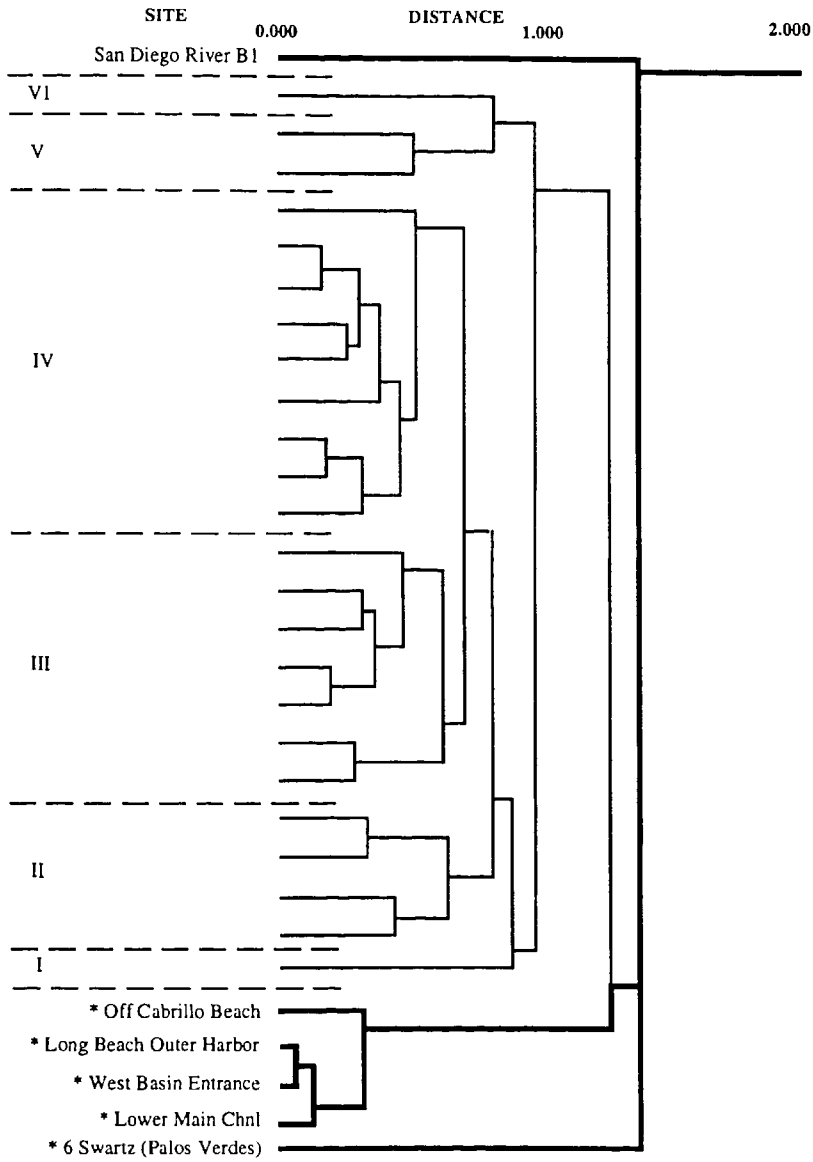

Figure 16. Numerical classification of mean abundance data from San Diego Bay and vicinity and Los Angeles Harbor.

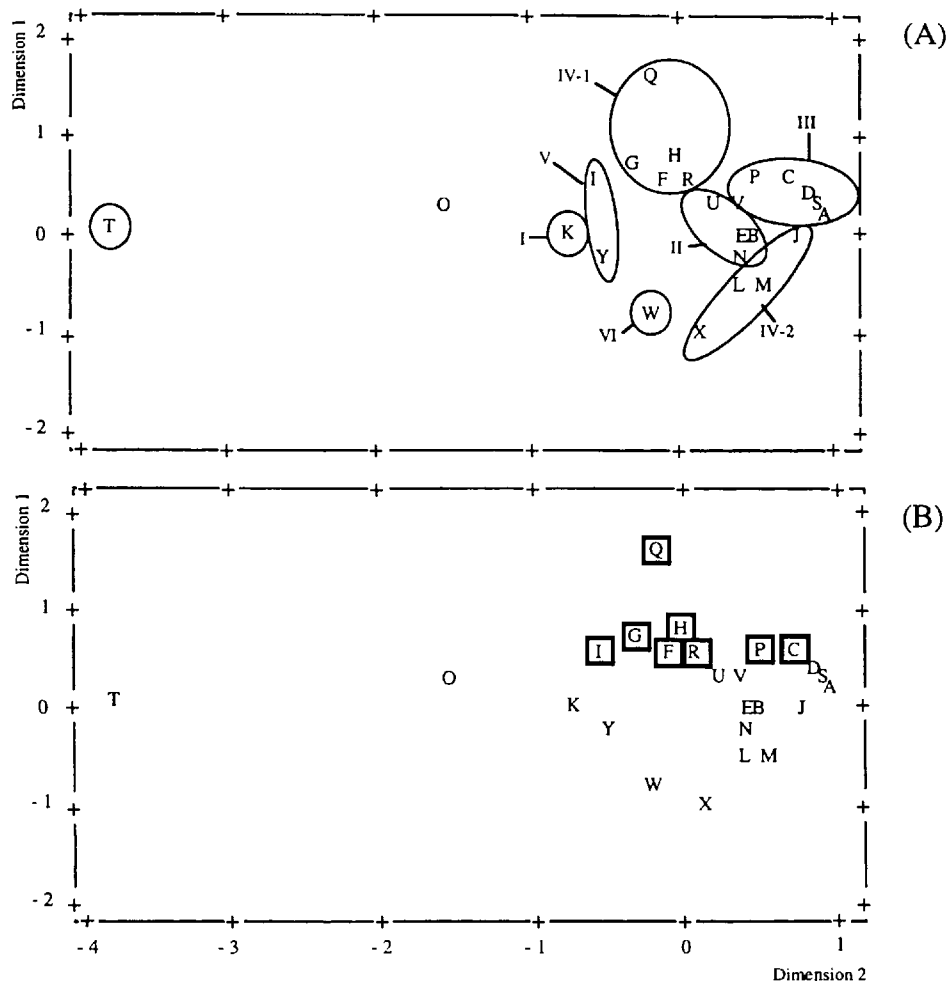

Figure 17. Multidimensional scaling (ms) ordination of site samples from San Diego Bay based on the abundance matrix of 198 macrobenthic species. (A) Clusters deliniated and numbered in Figure 15 dendogram are shown here as circled groups. (B) Qualitative assessment of the relation of chemistries >ERM levels (site codes surrounded by boxes) to ms biotic configuration.

displays the 2-dimensional representation resulting from multidimensional scaling, using the same matrix data applied to classification analysis. Letters surrounded by each circle represent the partitioned cluster groups delineated in the cluster hierarchy. The configuration was not altered when the outlier (T) was removed. The x- and y-axes represent scores for the first and second ordination axes. These scores are based on species diversity data and abundance and composition data.

When sites with chemistry values which exceeded ERM levels were assessed on the MDS plot in a qualitative, cursory manner as shown in Figure 17b (shown with squares), the sites clustered together. When interpreted along the axis gradient, these data suggested dimension 1 likely defined the pollution gradient, where the top quadrant within the plot identified the most contaminated sites (*i.e.*, Q or H). This is assuming the plot configuration is affected by toxic pollution alone and not by any organic enrichment. The y-axis may represent responses to a salinity gradient or change in sediment grain size. These analyses are especially revealing when environmental variables (*e.g*, TOC, grain size, water depth, total PAHs, individual metals, etc.) and biota are scaled together to determine which variables influence the configuration. However, even in the absence of these parallel plots, patterns are apparent from the correlations illustrated in other sections of this report.

Indicator Species

Despite the numerous studies performed in San Diego Bay, there have been no analyses of the fauna as bioindicators (SCCWRP-Diener, personal communication). Indicator species are assessed to determine which species are responsible for the separation of groups in classification and ordination analyses (Field *et al.*, 1982). Indicator species used in this study were selected on the basis of overall abundance in the San Diego Bay data set, literature review which determined distribution, known life histories and habitat preference, and discussions with ecologists experienced with Southern California marine biota and marine habitats. Species indicative of control or reference sites were derived from frequency of occurrence data. The presence or absence of specific polychaetes in sediments provided one valuable indication of the condition or health (Pocklington and Wells, 1992) of the benthic communities in San Diego Bay. The presence of *Capitella capitata* or *Streblospio benedicti*, in the absence of other species, is widely accepted as pollution indicators. Sensitive species like *Harmothoe imbricata* are represented at sites Carrier Base V2 and Mission Bay A8, and are typically found in uncontaminated areas. Additionally, *Nereidae* are accepted as indicators of early successional phases of environmental recovery (Pearson and Rosenberg, 1978) and are evident at site Carrier Base V2. *Mediomastus* polychaetes are found throughout the bay and have been considered to be identifiers of environmentally stressed areas. However, this species was found at the majority of sites. Another common species found in 16 out of 25 station samples was *Diplocirrus* sp.

which had not been found in previous studies in San Diego Bay (SCCWRP, personal communication). *Dipolocirrus* sp. was significantly ($p>0.05$) abundant at the Mission Bay A8 site. This unusual species is thought to have been introduced from the arctic region (G. Ruff, personal communication).

The benthic index discussed later was used to rank and calculate site partitions using the following indicator species: *Capitella capitata* (polychaete), *Armandia brevis* (polychaete), *Dorvillea longicornis* (polychaete), *Heterophoxus oculatus* (gammarid amphipod), and *Diastylis* sp. (cumacean). The polychaete worm *C. capitata* is widely accepted as a pollution indicator. *Diastylis* sp. ("sand-licker") feeds on nutrients adhered to sand grains and its presence indicates a relatively clean sample. Although it can tolerate moderately contaminated sediments, *H. oculatus* is a burrower and is considered an indicator of clean sediment.

One of the limitations in benthic community assessment is that patterns are more apparent where there is a strong gradient of pollutants, or when samples are selected from areas with distinctively low and high pollutant signals. There are limitations to what can be surmised from analyses of abundance of specific species, and selection of indicator species are highly site specific (Swartz *et al*., 1985). However, these species, combined with information from ordination and other supplemental analyses, make it apparent that these are important as ecologically relevant data. Many species used to assess environmental quality are used because they respond quickly to changes in environmental conditions. (Pocklington and Wells, 1992). Therefore, a station designated in the initial phases of sample collection as a having reference conditions, based on toxicity test or chemical analysis results, could be removed from the reference station list based on subsequent benthic community analyses.

Benthic Index

Benthic communities, and occasionally single benthic species, have been used to elucidate the severity of human disturbance to nearshore marine and estuarine environments. It is possible to develop a comparable disturbance classification for species and use a simple numerical infaunal index with these species. Distinct pollution gradients are rare in most embayments because of confounding environmental gradients and historical changes. Still, an index has the best potential to quantitatively assess benthic community responses to disturbance. Some benthic indices are based on *a priori* information and are developed using test sites representing the extremes within a range of environmental conditions which adversely affect benthos. In contrast, the index developed and used in this study was based solely on information which characterized the benthic community, such as specific indicator species and community parameters (species richness, abundance, presence of pollution indicator species, etc.). This elementary index approach may be best for this study because San Diego Bay encompasses a variety of habitats, each of which may

require a very specific set of index variables (SCCWRP-Diener, personal communication). Note that identification of degraded and undegraded sites here resulted from evaluation of a limited data set, without site comparison to an existing known reference. The index was used within this limited data set to designate the partition between degraded, undegraded and transitional areas.

Site and Station Application of Benthic Index

Table 10 shows the results of benthic index application to data from sampling sites in legs 20-23. Sites (25 sites with 5 replicates each) were ranked and partitioned into 9 degraded, 3 undegraded and 13 transitional sites using 8 biotic parameters. Due to spatial differences in sampling of the benthic replicates at the 25 sites, the benthic index was also applied to individual stations (n=75). When benthic community structure was evaluated "by site", 5 replicates were used. Replicates 1, 2 and 3 were sampled at numbered stations locations (Table 6) where associated toxicity and chemistry data could be directly compared. When later analyses were expanded to a "by station" evaluation, the 4th and 5th replicates were not included in the per station assessment. These replicates were randomly sampled within the "site" for benthic community analysis only and did not receive synoptic chemistry and toxicity analysis. While the results did not alter the degraded and undegraded determination of sites assessed "by site", it did separate stations within the initial "transitional" status into one of the three categories (*e.g.*, degraded, transitional or undegraded). Station analyses heavily emphasized benthic index, amphipod abundance, species diversity and crustacean numbers.

As part of analytical procedure, the BPTCP Scientific Planning and Review Committee (SPARC) recommended additional emphasis on the use of amphipod abundance and overall species diversity as indicators of degraded and undegraded areas. These parameters were assessed and incorporated into the "station evaluation" versions of the benthic index. Species number and abundance of amphipods were calculated from the proportions of total species and total individuals, respectively. The resultant categorization of stations into one of the three partitions (*e.g.*, degraded, transitional, undegraded) did not change, so the assessment of amphipods further supported the partition derived from previous analyses. The density of all amphipods was significantly more abundant at the following stations: West Basin (90050, 93199, 93200), East Basin (90001, 93201), Downtown Anchorage (93221, 93222), Coronado Cays (90053, 93203), Sweetwater Channel (93220), Mission Bay A8 (93112), Carrier Base V2 (90025) and Grape St. Stormdrain (90037). No amphipods were found at stations 14 Downtown Piers (90003), Naval Base O7 (93212), Naval Base/SY O10 (93223, 93224), Naval Base/SH O13 (93225, 93226), 7th St. Channel Q1 (90009, 93227, 93228), Marine Terminal R3 (93229), K Swartz Naval Base O4 (93210), Sub Base C2 (93216, 93217), and Naval Base O12 (93215). Stations with abundant amphipods but dominated by *Grandidierella japonica* were evaluated with caution, because *G. japonica* has been found to be tolerant of high

Table 10. Results of Benthic Index application on San Diego Bay data. Benthic community condition based on mean abundance of 5 replicate samples per site. Community status indicates allocation of a station to an Index partition: 2-undegraded sites, 1=transitional sites, 0=degraded sites.

sediment toxicity (Slattery and Swartz, personal communication). Final benthic community evaluation of 75 stations (Table 11) resulted in the designation of 23 undegraded, 43 degraded and 9 transitional stations. A map of the distribution of degraded, transitional and undegraded stations is shown in Figure 18(a-d). Degraded stations were found at the submarine base in North San Diego Bay. Commercial shipping, storm drainages and the naval shipyard waterfronts all had degraded communities in the Mid San Diego Bay. In South San Diego Bay, industrial and small boat locations exhibited benthic community degradation. In Mission Bay the stations near Rose Inlet and in the San Diego River were found to be degraded.

Chemically clean sites, as determined by ERM and PEL summary quotients and lack of ERM and PEL guideline exceedances, were reexamined to expand the undegraded list from possible "borderline" transitional stations. Stations 93194 and 93231 appropriately fit this category (Table 4) and were used as undegraded stations in the construction of the reference envelope for toxicity determination, discussed earlier.

As shown earlier in Figure 14, the relationship between benthic community conditions and elevated chemical conditions (as determined by using ERM and PEL Summary Quotients) was quite dramatic. Benthic communities were always found to be degraded when chemical levels were elevated (ERMQ>0.85), where both analyses were performed at a station.

Distribution Of Toxicity

The results of all toxicity tests conducted as part of this study are presented in tables in Appendix D. These tables show means and standard deviations for each toxicity test response (e.g. percent survival of amphipods; percent normal development of larval sea urchins) for three to five replicates of each sample tested. Associated ammonia and hydrogen sulfide concentrations are also presented in Appendix D.

Toxicity Testing Quality Assurance/Quality Control Evaluation

All toxicity test data produced for this report were evaluated for acceptability using the Quality Assurance guidelines described in the BPTCP Quality Assurance Project Plan (QAPP; Stephenson *et al.*, 1994). Toxicity data reported here met all test acceptability standards for each protocol, with the following exceptions. Of the solid phase tests with amphipods, two samples (Station 93120- IDORG# 702 and Station 93107- IDORG# 721) were tested with only one laboratory replicate, due to a lack of sufficient sample volume. Survival in those two samples was 90% and 85%, respectively, indicating a lack of toxicity. All amphipod samples tested in Leg 15 (Appendix D) have the following QA qualification. The test protocol requires five replicates of a control sample to be tested concurrently with test samples. In some early sampling legs of this study, 15 laboratory replicates of the control sediment were tested, to

Table 11. Benthic Index results showing the recalculation of San Diego Bay data based on individual stations. Replicates 4 and 5 in the site evaluation were not included (see text). Community status indicates allocation of a station to an Index partition: 2=undegraded stations, 1=transitional stations, 0=degraded stations.

allow use of alternative statistical procedures. Of the fifteen control replicates in Leg 15, two had 75% survival, which is below the 80% criterion given in the protocol. In tests using the *Neanthes arenaceodentata* (hereafter *Neanthes*) protocol on solid phase sediments, all samples tested in Leg 21 used sediment that was held in the laboratory three days beyond the fourteen-day specified holding time. These QA exceptions in solid phase tests have been judged by the toxicity project officers to not adversely affect interpretation of toxicity results. These and lesser departures from acceptable standards are recorded in the Quality Assurance Evaluative Reports accompanying each dataset for this study. Quality Assurance Evaluative Reports for toxicity testing are available for review from the SWRCB. Minor departures not mentioned above included elevated dissolved oxygen measurements in overlying water and other variations in water quality measurement that were considered to have little probability of affecting the outcome of the respective toxicity test.

There were no deviations from quality assurance criteria, other than minor deviations in measurement of water quality parameters as cited above, in any of the abalone, mussel, or sea urchin larval development tests in pore water or water column samples (subsurface water).

Sea urchin fertilization tests were conducted on over 300 pore water samples. Many of these were retested because of poor response in brine controls. Bay *et al.* (1993) discussed commonly observed problems using the *Strongylocentrotus purpuratus* (hereafter *Strongylocentrotus*) fertilization test in samples requiring salinity adjustment with hypersaline brine. Through numerous repeated tests, acceptable brine control results were produced for all but one sample. However, as described in BPTCP QA reports to the SWRCB, an additional control for the storage effects of frozen pore water samples in Teflon bottles was included in later tests. These additional controls, which were not required by the original QAPP, indicated that toxicity may be associated with frozen sample storage in Teflon bottles. Because all pore water samples for fertilization tests were stored frozen in Teflon bottles, we have no assurance the data from any of these fertilization tests is truly indicative of sample toxicity. Any toxicity observed in the fertilization tests may be wholly or partially due to storage effects. For this reason, we retested all samples from legs 15-23 with the sea urchin larval development test, unless those samples had already been tested with the development test. The urchin larval development test has been unaffected by storage artifacts, as indicated by response in frozen storage bottle controls. While sea urchin fertilization data are reported in Appendix D, they were not used in any further data analysis for this report. The use of fertilization data, for determination of toxicity, was therefore not considered prudent considering the possibility of false positive results related to sample storage.

Areal Extent of Toxicity Based on the EMAP Approach

The Cumulative Distribution Frequency (CDF) analyses indicated that 56% of the total area sampled was toxic to *Rhepoxynius abronius* (hereafter *Rhepoxynius*) (Table 12, Figure 19). The sea urchin larval development test of undiluted (100%), 50%, and 25% pore water indicated 74%, 54%, and 29% percent of the total study area was toxic, respectively (Table 12, Figure 20). A number of samples were toxic to both sea urchins and amphipods. Samples representing 36%, 27%, or 14% of the study area were toxic to *Rhepoxynius* in solid phase sediment and to sea urchin larvae in 100%, 50%, or 25% pore water, respectively. The percentage of area toxic was based on comparisons with laboratory controls using the EMAP statistical approach described in the methods section. These analyses utilized data from random stations within the stratified sampling blocks, and did not include data from stations utilizing the non-random, directed sampling design (Figure 21a-d, Figure 22a-d).

The curves on the CDF plots indicate the magnitude of toxicity throughout the Region. Each point on the CDF plot represents a single sample. The distribution of the amphipod data (Figure 19) show there were few samples with survival less than 40%, a greater number of samples with survival between 40% and 80%, and about half of all samples with survival greater than 80%. NOAA surveys of Tampa Bay, Florida and EMAP surveys of the Mid-Atlantic coast region (Virginian Province) produced CDF curves for amphipod mortality data further right on the scale and much steeper than the San Diego Bay Region plot, and had more than 90% of samples with greater than 90% survival in both regions (Long *et al*., 1994; Schimmel *et al*., 1991).

The CDF plot of San Diego Bay Region sea urchin larval development test data (Figure 20) shows a cluster of samples with 0% normal larval development, a smaller number of samples with intermediate response, and a cluster of samples with percent normal development roughly equal to that observed in controls. The 25% pore water dilutions had a majority of samples resulting in percent normal larval development roughly equal to controls. As pore water concentration increased to 50% and 100% pore water, the distribution of samples shifted toward the more toxic end of the scale, and the 100% pore water tests had a majority of samples resulting in 0% normal larval development. A similar pattern was observed in sea urchin fertilization tests of pore water from Tampa Bay, Florida (NOAA, 1994). As with the amphipod data, the San Diego distribution is shifted further to the left, indicating higher overall toxicity observed from San Diego Bay Region samples.

Toxicity Based on Reference Envelope Approach

Using the *Rhepoxynius* data and a p-value of 1%, a lower reference envelope tolerance bound of 48% survival was calculated, indicating that samples with survival values below 48% are significantly more toxic than samples representative of less

Table 12. Percent of total area sampled determined to be toxic with each toxicity test protocol. Sample toxicity is based on the EMAP statistical approach using two criteria for any given sample: significant difference from the control using a separate variance t-test and an alpha of 0.05 and a sample mean value less than 80% of the control value. Calculations for cumulative distribution frequency (CDFs) used to compute the percent of area toxic are explained in text and presented in Appendix F. Total study area was 47 square kilometers.

Toxicity Test and Pore Water Dilution	**Percent of Total Area Determined to be Toxic**
Rhepoxynius abronius Survival in Solid Phase	56%
Strongylocentrotus purpuratus Development in:	
100% (undiluted) Pore Water	74%
50% Pore Water	54%
25% Pore Water	29%

contaminated ambient conditions in the San Diego Bay Region. There is a 95% probability that samples with survival values less than 48% are more toxic than the most toxic 1% of samples from the reference site population. Of 350 samples tested with the *Rhepoxynius* test (from both random and non-randomly selected stations), 61 samples were found to be toxic using the reference envelope analysis (Figure 23a-d). Toxicity based on the reference envelope approach is used later in this report for prioritizing stations of concern.

Strongylocentrotus pore water data from reference stations produced a lower mean value and greater variability than was found for the amphipod solid phase data (Table 4). The variability in pore water data from sea urchin larval development tests produced a reference site distribution extending across the range from 0 to 100% normal development. A p-value of 1% (see Methods Section) produced a tolerance bound (reference envelope edge) which was below zero, indicating no distinctions could be made between reference and toxic stations. The high degree of variability in the pore water results from the reference sites may be related to the sensitivity of this test to measured or unmeasured toxicants, and/or may reflect artifacts related to pore water extraction and handling. Potential artifacts and sources of variability related to pore water testing are discussed below.

Comparison of Toxicity Test Protocols

Solid phase toxicity tests using the amphipod *Rhepoxynius* provided a wide range of response, from 0 to 98% survival. Amphipod survival ranged from 68-98 % for the eleven reference stations, suggesting that relatively high *Rhepoxynius* survival is a consistent feature of sites with relatively low chemical concentrations and undegraded benthic communities. The *Rhepoxynius* test identified multiple toxic samples, which indicated adequate sensitivity. Of the two solid phase protocols used in this study, the *Rhepoxynius* test provided the best test performance in terms of convenience, consistency, and sensitivity.

Solid phase toxicity tests which used the polychaete *Neanthes* were less sensitive than the *Rhepoxynius* test, and usually indicated no toxicity in samples that were toxic to test organisms using other protocols. In all instances where a sediment sample was toxic to *Neanthes* (survival or growth - relative to controls), it was also toxic to *Rhepoxynius*, whereas many samples that were toxic to *Rhepoxynius* were not toxic to *Neanthes* test. Because the *Neanthes* test demonstrated considerably less sensitivity than the *Rhepoxynius* test, the *Neanthes* test was not recommended for continued use in this program.

Two pore water tests, using *Strongylocentrotus* fertilization and larval development protocols, were performed on three concentrations of pore water samples to evaluate their usefulness

as components of the BPTCP. Results indicated these tests were extremely sensitive to pollutants and/or other pore water constituents in the study area, particularly at the 100% porewater concentration. It is reasonable to expect that pore water sea urchin tests, which measure sublethal effects on sensitive early life stages, would be more sensitive than the amphipod solid phase tests, which measure adult mortality. It is also likely that all three protocols respond differently to different contaminants. The high sensitivity of the sea urchin protocols has been observed in other studies assessing pore water toxicity (Burgess *et al.*, 1993; Carr and Chapman, 1992; Long *et al.*, 1990).

Rhepoxynius solid phase test results agreed with *Strongylocentrotus* development (100% and 50%) pore water results in 61 of 117 concurrently tested samples (52%). For the 25% pore water dilution, results agreed in 48% of samples. The three dilutions for the *Strongylocentrotus* tests agreed with each other 56% of the time. In all but two cases, *Strongylocentrotus* results differed from each other because samples were less toxic as pore water was increasingly diluted. In one case the 50% pore water was toxic when the 100% and 25% were not, and in another case, the 50% and 25% were toxic when the 100% was not.

Carr and Chapman (1992) noted that sensitive toxicity test protocols are necessary to adequately characterize the toxicity of potentially contaminated sediments. Pore water tests provide the following advantages: allow the use of a variety of sensitive sublethal toxicity test protocols which have not yet been developed for solid phase tests; eliminate interference from physical factors such as sediment grain size; and allow test organisms to be directly exposed to the aqueous sediment fraction, the probable primary route of pollutant exposure to organisms (Adams *et al.*, 1985; DiToro, 1990). In addition, pore water is currently the only sediment matrix suitable for toxicity identification evaluations that may be useful in identifying toxicants responsible for observed sediment toxicity.

Despite the need to evaluate pore water toxicity, logistical issues of pore water extraction and handling are still a focus of current research (Carr *et al.*, 1995). Among the samples associated with high toxicity in the sea urchin pore water tests were a number from the selected reference stations. These stations had non-degraded benthic communities, relatively low concentrations of pollutants, and ammonia concentrations below levels expected to have an observable effect. The wide range in pore water toxicity at the reference stations was unexpected, and prevented identification of toxic sites using the reference envelope approach. Pore water properties and sampling manipulations that may have affected pore water test results are discussed later.

Samples of water collected one meter above the sediment surface were tested for toxicity at a number of stations. These subsurface water samples were tested as one of the suite of

screening bioassays conducted on suspected areas of water quality impairment. Sixty-five subsurface water samples were tested with the red abalone (*Haliotis rufescens*) larval shell development protocol. Of these, eleven samples were significantly toxic, indicating degradation of the water column in 17% of the stations tested. Water column testing has not been a consistent component of the BPTCP, and will probably be reserved for special investigations. The abalone test appears appropriate for this application.

The bivalve (*Mytilus sp.)* larval shell development test was used to test eight subsurface water samples and three pore water samples. This test was used only in cases where salinity was less than 30 or 26 parts per thousand, the low end of salinity ranges for abalone and sea urchin larval development tests, respectively. Because seawater salinities in the San Diego Bay region were usually in the acceptable range for abalone and sea urchins, the bivalve test was used sparingly. None of the subsurface water samples tested with mussels were significantly toxic, and one of three pore water samples tested with mussels was significantly toxic. This protocol is well established as a sensitive test method, and has the advantage of a relatively wide salinity range. In situations where the salinity range precludes the use of abalone or sea urchins, the bivalve test is an acceptable alternative.

The presence of mitotic aberrations in anaphase cells (cytogentic abnormalities) of *Strongylocentrotus* were determined in some samples. Cells undergoing mitosis were analyzed for chromosomal abnormalities. This porewater test is appropriate for identifying samples containing genotoxic compounds, which may affect reproductive capacity in a wide variety of organisms. Though the test is useful for specific applications, it proved time-consuming for assessing large numbers of samples. Most porewater samples that demonstrated increased aberration rates also were significantly toxic in larval development tests. Since the larval development test was considerably easier to quantify and was being used routinely as part of the study, the mitotic aberration endpoint was discontinued for logistical reasons. It would be useful in specific applications where the effects of genotoxic compounds must be assessed.

Evaluation of Utilization of Pore Water as a Test Medium for the BPTCP

The diffusive flux of dissolved chemicals through the sediment water interface into the overlying water column is a major component of sediment diagenesis and chemical cycles. Bioassay testing of the filtered pore water is an attempt to address exposure of animals living in the sediment matrix, or near the sediment/water interface, to chemicals not associated with the particulate phase. Equilibrium-partitioning theory predicts pore water is the controlling exposure medium in the toxicity of sediments to infaunal organisms (Adams *et al.*, 1985; DiToro, 1990). To accurately interpret pore water test results, it is

important to determine how manipulations of pore water during extraction and handling may have affected observed toxicity. The BPTCP utilized a low pressure (<200psi) squeezing extraction technique with filtration to 0.45 um, and subsequent freezing of pore water samples, prior to testing. There has been some debate regarding appropriate pore water extraction methods and sample manipulations for the purposes of toxicity testing (Carr et al., 1995; Schults et al., 1992). Squeezing techniques allow pore water to be selectively filtered, thus eliminating particulates.

Suspected artifacts from the squeezing technique may include chemical disequilibria through physical disruption of weakly charged ion/particulate associations or lysing of cell walls with resultant changes in concentration of dissolved and particulate organic carbon or other organic components. There is also concern that filtration has a profound effect on observed toxicity. Pore size and filter material can cause variability in measured chemical concentrations (Schults, *et al.*, 1992). Many scientists are now using centrifugation to obtain pore water from sediment for toxicity testing, because this method may be less subject to toxicity artifacts than squeezing (Lange *et al*., 1992; Giesy *et al.*, 1990).

Toxicity has been observed to decrease in bedded sediments which are tested after freezing and thawing, with observed changes assumed to be related to the release of soluble organic carbon through disruption of natural lattices, clay aggregates and organic matter (Schuytema *et al.*, 1989). Although solids are removed from pore water samples, there remain some soluble organic carbon concerns due to disruption of colloidal aggregations in the pore water, however centrifugation of pore water samples prior to freezing helps minimize this effect (Carr and Chapman, 1995). There are other unresolved concerns related to the toxicity testing of sediment pore waters which require additional study. These include sediment sample handling and storage conditions prior to testing, oxygen contamination, storage time of pore water samples prior to testing (Lange *et al.*, 1992) and sorption kinetics in toxicity test containers and extraction devices (Pittinger, 1988).

Dose responses from the three pore water dilutions demonstrate decreasing toxicity with increasing pore water dilution, confirming that some factor associated with pore water was causing toxicity. However, considering the uncertainty of introduced artifacts during sample manipulations, the ability to discriminate more severely impacted sediments from less severely impacted sediments (a primary goal of the BPTCP) is clearly compromised. As a result of this uncertainty, toxicity testing using pore water as the test medium was suspended in August, 1993, pending further method evaluation. Pore water extraction methods and pore water sample handling have been under evaluation by the BPTCP since that time, with preliminary results indicating that centrifugation and refrigerated (not frozen) sample storage may be the preferable methods when testing this matrix. Recent method comparison research of Carr and Chapman (1995) supports

the use of squeezing technique yet concludes that in situations where hydrophobic organic compounds are a concern (as they are in this program), centrifugation is the method of choice for maximizing the sensitivity of the toxicity test. Sample storage and holding times were critical for all methods evaluated and require further investigation (Schults *et al.*, 1992).
As pore water test methods, test organism selection, and the interpretation of results continue to evolve, they will be evaluated for use by the BPTCP. Because test sensitivity is necessary for accurate sediment characterization, the *Strongylocentrotus* pore water larval development toxicity test protocol should continue to be included in BPTCP. At present, pore water toxicity data by themselves are difficult to interpret. If pore water toxicity tests are used in conjunction with solid phase toxicity tests, chemical measurements and benthic community evaluations, they can provide useful additional information when using a weight of evidence approach toward site characterization.

Distribution of P450 Reporter Gene System Response

Induction of the CYP1A1 gene on the human chromosome is produced by such compounds as dioxins, furans, dioxin-like PCB congeners (coplanar), and several high molecular weight polycyclic aromatic hydrocarbons. This induction and resulting production of the detoxifying enzyme, P450, infers that these xenobiotics are present at levels that are potentially toxic, carcinogenic, or mutagenic to organisms. The P450 Reporter Gene System (RGS) assay can measure the response of human (101L) cells to organic extracts when a firefly plasmid at the CYP1A1 site produces the enzyme luciferase. A luminometer is used to quantify the luciferase as a function of concentration and potency of the organics in the extract. Solvent extracts (using standard extraction methods EPA 3510, 3450 or 3550) of water, aquatic sediments, soils and tissues can be tested in the assay system, with a measured response in 16 hours (Anderson *et al.,* 1996).

Findings of the P450 Reporter Gene System (RGS) assay of sediment extracts from 30 stations are summarized in Figure 24, where the RGS responses (in 101L cells) are expressed as μg/g (ppm) of benzo(a)pyrene equivalents (BaPEq). The Mission Bay A8 (93112) station, Coronado Cays T2 (93203, 93204) stations, Shelter Island E1 & E3 (93138, 63164) and the Sweetwater Channel stations produced baseline responses in the range of 5.3 to 10.4 μg/g BaPEq. Figure 24 shows that all Naval Shipyard stations, the Commercial Basin station, the Marine Terminal and Downtown piers, as well as Seventh Street and the Sub Base stations all produced strong RGS responses. These responses suggest that benthic fish and invertebrates living in contact with these sediments have a high probability of P450 enzyme levels above background, which could result in chronic toxicity, and/or damage to tissues and reproductive potential.

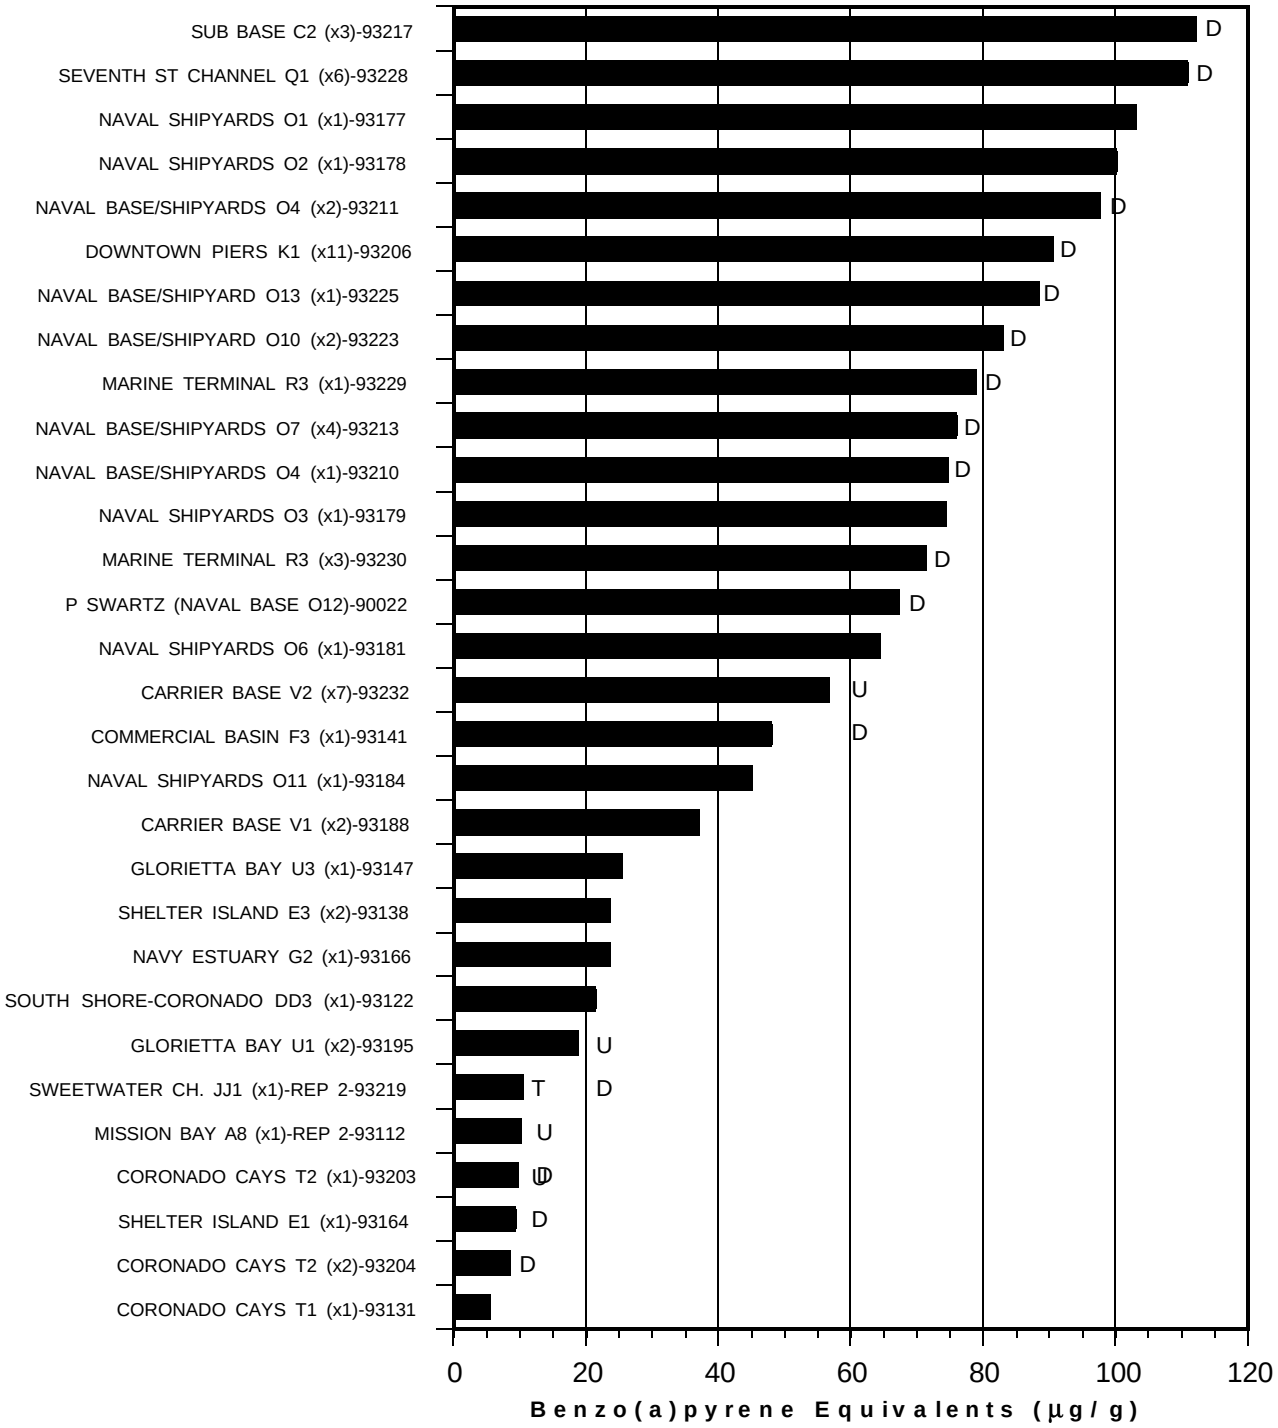
Examination of the relationship between RGS response to sediment extracts and total PAHs concentration in sediments demonstrates

Figure 24. P450 Responses to Extracts of Sediments From San Diego Bay



P450-RGS response (expressed as benzo(a)pyrene equivalents) and benthic community index. Stations with degraded benthic communities are shown with a "D" label. Undegraded are shown with "UD," and transitional stations are shown with "T." Benthic community analysis was not performed on unlabeled stations.

a strong correlation (r^2= 0.86) between the two measures (Figure 25). This is expected, because samples significantly contaminated with PAHs and/or other compounds (coplanar PCBs) have been shown to produce induction of the CYP1A1 gene and the RGS response (Anderson *et al.*, 1995).

Figures 9a-d show stations with high molecular weight PAHs at the PEL (6676 ng/g) and above in black. Examination of these data demonstrated that RGS responses above 60 μg/g BaPEq were always associated with total PAHs at levels above the PEL. This comparison with the PEL suggested that sediment samples with RGS responses above 60 μg/g BaPEq also had a high probability of demonstrating a toxic biological effect, based on sediment quality guidelines. Interestingly, stations identified by RGS to contain significant amounts of inducing organic compounds (> 60μg/g BaPEq) were also found to have degraded benthic communities, at all stations where both analyses were performed. Toxicity test results did not demonstrate a similar strong association with the RGS response.

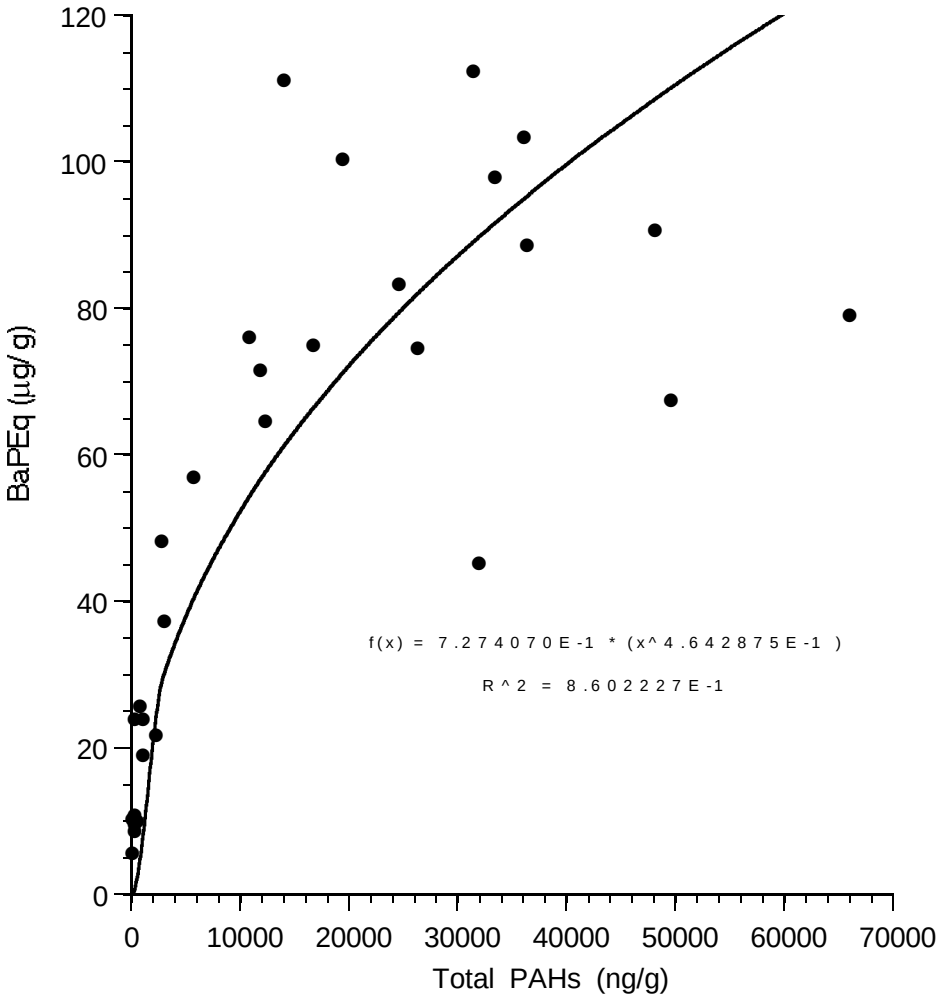
The P450 Reporter Gene System proved to be effective for rapidly (16 hr test) and inexpensively assessing the magnitude of PAHs at selected stations in the San Diego Bay Region. It further proved useful by demonstrating a RGS response threshold above which benthic community degradation was expected. This method may be appropriate as a screening test at additional locations when benthic community degradation and contamination from multiple PAHs, coplanar PCBs, dioxins and furans is suspected. The bioeffects branch of NOAA has utilized this assay in investigations of coastal studies in southern California, Charleston Harbor, S.C., Sabine Lake and Galveston Bay, Texas, and Biscane Bay Florida. In concert with other chemical and biological measures, this method provides additional convincing evidence for the assessment of overall pollution at sites of chemical concern.

Determination of Relationships Between Toxicity and Chemistry

Linear regression was used to describe the relationship between toxicity and chemical concentrations. The dependent variable values are assumed to be normally distributed around the predicted values on the regression line. If this assumption has been met, then a significance test evaluating the null hypothesis (slope of the regression equation is equal to zero), is performed. In addition to a significant probability ($p < 0.05$), the coefficient of determination (r^2) is also an indication of regression strength. The coefficient of determination value represents the proportion of total variance of the dependent variable which can be explained by the independent variable, with a r^2 value of greater than 0.60 being significant. Regression is preferable to non-parametric tests because there is greater power to detect significant relationships with this method (Zar, 1984).

Linear regressions were used to assess the relationship between *Rhepoxynius* (amphipod) mean survival and chemical concentration.

Figure 25. Total PAHs vs P450-RGS Response Expressed as Benzo(a)pyrene Equivalents



Systat® v.5.04 was used for all analyses. The arcsine (square root) transformation is utilized to equalize variance over the entire range of proportions. Chemistry data were checked for normality and transformed using Log(x+1), when necessary (Zar, 1984). Examination of residuals reveal homogeneity of variances exists when these transformations are performed and therefore, the statistical assumptions of a regression can be met. The coefficient of determination (r^2) was reported only when the linear regression was significant ($p<0.05$).

Regressions using amphipod data and chemical concentrations for all stations were analyzed. Testing the degree of dependence of amphipod survival on individual chemical concentrations yielded several regressions which are significant, however, there were no r^2 values greater than 0.072 (Table 13).

To investigate dependence of amphipods on chemistry within specific areas of the Bay, all stations were grouped into one of six specific areas (Appendix B). Groupings were performed to combine stations with similar physical characteristics or uses. These six groups were military use areas (Navy), commercial basins for shipping and industrial activities, small boat harbors and marinas, Mission Bay, rivers (San Diego and Tijuana), and "other" stations, which generally were in open areas removed from San Diego Bay shorelines. The area into which each station was grouped is reported in Appendix B. These regressions were used to test the degree of relationship between amphipod survival and specific areas in the San Diego Bay Region.

Regressions using the navy station group were significant for some chemical groups although no regression had an r^2 value greater than 0.272 (Table 14). In commercial basins, low and high molecular weight PAHs, several metals and one PCB compound were significant, but all had low r^2 values (Table 15). In the small boat harbor group, several PAH and PCB compounds and one pesticide were significant, however, no r^2 values were greater than 0.167 (Table 16). In river stations low molecular weight PAHs were strongly correlated with amphipod survival (Table 17), producing the most significant regressions of the statistical analysis. These regression results from the river stations were somewhat misleading, however, because PAH levels were low relative to most stations in San Diego Bay and to ERM guidelines. For regressions using the "other" station designations, several metals and PCB compounds and one PAH, were significant (Table 18) yet, r^2 values were never better than 0.265. When testing the six station groups, there were no significant regressions for chemistry or amphipods within the Mission Bay group. This was expected because of the low chemical concentrations, therefore no table is shown.

Ammonia, hydrogen sulfide and grain size are suspected non-anthropogenic contributors to toxicity, and have been discussed previously by Ankley *et al.*(1990), Knesovich *et al.* (In Press), and DeWitt *et al.* (1988). To investigate whether these natural

factors influenced the effects of anthropogenic chemicals in test sediments from the San Diego Bay Region, data were adjusted to exclude tests where unionized ammonia was greater than O.4 mg/L in overlying water and/or hydrogen sulfide was greater than 0.06 mg/L. The 0.4 mg/L ammonia threshold value is based on the NOEC value for the EPA test protocols for marine amphipods (USEPA, 1994) and the 0.06 mg/L hydrogen sulfide threshold value is based on data presented by Knesovich *et al*. (In Press). A general trend is seen by DeWitt *et al.* (1988), in which survival decreases with increasing fines. However, because this trend was not apparent in the San Diego Bay Region and no clear cutoff has been conclusively demonstrated, data were not adjusted to exclude samples with a high percentage of fines. NH_3 and H_2S adjusted amphipod data were compared to the thirty two chemicals or chemical groups, for which PEL values have been derived, and to ERM and PEL summary quotients. Regressions were significant for cadmium, chromium, copper, nickel, silver, zinc, DDT, dieldrin, acenapthene, and the ERM and PEL summary quotients (Table 19). By eliminating high ammonia concentrations (>0.4 mg/L) and high hydrogen sulfide concentrations (0.06 mg/L), regressions do improve slightly, however r^2 values are generally low. It is prudent though to recognize that these natural factors may confound interpretation of toxicity results and that caution should be exercised when elevated ammonia or hydrogen is noted.

In summary, simple linear regressions provide few clues to understanding the relationship between amphipod survival in the toxicity tests and measured single chemical concentrations. When viewing scatter plots, it remains difficult to convincingly argue that there is, or should be, a linear toxic response to increasing chemical concentrations in natural settings. In industrialized settings such as San Diego Bay, where multiple pollutants are common, co-variation and possible synergistic effects within a group of multiple pollutants further confound the separation of effects to single pollutants. A single multiple regression or a variable selection technique may statistically better describe the relationship between toxicity and multiple chemicals, but these were not performed in this analysis.

Figure 26 is typical of chemical vs. toxicity scatter plots seen throughout the region, with considerable scatter at low chemical concentrations and a gradual decrease in survival at elevated chemical concentrations. Because regressions did not generally support a linear toxic response to chemical pollutants, it is suspected that most organisms are tolerant of pollutants until a threshold is exceeded. This threshold effect appears well demonstrated in the San Diego Bay Region's benthic communities setting, as illustrated in Figure 14.

Although it was less evident for acute toxicity tests, where high amphipod survival was observed even at elevated chemical levels (Figure 26), a distinct response pattern still emerges. When the EMAP approach for determination of toxicity (significantly different from controls and less than 80% of controls) was used, 28 of 39 (72%) sediment samples were toxic when copper

Table 19. Linear regression of amphipod survival dependence on chemical analytes for which PEL levels have been developed. Amphipod data has overlying unionized ammonia values >0.4 ppm and hydrogen sulfide values >0.06 ppb removed (all chemical data are Log (x+1) transformed. r^2 is presented when $p<0.05$, ns= nonsignificant).

concentrations exceeded the ERM value whereas only about 7 of 28 samples (25%) were toxic when copper concentrations were below the ERL value. This was also seen with total PCBs with 73% of the samples being toxic when PCB concentrations exceeded the ERM value and only 53% toxic below the ERL. Because it is suspected that toxicity in urban bays is caused by exposure to complex mixtures of chemicals comparisons to ERM summary quotients (multiple chemical indicators) were made. The highest incidence of toxicity (>78%) is found in samples with elevated ERM summary quotients (>0.85), supporting the theory that the effects of elevated levels of multiple pollutants may elucidate the toxic response. This pattern of increased incidence of toxicity when chemical concentrations exceed established sediment quality guidelines or the summary quotient 90% confidence interval seems to support the threshold response theory for amphipod bioassays in the San Diego Bay Region.

Guideline thresholds are quantitatively estimated from large national or statewide data sets, as described earlier, but the applicability of calculated values may be limited in specific water bodies. Use of unique guidelines for the San Diego Bay Region, which account for local physical, chemical and biological conditions, would be optimal when evaluating data. However, without substantial additional data, chemical specific thresholds for the San Diego Bay region cannot be accurately determined. Currently the most useful tools for addressing the relationship between toxicity and chemical concentration appears to be threshold approaches, such as the ERM/ERL and TEL/PEL guidelines.

Station Specific Sediment Quality Assessments

One of the primary goals of the BPTCP is to establish state guidelines under which contaminated or toxic stations can be designated "toxic hot spots". These guidelines are currently being developed based on data collected throughout the state. Although final guidelines are contingent upon further data analysis, the "toxic hot spot" definition currently utilized by the BPTCP, requires that one or more of the following criteria must be met:

1. The water or sediment exhibits toxicity associated with toxic pollutants, based on toxicity tests acceptable to the SWRCB or the RWQCB. To determine whether toxicity exists, recurrent measurements (at least two separate sampling dates) should demonstrate an effect.

2. Significant degradation in biological populations and/or benthic communities associated with presence of elevated levels of toxic pollutants.

3. The site exceeds water or sediment quality objectives for toxic pollutants which are contained in appropriate water quality control plans, or exceeds water quality criteria promulgated by the U.S. Environmental Protection Agency.

4. The tissue toxic pollutant levels of organisms collected from the site exceed levels established by the United States Food and Drug Administration (FDA) for protection of human health, or the National Academy of Sciences (NAS) for the protection of human health or wildlife.

Because tissue residues were not analyzed in this study, criteria are limited to the first three. Satisfying any one of these criteria can designate a site a "toxic hot spot". Satisfying more than one criterion and the severity demonstrated within each criterion determines the weighting for which qualitative rankings can be made. In this report, stations were not designated as "toxic hot spots", because this designation is still under evaluation and development by the BPTCP. Instead, stations were prioritized for further evaluation for hot spot status. This priority was classified as high, moderate, low, or no action and may be used by State and Regional Water Board staff to direct further investigations at these stations. Each station receiving a high to low priority ranking meets one or more of the first three criteria established above. Those meeting all three criteria were designated as the highest priority for further action.

Stations were evaluated for repeat toxicity (criterion 1) using the reference envelope method, the most conservative measure developed. Only those stations which demonstrated amphipod survival less than 48% in repeated tests, without confounding ammonia, hydrogen sulfide or grain size effects, were considered to exhibit repeat toxicity hits. Because only one critical value could be determined for any of the dilutions of the pore water bioassays, pore water toxicity results were not evaluated for repeat toxicity when prioritizing stations.

Stations with repeat toxicity and elevated chemistry and/or degraded benthic communities, were assigned a moderate or high priority. Stations with repeat toxicity, but lacking elevated chemistry or degraded benthic communities, were assigned a low priority (Tables 20 and 21- REPEAT TOXICITY HITS).

Stations with only a single toxicity hit were also considered a moderate or high priority, when associated with elevated chemistry and/or degraded benthic communities. Stations with a single toxicity hit, but lacking elevated chemistry or degraded benthic communities, were assigned a low priority. (Tables 20 and 21- SINGLE TOXICITY HITS).

Nineteen stations demonstrated repeat or single toxicity hits but were given a "no action" recommendation at this time (Tables 20 and 21). These stations had measured hydrogen sulfide or ammonia concentrations which confounded interpretation of the bioassay test results. Chemistry levels were low, or not analyzed, and the benthic community was undegraded or transitional, where sampled. These results provided little or no evidence that these stations should be prioritized for hot spot status. A toxicity identification evaluation (TIE) should be considered for these

sites to confirm the source of toxicity as non-anthropogenic. Stations were evaluated for benthic community condition using the benthic index discussed earlier (Table 11). Stations determined to be degraded, with elevated chemistry and/or toxicity, were assigned a moderate or high priority. Stations determined to be degraded, but which did not demonstrate elevated chemistry or toxicity, were assigned a low priority. Transitional and undegraded stations were not considered a priority unless chemical or toxicity results initially prioritized the stations. (Table 20- DEGRADED BENTHICS)

Stations were evaluated for elevated chemistry (criterion 3) using an ERM Summary Quotient >0.85 or a PEL Summary Quotient >1.29. In the earlier discussion of ERM and PEL summary quotients, it was determined these values are statistically above the 90% confidence interval of summary quotients from all stations analyzed. These quotients were used to identify stations where multiple pollutants were near or above established ERM and PEL guidelines (Table 22-CHEMISTRY-Summary Quotients). As shown in Figure 14, 100% of the stations analyzed for benthics were found to be degraded when chemical analysis demonstrated an ERMQ above 0.85. Although the eighteen stations in Table 22 (CHEMISTRY-Summary Quotients) did not have benthic community analysis performed, it is likely these stations will demonstrate degraded benthic communities, when analyzed. In consideration of this concern, all stations with elevated chemistry, based on ERM summary quotients above 0.85, were assigned a moderate priority ranking.

In situations where high summary quotient values were not found, but where any single chemical concentration exceeded four times (4x) its associated ERM or 5.9 times (5.9x) its associated PEL, the station was also considered to exhibit elevated chemistry. The 4x and 5.9x cutoffs were not statistically determined using the 90% confidence interval as they were with the summary quotients. Values for individual chemical quotients were not normally distributed and transformations did not improve distributions, so statistical determination of confidence limits was not appropriate. Instead, a qualitative examination of the data set indicated that only in the top 10th percentile of chemical measurements do values exceed four times their respective ERM or 5.9 times their respective PEL (Tables 20 and 22- CHEMISTRY-Individual Chemicals). These cutoffs were used to help identify stations where any single chemical was extremely elevated. Stations with elevated individual chemical quotients and evidence of benthic community degradation were assigned a moderate ranking. Stations which exhibited elevated chemistry, but showed no biological effects, were assigned a low priority.

Stations which satisfied all three of the criteria were considered a triad hit and are given the highest priority ranking. These stations demonstrated toxicity in the bioassay tests, benthic community degradation and elevated chemistry. Four stations (representing three sites) fell in this category: the Seventh Street Channel (90009-leg 23 and 93228), 12 Swartz

Downtown Anchorage (90002) and Naval Base/Shipyards O4 (93210). Three stations were given a high priority ranking although not all conditions of the triad were met (Seventh Street Channel (90009-leg 7) and Naval Shipyards O3 (93179- legs 19 & 27)). These stations demonstrated repeated toxicity and elevated chemistry but no benthic analyses were performed. However, benthic data for stations analyzed in the same proximity, or later sampling of the station, led to the concern that these sites would have been found degraded, if analyzed. In addition, chemical summary quotients at these three stations were at levels which suggest probable benthic community degradation, as discussed earlier. These concerns warranted upgrading these three stations from a moderate priority to a high priority. Forty three stations were given moderate priorities and 57 were given low priorities, based on the methods of prioritization previously discussed. Prioritized stations are mapped in Figure 27(a-d).

Stations were prioritized to assist SWRCB and RWQCB staff in meeting sediment quality management objectives for San Diego Bay. These recommendations were based on scientific evaluation of data collected between 1992 and 1994. They are intended to focus future efforts toward scientifically and economically responsible characterization of locations which have a high probability of causing adverse effects to aquatic life. This report should be evaluated in conjunction with all available information and additional research when management and policy decisions are made by SWRCB and RWQCB staff.

Possible Sources of Pollutants at Prioritized Stations

A brief description is given, where additional information was available, of factors which may have contributed to elevated chemical levels, toxicity, or benthic community degradation at the prioritized stations. Descriptions are given in order of geographic distribution, proceeding from north (Mission Bay) to south (Tijuana River Estuary).

In Mission Bay only one location was given the moderate priority ranking (station 93116). This station was located in the San Diego River flood control channel and demonstrated high total chlordane concentrations (36.1 ppb). Chlordane is not expected to undergo significant hydrolysis, oxidation, or direct photolysis in water, thus it may persist in soils for extended periods of time (Howard, 1991). Cohen *et al.* (1990) conducted a study on chlordane in soil samples near golf courses and found unusually high concentrations of chlordane (4.75-4310 ppb). Station 93116 is located directly down river from a golf course, therefore, runoff from this facility could be a chlordane source. Station 93107, in the mouth of Rose Inlet (northern Mission Bay), received a moderate priority listing, based on high chlordane concentrations. Its location is also near a golf course.

One site in North San Diego Bay (Point Loma area) received a moderate priority recommendation; stations 90028 (Submarine Base). This station had degraded benthic communities, high

concentrations of low and high molecular weight PAHs, and moderate levels of metals. Historically the Naval Complex at Point Loma has received plating waste, sewage, and sludge containing high concentrations of metals and chlorinated hydrocarbons (Johnston *et al.*, 1989). Although it is difficult to identify the source of high concentrations of PAHs at these stations, Lung (1983) suggests ground water gradients promote groundwater flow towards San Diego Bay, thus potentially allowing PAHs in the nearby soil to migrate to the Bay. A number sites investigated by the Navy (Eakes and Smith, 1986), which were previously used for waste oil and drum disposal, are located onshore adjacent to and immediately north of stations 93216, 93217 and 90028. Migration of pollutants from these onshore sites is likely. Minor spills during fueling operations at the submarine base are also possible.

Station 90002 (Downtown Anchorage), located in the northern end of mid San Diego Bay, was one of the stations which received a high priority recommendation. High concentrations of metals and chlordane were present, as well as a degraded benthic community. This station also had a low survival for *Rhepoxynius* in solid phase toxicity tests. Perhaps the most obvious explanation for these data would be the presence of a large storm drain and numerous smaller storm drains, which empty into the Bay near this station. These storm drains drain parking lots, light industrial and commercial areas (Conway and Gilb, 1990). Another possible source for observed toxicity and chemistry is runoff from nearby San Diego International Airport. Results from the State Mussel Watch Program 1987-1993 indicate elevated levels of both metals and pesticides in mussel tissue and sediments in this area. Elevated levels of metals could have originated from anti-fouling paints on private boats anchored near the station (90002). The area around this station becomes a modified eddy during ebb tide and may serve to recirculate pollutants, creating a pollutant sink and preventing chemicals from being flushed out of the area (Peeling, 1974).

Located just south of station 90002, stations 93205 and 93206 (Downtown Piers) were given moderate priority ratings based on high chlordane and PAHs concentrations, and degraded benthic communities. Located between the B street pier and the Broadway pier, elevated levels of pollutants can most likely be attributed to sources similar to those described above. Commercial shipping is likely an additional contributor to the observed PAH signal in this area.

Two stations, 90017 and 90039 (located immediately north of the 10th avenue marine terminal), were assigned moderate priority rankings based on high concentrations of chlordane, metals, and PAHs at each of these stations. Campbell Industries operate five ship repair piers and four dry-docking facilities in this area. Sandblasting, painting, and other ship repair activities are probably the cause of the elevated levels of copper, zinc and mercury. High concentrations of metals have historically been detected at this site (Barry, 1972). The 10th avenue Marine

Terminal berths 1 and 2 are also located in this area (station 90039). Ships are loaded and unloaded at this site and supplied with fuel from four steel storage tanks located near the berths. Increased levels of PAHs and metals detected in this area may be related to the cargo transfer facility.

In addition to the ship repair facilities and cargo transfer areas, there is a large storm drain system which is directly south of the 10th and Imperial Trolley station. The system drains approximately eleven square kilometers of residential (including Balboa Park) and industrial areas before emptying into the Bay. The elevated levels of chlordane and PAHs at both of the sites could have additional sources from within this drainage system.

Immediately south of the Coronado Bridge was station 93179 (Naval Shipyards-O3) which was designated as a high priority site for future investigations. To the north and south of this site are numerous stations assigned a moderate prioritization. The predominant activity in this area is ship building and repair (NASSCO, Continental Maritime, Southwest Marine), thus indicating the probable source of high levels of metals, PCBs and PAHs found at stations sampled in this area. A stormdrain, which drains an industrial area and empties into the Bay immediately adjacent to the bridge, is the likely chlordane source to the area. Runoff from the bridge itself could also be viewed as a potential source of PAHs and metals in the Bay. The California State Mussel Watch Program (1995) has sampled extensively in this area of San Diego Bay and found chemistry values for mussels and sediment to be comparable to the current study. This area has also been extensively sampled in other studies resulting in similar conclusions (de Lappe, 1989; Martin, 1985; Anderson, 1989). Toxicity, chemical pollution and benthic community degradation are extensive in this area and warrant further site characterizations.

Stations 93212, 93213, and 90006 (Naval Shipyards-O7) were located near the 28th Street pier and were each given a moderate priority ranking. Chollas Creek empties into the Bay near this site, carrying with it runoff from a large urban area. This creek is believed to carry high concentrations of PAHs into the Bay (McCain *et al.*, 1992) and is the likely source of high chlordane levels at the site.

Numerous low, moderate and high priority sites were located in the Naval Station between the 28th Street pier and 7th Street channel. This area demonstrated toxicity, high metal and chemistry concentrations and degraded benthic communities. The area is predominantly used for ship repair, outfitting, and conversion. Sand blasting, painting, and the changing of zinc electrolysis plates are some of the specific activities conducted in this area and are likely the main sources of metals found in the sediments.

Station 93227 was located in the 7th Street Channel at the southern end of the San Diego Naval Station. This site was given

the high priority ranking based on high metal, chlordane and PAH concentrations, as well as toxicity and degraded benthic communities. Repeated sampling of this site resulted in similar findings. Paleta Creek runs directly into 7th Street channel with numerous drains located in the immediate area emptying into the creek and bay. Also, a large stormdrain is present which drains a residential area east of Interstate 5 and the Naval station adjacent to the channel.

The Navy has used 7th Street channel and the surrounding area for a variety of activities. Excess materials (solid waste, ships stores, and waste hydraulic fluids) from decommissioned ships were disposed of in the ship repair basins. Overflow from salvage yards, lube and hydraulic oil wastes, and paint sludge from nearby Naval repair facilities were often taken to the area's wet docks for disposal. In the late 1970's trucks and heavy equipment returning form Vietnam were routinely decontaminated by spraying with diesel fuel and dunking (by crane) into Paleta Creek. It is estimated that approximately 75,000 to 360,000 gallons of petroleum based material were disposed of at this site during its period of operation (1945-1973).

The 7th Street channel is located near a Navy salvage yard which has stormdrains emptying directly into the channel. In 1976, soil samples retrieved from the area contained PCB concentrations high enough to result in the upper eight inches of soil being removed as contaminated waste and the entire area paved. Although the Navy has attempted to deal with this historic pollution in the area, further investigations were requested by a Naval initial assessment team in 1986 (Eakes and Smith, 1986). Furthermore, the California State Mussel Watch program has stations located in the area and concluded 7th Street channel had some of the highest chemical concentrations in San Diego Bay (State Mussel Watch Program, 1995).

The Marine terminal site (stations 90010, 93230 and 93229) demonstrated elevated copper and PAH levels and a degraded benthic community. Moderate and low priorities were assigned to these stations even though a portion of this area is currently undergoing cleanup activities. Due to the large amount ore spillage at the PACO copper loading facility, this area should continue to be monitored after cleanup activities are completed.

The southern portion of San Diego Bay, from 7th Street channel to the Otay River, did not receive any moderate or high priority rankings. Although this result could give the impression south San Diego Bay is in not polluted, it is important to note some stations still demonstrated high metals concentrations. The Sweetwater channel area (station 93220), and other sites in the South San Diego Bay had high concentrations of copper, most likely reflecting the input from the copper ore loading facility (Martin, 1985). Three stations in the Chula Vista area and one in Coronado Cays received low priority rankings due to elevated levels of metals and degraded benthic communities. Each of these stations were located within marinas where numerous private boats

are berthed. Increased levels of metals detected in this area are probably from anti-fouling paint scrapings or zinc electrolysis blocks used on virtually all boats. Few studies have concentrated sampling in the South San Diego Bay, presumably due to reduced shipping activity and population.

Stations from the Tijuana River Estuary demonstrated elevated concentrations of DDT and DDE, as well as toxicity to amphipods. This resulted in a number of stations receiving moderate and low prioritizations. The presumed sources of this pesticide were wastewater discharges from Mexico, into the Tijuana River (California State Coastal Conservancy, 1989).

Comparison of Pollution with Other Water Bodies

Numerous studies comparing San Diego Bay with other bays and harbors have been conducted (NOAA, 1991; Grovenhoug *et al.*, 1987; Goldberg *et al.*, 1978). In one such study, Robertson (1989) analyzed sediments for a number of organic pollutants at approximately 200 sites around the coasts of the United States. Results ranked San Diego Bay seventh highest in the country for total concentrations of PCBs. Interestingly, San Diego Bay did not rank high in comparison to the rest of the country for any other organic pollutant, although results from the current study clearly showed elevated concentrations (relative to ERMs and PELs) of total PAHs, chlordane, and certain trace metals throughout the Bay.

In a similar study, Johnston (1990) evaluated 367 waste disposal sites at 58 Navy and Marine Corps bases located throughout the country. Each of the bases, or areas of activity, were located in the coastal zone and were reviewed to characterize the pollutants, disposal methods, and potential impact to the surrounding aquatic environment. Four sites were chosen in San Diego Bay: Naval Station San Diego (located immediately south of the seventh street channel), Naval Amphibious Base (near Glorietta Bay), Naval Training Center, and Naval Complex Point Loma. Although these sites were not ranked or compared with sites in other parts of the country, the types of contamination listed were somewhat similar for each of the sites described. Paint, oil, and solvent contamination was reported at all of the sites in addition to some site specific forms of contamination(*i.e.* sandblasting grit disposal area at the Naval Amphibious Base and drum disposal area at the Naval Complex Point Loma).

San Diego Bay has also been compared to other bodies of water on a regional scale. In a SCCWRP project funded by the State Board, Anderson and Gossett (1987) analyzed PAHs in sediments collected at stations between Santa Monica Bay and San Diego Bay and found the Seventh Street (Paleta Creek) and Chollas Creek stations to contain the highest levels of these hydrocarbons. In a follow-up State Board/SCCWRP study Anderson *et al.* (1988) compared ten coastal sites in southern California for concentrations of trace metals, PAHs, chlorinated hydrocarbons and toxicity. Samples from San Diego Bay were shown to have the highest concentrations of

metals, PAHs, and hydrocarbons of all stations sampled, and were the most toxic in two out of three toxicity tests used. Anderson *et al.* (1988) identified the Seventh Street Channel station as the most polluted area in the San Diego Bay Region. This conclusion is corroborated by the current study which also found sampling stations in the Seventh Street Channel to be the most polluted and most toxic stations in the region. Flegal and Sanudo-Wilhelmy (1993) showed total dissolved trace metal (Ag, Cd, Co, Cu, Ni, and Pb) concentrations in San Diego Bay are comparable to levels of trace element pollution in south San Francisco Bay. Specifically, copper was found in elevated concentrations in both bays. The current study found copper to be the predominant trace element pollutant in San Diego Bay. Flegal and Sanudo-Wilhelmy concluded that unlike south San Francisco Bay, elevated trace metal concentrations in San Diego Bay could not be directly linked to point-source inputs, because all wastewater discharges to San Diego Bay were terminated in 1964. Copper based anti-fouling paints and urban runoff are currently the most likely sources of copper. Elevated concentrations of copper in San Diego Bay have also been reported in other studies (Zirino *et al.*, 1978).

It is also important to analyze available site specific data within San Diego Bay from previous studies. In the current study, commercial and naval shipyards located near the Coronado Bridge consistently demonstrated high concentrations of pollutants, a high incidence of toxicity, and benthic community degradation. Shipbuilding activity, in addition to storm drains and creeks, appear to be the primary sources of organic and trace metal pollutants in these areas (Conway and Gilb, 1990). Secondary sources of contamination may include runoff from the Coronado Bridge (San Diego Interagency Water Quality Panel, 1989) and polluted fill in the area (Peter Michael, San Diego Regional Water Quality Control Board, personal communication). This is supported by the conclusions of McCain (1992) who found several major sources of pollutants in the central portion of San Diego Bay.

Specific organic pollutants such as PCBs have been historically identified in certain parts of the bay. In one of the earliest studies of PCBs in San Diego Bay, Young and Heesen (1977) identified PCBs in mussel tissues. The highest measured concentrations occurred in Commercial Basin (Shelter Island). Subsequent studies have also shown elevated levels of PCBs in the Shelter Island area, as well as near Harbor Island and numerous other spots throughout the Bay (Stephenson *et al.*, 1980; Martin, 1985). Similar results were obtained from sediment samples in the current study in which high concentrations of PCBs were reported from areas near the Coronado Bridge, west Commercial Basin and East Basin near Harbor Island. The Regional Water Quality Control Board has identified a 60 inch storm drain as the main source of PCBs into the East Basin site. Cleanup and Abatement Orders, regarding PCBs, have been issued to boatyards in and around Shelter Island and Harbor Island (San Diego Interagency Water Quality Panel, 1994).

Tributyltin (TBT), an organic based biocide, was widely used as an antifoulant on ships and small craft until 1988 (Richard and Lillebo, 1988). Although TBT is highly efficient at killing fouling organisms it is also acutely toxic to non-target organisms, making it a continuing concern in the San Diego Bay Region. Toxic effects have been observed in concentrations as low as 1 ng/L (Henderson, 1988). Long term monitoring of U.S. harbors indicates that among naval bases, San Diego has relatively low concentrations of TBT (Kram *et al.*, 1989; Seligman *et al.*, 1990). These studies focused on comparisons between U.S. Naval facilities (i.e. Pearl harbor, Norfolk harbor) where use of TBT anti-fouling paints is not restricted on vessels over 25 meters in length (Organotin Antifouling Paint Control Act, 1988). Because San Diego Bay is a multi-use port, where smaller non-naval vessels must conform to the 1988 legislation, TBT values are expectedly lower than harbors which solely contain large naval vessels. In the current study, TBT values were highest in naval and commercial basin areas, similar to the findings of Seligman *et al.* (1990). Although both studies found elevated levels of TBT in commercial and naval sites, data from the current study indicates an overall decline in TBT sediment concentrations at these locations. This is most likely a reflection of restrictive legislation on TBT use in antifouling paints. Given the historical use of antifouling paints in San Diego Bay, continued monitoring is recommended, although results from the current study were encouraging.

Limitations

The two step sampling design of this study relied on an initial "screening phase" to give a broad assessment of toxicity in the San Diego Bay Region. Subsequent toxicity test, chemical analysis and benthic community analysis were performed only on selected stations ($\approx$ 40% of the screened stations) which demonstrated toxicity during the screening phase, or were considered candidates as reference stations. The remaining stations, from the screening phase, did not receive additional testing or analysis. Therefore, statistical analyses, comparisons to chemical specific screening values, identification of undegraded and degraded habitats, and prioritized rankings could not be performed on all stations sampled. Currently these stations fall under a no action recommendation, but it should be understood that for these stations a weight-of-evidence evaluation was not performed, due to the absence of chemical and/or benthic community data.

In determination of toxicity for the reference envelope approach, values must be chosen for alpha and the percentile (p) to calculate the edge of the reference envelope (L) using the following equation:

$$L = X_r - [\, g_{a,p,n} * S_r \,]$$

The values of alpha and p are chosen to express the degree of certainty desired when classifying a sample as toxic. In this study values of alpha=.05 and p=1 were used to distinguish the most toxic samples which have a 95% certainty of being in the most toxic 1% (Figure 4). This calculation resulted in a determination of toxicity for the *Rhepoxynius* test when samples had a mean survival of less than 48%. If the value of p was chosen to equal 10% (*i.e.*, a 95% certainty of being in the most toxic 10%) the determination of toxicity (edge of the reference envelope) would have been at 63% survival. Obviously, a choice of p=10% would broaden the range of samples which would be classified as "toxic". It must be recognized the 48% level used in this study was chosen as a conservative guideline to identify only the most toxic stations for setting priorities for future work. The 48% survival cutoff used in this study should be recognized as a statistical determination which may or may not reflect the certainty desired by SWRCB and RWQCB staff for sediment quality management purposes.

There is a necessary caution to the ecological applicability of data collected from studies such as reported here. Although measures of toxicity and chemical concentration are used extensively in this study, they can only be used as indicators of possible adverse effects to indigenous communities. Benthic community assessment is the only tool used in this study which can demonstrate actual effects to resident biological communities. In combination, these three measures provide a strong weight of evidence for the conditions found at a particular sampling location. However, it is recommended these lines of evidence be supported with an ecological risk assessment during subsequent investigations of stations of concern.

CONCLUSIONS

The major conclusions of this study were:

1. Two sets of sediment quality guidelines were useful in demonstrating chemical pollution: The ERL/ERM thresholds developed by NOAA (Long and Morgan, 1990; Long *et al.*, 1995) and the TEL/PEL thresholds used in Florida (MacDonald, 1993; MacDonald, 1994). Copper, mercury, zinc, total chlordane, total PCBs, and PAHs were most often found to exceed critical ERM or PEL values. These were considered the major chemicals or chemical groups of concern in the San Diego Bay Region. ERM and PEL summary quotients were developed as chemical indices for evaluating pollution of sediments with multiple chemicals. An ERM summary quotient >0.85 or a PEL summary quotient >1.29 was indicative of sites where multiple chemicals were significantly elevated. Stations with any chemical concentration >4 times its respective ERM or >5.9 times its respective PEL were considered to exhibit elevated chemistry.

2. The identification of degraded and undegraded habitat was determined by macrobenthic community structure, using a cumulative, weight-of-evidence approach. Analyses of the 75 stations sampled for benthic community structure identified 23 undegraded stations, 43 degraded and 9 transitional stations. All sampled stations with an ERM quotient>0.85 were found to have degraded communities. All sampled stations with P450 responses above 60 μg/g BaPEq. were found to have degraded benthic communities.

3. Exceedances of toxicity thresholds were determined using two approaches: the reference envelope approach and laboratory control comparison approach. The reference envelope approach was the more conservative of the two, indicating toxicity for the *Rhepoxynius* (amphipod) sediment test was significant when survival was less than 48%, in samples tested. No reference envelope was determined for the *Strongylocentrotus* (urchin) fertilization or development tests. High variability in pore water data from reference stations produced a lower confidence boundary for the reference envelope below 0% survival. This indicates no significant distinction in toxicity could be made between reference stations and other stations for these pore water tests.

4. Using the EMAP definition of toxicity, 56% of the total area sampled in the San Diego Bay Region was toxic to *Rhepoxynius*. For *Strongylocentrotus* development test, percent of total area toxic was 29%, 54%, and 72% respectively for 25%, 50%, and undiluted pore water concentrations. Samples representing 36%, 27%, or 14% of the study area were toxic to both *Rhepoxynius* in solid phase sediment and to *Strongylocentrotus* larvae in 100%, 50%, or 25% pore water, respectively. Spatial extent of toxicity was not determined using the reference envelope definition of toxicity.

5. Linear regression analyses failed to reveal strong correlations between amphipod survival and chemical concentration. It is suspected instead of a linear response to chemical pollutants, most organisms are tolerant of pollutants until a threshold is exceeded. Comparisons to established sediment quality guideline thresholds demonstrate an increased incidence of toxicity for San Diego Bay Region samples with chemical concentrations exceeding the ERM or PEL values. It is further suspected toxicity in urban bays is caused by exposure to complex mixtures of chemicals. Comparisons to ERM summary quotients (multiple chemical indicators) demonstrate that the highest incidence of toxicity (>78%) is found in samples with elevated ERM summary quotients (>0.85).

Statistical analyses of the P450 Reporter Gene System responses versus the PAHs in sediment extracts demonstrated that this biological response indicator was significantly correlated (r^2 = 0.86) with sediment PAH (total and high molecular weight) concentrations.

6. Stations requiring further investigation were prioritized based on combined evidence from toxicity, chemical and benthic community data. Prioritizations were developed to help direct future investigations by State and Regional Water Board staff at these stations. Each station receiving a high, moderate, or low priority ranking meets one or more of the criteria under evaluation for determining hot spot status in the Bay Protection and Toxic Cleanup Program. Those meeting all criteria were given the highest priority for further action.

Seven stations (representing four sites) were given a high priority ranking, 43 stations were given a moderate priority ranking, and 57 stations were given a low priority ranking. The seven stations receiving the high priority ranking were in the Seventh Street channel area, two naval shipyard areas near the Coronado Bridge, and the Downtown Anchorage area west of the airport. The majority of stations given moderate rankings were associated with commercial areas and naval shipyard areas in the vicinity of the Coronado Bridge. Low priority stations were interspersed throughout the San Diego Bay Region.

7. A review of historical data supports the conclusions of the current research. Possible sources for pollution at prioritized stations are given. Recommendations are made for complementary investigations which could provide additional evidence for further characterizing stations of concern.

RECOMMENDATIONS

Given the supporting evidence of previous studies, the patterns of chemical pollution and bioeffects observed during this assessment of the San Diego Bay Region are convincing. There are additional avenues of investigation though which would complement the results of this study. The results also should be confirmed with further studies before any adverse ecological impacts can be conclusively demonstrated.

Due to the large number of elevated chemicals at the majority of the prioritized sampling stations, toxic biological responses can only be associated with overall chemical pollution, rather than a particular chemical. However, stations on the priority list, where the number of ERM or PEL exceedances is low and the exceedance for a particular chemical is high, are excellent candidates for toxicity identification evaluations (TIE). The ability to distinguish between causative factors of toxicity is enhanced when multiple chemicals are not involved. Stations Naval Base O7(x1), 12 Swartz (Downtown Anchorage), and the San Diego River, where high chlordane concentrations are found, are well suited for TIE manipulations which would attempt to test this organic pesticide as the causative toxicity agent. The Naval Base/Shipyard O10(x6) station, which only demonstrates ERM or PEL exceedances for trace metals, is well suited for manipulations which could remove metal toxicity (*e.g.*, EDTA additions).

Several chemicals of concern identified in the San Diego Bay region have been shown to bioconcentrate and biomagnify in the tissues of marine species. A tissue contamination study for lipophilic compounds such as PCBs, chlordane, and possibly methylmercury is recommended to address human health concerns due to consumption of impacted resident species. This line of investigation seems necessary considering tissue contamination is the only BPTCP criterion not investigated during this study.

Although specific stations are identified as having a high probability of causing adverse effects, no attempt can be made to define the boundaries of the impacted area. Sampling specifically designed to quantify areal extent of an impacted area must be addressed during intensive site characterizations.

Moss Landing, CA 95039

September, 1996

I. OVERVIEW OF THE BAY PROTECTION PROGRAM

The California State Water Resources Control Board (SWRCB) has contracted the California Department of Fish and Game (CDFG) to coordinate the scientific aspects of the Bay Protection and Toxic Cleanup Program (BPTCP), a SWRCB program mandated by the California Legislature. The BPTCP is a comprehensive, long-term effort to regulate toxic pollutants in California's enclosed bays and estuaries. The program consists of both short-term and long-term activities. The short-term activities include the identification and priority ranking of toxic hot spots, development and implementation of regional monitoring programs designed to identify toxic hot spots, development of narrative sediment quality objectives, development and implementation of cleanup plans, revision of waste discharge requirements as needed to alleviate impacts of toxic pollutants, and development of a comprehensive database containing information pertinent to describing and managing toxic hot spots. The long-term activities include development of numeric sediment quality objectives; development and implementation of strategies to prevent the formation of new toxic hot spots and to reduce the severity of effects from existing toxic hot spots; revision of water quality control plans, cleanup plans, and monitoring programs; and maintenance of the comprehensive database.

Actual field and laboratory work is performed under contract by the California Department of Fish and Game (CDFG). The CDFG subcontracts the toxicity testing to Dr. Ron Tjeerdema at the University of California at Santa Cruz (UCSC) and the laboratory testing is performed at the CDFG toxicity testing laboratory at Granite Canyon, south of Carmel. The CDFG contracts the majority of the sample collection activities to Dr. John Oliver of San Jose State University at the Moss Landing Marine Laboratories (MLML) in Moss Landing. Dr. Oliver also is subcontracted to perform the TOC and grain size analyses, as well as to perform the benthic community analyses. CDFG personnel perform the trace metals analyses at the trace metals facility at Moss Landing Marine Laboratories in Moss Landing. The synthetic organic pesticides, PAHs and PCBs are contracted by CDFG to Dr. Ron Tjeerdema at the UCSC trace organics facility at Long Marine Laboratory in Santa Cruz. MLML currently maintains the Bay Protection and Toxic Cleanup Database for the SWRCB. Described below is a description of that database system.

II. DESCRIPTION OF COMPUTER FILES

The sample collection/field information, chemical, and toxicity data are stored on hard copy, computer disks and on a 486DX PC at Moss Landing Marine Laboratories. Access is limited to Russell Fairey. Contact Russell Fairey at (408) 633-6035 for copies of data. The data are stored in a dBase 4 program and can be exported to a variety of formats. There are three backups of this database stored in two different laboratories. The data are entered into 1 of 2 files. REG9CHEM.DBF file contains all the collection and chemical data. REG9TOX.DBF file contains all the collection and toxicity test data. A hardcopy printout of the dBase database structure is attached, showing precise characteristics of each field.

The REG9CHEM.DBF file is the chemistry data file which contains the following fields (the number at the start of each field is the field number):

1. STANUM. This numeric field is 7 characters wide with 1 decimal place and contains the CDFG station numbers that are used statewide. The format is YXXXX.Z where Y is the Regional Water Quality Control Board Region number and XXXX is the number that corresponds to a given location or site and Z is the number of the station within that site. An example is West Basin in San Diego Harbor where the STANUM is 90050.0. The 9 indicates Region 9. The 0050 indicates that it is Site 50 and the .0 is the replicate (if any) at the station within Site 50.

2. STATION. This character field is 30 characters wide and contains the exact name of the station.

3. IDORG. This numeric field is 8 characters wide and contains the unique i.d. organizational number for the sample. For each station collected on a unique date, an idorg sample number is assigned. This should be the field that links the collection, toxicity, chemical, and other data bases.

4. DATE. This date field is 8 characters long and is the date that each sample was collected in the field. It is listed as MM/DD/YY.

5. LEG. This numeric field is 6 characters wide and is the leg number of the project in which the sample was collected.

6. LATITUDE. This character field is 12 characters wide and contains the latitude of the center of the station sampled. The format is a character field as follows: XX,YY,ZZ, where XX is in degrees, YY is in minutes, and ZZ is in seconds or hundreds.

7. LONGITUDE. This character field is 14 characters wide and contains the longitude of the center of the station sampled. The format is a character field as follows: XX,YY,ZZ, where XXX is in degrees, YY is in minutes, and ZZ is in seconds or hundreds.

8. GISLAT. This numeric field is 12 characters wide with 8 decimal places and contains the latitude of the station sampled in Geographical Information System format. The format is a numeric field as follows: XX.YYYYYYYY, where XX is in degrees and YYYYYYYY is a decimal fraction of the preceding degree.

9. GISLONG. This character field is 14 characters wide with 8 decimal places and contains the longitude of the station sampled. The format is a character field as follows: XXXX.YYYYYYYY where XXXX is in degrees and YYYYYYYY is a decimal fraction of the preceding degree.

10. HUND_SECS. This character is 1 character wide and contains the designation "h" if the latitude and longitude are

given in degrees, minutes and hundredths of a minute. The designation "s" is given when latitude and longitude are given in degrees, minutes and seconds.

11. DEPTH. This character field is 4 characters wide and contains the depth at which the sediment sample was collected, in meters to the nearest one half meter.

12. METADATA. This is an index directing the user to tables or files of ancillary data pertinent to associated test. Character field, width 12.

TRACE METALS IN SEDIMENT are presented in fields 13 through 32. All sediment trace metal results are reported on a dry weight basis in parts per million (ppm).

A. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed.
B. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected.

Sediment trace metals are numeric fields of varying character width, and including the following elements, listed by field number, then field name as it appears in the database, then numeric character width and number of decimal places:

13. TMMOIST. 6.2
14. ALUMINUM. 9.2
15. ANTIMONY. 7.3
16. ARSENIC. 6.3
17. CADMIUM. 7.4
18. CHROMIUM. 8.3
19. COPPER. 7.2
20. IRON. 7.1
21. LEAD. 6.3
22. MANGANESE. 7.2
23. MERCURY. 7.4
24. NICKEL. 7.3
25. SILVER. 7.4
26. SELENIUM. 6.3
27. TIN. 8.4
28. ZINC. 9.4
29. ASBATCH. 5.1
30. SEBATCH. 5.1
31. TMBATCH. The Batch number that the sample was digested in, numeric character width 5 and 1 decimal places.
32. TMDATAQC. Data qualifier codes are notations used by data reviewers to briefly describe, or qualify data and the systems producing data, numeric character width 3. Data qualifier codes are as follows:

A. When the sample meets or exceeds the control criteria requirements, the value is reported as "-4".
B. When the sample has minor exceedances of control criteria

but is generally usable for most assessments and reporting purposes, the value is reported as "-5". For samples coded "-5" it is recommended that if assessments are made that are especially sensitive or critical, QA evaluations should be consulted before using the data.

C. When QA samples have major exceedances of control criteria requirements and the data are not usable for most assessments and reporting purposes, the value is reported as "-6".
D. When the sample has minor exceedances of control criteriaand is unlikely to affect assessments, the value is reported as -3.

SYNTHETIC ORGANICS are presented in fields 33 through 147. All synthetic organic results are reported on a dry weight basis in parts per billion (ppb or ng/g).

A. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed.
B. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected.

Synthetic organics are reported on a dry weight basis in parts per billion (ppb or ng/g) and are numeric fields of varying character width, and include the following compounds, listed by field number, then field name as it appears in database (and followed by the compound name if not obvious), and then finally, the numeric character width and number of decimal places is given:

33. SOWEIGHT. This numeric field is 6 characters wide with 2 decimal places and contains the weight of the sample extracted for analysis.
34. SOMOIST. This numeric field is 6 characters wide with 2 decimal places and contains the percent moisture of the sample extracted.
35. ALDRIN. 9.3
36. CCHLOR. cis-Chlordane. 9.3
37. TCHLOR. trans-Chlordane. 9.3
38. ACDEN. alpha-Chlordene. 9.3
39. GCDEN. gamma-Chlordene. 9.3
40. CLPYR. Chlorpyrifos. 8.2
41. DACTH. Dacthal. 9.3
42. OPDDD. o,p'-DDD. 8.2
43. PPDDD. p,p'-DDD. 9.3
44. OPDDE. o,p'-DDE. 8.2

145. PAHBATCH. The batch number that the sample was extracted in, numeric character width 6 and 2 decimal places.
146. SOBATCH. The batch number that the sample was extracted in, numeric character width 6 and 2 decimal places.
147. SODATAQA. Data qualifier codes are notations used by data reviewers to briefly describe, or qualify data and the systems producing data, numeric character width 3. Data qualifier codes are as follows:

A. When the sample meets or exceeds the control criteria requirements, the value is reported as "-4".

B. When the sample has minor exceedances of control criteria but is generally usable for most assessments and reporting purposes, the value is reported as "-5". For samples coded "-5" it is recommended that if assessments are made that are especially sensitive or critical, the QA evaluations should be consulted before using the data.

C. When QA samples have major exceedances of control criteria requirements and the data are not usable for most assessments and

reporting purposes, the value is reported as "-6".
D. When the sample has minor exceedances of control criteria and is unlikely to affect assessments, the value is reported as -3.

SEDIMENT PARTICULATE SIZE ANALYSES DATA. Field 148, with a field name of "FINES", represents the sediment particulate size ("grain size") analyses data for each station. The grain size results are reported as percent fines.

148. FINES. Sediment grain size (percent fines) for each station. Numeric field, width 5 and 2 decimal places.
A. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed.
B. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected.
149. FINEBATCH. The batch number that the sample was analyzed in, numeric field character width 4.
150. FINEDATAQC. Data qualifier codes are notations used by data reviewers to briefly describe, or qualify data and the systems producing data, numeric character width 3. Data qualifier codes are as follows:
A. When the sample meets or exceeds the control criteria requirements, the value is reported as "-4".
B. When the sample has minor exceedances of control criteria but is generally usable for most assessments and reporting purposes, the value is reported as "-5". For samples coded "-5" it is recommended that if assessments are made that are especially sensitive or critical, QA evaluations should be consulted before using the data.
C. When QA samples have major exceedances of control criteria requirements and the data are not usable for most assessments and reporting purposes, the value is reported as "-6".
D. When the sample has minor exceedances of control criteria and is unlikely to affect assessments, the value is reported as -3.

SEDIMENT TOTAL ORGANIC CARBON (TOC) ANALYSES DATA. Field 151 presents the levels of total organic carbon detected in the sediment samples at each station. All TOC results are reported as percent of dry weight.

151. TOC. Total Organic Carbon (TOC) levels (percent of dry weight) in sediment, for each station. Numeric field, width 6 and 2 decimal places.
A. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed.
B. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected.
152. TOCBATCH. The batch number that the sample was analyzed in, numeric field character width 4.
153. TOCDATAQC. Data qualifier codes are notations used by data reviewers to briefly describe, or qualify data and the systems producing data, numeric character width 3. Data qualifier codes are as follows:
A. When the sample meets or exceeds the control criteria

requirements, the value is reported as "-4".

B. When the sample has minor exceedances of control criteria but is generally usable for most assessments and reporting purposes, the value is reported as "-5". For samples coded "-5" it is recommended that if assessments are made that are especially sensitive or critical, the QA evaluations should be consulted before using the data.

C. When QA samples have major exceedances of control criteria requirements and the data are not usable for most assessments and reporting purposes, the value is reported as "-6".

D. When the sample has minor exceedances of control criteria and is unlikely to affect assessments, the value is reported as -3.

The REG9TOX.DBF file is the toxicity data file which contains the following fields (the number at the start of each field is the field number:

1. STANUM. This numeric field is 7 characters wide with 1 decimal place and contains the CDFG station numbers that are used statewide. The format is YXXXX.Z where Y is the Regional Water Quality Control Board Region number and XXXX is the number that corresponds to a given location or site and Z is the number of the station within that site. An example is West Basin in San Diego Harbor where the STANUM is 90050.0. The 9 indicates Region 9. The 0050 indicates that it is Site 50 and the .0 is the replicate (if any) at the station within Site 50.
2. STATION. This character field is 30 characters wide and contains the exact name of the station.
3. IDORG. This numeric field is 8 characters wide with 1 decimal place and contains the unique i.d. organizational number for the sample. For each station collected on a unique date, an idorg sample number is assigned. This should be the field that links the collection, toxicity, chemical, and other data bases.
4. DATE. This date field is 8 characters long and is the date that each sample was collected in the field. It is listed as MM/DD/YY.
5. LEG. This numeric field is 6 characters wide and is the leg number of the project in which the sample was collected.
6. TYPE. This character field is 7 characters wide and describes whether the sample was a field sample, replicate or control.
7. METADATA. This is an index directing the user to tables or files of ancillary data pertinent to associated test. Character field, width 12.
8. CTRL. This character field is 5 characters wide and describes the type of control being used.
9. LATITUDE. This character field is 12 characters wide and contains the latitude of the center of the station sampled. The format is a character field as follows: XX,YY,ZZ, where XX is in degrees, YY is in minutes, and ZZ is in seconds or hundreds.
10. LONGITUDE. This character field is 14 characters wide and contains the longitude of the center of the station sampled. The format is a character field as follows: XX,YY,ZZ, where XXX is in degrees, YY is in minutes, and ZZ is in seconds or hundreds.
11. GISLAT. This numeric field is 12 characters wide with 8 decimal places and contains the latitude of the station sampled

in Geographical Information System format. The format is a numeric field as follows: XX.YYYYYYYY, where XX is in degrees and YYYYYYYY is a decimal fraction of the preceding degree.

12. GISLONG. This character field is 14 characters wide with 8 decimal places and contains the longitude of the station sampled. The format is a character field as follows: XXXX.YYYYYYYY where XXXX is in degrees and YYYYYYYY is a decimal fraction of the preceding degree.

AMPHIPOD SURVIVAL TOXICITY TEST DATA. The following are descriptions of the field headings for the amphipod (Rhepoxynius abronius (RA), presented in fields 13 through 24.

13. RA_MN. Station mean percent survival. Numeric field, width 6 and 2 decimal places.
14. RA_SD. Station standard deviation of percent survival. Numeric field, width 6 and 2 decimal places.
15. RA_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
16. RASITE_MN. Station mean percent survival for replicate of three, when appropriate. Numeric field, width 6 and 2 decimal places.
17. RASITE_SD. Station standard deviation of percent survival for replicate of three, when appropriate. Numeric field, width 6 and 2 decimal places.
18. RASITE_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
19. RA_OTNH3. Total ammonia concentration (mg/L in water) in overlying water (water above bedded sediment used for amphipod tests) for each station analyzed using amphipod toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 7 and 3 decimal places.
20. RA_OUNH3. Unionized ammonia concentration (mg/L in water) in overlying water (water above bedded sediment used for amphipod tests) for each station analyzed using amphipod toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 7 and 3 decimal places.
21. RA_OH2S. Hydrogen sulfide concentration (mg/L in water) in overlying water (water above bedded sediment used for amphipod tests) for each station analyzed using amphipod toxicity tests. When the value is

missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 7 and 4 decimal places.

22. RA_ITNH3. Total ammonia concentration (mg/L in water) in interstitial water (water above bedded sediment used for amphipod tests) for each station analyzed using amphipod toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 10 and 3 decimal places.

23. RA_IUNH3. Unionized ammonia concentration (mg/L in water) interstitial water (water within bedded sediment used for amphipod tests) for each station analyzed using amphipod toxicity tests. When the value is missing or not analyzed, the value is reported as "9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 10 and 3 decimal places.

24. RA_IH2S. Hydrogen sulfide concentration (mg/L in water) in interstitial water (water within bedded sediment used for amphipod tests) for each station analyzed using amphipod toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 10 and 4 decimal places.

25. RABATCH. The batch number that the sample were run in, numeric character width 10.

26. RADATAQC. Data qualifier codes are notations used by data reviewers to briefly describe, or qualify data and the systems producing data, numeric character width 4. Data qualifier codes are as follows:

A. When the sample meets or exceeds the control criteria requirements, the value is reported as "-4".

B. When the sample has minor exceedances of control criteria but is generally usable for most assessments and reporting purposes, the value is reported as "-5". For samples coded "-5" it is recommended that if assessments are made that are especially sensitive or critical, the QA evaluations should be consulted before using the data.

C. When the QA sample has major exceedances of control criteria requirements and the data is not usable for most assessments and reporting purposes, the value is reported as "-6".

D. When the sample has minor exceedances of control criteria and is unlikely to affect assessments, the value is reported as -3.

ABALONE LARVAL SHELL DEVELOPMENT TOXICITY TEST DATA. The following are descriptions of the field headings for the larval (Haliotis rufescens) shell development toxicity tests, presented in fields 27 through 30. Results are given for undiluted

subsurface water (100%).

27. HRS100_MN. Station mean percent normal development in 100% subsurface water. Numeric field, width 6 and 2 decimal places.
28. HRS100_SD. Station standard deviation of percent normal development in 100% subsurface water. Numeric field, width 6 and 2 decimal places.
29. HRS100_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
30. HRS100_NH3. Unionized ammonia concentration (mg/L in water) in subsurface water for each station analyzed in abalone toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 6 and 3 decimal places.

The following are descriptions of the field headings for the sea urchin (Strongylocentrotus purpuratus) fertilization toxicity tests, presented in fields 31 through 41. Results are given for undiluted pore water (100% pore water), pore water that is diluted with Granite Canyon seawater to a 50% of original concentration (50% pore water), and pore water that is diluted with Granite Canyon seawater to a 25% of original concentration (25% pore water).

31. SPPF100_MN. Station mean percent fertilization in 100% pore water. Numeric field, width 6 and 2 decimal places.
32. SPPF100_SD.Station standard deviation of percent fertilization in 100% pore water. Numeric field, width 6 and 2 decimal places.
33. SPPF100_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
34. SPPF100NH3. Unionized ammonia concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 7 and 3 decimal places.
35. SPPF100H2S. Hydrogen sulfide concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0"= not detected. Numeric field,

width 7 and 4 decimal places.

36. SPPF50_MN. Station mean percent fertilization in 50% pore water. Numeric field, width 6 and 2 decimal places.
37. SPPF50_SD. Station standard deviation of % fertilization in 50% pore water. Numeric field, width 6 and 2 decimal places.
38. SPPF50_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
39. SPPF25_MN. Station mean percent fertilization in 25% pore water. Numeric field, width 6 and 2 decimal places.
40. SPPF25_SD. Station standard deviation of percent fertilization in 25% pore water. Numeric field, width 6 and 2 decimal places.
41. SPPF25_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.

The following are descriptions of the field headings for the sea urchin embryo (Strongylocentrotus purpuratus) development tests, presented in fields 42 through 54. Results are given for undiluted pore water (100% pore water), pore water that is diluted with Granite Canyon seawater to a 50% of original concentration (50% pore water), and porewater that is diluted with Granite Canyon seawater to a 25% of original concentration (25% pore water).

42. SPPD100_MN. Station mean percent normal development in 100% pore water. Numeric field, width 6 and 2 decimal places.
43. SPPD100_SD. Station standard deviation of percent normal development in 100% pore water. Numeric field, width 6 and 2 decimal places.
44. SPPD100_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
45. SPPD100NH3. Unionized ammonia concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 7 and 3 decimal places.
46. SPPD100H2S. Hydrogen sulfide concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-

9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0"= not detected. Numeric field, width 7 and 4 decimal places.

47. SPPD50_MN. Station mean percent normal development in 50% pore water. Numeric field, width 6 and 2 decimal places.
48. SPPD50_SD. Station standard deviation of percent normal development in 50% pore water. Numeric field, width 6 and 2 decimal places.
49. SPPD50_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
50. SPPD25_MN. Station mean percent normal development in 25% pore water. Numeric field, width 6 and 2 decimal places.
51. SPPD25_SD. Station standard deviation of percent normal development in 25% pore water. Numeric field, width 6 and 2 decimal places.
52. SPPD25_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
53. SPPDBATCH. The batch number that the samples were analyzed in, numeric character width 10.
54. SPPDQC. Data qualifier codes are notations used by data reviewers to briefly describe, or qualify data and the systems producing data, numeric character width 3. Data qualifier codes are as follows:
    A. When the sample meets or exceeds the control criteria requirements, the value is reported as "-4".
    B. When the sample has minor exceedances of control criteria but is generally usable for most assessments and reporting purposes, the value is reported as "-5". For samples coded "-5" it is recommended that if assessments are made that are especially sensitive or critical, the QA evaluations should be consulted before using the data.
    C. When the QA sample has major exceedances of control criteria requirements and the data is not usable for most assessments and reporting purposes, the value is reported as "-6".
    D. When the sample has minor exceedances of control criteria and is unlikely to affect assessments, the value is reported as -3.

The following are descriptions of the field headings for the sea urchin embryo (Strongylocentrotus purpuratus) cytogenetic tests, presented in fields 55 through 59. Results are given for undiluted pore water (100% pore water).

55. SPPC100_MN. Station mean percent normal mitosis in

100% pore water. Numeric field, width 6 and 2 decimal places.

56. SPPC100_SD. Station standard deviation of percent normal mitosis in 100% pore water. Numeric field, width 6 and 2 decimal places.
57. SPPC100_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 6.
58. SPPC100NH3. Unionized ammonia concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 6 and 3 decimal places.
59. SPPC100H2S. Hydrogen sulfide concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0"= not detected. Numeric field, width 7 and 4 decimal places.

MUSSEL LARVAL SHELL DEVELOPMENT TOXICITY TEST DATA. The following are descriptions of the field headings for the larval (Mytilus edulis) shell development toxicity tests, presented in fields 60 through 63. Results are given for undiluted subsurface water (100%).

60. MES100_MN. Station mean percent normal development in 100% subsurface water. Numeric field, width 6 and 2 decimal places.
61. MES100_SD. Station standard deviation of percent normal development in 100% subsurface water. Numeric field, width 6 and 2 decimal places.
62. MES100_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
63. MES100_NH3. Unionized ammonia concentration (mg/L in water) in subsurface water. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 6 and 3 decimal places.

The following are descriptions of the field headings for the larval (Mytilus edulis) shell development toxicity tests, presented in fields 64 through 68. Results are given for undiluted pore water (100% pore water).

64. MEP100_MN. Station mean percent normal development in 100% pore water. Numeric field, width 6 and 2 decimal places.
65. MEP100_SD. Station standard deviation of percent normal development in 100% pore water. Numeric field, width 6 and 2 decimal places.
66. MEP100_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.
67. MEP100_NH3. Unionized ammonia concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 6 and 3 decimal places.
68. MEP100_H2S. Hydrogen sulfide concentration (mg/L in water) in pore water samples (100%). When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0"= not detected. Numeric field, width 7 and 4 decimal places.

POLYCHAETE SURVIVAL TOXICITY TEST DATA. The following are descriptions of the field headings for the polychaete worm (Neanthes arenaceodentata) survival toxicity tests, presented in fields 69 through 71.

69. NASURV_MN. Station mean percent survival. Numeric field, width 6 and 2 decimal places.
70. NASURV_SD. Station standard deviation of % survival. Numeric field, width 6 and 2 decimal places.
71. NASURV_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not statistically significant. Character field, width 5.

POLYCHAETE WEIGHT TOXICITY TEST DATA. The following are descriptions of the field headings for the polychaete worm (Neanthes arenaceodentata) weight toxicity tests, presented in fields 72 through 80.

72. NAWT_MN. Station mean weight (gm). Numeric field, width 6 and 2 decimal places.
73. NAWT_SD. Station standard deviation of weight (gm). Numeric field, width 6 and 2 decimal places.
74. NAWT_SG. Station statistical significance, representing the significance of the statistical test between the home sediment and the sample. A single * represents significance at the .05 level, and double ** represents significance at the .01 level. ns = not

statistically significant. Character field, width 5.

75. NA_OTNH3. Total ammonia concentration (mg/L in water) in overlying water (water above bedded sediment used for polychaete tests) for each station analyzed using polychaete toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 7 and 3 decimal places.
76. NA_OUNH3. Unionized ammonia concentration (mg/L in water) in overlying water (water above bedded sediment used for polychaete tests) for each station analyzed using polychaete toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 7 and 3 decimal places.
77. NA_OH2S. Hydrogen sulfide concentration (mg/L in water) in overlying water (water above bedded sediment used for polychaete tests) for each station analyzed using polychaete toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 9 and 4 decimal places.
78. NA_ITNH3. Total ammonia concentration (mg/L in water) in interstitial water (water above bedded sediment used for polychaete tests) for each station analyzed using polychaete toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 9 and 3 decimal places.
79. NA_IUNH3. Unionized ammonia concentration (mg/L in water) in interstitial water (water within bedded sediment used for polychaete tests) for each station analyzed using polychaete toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 9 and 3 decimal places.
80. NA_IH2S. Hydrogen sulfide concentration (mg/L in water) in interstitial water (water within bedded sediment used for amphipod tests) for each station analyzed using amphipod toxicity tests. When the value is missing or not analyzed, the value is reported as "-9.0" = not analyzed. When the value is less than the detection limit of the analytical test, the value is reported as "-8.0" = not detected. Numeric field, width 9 and 4 decimal places.

CHEMICAL SUMMATIONS AND QUOTIENTS

In the following section, chemical summations (total chlordane, total DDT, total PCBs, LMW PAHs, HMW PAHs, total PAHs) and quotients (ERM and PEL) are presented. Beginning with samples collected during Leg 20 (June, 1993), additional analytes were added to the standard BPTCP synthetic organic analyte list. These additions were made to enable the data set to be more comparable with other monitoring programs. This included addition of analytes used for some of the chemical summations of the PAHs and total chlordane. Resulting summations may be conservative for the PAH and chlordane data for samples taken before Leg 20, because some of the constituents could not be included.

For purposes of these summations, samples which were found to have chemical concentrations less than the method detection limit (-8 in Appendix A) were adjusted to a value of one-half of the method detection limits given in the methods description. The summations were calculated as follows:

Total chlordane

Leg<15 (TTL_CHLR) = $\sum$ ([cis-Chlordane] [trans-Nonachlor])

Leg=15 (TTL_CHLR) = $\sum$ ([cis-Chlordane] [trans-Chlordane])

Leg>15 (TTL_CHLR) = $\sum$ ([cis-Chlordane] [trans-Chlordane] [cis-Nonachlor] [trans-Nonachlor] [Oxychlordane])

Total DDT

All Legs (TTL_DDT) = $\sum$ ([o',p' DDD] [p',p' DDD] [o',p' DDE] [p',p' DDE] [o',p' DDT] [p',p' DDT])

Total PCB

All Legs (TTL_PCB) = $\sum$ ([PCB8] [PCB18] [PCB28] [PCB44] [PCB52] [PCB66] [PCB101] [PCB105] [PCB118] [PCB128] [PCB138] [PCB153] [PCB170] [PCB180] [PCB187] [PCB195] [PCB206] [PCB209])

Low Molecular Weight PAHs

Leg<16 (LMW_PAH) = $\sum$ ([ACE] [ANT] [BPH] [DMN] [FLU] [MNP1] [MPH1] [PHN])

Leg$\geq$16 (LMW_PAH) = $\sum$ ([ACE] [ACY] [ANT] [BPH] [DMN] [FLU] [MNP1] [MNP2] [MPH1] [NPH] [PHN] [TMN])

High Molecular Weight PAHs

Leg<16 (HMW_PAH) = $\sum$ ([BAA] [BAP] [BEP] [CHR] [DBA] [FLA] [PER] [PYR])

Leg$\geq$16 (HMW_PAH) = $\sum$ ([BAA] [BAP] [BBF] [BKF] [BGP] [BEP] [CHR] [DBA] [FLA] [IND] [PER] [PYR])

Total PAHs

All legs (TTL_PAH) = $\sum$ ([LMW_PAH] [HMW_PAH])

ERM Quotients and PEL Quotients were calculated using summations of the individual chemicals for which ERMs and PELs have been

derived (Table 5). Chemical concentrations are divided by their respective ERM or PEL values to obtain a specific individual chemical quotient (example 1). A value greater than one indicates the chemical concentration in that sample exceeded its respective ERM or PEL. A value of five would indicate the chemical was five times higher than the ERM or PEL in that sample.

example - sample IDORG #199 Copper concentration= 170 mg/g
PEL for copper= 108.2

CopperQ= (170 mg/g) / (108.2 mg/g) = 1.57

Summations and averaging of the individual chemical quotients were calculated to give summary ERM Quotients (ERMQ) and PEL Quotients (PELQ). Each quotient summation is divided by the number of analytes used in the summation (Table 5) to yield an average summary quotient.

Summary ERM Quotient

ERMQ = ((ANTIMONYQ + ARSENICQ + CADMIUMQ + CHROMIUMQ + COPPERQ + LEADQ + MERCURYQ + SILVERQ + ZINCQ + TTL_DDTQ + TTL_CHLRQ + DIELDRINQ + ENDRINQ + TTL_PCBQ + LMW_PAHQ + HMW_PAHQ) / 16)

Summary PEL Quotient

PELQ = ((ARSENICQ + CADMIUMQ + CHROMIUMQ + COPPERQ + LEADQ + MERCURYQ + SILVERQ + ZINCQ + TTL_DDTQ + TTL_CHLRQ + DIELDRINQ + LINDANEQ + TTL_PCBQ + LMW_PAHQ + HMW_PAHQ) / 15)

Description of calculations for cumulative frequency distributions of percent area toxic.

The following identifies and describes each of the spreadsheet columns used to generate cumulative frequency functions for estimates of percent area toxic.

Idorg : lists all samples tested for each toxicity test protocol/pore water dilution.
Block#: lists assigned letter/number code for each area (block) based on EMAP block designations. See Figure 2.
 # samples/block: lists total number of samples collected in given block.
toxic: "1" indicates sample toxicity based on EMAP definition (both significant difference from laboratory control and toxicity value <80% of control value). Blank cell indicates no significant toxicity.
mn as % of control : lists sample toxicity means normalized to percentage of the control value.
Area/block : Area in km2 for block associated with each sample
Area/sample : Area in km2 represented by each sample, calculated as: Block area/number of samples collected in given block.
Area/sample as % of total : Area represented by each sample as a percent of the total area sampled.
Cum area/sample as % of total : Cumulative area per sample as a percent of the total area sampled.
% total area toxic/sample : Area represented by each toxic sample as a percent of the total area.
SUMS : Numbers in this row show column totals. Sum of Area/sample gives total area sampled for a given toxicity test protocol. Sum of % of total area toxic/sample gives the total area defined as toxic for given test protocol /pore water dilution.

Background Information Relevant to the Preparation of this Witness Statement

Nature of the Evidence Given

The evidence provided in the following witness statement consists of both factual and opinion evidence.

Professional Qualifications

The professional experience and educational qualifications which qualify me to give the opinions that I give in this witness statement are set out in my curriculum vitae, which is attached as Appendix 6 of this witness statement. My experience in the field of sediment quality assessment includes:

- Development of an approach to the derivation of Canadian sediment quality guidelines;
- Development of numerical sediment quality assessment guidelines for 34 chemical substances in Florida coastal waters;
- Development of Canadian sediment quality guidelines for freshwater ecosystems;
- Development of Canadian sediment quality guidelines for marine and estuarine ecosystems;
- Participation in the development of numerical sediment quality guidelines for NOAA's National Status and Trends Program;
- Development of procedures for deriving site-specific sediment quality remediation objectives;
- Participation in the development of a sediment toxicity database for evaluating matching sediment chemistry and biological effects data; and,
- Development of Canadian sediment quality guidelines for toxaphene, DDTs, and PCBs.

Conflict of Interest

I have no personal interest in this case other than as a paid consultant to the Respondent. My prior involvement with U.S. government agencies has been as a paid consultant on specific projects related to hazard and environmental assessments. I have had no prior involvement with the issue involving Montrose Chemical Corporation of California and others. My company and I will be paid the same regardless of the outcome of this case.

Documents Used to Prepare Evidence

In preparing this evidence, I have reviewed numerous texts, articles, protocols, and publications relating to the fate and effects of sediment-associated contaminants on aquatic organisms, including those related to the effects of dichlorodiphenyl trichloroethane (DDT) and polychlorinated biphenyls (PCBs).

Executive Summary

A review of the published and unpublished literature was conducted to evaluate the toxic effects of DDTs and PCBs in sediments. The primary objective of this review was to determine sediment effect concentrations (SECs) of DDTs and PCBs in Southern California Bight sediments. The secondary objective of this study was to determine if the concentrations of DDTs and PCBs in the sediments of the Southern California Bight would cause injury to one or more sediment-dwelling species that occur or would be expected to occur in this area. Injurious effects were considered to include any impairments to benthic habitats caused by DDTs or PCBs acting alone, or in any combination with other contaminants (for further information see glossary; Appendix 1).

In this review, DDTs were defined as *p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *o,p'*-DDE, *p,p'*-DDD, *o,p'*-DDD, and any metabolite or degradation product of these chemicals. The term "PCBs" is defined as all of the polychlorinated biphenyls found in Southern California Bight, plus the degradation products and metabolites of these chemicals (for further information see glossary; Appendix 1).

A tiered strategy was used to derive SECs for DDTs and PCBs in the Southern California Bight. This strategy relied preferentially on data from controlled laboratory studies to establish SECs for these substances (i.e., SECs were derived using the spiked-sediment bioassay approach; SSBA). Information from field studies and other sources were utilized when acceptable data from spiked-sediment bioassays were not available (i.e., SECs were derived using the weight-of evidence approach; WEA). These two approaches were considered to be complementary because cause-and-effect relationships between contaminant concentrations and toxic effects can be established from controlled laboratory experiments. While it is difficult to definitively identify the causes of toxic effects in field studies, SECs derived using the weight-of evidence approach may be more reliable than the SSBA because they reflect the toxicity of complex mixtures of contaminants. This is important in the Southern California Bight because DDTs, PCBs, and other substances occur in complex mixtures.

The SECs developed in this review were evaluated to determine their reliability and predictability. Reliability was evaluated to determine if the SECs accurately identified the concentrations of DDTs and PCBs that are likely to be associated with toxic effects in sediments from the Southern California Bight. The predictability of the SECs was evaluated to determine if information on the

concentrations of DDTs and PBs could be used to accurately predict toxic effects in sediments from elsewhere in the United States (i.e., outside the Southern California Bight). The reliability and predictability of several other concentrations of these substances were also evaluated to provide a basis of comparison with the SECs.

The potential for observing toxic effects due to DDTs and PCBs in Southern California Bight sediments was determined by comparing measured concentrations in toxic samples to the SECs derived in this study. If a group of substances was present in Southern California Bight sediments at concentrations in excess of the SEC, then that substance or group of substances was considered to have been associated with the observed sediment injury.

The available data on the toxic effects of SUM DDT (*p,p'*-DDT + *o,p'*-DDT), SUM DDE (*p,p'*-DDE + *o,p'*-DDE), SUM DDD (*p,p'*-DDD + *o,p'*-DDD), total DDT (sum of all six DDT compounds), Aroclor 1254, and total PCBs were summarized in this review. These groups of substances were the focus of this review because there was no evidence to suggest that there were significant differences in the toxicity of the o,p'- and p,p'-isomers of DDT, DDE, or DDD. In addition, insufficient toxicological information was available on the o,p'-isomers of DDTs or the individual PCB congeners to derive SECs. Acceptable dose-response data from controlled laboratory studies (i.e., spiked-sediment bioassays on sediment-dwelling arthropod species) were located for SUM DDT and Aroclor 1254. Therefore, the SECs for these groups of substances were derived using the SSBA. The SECs for the other groups of substances were derived using the WEA. The SECs for DDTs and PCBs were calculated using both summarized and unsummarized field data; both values have been reported in this document. The SECs derived for DDTs and PCBs are presented in the following table.

The results of the evaluations of reliability and predictability indicate that a high degree of confidence can be placed on the SECs that were derived in this study. Importantly, the dry weight-normalized SECs for all six groups of substances (SUM DDT, SUM DDE, SUM DDD, tDDT, Aroclor 1254, and tPCB) were considered to be reliable. That is, the SECs can be used to accurately classify, as toxic or non-toxic, sediments from the Southern California Bight. The SECs for SUM DDT, SUM DDD, tDDTs, and tPCBs were all highly predictive (i.e., predictability >80%); insufficient data were available to evaluate the predictability of the SECs for SUM DDE and Aroclor 1254. Therefore, most of the SECs can be used to accurately classify sediments from elsewhere in the United States. The agreement between the results of the reliability and predictability evaluations

increase the confidence that can be placed on the SECs. Higher reliability (i.e., 85%) and similar predictability (82%) were obtained for a somewhat higher SEC for SUM DDT (i.e., 0.06 mg/kg DW). A lower SEC for Aroclor 1254 (i.e., 0.4 mg/kg DW) would have been just as reliable (i.e., 95%) and could be used to classify more sediment samples from the Southern California Bight.

The results of these evaluations indicate that the organic carbon-normalized SECs are also reliable. The incidence of toxicity was ≥ 80% when any of these SECs were equalled or exceeded in sediments from the Southern California Bight, which indicates that the SECs provide effective tools for classifying sediments from this geographic area. Most of the SECs can also be used to accurately classify sediments from elsewhere in the United States. The predictability of the SECs for SUM DDT, tDDTs, and tPCBs ranged between 82% and 100%. Lower predictability (71%) was observed for the SEC for SUM DDD; a higher SEC (0.40 mg/kg $DW_{1\%OC}$) would have been more predictive of toxicity in the independent data set (i.e., 100% predictability). Insufficient data were available to evaluate the predictability of the SECs for SUM DDE and Aroclor 1254, indicating the concentrations of these substances tend to be much lower elsewhere in the United States than they are in the Southern California Bight. The general agreement between the results of the reliability and predictability evaluations increases the confidence that can be placed on the SECs.

Based on a review of the existing information, it was concluded that the concentrations of DDTs and PCBs in the sediments of the Southern California Bight were sufficient to cause injury to sediment-dwelling organisms. While much of the information reviewed was from studies conducted in the 1970's and 1980's, the most recent data examined indicate that the concentrations of SUM DDT, SUM DDE, SUM DDD, tDDT, and tPCB in surficial sediments (0 to 2 cm) exceeded the SECs derived in this study at many sites (Bay *et al.* 1994; Sapudar *et al.* 1994; Fairey *et al.* 1996; Fairey 1997). Higher concentrations of these groups of substances were observed in deeper sediments (e.g., 7.5 to 47.5 cm) collected from the Palos Verdes Shelf in 1985 (Swartz *et al.* 1991); the concentrations of Aroclor 1254 in deeper sediments exceeded the SEC derived in this study. The majority of the samples that exceeded the SECs were also toxic, considering amphipod survival, amphipod abundance, or the sea urchin fertilization. These data indicate that the concentrations of DDTs and PCBs in the Southern California Bight were sufficient to cause injury to sediment-dwelling organisms.

A summary of the sediment effect concentrations (SECs) for DDTs and PCBs in in the Southern California Bight.

Substance	Sediment Effect Concentration	Reliability	Predictability
SUM DDT	0.031 mg/kg DW	76%	82%
	0.06 mg/kg DW	**85%**	**82%**
	0.111 mg/kg DW (1%OC)	**91%**	**82%**
	0.333 mg/kg DW (3% OC)	91%	82%
	0.555 mg/kg DW (5% OC)	91%	82%
SUM DDE	***6.58 mg/kg DW***	**97%**	**NA**
	1.58 mg/kg DW (1% OC)	**87%**	**NA**
	4.74 mg/kg DW (3% OC)	87%	NA
	7.90 mg/kg DW (5% OC)	87%	NA
SUM DDD	***0.89 mg/kg DW***	**95%**	**83%**
	0.23 mg/kg DW (1% OC)	91%	71%
	0.40 mg/kg DW (1% OC)	**95%**	**100%**
	1.20 mg/kg DW (3% OC)	95%	100%
	2.00 mg/kg DW (5% OC)	95%	100%
tDDT	***7.15 mg/kg DW***	**95%**	**100%**
	2.00 mg/kg DW (1% OC)	**82%**	**100%**
	6.00 mg/kg DW (3% OC)	82%	100%
	10.0 mg/kg DW (5% OC)	82%	100%
Aroclor 1254	***0.4 mg/kg DW***	**95%**	**33%**
	2.1 mg/kg DW	93%	NA
	0.20 mg/kg DW (1% OC)	**95%**	**25%**
	1.08 mg/kg DW (1% OC)	100%	NA
	0.60 mg/kg DW (3% OC)	95%	25%
	1.00 mg/kg DW (5% OC)	95%	25%
tPCB	***0.835 mg/kg DW***	**87%**	**98%**
	0.577 mg/kg DW (1% OC)	**80%**	**100%**
	1.73 mg/kg DW (3% OC)	80%	100%
	5.40 mg/kg DW (5% OC)	80%	100%

The most highly recommended SECs are shown in bold italics..
NA - Insufficient data available to evaluate predictability.

Sediment Injury in the Southern California Bight: Review of the Toxic Effects of DDTs in Sediments

1.0 Introduction

Bed sediments in the Southern California Bight are known to be contaminated by a variety of toxic and bioaccumulative substances (Word and Mearns 1979; Swartz *et al.* 1986; Mearns *et al.* 1991). Specifically, bed sediments on the Palos Verdes Shelf and elsewhere in the Bight have been contaminated by DDTs and PCBs, primarily as a result of discharges from the Whites Point sewage outfall (Mearns *et al.* 1991). These contaminants in the sediments of the Southern California Bight represent a significant environmental concern because:

(i) bed sediments provide essential and productive habitats for communities of benthic and epibenthic (for further information see glossary; Appendix 1) organisms;

(ii) sediment-dwelling biota are important elements of coastal ecosystems; and,

(iii) the presence of elevated concentrations of-sediment-associated contaminants, specifically DDTs and PCBs, could be harmful to sediment-dwelling organisms.

The purpose of this witness statement is to conduct a review of the toxic effects of DDTs and PCBs in sediments. In this review, the term "DDTs" is defined as *p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *o,p'*-DDE, *p,p'*-DDD, *o,p'*-DDD, and any metabolite or degradation product of these chemicals. The term "PCBs" is defined as all of the polychlorinated biphenyls found in Southern California Bight, plus the degradation products and metabolites of these chemicals. The primary objectives of this witness statement are:

(i) to review the published literature and other existing information on the effects of sediment-associated DDTs and PCBs;

(ii) to determine sediment effect concentrations (SECs) of DDTs and PCBs in Southern California Bight sediments; and,

(iii) to determine if DDTs and/or PCBs occur in the sediments of the Southern California Bight at concentrations that are sufficient to cause injury to one or more sediment-dwelling species that occur or would be expected to occur in this area.

In this study, SECs are defined as the concentrations of DDTs and PCBs in bed sediments that would be sufficient to cause injury to sediment-dwelling organisms (including infaunal and epibenthic organisms). Injurious effects were considered to include any impairments to benthic organisms and habitats caused by DDTs or PCBs acting alone or in any combination with other contaminants. Such impairments to sediment-dwelling organisms and benthic habitats were considered to be indicated by:

(i) acute or chronic mortality;

(ii) reduced growth;

(iii) impaired reproduction;

(iv) abnormal development;

(v) increased incidence of tumours or pre-cancerous lesions;

(vi) altered organ morphology or size;

(vii) avoidance behavior; or,

(viii) altered benthic invertebrate community structure.

The SECs derived in this study do not consider the potential effects of sediment-associated contaminants on fish or other species that reside in the water column. In addition, the SECs do not consider the potential for bioaccumulation in marine organisms nor the potential effects that could occur throughout the food web as a result of the bioaccumulation of these substances.

The SECs reported in this document may be used to determine the areal extent of sediment injury in the Southern California Bight. In addition, these SECs may be used as a scientific basis for establishing target clean-up levels for DDTs and PCBs in bed sediments, if the results of a damage assessment indicate the need for sediment remediation. **However, the sediment effect concentrations represent the concentrations of DDTs and PCBs at which adverse biological effects have been demonstrated in laboratory and/or field studies; therefore, target clean-up levels would have to be lower to ensure that bed sediments would support healthy and diverse populations of sediment-dwelling organisms.**

1.1 Glossaries of Terms and Acronyms

Many of the terms and acronyms used in this review may not be familiar to the reader. For this reason, glossaries of terms and acronyms have been included to facilitate interpretation of the information presented in this review (see Appendices 1 and 2). In addition, the following table provides a means of quickly converting data between the various units that have been utilized.

Table 1. Conversion factors for standard and scientific units.

Standard Units		Scientific Units
1 part per million (ppm)	=	1 mg/kg, 1 µg/g, 1000 µg/kg
1 part per billion (ppb)	=	1 µg/kg
1 mg/kg OC	=	0.01 mg/kg $DW_{1\%OC}$

2.0 Methods

2.1 Introduction

This review of the toxic effects of DDTs and PCBs in the Southern California Bight consisted of four main steps. First, procedures for deriving sediment effect concentrations (SECs) were selected from the existing approaches that have been established for developing sediment quality guidelines and criteria (for further information see glossary; Appendix 1). Next, the available data on the toxic effects of DDTs and PCBs were collected, evaluated, and compiled. Subsequently, SECs for DDTs and PCBs were derived using the available toxicity data. Finally, the SECs for DDTs and PCBs were evaluated to determine their reliability and predictability. Each of these steps is described in more detail below and in Appendix 3.

2.2 Selection of Procedures for Deriving SECs for DDTs and PCBs in the Southern California Bight

Sediment quality guidelines (SQG) and criteria (SQC) are numerical limits or narrative statements that are recommended to support and maintain the designated uses of an aquatic environment (CCME 1994). In contrast, the SECs derived in this study are intended to identify the concentrations of sediment-associated contaminants that are likely to cause, or to be associated with, adverse effects on sediment-dwelling organisms. While the level of protection afforded to sediment-dwelling organisms differs among the various assessment tools (e.g., SQGs, SQC, SECs, etc.), the general procedures used to derive these values may be similar.

A variety of approaches has been used to derive SQGs for sediment-associated contaminants (for reviews see Beak Consultants Ltd. 1987; 1988; Chapman 1989; Persaud *et al.* 1989; Sediment Criteria Subcommittee 1989; Adams *et al.* 1992; USEPA 1992; MacDonald *et al.* 1992). However, there is no general agreement as to which approach will provide the most reliable, flexible, and credible guidelines for evaluating sediment quality (Long *et al.* 1995a). For this reason, the procedures for deriving SECs were selected by considering both the need for reliable SECs and the availability of data on the toxic effects of DDTs and PCBs. Dose-response data, generated in controlled laboratory studies, provide information that can be used directly to evaluate the toxicity of sediment-associated contaminants; however, only a limited number of such studies (i.e., spiked-sediment bioassays) have been conducted to assess the effects of sediment-

associated DDTs and PCBs on estuarine and marine organisms. To optimize the use of the available information, a tiered strategy was established to develop SECs in DDTs and PCBs in the Southern California Bight. This strategy relies preferentially on the spiked-sediment bioassay approach (SSBA) for deriving SECs, with the weight-of-evidence approach (WEA) utilized when insufficient data are available to support the SSBA.

The information from spiked-sediment bioassays was used preferentially because it provided dose-response data for quantitatively determining the effects of contaminants in sediments. By establishing cause-and-effect relationships between contaminant concentrations and adverse biological effects, spiked-sediment bioassays generate high confidence in the resultant SECs. In addition, data from controlled laboratory studies can provide important information for identifying the sediment characteristics that affect the bioavailability and, hence, toxicity of sediment-associated contaminants (Swartz *et al.* 1990).

The weight-of-evidence approach was also a central component of the tiered strategy for deriving SECs. In contrast to the SSBA, the WEA integrates data on the effects of sediment-associated contaminants from many different sources, mainly from field studies. This is important because the biological effects associated with a chemical substance in the field may be affected by factors such as the occurrence of other contaminants, by the presence of substances or conditions that affect contaminant bioavailability (e.g., organic carbon), or by the nature of the resident biological community. By integrating data on many species, life stages, endpoints, exposure durations, and locations, the weight-of-evidence approach facilitates the development of SECs that are likely to be directly relevant for assessing the potential for observing toxic effects in field-collected sediments.

These two approaches are complementary because they address two major issues associated with the quality of the SECs, precision and reliability. Because the SSBA utilizes data from controlled laboratory studies, it tends to provide precise SECs (i.e., the results of toxicity tests conducted under similar experimental conditions in different laboratories are likely to be similar. Hence, effect concentrations for a specific species and life stage can be defined precisely; Lamberson and Swartz 1992). Because the WEA primarily utilizes data on the toxicity of field-collected sediments and on *in situ* benthic invertebrate community alterations, it tends to provide reliable SECs (i.e., the SECs are likely to correctly predict the toxic effects of chemicals in the field). Correspondence between the SECs derived using these two approaches generates additional confidence in the applicability of the SECs for assessing contaminated sediments.

It should be noted that safety factors (for further information see glossary; Appendix 1) were not applied to the SECs derived using either the spiked-sediment bioassay or weight-of-evidence approaches. Therefore, the SECs derived in this study are not considered to be protective of aquatic life and should not be used as target clean-up levels. Rather, the SECs represent the levels of DDTs and PCBs at which adverse biological effects on sediment-dwelling organisms in the Southern California Bight would be expected to occur. The development of sediment quality remediation objectives (i.e., target clean-up levels) for DDTs and PCBs in the Southern California Bight will require implementation of additional procedures (such as those described by MacDonald and Sobolewski 1993). Sediment quality remediation objectives would, necessarily, be lower than the SECs derived in this review, if they are intended to protect sediment-dwelling organisms.

2.3 Collection, Evaluation, and Compilation of Toxic Effects Data

Information on the toxic effects of DDTs and PCBs was collected in two stages. In the first stage, more than ten bibliographic databases were searched for information relevant to the derivation of SQGs. In addition, over 300 scientists were contacted by telephone or letter to obtain recent or unpublished information. This data collection effort resulted in the identification and retrieval of more that 780 references that, potentially, included information on the toxic effects of sediment-associated contaminants.

In the second stage, several additional bibliographic databases were searched to obtain more recent published information on DDTs and PCBs. These databases included Enviroline, CAS Online, Aquatic Sciences and Fisheries Abstracts, and the National Technical Information Service. Additionally, many researchers active in the sediment quality assessment field were contacted directly to acquire the most recent published and unpublished information on these substances. Several new references were obtained as a result of this ancillary data acquisition effort. The information that was collected during the course of this investigation was considered to provide a comprehensive basis for evaluating the toxic effects of DDTs and PCBs in sediments.

All of the references retrieved during the course of the study were critically reviewed to determine their applicability to the SEC derivation process. The screening criteria used in this data evaluation are described in Appendix 3. Data from the Southern California Bight which met all of the screening criteria were

incorporated into a project database and used to derive the SECs for DDTs and PCBs. Data from other areas that met all but the geographic screening criteria were incorporated into an independent database and used to evaluate the SECs.

2.4 Derivation of the SECs

A tiered strategy was used to develop SECs for DDTs and PCBs for the Southern California Bight. In the first tier of this strategy, SECs were derived using the spiked-sediment bioassay approach (SSBA). The weight-of-evidence approach (WEA) was utilized when a sufficient quantity of acceptable data were not available to support the SSBA. Specifically, SECs were derived as follows (the detailed procedures used to derive the SECs for DDTs and PCBs are described in Appendix 3):

(i) if acceptable data from spiked-sediment bioassays were available on at least one infaunal or epibenthic arthropod species, then the lowest observed effect level (LOEL) for the most sensitive life stage of the most sensitive species was identified and adopted as the SEC; and,

(ii) if acceptable data from spiked-sediment bioassays were not available, then the WEA was used to calculate an effects range-median (ER-M) from the information assembled in each toxicological data set. Both summarized and unsummarized data sets were used to calculate dry weight normalized and organic normalized ER-Ms (see Appendix 3). The lower of the two ER-Ms calculated was adopted as the SEC.

Dose-response data on the most sensitive life stage of the most sensitive species (from controlled laboratory studies) are considered to provide a precise basis for identifying the concentrations of DDTs and PCBs that would be sufficient to cause injury to sediment-dwelling species. However, SECs derived using this approach could underestimate the toxicity of contaminants. Toxicity could be underestimated because the test species and life stages used in bioassays may not fully represent the range of sensitivities of sediment-dwelling organisms in the Southern California Bight. In addition, short-term (acute) toxicity tests which measure mortality as the experimental endpoint may not be as sensitive as longer-term (chronic) tests that consider non-lethal endpoints (e.g., growth and reproduction). Furthermore, the presence of additional contaminants in sediments

Therefore, it is likely that effects on sensitive species in the environment would be observed when SECs, derived using the SSBA, are exceeded in sediments.

The ER-Ms derived using the WEA are considered to provide a reliable basis for identifying the concentrations of DDTs and PCBs that would be sufficient to cause injury to sediment-dwelling species. Effects range-median values often correspond with the results of spiked-sediment bioassays. For example, Long *et al.* (1995a) reported ER-Ms for cadmium, zinc, and fluoranthene of 9.6, 410, and 5.1 mg/kg DW for marine and estuarine ecosystems. By comparison, the 10 day median lethal concentrations (LC_{50}s; for further information see glossary; Appendix 2) of these substances to the amphipod, *Rhepoxynius abronius*, are 6.9 to 11.5 mg/kg DW (Kemp *et al.* 1986; Robinson *et al.* 1988), 276 mg/kg DW (Swartz *et al.* 1988), and 3.3 to 10.5 mg/kg DW (Swartz *et al.* 1987; Swartz *et al.* 1988) for cadmium, zinc, and fluoranthene, respectively. Therefore, effects on sensitive species in the environment are likely to be observed when ER-Ms are exceeded in sediments.

2.5 Evaluation of the SECs

The SECs derived in this study were evaluated in two ways. First, the reliability of the SECs was evaluated, using matching sediment chemistry and biological effects data from Southern California. In this study, reliability is a measure of the ability of the SECs to correctly predict toxic effects in sediments from the Southern California Bight. Second, the predictability of the SECs was evaluated using a series of independent data sets from marine and estuarine sites located elsewhere in the United States (i.e., matching sediment chemistry and biological effects data that were not used to derive the SECs). In this study, predictability is a measure of the ability of the SECs to correctly predict toxic effects in the sediments from outside the Southern California Bight. Together, the determinations of reliability and predictability provide a technical basis for determining the level of confidence that can be placed on the various SECs.

The reliability of the SECs was evaluated using matching sediment chemistry and biological effects data from sites located in the Southern California Bight (i.e., Point Conception to the United States-Mexico border). In the reliability evaluation, the concentrations of DDTs and PCBs in each sediment sample were compared to the SECs. These comparisons formed the basis for the predictions that were made regarding the toxicity of each sediment sample. Sediment samples with concentrations of DDTs and/or PCBs that equaled or exceeded the SECs

were predicted to be toxic. The reliability of the SECs was then evaluated by comparing the predictions with the results of solid phase and porewater toxicity tests and benthic invertebrate community assessments. In the reliability evaluation, the following endpoints were considered to be indicative of toxicity:

- Impaired amphipod survival;
- Impaired sea urchin survival, growth, and reproduction (as indicated by rates of fertilization and normal development);
- Impaired polychaete survival, growth, and reproduction (as indicated by the production of emergent juveniles);
- Impaired sand dollar growth and reproduction (as indicated by the rate of normal development);
- Impaired nematode reproduction (as indicated by population growth); and,
- Altered community composition (as indicated by reduced abundance of sensitive taxa; specifically, amphipods and arthropods).

The reliability of each SEC was calculated as the ratio of the number of samples that were correctly predicted to be toxic and the number of samples that were originally predicted to be toxic (expressed as a percentage; Ingersoll *et al.* 1996). Toxic samples were defined as those for which one or more of the measured endpoints were significantly different from control or reference samples (MacDonald *et al.* 1996). The SECs were considered to be reliable if greater than 75% of the samples that were predicted to be toxic actually were toxic (Long *et al.* In review).

The predictability of the SECs was evaluated using the same procedure that was used to evaluate the reliability of the SECs. In this case, however, an independent data set was used to evaluate the SECs. The independent data set was comprised of matching sediment chemistry and biological effects data from sites located throughout the United States that were not considered during the derivation of the SECs (i.e., outside the Southern California Bight). Data were included in the independent data set if they met all of the screening criteria outlined in Appendix 3 (except the geographic criterion). The independent data used in this evaluation are presented in Appendix 5.

In the predictability evaluation, the concentrations of the concentrations of DDTs and PCBs in each sediment sample were compared to the SECs. These comparisons formed the basis for the predictions that were made regarding the

toxicity of each sediment sample. Sediment samples with concentrations of DDTs and/or PCBs that equaled or exceeded the SECs were predicted to be toxic. The predictability of the SECs was then evaluated by comparing the predictions with the results of solid phase and porewater toxicity tests and benthic invertebrate community assessments. The following endpoints were considered to be indicative of toxicity in the evaluation of predictability:

- Impaired amphipod survival;
- Impaired sea urchin survival, growth, and reproduction (as indicated by rates of fertilization and normal development);
- Impaired polychaete survival, growth, and reproduction (as indicated by the production of emergent juveniles);
- Impaired sand dollar growth and reproduction (as indicated by the rate of normal development);
- Impaired nematode reproduction (as indicated by population growth); and,
- Altered community composition (as indicated by reduced abundance of sensitive taxa; specifically, amphipods and arthropods).

The predictability of each SEC was calculated as the ratio of the number of samples that were correctly predicted to be toxic and the number of samples that were originally predicted to be toxic (expressed as a percentage). In this evaluation, toxic samples were defined as those for which one or more of the measured endpoints were significantly different from control or reference samples (MacDonald *et al.* 1996). The SECs were considered to be predictive if greater than 75% of the samples that were predicted to be toxic actually were toxic (Long *et al.* In review).

The SECs are intended to identify the concentrations of DDTs and PCBs that are likely to be associated with adverse effects on sediment-dwelling organisms in the Southern California Bight. As such, the SECs should be established at levels that maximize the potential for correctly classifying of toxic samples as toxic and minimize the potential for incorrectly classifying non-toxic samples as toxic (i.e., false positives). The criteria for assessing the reliability and predictability of the SECs support this objective by establishing target levels for correct classification and false positives at $\geq$ 75% and $\leq$ 25%, respectively (Long *et al.* 1995a). By comparison, the overall incidence of toxicity in the dependent (i.e., with the Southern California Bight) and the independent (i.e., elsewhere in the United States) data sets ranged from 52 to 61% and from 10 to 64%, respectively.

3.0 Evaluation of the Toxicity of Sediment-Associated DDTs

3.1 Identity and Nomenclature of DDTs

Technical grade DDT is a broad spectrum chlorinated hydrocarbon insecticide that was used in a variety of applications for over 30 years in the United States (USEPA 1980a). As a persistent, non-systemic (i.e., not incorporated into the plant) contact and ingested insecticide, DDT provides effective control of a variety of insect pests over extended time periods (Worthing and Hance 1991). While this persistence decreases the need for repeated use of the pesticide at the application site, it also increases the potential for effects on non-target species. In addition, the physicochemical properties of this substance (i.e., low solubility in water and high solubility in lipids) are such that DDT and its metabolites tend to accumulate in the tissues of aquatic organisms and magnify in the food web (USEPA 1980a). While the use of this pesticide has been suspended in the United States, it is still manufactured and used in a number of countries worldwide.

Technical grade DDT (CAS RN: 50-29-3), or dichlorodiphenyltrichloroethane, is comprised primarily of six compounds, including *p,p'*-DDT (77.1%), *o,p'*-DDT (14.9%), *p,p'*-DDE (4.0%), *o,p'*- DDE (0.1%), *p,p'*-DDD (0.3%) and *o,p'*-DDD (0.1%). In addition, technical grade DDT also includes a number of compounds that have not been identified (3.5%; USEPA 1980a). DDT has several metabolites that are frequently found in the environment, including DDEs and DDDs (or Rhothane, which was also manufactured and used as an insecticide for several years; USEPA 1980a). Several other metabolites and degradation products have also been identified (see USEPA 1980a for more information).

In this review, the term "total DDT (tDDT)" is used to refer to the sum of the concentrations of six compounds, including *p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *o,p'*-DDE, *p,p'*-DDD, and *o,p'*-DDD. The term "SUM DDT" is used to refer to the sum of the concentrations of *p,p'*-DDT and *o,p'*-DDT isomers. The term "SUM DDE" is used to refer to the sum of the concentrations of *p,p'*-DDE and *o,p'*-DDE isomers. The term "SUM DDD" is used to refer to the sum of the concentrations of *p,p'*-DDD and *o,p'*-DDD isomers. The more general term "DDTs" is used to refer to any of the six substances identified above and their metabolites and degradation products.

While it would be desirable to identify sediment effect concentrations for each of the six DDT compounds, toxicological data were not always available on all of these substances. In some field studies (e.g., Word and Mearns 1979), only the concentrations of total DDT were reported. In other field studies (e.g., Swartz *et*

al. 1985; Swartz *et al.* 1986; Ferraro *et al.* 1991), the concentrations of the *p,p'*-isomers of DDE, DDT and/or DDD were reported; however, the concentrations of the *o,p'*-isomers were not measured. In the most recent field surveys, however, the concentrations of all six DDT compounds were reported (Anderson *et al.* 1988; Bay *et al.* 1994). Typically, the concentrations of total DDT have been reported in spiked-sediment bioassays, which is considered to be comprised of >90% *p,p'*-DDT and *o,p'*-DDT. The inconsistencies in the analytes represented in sediment chemistry data make it difficult to compare the results obtained for different substances and from different studies.

To facilitate the development of SECs, data were compiled for four groups of substances: SUM DDT; SUM DDE; SUM DDD; and, tDDT. This approach to data reduction was considered to be appropriate because few data were available on several of the individual DDT isomers. In addition, no information was located that indicated that the toxicity of, for example, DDE varied depending on which isomer was considered (i.e., *p,p'*-DDE or *o,p'*-DDE).

As indicated above, individual field studies have reported a variety of chemical concentration data. When information on the concentrations of both the *o,p'*- and *p,p'*-isomers was reported, the sum of the two values was calculated (e.g., *o,p'*-DDE + *p,p'*-DDE = SUM DDE). Alternatively, the sum of the concentrations of the two isomers was estimated from the concentration of the *p,p'*-isomer. The conversion factor used in these calculations was the mean ratio of the concentration of the *p,p'*-isomer to the concentration of the sum of the two isomers and was determined using the data reported by Bay *et al.* (1994). For example, the mean ratio of *p,p'*-DDE to SUM DDE in Palos Verdes sediments was 0.886 ± 0.021 (Bay *et al.* 1994). Therefore, SUM DDE concentrations were estimated, as necessary, by dividing the concentrations of *p,p'*-DDE by the conversion factor (0.886). The conversion factors used to estimate SUM DDT and SUM DDD concentrations were 0.894 and 0.863, respectively.

The concentrations of tDDT were determined using one of three methods. When the concentrations of all six analytes were reported, the sum of these values was calculated. When the concentrations of *p,p'*-DDT, *p,p'*-DDE, and *p,p*-DDD were reported, the sum of these three values was determined. Subsequently the concentration of tDDT was estimated by summing the estimated concentrations of the SUM DDT, SUM DDE, and SUM DDD. When only the concentration of *p,p'*-DDE was measured, this value was divided by an empirically derived conversion factor (0.787; which was determined using data from Bay *et al.* 1994) to estimate tDDT concentrations.

The sediment chemistry data used to estimate the concentrations of DDTs in field studies (i.e., Bay *et al.* 1994) were revised after these calculations had been completed. The data reported from Bay *et al.* (1994) reflect these revisions. However, the estimated concentrations of DDTs (i.e., derived using the above conversion factors) in other field studies were not revised. As such, the actual concentrations of DDTs could be higher or lower (by up to 1.1%) than the concentrations reported in this document. This uncertainty in the concentrations of DDTs was considered to be negligible; therefore, the data reported herein were not revised.

3.2 Toxic Effects of SUM DDT

Information on the toxic effects of sediment-associated SUM DDT are available from two types of studies, including controlled laboratory studies and field investigations. Once again, information from controlled laboratory spiked-sediment bioassays provides precise dose-response data for assessing the toxic effects of SUM DDT. By comparison, data from field surveys provide information that can be used to link contaminant concentrations to adverse biological effects; however, these data do not provide dose-response information for definitively identifying causality. A variety of factors, other than the concentration of DDTs, could also have contributed to, or been responsible for, the effects observed in these types of investigations. However, the co-occurrence analyses used to evaluate these field data identify the contaminants that are most strongly linked to the observed toxic effects. Both types of data are summarized in the following sections.

3.2.1 Spiked-Sediment Bioassay Data

Acute toxicity data are available on three species of benthic macroinvertebrates, including one polychaete, one decapod, and one amphipod. One of these species is known to occur in the Southern California Bight (an amphipod, *Rhepoxynius abronius*), while the other two species (a polychaete, *Nereis virens* and a decapod, *Crangon septemspinosa*) are closely related to species that occur in this area (i.e., members of the same genera were recorded in this area; SCAMIT 1994). Therefore, these toxicity data were considered to be relevant for identifying sediment effect concentrations of SUM DDT in the Southern California Bight. None of these studies provided information on the composition of the DDTs used in the bioassays (i.e., *p,p'*-DDT vs. *o,p'*-DDT); it was assumed that either technical

grade or reagent grade DDTs were utilized in these investigations. Both of these formulations consist of greater than 90% SUM DDT (USEPA 1980a).

The information available suggests that the sand shrimp, *Crangon septemspinosa*, is the most sensitive species to the effects of sediment-associated DDTs represented in the toxicological data set. McLeese and Metcalfe (1980) spiked sandy sediments (97% sand) by dissolving DDT in hexane and adding the mixture to the bottom of two liter beakers. After the solvent had evaporated, sediment and seawater were added to the beaker. The sand shrimp were added to the test chambers after the sediment had settled and were exposed to DDT-spiked sediment for 96 hours. Neither the sediment nor the overlying water were renewed at any time during this test (i.e., a static toxicity test design was employed). These investigators reported a median lethal concentration of 0.031 mg SUM DDT/kg DW for this species (at 0.28% TOC DW; McLeese and Metcalfe 1980). As the exposure system was not at equilibrium (for further information see glossary; Appendix 1) during the tests (i.e., concentrations of DDTs in sediments increased over the four day period), the LC_{50} was determined based on the average concentrations of DDT measured during the experiment. By dividing the original LC_{50} by the level of TOC in the sediment, it was possible to calculate an LC_{50} of 0.111 mg SUM DDT/kg $DW_{1\%OC}$ for the sand shrimp.

Data from a related study indicate that the sand worm, *Nereis virens*, is not as sensitive as the sand shrimp to the effects of SUM DDT (when mortality was considered as the experimental endpoint). In static renewal tests (i.e., the animals were transferred to newly prepared sediments every 4 days), McLeese *et al.* (1982) exposed sand worms to concentrations of up to 16.5 mg SUM DDT /kg DW (at 2% TOC DW) for a period of 288 hours (12 days). No mortalities were observed in any of the test chambers over this period. Therefore, an LC_{50} of >16.5 mg SUM DDT/kg DW, or >8.25 mg DDTs/kg $DW_{1\%OC}$, was calculated for this species. Based on the results of this test, these authors concluded that the sand worm was less sensitive to organochlorines (including DDTs) than was the sand shrimp. Once again, the methods used in this study did not produce equilibrium conditions in the test chambers; hence, calculated average concentrations of SUM DDT were used to determine the LC_{50}s.

In a more recent study, Plesha *et al.* (1988) examined the toxicity of a mixture of four chlorinated hydrocarbons to the amphipod, *Rhepoxynius abronius*. The chlorinated hydrocarbons used in this investigation included Aroclor 1254, hexachlorobutadiene, 2,2-bis(*p*-chlorophenyl)-1,1,1-trichloroethane (*p,p'*-DDT), and hexachlorobenzene, at nominal concentrations of 1.0, 0.1, 0.2, and 0.05 mg/kg DW. The sediment used in this study was a silty sand (54% sand) with 0.9%

organic carbon (0.9% OC DW). The contaminants were added to the sediments in an acetone solution, processed, and stored for 48 hours prior to adding the test organisms. The results of the acute (10 day) toxicity bioassays, in which mortality was the endpoint measured, indicated that the sediments with 0.2 mg/kg DW of SUM DDT were significantly toxic to amphipods (survival was reduced by more than 20% relative to control treatments). Much lower survival rates (i.e., <20% survival) were observed when the amphipods were exposed to sediments that had higher nominal concentrations of chlorinated hydrocarbons (1 mg/kg DW of SUM DDT). These results suggest that SUM DDT, when present in mixtures of chlorinated hydrocarbons, may be toxic to amphipods at concentrations as low as 0.200 mg/kg DW or 0.222 mg/kg $DW_{1\%OC}$.

3.2.2 Field Data

In the past 20 years, a number of studies have been conducted in the Southern California Bight to address environmental concerns associated with contaminated sediments. While the majority of these studies were conducted in the late 1970's and early 1980's (Word and Mearns 1979; Swartz *et al.* 1985; Swartz *et al.* 1986), several follow-up surveys have been implemented to assess trends in sediment contamination and/or toxicity. A total of seven studies from the Southern California Bight with matching chemistry and biological effects data were reviewed to support the development of SECs for SUM DDT (Anderson *et al.* 1988; Swartz *et al.* 1991; Ferraro *et al.* 1991; Bay *et al.* 1994; Sapudar *et al.* 1994; Fairey *et al.* 1996; Fairey 1997; Tables A4-1 to A4-4).

In 1980, Swartz *et al.* (1985) examined sediment toxicity, contamination, and benthic macroinvertebrate community structure at seven sites in the vicinity of the Los Angeles County Sanitation District's sewage outfalls on the Palos Verdes Shelf. Sediment toxicity was evaluated in laboratory bioassays that utilized the amphipod, *Rhepoxynius abronius*, as the test organism. The results of this study indicated that the sediments from three stations (1, 2, and 3) were acutely toxic to amphipods during 10-day exposures. These investigators reported that benthic macroinvertebrate community structure (as indicated by infaunal index) had also been altered at these sites. The average concentration of SUM DDT at the stations 1, 2, and 3 was 0.062 ± 0.058 mg/kg DW (0.016 ± 0.014 mg/kg $DW_{1\%OC}$). The average concentration of this substance at the non-toxic stations (4, 5, 6, and 7) was 0.021 ± 0.041 mg/kg DW (0.005 ± 0.011 mg/kg $DW_{1\%OC}$). Several other metrics (including species richness, crustacean abundance, echinoderm abundance, and total abundance) indicated that the benthic invertebrate community

structure was altered at sites that had mean SUM DDT concentrations of between 0.070 and 0.537 mg/kg DW (0.010 to 0.017 mg/kg $DW_{1\%OC}$). As the analytical detection limits were not reported in this study, the mean SUM DDT concentrations were calculated using an assumed value of 0.0 mg/kg DW for the sites without detectable levels of SUM DDT.

In 1985, Swartz *et al.* (1991) collected sediment cores from four stations on the Palos Verdes shelf and Santa Monica Bay. Two cores (up to 50 cm in depth) were collected from each station and cut into 5 cm vertical sections. Acute (10 day) toxicity tests using amphipods (*Rhepoxynius abronius*) were conducted on each of the core sections. The results of this investigation indicates that the mid-depth (12.5 - 32.5 cm) sediments from the stations located nearby the Los Angeles County outfalls were the most toxic to amphipods (78.6 ± 8.7% mortality). The concentrations of SUM DDT averaged 6.28 ± 3.07 mg/kg DW (0.799 ± 0.407 mg/kg $DW_{1\%OC}$) in these sediments. Shallower and deeper sediments (2.5 - 12.5 cm and 37.5 to 47.5 cm) from these sites were moderately toxic to amphipods (35.9 ± 12.1% mortality); these samples had, on average, 1.86 ± 1.77 mg/kg DW (0.475 ± 0.455 mg/kg $DW_{1\%OC}$) of SUM DDT. By comparison, the samples that were the least toxic to amphipods (8.7 ± 3.3% mortality) had average SUM DDT concentrations of 0.191 ± 0.509 mg/kg DW (0.055 ± 0.100 mg/kg $DW_{1\%OC}$).

In 1987, Anderson *et al.* (1988) sampled sediments from seven sites in the vicinity of Palos Verdes and three sites in San Diego Harbor. Only the data from the sites located in the Palos Verdes area was used in this review. While this survey was explicitly designed to evaluate the toxicity of PAH-contaminated sediments, at least one of the sites sampled also had relatively elevated levels of DDTs. Matching sediment chemistry and biological effects data were available for all of these sites. The sediment chemistry data consisted of information on over 50 substances, including six DDT isomers. The biological effects information collected during this survey were generated using three laboratory bioassays (Microtox, amphipod, and sea urchin). However, the Microtox data (which are based on measurements of bacterial luminescence) were not considered because the ecological relevance of this test is uncertain. While benthic invertebrate community structure data were also collected, differences in the depth and other physical features (i.e., open ocean vs. sheltered) at the various sites that were sampled complicated the interpretation of this information. Therefore, these latter data were not used in this review.

The results of the 10-day acute toxicity tests conducted in this study indicated that the survival and reburial of the amphipod, *Grandidierella japonica*, were not correlated with concentrations of SUM DDT in Southern California Bight sediments (Anderson *et al.* 1988). For example, the mean concentration of SUM

DDT was 0.004 ± 0.002 mg/kg DW (0.002 ± 0.002 mg/kg $DW_{1\%OC}$) in sediments that were significantly toxic to this species. In contrast, the mean concentration of SUM DDT in sediments that did not affect amphipod survival was 0.070 ± 0.150 mg/kg DW (0.019 ± 0.035 mg/kg $DW_{1\%OC}$). As the concentrations of these substances were lower at the toxic sites than they were at the non-toxic sites, something other than the concentrations of SUM DDT must have been responsible for the observed toxicity.

The results of the 35-day chronic toxicity tests conducted by Anderson *et al.* (1988) indicate that the survival, sediment preference (i.e., avoidance behavior), and gonad growth of the sea urchin, *Lytechinus pictus*, were not correlated with the concentrations of sediment-associated DDTs (i.e., there was no concordance between sediment chemistry and the biological effects). However, sea urchin growth (as measured by increases in weight or test width; the test is the hard outer covering of the sea urchin) was linked with concentrations of SUM DDTs. Reduced growth rates were observed in sediments with a mean concentration of 0.191 ± 0.261 mg SUM DDT/kg DW (0.045 ± 0.063 mg/kg $DW_{1\%OC}$). No effects on growth were evident at the sites with an average concentration of 0.007 ± 0.009 mg SUM DDT/kg DW (0.005 ± 0.003 mg/kg $DW_{1\%OC}$). It should be noted that this analysis was significantly affected by one sample (Palos Verdes) that had concentrations of DDTs that were more than an order of magnitude higher than those that were measured at other sites.

In a study commissioned by the Santa Monica Bay Restoration Project, Bay *et al.* (1994) collected sediments from 12 sites located in the vicinity of the Palos Verdes Peninsula during June and July, 1992. A station located near Dana Point in Orange County was used as a reference site in this study. This study was designed to evaluate the toxicity of Palos Verdes sediments to infaunal and epibenthic organisms, and included both bulk sediment and porewater bioassays. The toxicity of bulk sediments was assessed in acute (10-day) tests on the amphipod, *Rhepoxynius abronius*, and chronic (28-day and 35-day) tests on the amphipod, *Grandidierella japonica*, and the white sea urchin, *Lytechinus pictus*. As poor survival was observed among all of the treatment groups (including controls) in the amphipod (*G. japonica*) growth bioassay, these data were not considered for identifying sediment effect concentrations of DDTs. In this survey, the toxicity of porewater was evaluated in short-term (< 2-hour) bioassays using purple sea urchin, *Strongylocentrotus purpuratus*, gametes.

Acute toxicity bioassays were conducted using sediments from five of the 13 sites sampled near the Palos Verdes Peninsula in the 1992 survey; none of these sediments were acutely toxic to the amphipod, *Rhepoxynius abronius* (Bay *et al.*

1994). While the survival, gonad size, and diameter of white sea urchins were not affected by exposure to Palos Verdes sediments, the growth rate [as indicated by changes in wet weight (WW) during the test] of this species was reduced in certain Palos Verdes sediments. Relatively low growth rates (i.e., ≤ 0.002 g WW/day) were observed at sites with a mean concentration of SUM DDT of 0.762 ± 1.31 mg/kg DW (0.24 ± 0.427 mg/kg $DW_{1\%OC}$). The average SUM DDT concentrations were lower (0.117 ± 0.156 mg/kg DW or 0.048 ± 0.050 mg/kg $DW_{1\%OC}$) in the sediments that were not associated with effects on sea urchin growth (i.e., growth rates of ≥ 0.005 g WW/day).

Impaired fertilization of sea urchin, *Strongylocentrotus purpuratus*, gametes was also associated with elevated SUM DDT concentrations in Palos Verdes sediments (Bay *et al.* 1994). High fertilization rates (80.0 ± 10.2%) were observed when sea urchin gametes were exposed to porewater from sediments with low concentrations of SUM DDT (0.048 ± 0.066 mg/kg DW or 0.021 ± 0.022 mg/kg $DW_{1\%OC}$). The fertilization of sea urchin eggs was lower (9.4 ± 16.2%) in porewater from sediments with higher SUM DDT concentrations (0.749 ± 1.12 mg/kg DW or 0.244 ± 0.359 mg/kg $DW_{1\%OC}$; Bay *et al.* 1994).

In 1992, sediments from a number of locations in the vicinity of Los Angeles and Long Beach Harbors were sampled to assess sediment contamination and toxicity in San Pedro Bay (as part of the Bay Protection and Toxics Cleanup Program; Sapudar *et al.* 1994). The toxicity of each sample was evaluated using two toxicity tests, including 48-hour red abalone (*Haliotus rufescens*) larval development test (using pore water) and 10-day amphipod (*Rhepoxynius abronius*) survival test (using bulk sediments). The data from the porewater test on abalone larval development were not used in this evaluation because they provided little ability to discriminate between sampling sites (i.e., nearly 90% of the samples were shown to be toxic based on the results of this test). Toxic samples were identified as those in which amphipod survival was more than 20% lower than the average survival in the control treatments (Long *et al.* In review).

The results of this investigation indicated that sediments from several locations in San Pedro Bay were acutely toxic to amphipods, including Los Angeles Inner Harbor, Inner Fish Harbor, East Basin, and Alamitos Bay. The average concentration of SUM DDT in the toxic samples was 0.008 ± 0.013 mg/kg DW or 0.004 ± 0.004 mg/kg $DW_{1\%OC}$. By comparison, SUM DDT concentrations averaged 0.003 ± 0.004 mg/kg DW or 0.003 ± 0.003 mg/kg $DW_{1\%OC}$ at the non-toxic sites in this survey. Analysis of these results suggests that dry weight concentrations of SUM DDT were associated with the observed toxicity to

amphipods; however, there was little concordance between amphipod mortality and organic carbon-normalized SUM DDT concentrations.

In a related study, sediments were collected at several locations on the Palos Verdes Shelf and in Santa Monica Bay during 1992 and 1993 (Fairey 1997). The results of 10-day toxicity tests with the amphipod, *Rhepoxynius abronius*, indicated that the sediments from 11 of the 19 sites tested were acutely toxic (as indicated by a > 20% difference from control survival; Long *et al.* In review). The average concentration of SUM DDT at these sites was 0.091 ± 0.228 mg/kg DW or 0.079 ± 0.230 mg/kg $DW_{1\%OC}$. The average concentrations of SUM DDT were 0.042 ± 0.034 mg/kg DW or 0.023 ± 0.024 mg/kg $DW_{1\%OC}$ at the non-toxic sites in this survey. These results indicate that amphipod survival was linked with both dry weight- and organic carbon-normalized concentrations of SUM DDT. Due to the small number of sediments tested (4), the results of the polychaete survival and growth tests were not used in this evaluation.

A total of 350 stations in the vicinity of San Diego were also sampled between October, 1992 and May, 1994 under the Bay Protection and Toxics Cleanup Program (Fairey *et al.* 1996). The data for the sediment samples from the middle portion of San Diego Bay were included in the data set assembled for this investigation because substantial concentration gradients were observed for in several of the contaminants of concern. Several solid phase and porewater toxicity tests were conducted on each of the samples collected in this portion of the bay (i.e., the vicinity of the naval shipyards), including amphipod (*Rhepoxynius abronius*) survival, sea urchin (*Strongylocentrotus purpuratus*) fertilization, and sea urchin (*S. purpuratus*) larval development. The results of the polychaete growth and survival test, the bay mussel larval development test, and the red abalone larval development tests were not used due to incomplete designation of toxic samples. The results of the power analyses conducted by Long *et al.* (In review) were used to designate toxic samples for the amphipod and sea urchin tests (i.e., samples were designated as toxic if the response measured differed by more than 20% from that of the control samples).

Based on the results of the solid phase tests, sediments from the eastern portion of middle San Diego Bay were the most toxic to amphipods. The average concentration of SUM DDT at the toxic sites was 0.005 ± 0.020 mg/kg DW (0.009 ± 0.053 mg/kg $DW_{1\%OC}$). By comparison, the average concentration of SUM DDT in the samples that were not acutely toxic to amphipods was 0.003 ± 0.003 mg/kg DW (0.002 ± 0.004 mg/kg $DW_{1\%OC}$). Because dry weight-normalized SUM DDT concentrations were similar in the toxic and non-toxic samples, it is unlikely that this substance contributed significantly to amphipod mortality in the

middle portion of San Diego Bay. However, the linkage between amphipod survival and SUM DDT was stronger when organic carbon-normalized concentrations were considered.

The results of the sea urchin fertilization and larval development tests also provide relevant information for evaluating the toxic effects of SUM DDT. In samples from San Diego Bay, decreased the fertilization success of sea urchin gametes was observed in porewater from sediments that contained, on average, 0.008 ± 0.028 mg/kg DW (0.004 ± 0.013 mg/kg $DW_{1\%OC}$) of SUM DDT. Higher rates of abnormal development of sea urchin embryos were also observed in pore water from sediments that contained average SUM DDT concentrations of 0.008 ± 0.026 mg/kg DW (0.014 ± 0.074 mg/kg $DW_{1\%OC}$). SUM DDT were lower in the sediment samples that did not influence sea urchin fertilization or larval development.

3.2.3 SECs for SUM DDT

Using the spiked-sediment bioassay approach, a sediment effect concentration of 0.031 mg/kg DW or 0.111 mg/kg $DW_{1\%OC}$ was derived for SUM DDT (i.e., the sum of the concentrations of *p,p'*-DDT and *o,p'*-DDT).

Rationale: Data from three spiked-sediment toxicity investigations (McLeese and Metcalfe 1980; McLeese *et al.* 1982; Plesha *et al.* 1988) indicate that median lethal concentrations of SUM DDT, expressed on a dry weight basis, ranged from 0.031 to >16.5 mg/kg DW (Tables A4-1 and A4-2). At 1% OC, these LC_{50}s ranged from 0.111 to >8.25 mg/kg $DW_{1\%OC}$ (Table A4-3 and A4-4). While the DDT formulations used in these studies probably included a variety of substances besides *p,p'*-DDT and *o,p'*-DDT, these data were considered for identifying sediment effect concentrations of SUM DDT because these formulations most likely contained at least 92% of the SUM DDT.

The available spiked-sediment bioassay data include toxicological information on three sediment-dwelling invertebrate species (including two arthropod species) and, therefore, satisfy the minimum data requirements established in this study (see Appendix 3). In accordance with the procedures identified in Section 2.4, the lowest observed effect level (LOEL) for the most

sensitive species, from an acceptable spiked-sediment bioassay, was identified as the sediment effect concentration of SUM DDT (0.031 mg/kg DW or 0.111 mg/kg $DW_{1\%OC}$ for the sand shrimp, *Crangon septemspinosa*). The LOEL is from an acute toxicity study in which lethality was the endpoint measured; no information was available to convert it to a chronic LOEL (i.e., an acceptable acute to chronic ratio was not available). Therefore, it should be recognized that adverse biological effects could occur in the Southern California Bight at SUM DDT concentrations below the recommended SEC.

The results of the toxicity test on the sand shrimp are supported by data on the toxicity of SUM DDT to amphipods. Plesha *et al.* (1988) reported significant mortality (>20%) when amphipods, *Rhepoxynius abronius*, were exposed to 0.200 mg SUM DDT/kg DW (0.222 mg/kg $DW_{1\%OC}$) for a period of ten days. These sediments contained a mixture of other chlorinated hydrocarbons, which probably enhanced the toxicity of SUM DDT. Sediments in the Southern California Bight are known to contain elevated concentrations of several chlorinated hydrocarbons (Mearns *et al.* 1991). Therefore, the results reported by Plesha *et al.* (1988) support the SEC derived for SUM DDT.

3.2.4 Evaluation of the SECs for SUM DDT

Reliability:

The degree of confidence that can be placed on the SECs for SUM DDT was evaluated using matching sediment chemistry and biological effects data from the Southern California Bight. A total of seven studies provided the requisite information on SUM DDT concentrations, in conjunction with the results of laboratory toxicity tests or benthic invertebrate community assessments. These studies included Swartz *et al.* (1985), Anderson *et al.* (1988), Swartz *et al.* (1991), Bay *et al.* (1994), Sapudar *et al.* (1994), Fairey *et al.* (1996), and Fairey (1997).

The results of this evaluation indicate that the dry weight-normalized SEC for SUM DDT provides a reliable basis for classifying sediment

samples in the Southern California Bight (Table 2). Of the 50 sediment samples with SUM DDT concentrations at or above the SEC, 38 (76%) were found to be toxic, as defined in Section 2.5. Therefore, there is a high probability of observing adverse effects on sediment-dwelling organisms when SUM DDT concentrations exceed the SEC.

The probability of observing adverse biological effects increased at higher concentrations of SUM DDT. For example, 85% of the sediment samples (33 of 39 samples) with SUM DDT concentrations at or above 0.06 mg/kg DW were found to be toxic. The incidence of adverse effects increased to 88% (21 of 24 samples) when SUM DDT concentrations equaled or exceeded 0.20 mg/kg DW. The increasing incidence of toxicity with increasing concentrations of SUM DDT indicates that a dose-response relationship exists for this substance in Southern California Bight sediments. The presence of such a relationship increases the confidence that can be placed in the SECs.

Using the data that were compiled in this study, it is apparent that the organic-carbon normalized SEC also provides a reliable basis for classifying sediments in the Southern California Bight (Table 3). The probability of observing adverse biological effects (considering a variety of species, life stages, and endpoints) when concentrations of SUM DDT equaled or exceeded 0.111 mg/kg $DW_{1\%OC}$ is approximately 91% (20 of 22 sediment samples).

There is a lower probability of observing adverse effects at lower concentrations of SUM DDT. For example, the incidence of toxic effects was roughly 73% (32 of 44 samples) when SUM DDT concentrations equaled or exceeded 0.02 mg/kg $DW_{1\%OC}$. The probability of observing toxic effects increased to 87% at SUM DDT at or above 0.06 mg/kg $DW_{1\%OC}$. Once again, the increasing incidence of effects with increasing concentrations of SUM DDT enhances the confidence that can be placed in the SECs.

Predictability

Matching sediment chemistry and biological effects data were compiled from a total of five studies to evaluate the predictability of the SECs

Table 2. An evaluation of the reliability of the dry weight-normalized SECs for SUM DDT.

for SUM DDT (Munns *et al.* 1991; Swartz et al. 1994; Long *et al.* 1994; Long *et al.* 1995b; Long 1997). All of these data applied to marine and estuarine sediments from outside the Southern California Bight (Table A5-1). Using these data, the dry weight-normalized SEC was found to accurately predict toxicity in sediments with elevated levels of SUM DDT (Table 4). Thirty-six of the 44 sediment samples (82%) with SUM DDT concentrations at or above 0.031 mg/kg DW were found to be toxic. The incidence of adverse biological effects was similar when SUM DDT concentrations equaled or exceeded 0.06 mg/kg DW (i.e., 82%; 23 of 28 samples) or 0.20 mg/kg DW (i.e., 85%; 11 of 13 samples).

Based on the results of this evaluation, the organic carbon-normalized SEC was as predictive of toxicity as the dry-weight normalized SEC (Table 5). The incidence of toxic effects was 82% (9 of 11 samples) when SUM DDT concentrations equaled or exceeded 0.111 mg/kg $DW_{1\%\ OC}$ in marine and estuarine sediments. The probability of observing toxic effects was lower when SUM DDT concentrations equaled or exceeded 0.02 mg/kg $DW_{1\%OC}$ (79%; 22 of 28 samples were toxic) or 0.06 mg/kg $DW_{1\%OC}$ (75%; 9 of 12 samples were toxic).

While no directly applicable to marine and estuarine sediments, the results of a study conducted in a freshwater system that was contaminated by DDTs provides additional insight into the predictability of the SECs for SUM DDT. In 1991, Hoke *et al.* (1994) evaluated the acute toxicity of field-collected sediments from the Huntsville Spring Branch-Indian Creek system in Alabama. In this study, the toxicity of sediments collected nearby the Redstone Army Arsenal was evaluated in 10-day toxicity tests using amphipods (*Hyalella azteca*). The concentrations of SUM DDT ranged from below detection limits (BDL) to 147 mg/kg DW in the 15 sediment samples that were collected. The SEC of 0.031 mg/kg DW for SUM DDT was exceeded in 13 of the 15 sediment samples. The results of the toxicity tests indicated that 12 of these samples were toxic to amphipods (statistical analyses of the mortality data were not performed by these investigators; samples with mortality of >20% were defined as toxic in this evaluation of the predictability of the SECs). Therefore, the predictability of the DW-normalized SEC for SUM DDT was calculated to be 92.3%. All of the samples that were

Table 4. An independent evaluation of the predictability of the dry weight-normalized SECs for SUM DDT.

predicted to be toxic using the OC-normalized SEC were toxic to amphipods (12 of 12 samples; predictability = 100%).

3.3 Toxic Effects of SUM DDE

3.3.1 Spiked-Sediment Bioassay Data

Only one controlled laboratory study (i.e., spiked-sediment bioassay) was located on the effects of sediment-associated SUM DDE on marine organisms. Bay *et al.* (1994) spiked sediments that were collected from a reference site (which was located near Dana Point in Orange County, California), with *p,p'*-DDE at concentrations ranging from 0 to 8.7 mg/kg DW. After an equilibration period of two days, sea urchins (*Lytechinus pictus*) were exposed to test sediments for a period of 35 days. While this study was designed explicitly as a bioaccumulation test, survival and growth were also monitored to provide data on the biological effects of this substance. No dose related effects in the survival, growth, or gonad weight of sea urchins exposed to DDE-spiked sediments were reported at any DDE concentration. Therefore, the LC_{50} and EC_{50}s (for further information see glossary; Appendix 2) of DDE for this species were all greater than 8.7 mg/kg DW. As the level of OC in these reference sediments was 1%, the OC-normalized concentrations of DDE at 1%OC were the same as the dry weight concentrations of DDE in this study.

3.3.2 Field Data

The results of nine field surveys provide data for evaluating the effects of SUM DDE in the Southern California Bight. In six of these studies, the concentrations of both DDE isomers were measured, which facilitated the calculation of SUM DDE concentrations. In the other three studies, only the concentrations of *p,p'*-DDE were measured; these data were converted to SUM DDE concentrations (as outlined in Section 3.1).

In the 1980 study conducted in the vicinity of the Los Angeles County Sanitation District's sewage outfalls, Swartz *et al.* (1985) examined sediment toxicity, contamination, and benthic macroinvertebrate community structure at seven sites on the Palos Verdes Shelf. The results of this study indicated that the sediments

from three sites were toxic to amphipods during 10-day exposures. Evaluation of a number of metrics (e.g., invertebrate biomass and infaunal index) indicated that the benthic macroinvertebrate community structure had also been altered at these sites. Sediments from the other four sites were not toxic. At the toxic sites, the concentration of SUM DDE averaged 5.82 ± 1.21 mg/kg DW or 1.47 ± 0.38 mg/kg $DW_{1\%OC}$. The mean concentration of this substance at the non-toxic sites was 2.91 ± 4.01 mg/kg DW or 0.852 ± 1.00 mg/kg $DW_{1\%OC}$.

In a follow-up survey conducted in 1983, Swartz *et al.* (1986) collected sediment and macrobenthos samples from a total of nine sites on the Palos Verdes Shelf and Santa Monica Bay. Matching sediment chemistry and biological effects (including acute toxicity bioassays and benthic invertebrate community structure) data were reported for six of these sites. These stations were considered to be located at the same sites as those sampled in the 1980 survey. The results of 10-day tests on the amphipod, *Rhepoxynius abronius*, indicated that the sediments collected from only one station (#6) were acutely toxic (Ferraro *et al.* 1991). The concentration of SUM DDE at this station was 3.15 mg/kg DW or 1.31 mg/kg $DW_{1\%OC}$. The mean concentration of SUM DDE at the non-toxic sites was 4.66 ± 3.83 mg/kg DW or 1.60 ± 1.14 mg/kg $DW_{1\%OC}$. The lack of concordance between the amphipod survival and SUM DDE concentrations indicates that this substance was not responsible for observed biological effects.

In the 1983 study, benthic invertebrate community structure was altered at several sites with elevated levels of SUM DDE. For example, low echinoderm densities were observed at sites with mean concentrations of SUM DDE of 5.26 ± 3.10 or 1.85 ± 0.83 mg/kg $DW_{1\%OC}$. In contrast, high densities of echinoderms were observed at a site with 0.124 mg SUM DDE/kg DW or 0.095 mg SUM DDE/kg $DW_{1\%OC}$. Similarly, low amphipod densities were observed at sites with mean concentrations of SUM DDE of 7.33 ± 1.51 mg/kg DW or 2.36 ± 0.59 mg/kg $DW_{1\%OC}$. Higher densities of amphipods were observed at sites with 1.49 ± 1.53 mg DDE/kg DW or 0.752 ± 0.614 mg/kg $DW_{1\%OC}$. Similar results were observed when total benthic invertebrate density, species richness, and infaunal index were considered.

In 1985, Swartz *et al.* (1991) collected sediment cores from four stations on the Palos Verdes shelf and Santa Monica Bay. Two cores (up to 50 cm in depth) were collected from each station and cut into 5 cm vertical sections. Acute (10 day) toxicity tests using amphipods (*Rhepoxynius abronius*) were conducted on each of the core sections. The results of this investigation indicates that the mid-depth (12.5 - 32.5 cm) sediments from the stations located nearby the Los Angeles County outfalls were the most toxic to amphipods (78.6 ± 8.7% mortality). The

mean concentration of SUM DDE in these sediment samples was 123 ± 45.5 mg/kg DW or 14.6 ± 2.88 mg/kg $DW_{1\%OC}$. Moderate toxicity to amphipods (35.9 ± 12.1% mortality) was observed in shallower and deeper sediments (2.5 to 12.5 cm and 37.5 to 47.5 cm); these samples had, on average, 19.1 ± 15.4 mg/kg DW (3.45 ± 2.34 mg/kg $DW_{1\%OC}$) of SUM DDE. The samples that were the least toxic to amphipods (8.7 ± 3.3% mortality) had average SUM DDE concentrations of 1.44 ± 3.54 mg/kg DW (0.440 ± 0.596 mg/kg $DW_{1\%OC}$).

One year later (1986), another follow-up survey was conducted to evaluate trends in sediment contamination, toxicity, and benthic macroinvertebrate community structure on the Palos Verdes Shelf and Santa Monica Bay (Ferraro *et al.* 1991). A total of eight sites were sampled in this survey; none of the sediments tested were acutely toxic to the amphipod, *Rhepoxynius abronius*, during 10-day exposures. The mean concentration of DDE at the eight sites was 6.16 ± 4.16 mg/kg DW or 1.63 ± 0.82 mg/kg $DW_{1\%OC}$.

Data on benthic invertebrate community structure, which reflects continuous exposure to sediment-associated contaminants, indicates that adverse effects on sediment-dwelling organisms occur at elevated levels of SUM DDE (Ferraro *et al.* 1991). For example, low densities of amphipods (4.1 ± 2.5/0.1 m^2) were observed at three of the eight sites sampled on the Palos Verdes Shelf. At these sites, concentrations of SUM DDE averaged 9.47 ± 4.04 mg/kg DW or 2.36 ± 0.22 mg/kg $DW_{1\%OC}$. Higher amphipod (54.6 ± 5.1/0.1 m^2) densities were observed at the sites with lower concentrations of SUM DDE (0.976 ± 1.09 mg/kg DW or 0.439 ± 0.262 mg/kg $DW_{1\%OC}$). Similarly, low echinoderms densities (2.4 ± 5.7/0.1 m^2) were observed at seven of the eight sites sampled during this survey, with DDE concentrations averaging 7.02 ± 3.67 mg/kg DW or 1.82 ± 0.65 mg/kg $DW_{1\%OC}$. Echinoderm densities (208/0.1 m^2) were higher at the site with lower concentrations of SUM DDE (0.203 mg/kg DW or 0.254 mg/kg $DW_{1\%OC}$). Species richness, total benthic invertebrate density, and total benthic invertebrate biomass were not correlated with SUM DDE concentrations.

Matching sediment chemistry and biological effects data were collected at seven sites in the Southern California Bight during 1987 (Anderson *et al.* 1988). While this study was conducted primarily to evaluate the effects associated with PAH-contaminated sediments, it also provides some information for assessing the potential effects of mixtures of SUM DDE and other substances. In this study, the survival and reburial of the amphipod, *Grandidierella japonica*, (in 10-day acute toxicity tests) were not linked with concentrations of SUM DDE. The mean concentration of SUM DDE was 0.078 ± 0.081 mg/kg DW or 0.027 ± 0.027 mg/kg $DW_{1\%OC}$ in sediments that were significantly toxic to this species. By

comparison, the mean concentration of SUM DDE in sediments that did not affect survival was 0.861 ± 2.07 mg/kg DW or 0.212 ± 0.494 mg/kg $DW_{1\%OC}$. As the concentration of this substance was lower at the toxic sites than it was at the non-toxic sites, factors other than SUM DDE must have been responsible for the observed effects.

The survival, sediment preference (i.e., avoidance behavior), and gonad growth of the sea urchin, *Lytechinus pictus*, (in 35-day chronic exposure tests) were not correlated with the concentrations of sediment-associated SUM DDE measured in Palos Verdes sediments (i.e., there was no concordance between sediment chemistry and the biological effects; Anderson *et al.* 1988). However, sea urchin growth was correlated with concentrations of DDTs, with reduced growth rates observed in sediments with mean concentrations of 2.62 ± 3.47 mg/kg DW or 0.618 ± 0.852 mg/kg $DW_{1\%OC}$ of SUM DDE. It should be noted that this analysis was significantly affected by one sample (Palos Verdes) that had concentrations of DDEs that were more than an order of magnitude higher than those that were measured at other sites.

In a study commissioned by the Santa Monica Bay Restoration Project, Bay *et al.* (1994) collected sediments from 12 sites located in the vicinity of the Palos Verdes Peninsula and one reference site near Dana Point. Acute toxicity bioassays were conducted using sediments from five of the 13 sites sampled in the 1992 survey; none on these sediments were toxic to amphipods (*Rhepoxynius abronius*; Bay *et al.* 1994). The mean concentrations of SUM DDE at these sites were 5.53 ± 4.66 mg/kg DW or 2.18 ± 1.41 mg/kg $DW_{1\%OC}$. Similarly, the survival, avoidance behavior, gonad growth and growth (as indicated by diameter) of white sea urchins (*Lytechinus pictus*) were not affected at mean SUM DDE concentrations of 4.77 ± 4.66 mg/kg DW or 1.69 ± 1.18 mg/kg $DW_{1\%OC}$.

Unlike the other bioassay endpoints, the growth rate (as measured by wet weight change over a 35-day exposure period) of white sea urchins was influenced by exposure to Palos Verdes sediments (Bay *et al.* 1994). Reduced growth rates were observed at sites with mean concentrations of SUM DDE of 8.73 ± 5.49 mg/kg DW or 2.50 ± 1.34 mg/kg $DW_{1\%OC}$. The concentrations of this substance were lower in the sediments that were not associated with growth effects (3.02 ± 3.15 mg/kg DW or 1.33 ± 0.962 mg/kg $DW_{1\%OC}$. Similar results were obtained when the fertilization of sea urchin, *Strongylocentrotus purpuratus*, gametes was the experimental endpoint considered in the bioassay. The results of this short-term (< 2 hours) test indicated that low fertilization rates (9.4 ± 16.2%) were associated with exposure to porewater from sediments that had mean SUM DDE concentrations of 8.41 ± 4.19 mg/kg DW or 2.56 ± 0.935 mg/kg $DW_{1\%OC}$.

Exposure to porewater from sediments with 2.80 ± 3.60 mg SUM DDE/kg DW or 1.21 ± 1.05 mg SUM DDE/kg $DW_{1\%OC}$ was associated with higher fertilization rates.

As part of the Bay Protection and Toxics Cleanup Program, sediment samples were collected from a number of locations in the vicinity of Los Angeles and Long Beach Harbours in 1992 (i.e., San Pedro Bay; Sapudar *et al.* 1994). The toxicity of each sample was evaluated using two toxicity tests, including 48-hour red abalone (*Haliotus rufescens*) larval development test (using pore water) and 10-day amphipod (*Rhepoxynius abronius*) survival test (using bulk sediments). The data on the effects of pore water on abalone larval development were not used in this evaluation because they provided little ability to discriminate between sampling sites (i.e., nearly 90% of the samples were shown to be toxicity based on the results of this test). Toxicity to amphipods was designated based on comparisons to control survival, using the minimum significant difference reported by Long *et al.* (In review).

The results of the Sapudar *et al.* (1994) study indicate that the sediments from Los Angeles Inner Harbour, Inner Fish Harbour, East Basin, and Alamitos Bay were found to be the most toxic to amphipods. The average concentrations of SUM DDE in the toxic samples were 0.124 ± 0.103 mg/kg DW or 0.066 ± 0.059 mg/kg $DW_{1\%OC}$. By comparison, SUM DDE concentrations averaged 0.097 ± 0.077 mg/kg DW or 0.100 ± 0.109 mg/kg $DW_{1\%OC}$ in sediments from the non-toxic sites. The limited concordance between amphipod survival and SUM DDE concentrations indicates that SUM DDE probably contributed minimally to the observed toxicity.

During 1992 and 1993, sediments were also collected at several locations on the Palos Verdes Shelf and in Santa Monica Bay (Fairey 1997). Two toxicity tests were conducted during this investigation, including a 10-day acute lethality test with the amphipod, *Rhepoxynius abronius*; and, a 20-day lethality and growth test with the polychaete, *Neanthes arenaceodentata*. However, the results of the polychaete test were not used in this evaluation because only four sediment samples were tested. Of the 19 sites for which matching sediment chemistry and toxicity data were reported, sediments from 11 sites were found to be acutely toxic to amphipods. The average concentrations of SUM DDE at the toxic sites were 0.485 ± 0.991 mg/kg DW or 0.324 ± 0.648 mg/kg $DW_{1\%OC}$. By comparison, SUM DDE concentrations averaged 2.68 ± 0.516 mg/kg DW or 1.63 ± 1.02 mg/kg $DW_{1\%OC}$ in the sediments from the non-toxic sites. The lack of concordance between amphipod survival and SUM DDE concentrations indicates that this group of substances was not responsible for the observed biological effects.

Between October, 1992 and May, 1994, sediment samples were also collected at a total of 350 stations in the vicinity of San Diego under the Bay Protection and Toxic Cleanup Program (Fairey *et al.* 1996). The sediment samples from the middle portion of San Diego Bay (i.e., the vicinity of the naval shipyards) were included in the data set assembled for this investigation because substantial concentration gradients in several of the contaminants of concern were observed. Effects on several marine organisms and endpoints were examined in this study, including amphipod (*Rhepoxynius abronius*) survival, sea urchin (*Strongylocentrotus purpuratus*) fertilization, and sea urchin (*S. purpuratus*) larval development. The results of the polychaete growth and survival test, the bay mussel larval development test, and the red abalone larval development tests were not used due to incomplete designation of toxic samples. The results of the power analyses conducted by Long *et al.* (In review) were used to designate toxic samples for the amphipod and sea urchin tests (i.e., samples were designated as toxic if the response measured differed by more than 20% from that of the control samples).

Based on the measured toxicity to amphipods, sediments from the eastern portion of middle San Diego Bay were the most toxic. The average concentration of SUM DDE at the toxic sites was 0.010 ± 0.013 mg/kg DW (0.009 ± 0.0223 mg/kg $DW_{1\%OC}$). By comparison, the average concentration of SUM DDE in the samples that were not acutely toxic to amphipods was 0.014 ± 0.017 mg/kg DW (0.007 ± 0.007 mg/kg $DW_{1\%OC}$). Because SUM DDE concentrations in the toxic samples were similar to or lower than they were in the non-toxic samples, it is unlikely that SUM DDE contributed significantly to amphipod mortality in the middle portion of San Diego Bay. Similarly, little concordance was observed between sea urchin fertilization or embryo development and the concentrations of SUM DDE in sediment samples from middle San Diego Bay.

3.3.3 SECs for SUM DDE

Using the weight-of-evidence approach, SECs of 6.58 mg/kg DW and 1.82 mg/kg $DW_{1\%OC}$ were derived for SUM DDE (i.e., the sum of the concentrations of *p,p'*-DDE and *o,p'*-DDE).

Rationale: Data from only one spiked-sediment toxicity test (Bay *et al.* 1994) were available to evaluate the toxicity of sediment-associated SUM DDE. The results of this study indicated that SUM DDE was not toxic to the sea urchin, *Lytechinus pictus*, at

concentrations as high as 8.7 mg/kg DW (8.7 mg/kg $DW_{1\%OC}$). As no toxicological data were available on a sediment-dwelling arthropod species, a threshold concentration was not calculated using the spiked-sediment bioassay approach. Hence, the threshold concentration of SUM DDE was derived using the weight-of-evidence approach.

The summarized and unsummarized toxicological data sets for SUM DDE (mg/kg DW; Tables A4-5 and A4-6) contained a total of 23 and 108 effects data records (hits; designated by an *), respectively. Evaluation of these data sets, using the procedures described in Section 2.4, resulted in the calculation of ER-Ms (effects range median) of 6.58 and 7.07 mg/kg DW, respectively, for SUM DDE. The lower of these two values was identified as the SEC.

Similarly, the summarized and unsummarized toxicological data sets for SUM DDE (Tables A4-7 and A4-8), expressed on an OC-normalized basis (mg/kg $DW_{1\%OC}$) contained 17 and 88 effects data entries, respectively. The ER-Ms derived from these two data sets were 1.82 and 2.21 mg/kg $DW_{1\%OC}$, respectively. The lower of these two values was identified as the SEC.

3.3.4 *Evaluation of the SECs for SUM DDE*

Reliability:

Matching sediment chemistry and biological effects data were compiled from nine studies that were conducted in the Southern California Bight, including Swartz *et al.* (1985), Swartz *et al.* (1986), Anderson *et al.* (1988), Ferraro *et al.* (1991), Swartz *et al.* (1991), Bay *et al.* (1994), Sapudar *et al.* (1994), Fairey *et al.* (1996), and Fairey (1997). Both the dry weight-normalized and organic carbon-normalized SECs were evaluated using the procedures described in Section 2.5. The results of this evaluation indicate that the SECs for SUM DDE are generally reliable.

Based on the results of this assessment, the dry-weight normalized SEC can be used to reliably classify sediments from the Southern

California Bight (Table 6). Of the 29 sediment samples with concentrations of SUM DDE at or in excess of 6.58 mg/kg DW, 97% (28 samples) were found to be toxic. A lower value (2.00 mg/kg DW) was less reliable than the recommended SEC, as indicated by the incidence of toxic effects at or above this concentration (79.2%; 38 of 48 samples). In contrast, the reliability of a higher value of SUM DDE (10.0 mg/kg DW) was similar to that of the recommended SEC (94% correct classification; 17 of 18 samples).

The organic carbon-normalized SEC also provided a reliable basis for classifying sediment samples with elevated levels of SUM DDE in the Southern California Bight (Table 7). Based on the results of laboratory toxicity tests and benthic invertebrate community assessments, 87% (26 of 30) samples of the sediment samples with SUM DDE concentrations at or in excess of 1.82 mg/kg $DW_{1\% OC}$ were toxic to seidment-dwelling organisms. A lower value (0.50 mg/kg $DW_{1\% OC}$) was found to be less reliable, as indicated by the relatively lower incidence of toxic effects (68%; 41 of 60 samples) that was observed when SUM DDE concentrations equaled or exceeded this level. In contrast, a high incidence of toxic effects (100%; 14 of 14 samples) was observed when SUM DDE concentrations equaled or exceeded 3.00 mg/kg $DW_{1\% OC}$. Confidence in both SECs is enhanced by the concordance between the concentrations of SUM DDE and the incidence of toxic effects.

Predictability:

The predictability of the SECs for SUM DDE was evaluated using an independent data set, which was comprised of matching sediment chemistry and biological effects data for 254 sampling sites located outside the Southern California Bight. These studies were conducted in Narragansett Bay (Munns *et al.* 1991), San Francisco Bay (Swartz *et al.* 1994), Tampa Bay (Long *et al.* 1994), Hudson-Raritan Estuary (Long *et al.* 1995b), and Biscayne Bay (Long 1997; Table A5-2). None of the sediment samples from these marine and estuarine sites had concentrations of SUM DDE that equaled or exceeded the SECs (Tables 8 and 9). Therefore, it was not possible to evaluate the predictability of the SECs for SUM DDE. However, data from one freshwater site provide some relevant information for evaluating the predictability of the SECs.

Toxic samples were identified based on toxicity to amphipods, impaired fertilization of sea urchin gametes, or reduced amphipod abundance.

In 1991, Hoke *et al.* (1994) evaluated the acute toxicity of field-collected sediments from the Huntsville Spring Branch-Indian Creek system in Alabama. In this study, the toxicity of sediment samples collected nearby the Redstone Army Arsenal were evaluated using 10-day amphipod (*Hyalella azteca*) toxicity tests. The concentrations of SUM DDE ranged from below detection limits (BDL) to 12.2 mg/kg DW in the 15 samples collected in this investigation. The DW-normalized SEC of 6.58 mg/kg DW for SUM DDE was exceeded in three of the 15 sediment samples; hence, three samples were predicted to be toxic. The results of the toxicity tests that were performed indicated that all three samples were toxic to amphipods (statistical analyses of the mortality data were not performed by these investigators; samples with mortality of >20% were defined as toxic in this evaluation of the predictability of the SECs). All four of the samples that were predicted to be toxic using the OC-normalized SEC (1.68 mg/kg $DW_{1\%OC}$) were toxic to amphipods. Therefore, the predictability of both the DW-normalized and OC-normalized SECs for SUM DDE was calculated to be 100%.

3.4 Toxic Effects of SUM DDD

3.4.1 Spiked-Sediment Bioassay Data

No spiked-sediment bioassay data were located on the toxic effects of sediment-associated SUM DDD on marine organisms.

3.4.2 Field Data

In 1980, Swartz *et al.* (1985) examined sediment toxicity, contamination, and benthic macroinvertebrate community structure at seven sites in the vicinity of the Los Angeles County Sanitation District's sewage outfalls on the Palos Verdes Shelf. The results of this study indicated that the sediments from three stations (1, 2, and 3) were acutely toxic to amphipods, *Rhepoxynius abronius*, during 10-day tests. These investigators reported that benthic macroinvertebrate community structure (as indicated by infaunal index and invertebrate biomass) at these sites differed from that of the reference sites. The average concentration of SUM

DDD at the stations 1, 2, and 3 was 1.26 ± 0.769 mg/kg DW or 0.321 ± 0.173 mg/kg $DW_{1\%OC}$. The average concentration of this substance at the non-toxic stations (4, 5, 6, and 7) was 0.282 ± 0.411 mg/kg DW or 0.082 ± 0.105 mg/kg $DW_{1\%OC}$. Phoxocephalid amphipods were absent from stations that had average SUM DDD concentrations of 1.17 ± 0.574 mg/kg DW (0.299 ± 0.147 mg/kg $DW_{1\%OC}$), while this family was represented at stations that had 0.078 ± 0.075 mg SUM DDD/kg DW (0.032 ± 0.035 mg/kg $DW_{1\%OC}$).

In 1985, Swartz *et al.* (1991) collected sediment cores from four stations on the Palos Verdes Shelf and Santa Monica Bay. Two cores (up to 50 cm in depth) were collected from each station and cut into 5 cm vertical sections. Acute (10 day) toxicity tests using amphipods (*Rhepoxynius abronius*) were conducted on each of the core sections. The results of this investigation indicated that the mid-depth (12.5 - 32.5 cm) sediments from the stations located nearby the Los Angeles County outfalls were the most toxic to amphipods (78.6 ± 8.7% mortality). The average concentration of SUM DDD in these samples was 14.5 ± 6.34 mg/kg DW or 1.82 ± 0.829 mg/kg $DW_{1\%OC}$. Higher survival rates (35.9 ± 12.1% mortality) were observed in shallower and deeper sediments (2.5 - 12.5 cm and 37.5 to 47.5 cm); these samples had, on average, 3.00 ± 3.59 mg/kg DW (0.672 ± 0.587 mg/kg $DW_{1\%OC}$) of SUM DDD. The samples that were the least toxic to amphipods (8.7 ± 3.3% mortality) had average SUM DDD concentrations of 0.303 ± 0.808 mg/kg DW (0.085 ± 0.155 mg/kg $DW_{1\%OC}$).

Matching sediment chemistry and biological effects data collected at seven sites in the vicinity of Palos Verdes in 1987 provide additional information for evaluating the potentially toxic effects of SUM DDD (Anderson *et al.* 1988). The results of the 10-day acute toxicity tests conducted in this study indicated that the survival and reburial of the amphipod, *Grandidierella japonica*, were not linked with concentrations of SUM DDD in Southern California Bight sediments (Anderson *et al.* 1988). The mean concentration of SUM DDD was 0.022 ± 0.017 mg/kg DW (0.013 ± 0.016 mg/kg $DW_{1\%OC}$) in sediments that were significantly toxic to this species. By comparison, the mean concentration of SUM DDD in sediments that did not affect amphipod survival was 0.106 ± 0.239 mg/kg DW (0.028 ± 0.056 mg/kg $DW_{1\%OC}$). As the concentrations of these substances were lower at the toxic sites than they were at the non-toxic sites, something other than the concentrations of SUM DDD must have been responsible for the observed effects.

The results of the 35-day chronic toxicity tests conducted by Anderson *et al.* (1988) indicate that the survival, sediment preference (i.e., avoidance behavior), and gonad growth of the sea urchin, *Lytechinus pictus*, were not linked to the

concentrations of sediment-associated DDDs (i.e., there was no concordance between the sediment chemistry and the biological effects). However, sea urchin growth (as measured by increases in weight or test width) was linked to concentrations of SUM DDDs, with reduced growth rates observed in sediments with a mean concentration of 0.310 ± 0.400 mg SUM DDD/kg DW (0.073 ± 0.099 mg/kg $DW_{1\%OC}$). No effects on growth were evident at the sites with an average concentration of 0.012 ± 0.014 mg SUM DDD/kg DW (0.009 ± 0.010 mg/kg $DW_{1\%OC}$). It should be noted that this analysis was significantly affected by one sample (Palos Verdes) that had concentrations of DDDs that were more than an order of magnitude higher than those that were measured at other sites.

In a study commissioned by the Santa Monica Bay Restoration Project, Bay *et al.* (1994) collected sediments from 12 sites located in the vicinity of the Palos Verdes Peninsula and a reference site near Dana Point. Acute toxicity bioassays were conducted using sediments from five of the 13 sites sampled in the 1992 survey; none of these sediments were acutely toxic to the amphipod, *Rhepoxynius abronius* (Bay *et al.* 1994). The mean concentration of SUM DDD at these stations was 0.893 ± 1.38 mg/kg DW (0.312 ± 0.431 mg/kg $DW_{1\%OC}$).

The survival, avoidance behavior, gonad size, and diameter of white sea urchins were not affected by exposure to Palos Verdes sediments (Bay *et al.* 1994). The mean concentration of SUM DDD at the 13 sites was 0.517 ± 0.883 mg/kg DW or 0.181 ± 0.276 mg/kg $DW_{1\%OC}$. However, the growth rate (as measured by WW change during the test) of this species was influenced by exposure to certain Palos Verdes sediments. Specifically, relatively low growth rates (i.e., ≤ 0.08 g WW/35 days) were observed at sites with a mean concentration of SUM DDD of 1.17 ± 1.47 mg/kg DW or 0.357 ± 0.481 mg/kg $DW_{1\%OC}$. The average concentrations of this substance were lower (0.227 ± 0.236 mg/kg DW or 0.103 ± 0.075 mg/kg $DW_{1\%OC}$) in the sediments that were not associated with growth effects (i.e. growth rates of ≥ 0.17 g WW/35 days). Similarly, the fertilization of sea urchin (*Strongylocentrotus purpuratus*) gametes was also linked to sediment SUM DDD concentrations, with low fertilization (9.4 ± 16.2%) observed in porewater from sediments with, on average, 1.10 ± 1.26 mg/kg DW (0.353 ± 0.402 mg/kg $DW_{1\%OC}$). Higher fertilization rates (80.0 ± 10.2%) were observed in porewater from sediments with mean concentrations of 0.170 ± 0.221 mg SUM DDD/kg DW (0.074 ± 0.068 mg SUM DDD/kg $DW_{1\%OC}$).

In 1992, sediment samples were collected from a number of locations in San Pedro Bay, including Los Angeles and Long Beach Harbours (Sapudar *et al.* 1994). The toxicity of each sample was evaluated using two toxicity tests, including 48-hour red abalone (*Haliotus rufescens*) larval development test (using

pore water) and 10-day amphipod (*Rhepoxynius abronius*) survival test (using bulk sediments). The data on the effects of pore water on abalone larval development were not used in this evaluation because they provided little ability to discriminate between sampling sites (i.e., nearly 90% of the samples were shown to be toxicity based on the results of this test).

The results of this investigation indicated that sediments from Los Angeles Inner Harbour, Inner Fish Harbour, East Basin, and Alamitos Bay were the most toxic to amphipods. In this study, toxic samples were identified as those in which amphipod survival was more than 20% lower than the average survival in the control treatments (Long *et al.* In review). The average concentrations of SUM DDD in the toxic samples were 0.029 ± 0.050 mg/kg DW or 0.012 ± 0.011 mg/kg $DW_{1\%OC}$. In the non-toxic samples, SUM DDD concentrations averaged 0.011 ± 0.016 mg/kg DW or 0.010 ± 0.007 mg/kg $DW_{1\%OC}$. While amphipod mortality was linked to dry weight-normalized concentrations of SUM DDD, the organic carbon-normalized SUM DDD concentrations appeared to contribute minimally to the biological effects that were observed.

In a related study, sediments were collected at several locations on the Palos Verdes Shelf and in Santa Monica Bay during 1992 and 1993 (Fairey 1997). Based on the results of 10-day toxicity tests, sediments from 11 of the 19 sites tested were acutely toxic to the amphipod, *Rhepoxynius abronius*. The average concentration of SUM DDD at the toxic sites was 0.107 ± 0.246 mg/kg DW or 0.092 ± 0.249 mg/kg $DW_{1\%OC}$. By comparison, SUM DDD concentrations averaged 0.116 ± 0.033 mg/kg DW or 0.072 ± 0.052 mg/kg $DW_{1\%OC}$ at the non-toxic sites in this survey. The limited concordance between amphipod survival and contaminant concentrations indicates that SUM DDD was unlikely to be responsible for the observed biological effects. While polychaete survival and growth tests were also conducted in this study, the data were not used in this evaluation because only four sediment samples were tested.

Under the Bay Protection and Toxics Cleanup Program, sediment samples were collected at a total of 350 stations in the vicinity of San Diego between October, 1992 and May, 1994 (Fairey *et al.* 1996). Sediment samples from the middle portion of San Diego Bay (i.e., the vicinity of the naval shipyards) were included in the data set assembled for this investigation because substantial concentration gradients in several of the contaminants of concern were observed. Several solid phase and porewater toxicity tests were conducted during this investigation, including an amphipod (*Rhepoxynius abronius*) survival test, a sea urchin (*Strongylocentrotus purpuratus*) fertilization tests, and a sea urchin (*S. purpuratus*) larval development test. The results of the polychaete growth and survival test,

the bay mussel larval development test, and the red abalone larval development tests were not used due to incomplete designation of toxic samples. The results of the power analyses conducted by Long *et al.* (In review) were used to designate toxic samples for the amphipod and sea urchin tests (i.e., samples were designated as toxic if the response measured differed by more than 20% from that of the control samples).

The results of this study indicated that sediments from the eastern portion of middle San Diego Bay were generally the most toxic to amphipods. The average concentration of SUM DDD at the toxic sites was 0.006 ± 0.018 mg/kg DW (0.010 ± 0.050 mg/kg $DW_{1\%OC}$). The average concentration of SUM DDD in the samples that were not acutely toxic to amphipods was 0.005 ± 0.005 mg/kg DW (0.003 ± 0.004 mg/kg $DW_{1\%OC}$). While there was little concordance between amphipod mortality and dry weight-normalized SUM DDD concentrations, the relationship was stronger for organic carbon-normalized SUM DDD concentrations.

The results of the tests with sea urchin gametes and embryos appear to agree with the results of the amphipod tests. Specifically, there was little concordance between sea urchin fertilization or embryo development and the dry weight-normalized concentrations of SUM DDD in sediment samples from middle San Diego Bay. However, sea urchin larval development was linked to organic carbon normalized concentrations of SUM DDD.

3.4.3 SECs for SUM DDD

Using the weight-of-evidence approach, SECs of 0.89 mg/kg DW or 0.23 mg/kg $DW_{1\%OC}$ were derived for SUM DDD (i.e., the sum of the concentrations of *p,p'*-DDD and *o,p'*-DDD).

Rationale: No dose-response data from controlled laboratory studies were located on the toxicity of SUM DDD. For this reason, SECs for SUM DDD could not be calculated using the spiked-sediment bioassay approach. Hence, the SECs for SUM DDD were derived using the weight-of-evidence approach.

A total of 15 effects records on the toxicity of-sediment-associated SUM DDD (hits; designated by an *) were included in the summarized toxicological data set (Table A4-9).

Evaluation of these data using the procedures described in Sections 2.4, resulted in the calculation of an ER-M (effects range median) of 1.17 mg/kg DW for SUM DDD. The unsummarized data set (Table A4-10) consisted of a total of 75 effects data records; the 50th percentile of this distribution was 0.89 mg/kg DW. The lower of these two values was identified as the SEC for SUM DDD.

The summarized toxicological data set for OC-normalized SUM DDD consisted of 16 effects data entries (Table A4-11). The median value in this data set was 0.299 mg/kg $DW_{1\%OC}$ for SUM DDD. Using the unsummarized toxicological data set (which had 72 effects data records; Table A4-12), an ER-M of 0.23 mg/kg $DW_{1\%OC}$ was determined for SUM DDD. The lower of these two values was identified as the SEC for this group of substances.

3.4.4 Evaluation of the SECs for SUM DDD

Reliability:

The reliability of the SECs for SUM DDD were evaluated using the procedures described in Section 2.5. To support this evaluation, matching sediment chemistry and biological effects data were compiled from a number of studies that were conducted in the Southern California Bight. These studies included Swartz *et al.* (1985), Swartz *et al.* (1986), Anderson *et al.* (1988), Ferraro *et al.* (1991), Swartz *et al.* (1991), Bay *et al.* (1994), Sapudar *et al.* (1994), Fairey *et al.* (1996), and Fairey (1997).

The results of this evaluation indicate that the dry weight-normalized SEC for SUM DDD provides a reliable basis for classifying sediment samples with elevated levels of this group of substances (Table 10). In total, 20 of the 21 (95%) sediment samples with SUM DDD concentrations at or in excess of the SEC were found to be toxic, based on the results of laboratory toxicity tests and benthic invertebrate community assessments. Therefore, there is a high probability of observing toxic effects at SUM DDD concentrations at or above the SEC. Most of the sediment samples with SUM DDD

concentrations at or above 0.5 mg/kg DW (93%; 27 of 29 samples) and 1.5 mg/kg DW (94%; 17 of 18 samples) were also toxic to sediment-dwelling organisms. These results suggest that a lower value could be used to evaluate sediment quality in the Southern California Bight without substantially reducing the reliability of the SEC.

The organic carbon-normalized SEC also provides a reliable basis for classifying sediment samples in the Southern California Bight (Table 11). Twenty-one of the 23 sediment samples (91%) with SUM DDD concentrations at or above the SEC were found to be toxic to sediment-dwelling organisms. These results indicate that there is a high probability of observing adverse biological effects when SUM DDD concentrations exceed the organic carbon-normalized SEC. A lower value would have been slightly less reliable, as indicated by the incidence of toxic effects at or above 0.10 mg/kg $DW_{1\% OC}$ (86%; 30 of 35 samples were toxic). The increasing incidence of toxicity with increasing concentrations of SUM DDD generates additional confidence in the SECs.

Predictability:

The predictability of the SECs for SUM DDD was evaluated using data from five studies that were conducted outside Southern California Bight. These studies were conducted in Narragansett Bay (Munns *et al.* 1991). San Francisco Bay (Swartz *et al.* 1994), Tampa Bay (Long *et al.* 1994), Hudson-Raritan Estuary (Long *et al.* 1995b), and Biscayne Bay (Long 1997; Table A5-3). Of the 254 sediment samples that were collected in these studies, only six had SUM DDD concentrations that equaled or exceeded the dry weight-normalized SEC (Table 12). Five of these samples were toxic to sediment-dwelling organisms, as indicated by the results of laboratory toxicity tests (predictability = 83%). The incidence of toxic effects was the same for a lower concentration of SUM DDD, while predictability was somewhat lower (i.e., 80%; 4 of 5 samples were correctly predicted to be toxic) for a higher concentration of SUM DDD (1.50 mg/kg DW).

While the available data were limited, the results of this evaluation indicated that the organic carbon-normalized SEC was less predictive of toxicity than the dry weight-normalized SEC (Table 13). Only five

	Overall	216	5	5	100.0

of the seven sediment samples with concentrations of SUM DDD equaled or exceeded the SEC were found to be toxic. Therefore, the predictability of the SEC was calculated to be 71%. By comparison, all of the sediment samples (5 of 5) were correctly classified when 0.40 mg/kg $DW_{1\%\ OC}$ was used as the sediment quality assessment value.

Matching sediment chemistry and biological effects data from one study conducted in a freshwater system provide additional information for evaluation the predictability of the SECs for SUM DDD. In 1991, Hoke *et al.* (1994) evaluated the acute toxicity of field-collected sediments from the Huntsville Spring Branch-Indian Creek system in Alabama. In this study, the effects of sediment-associated contaminants were evaluated in 10-day toxicity tests using amphipods (*Hyalella azteca*). The concentrations of SUM DDD ranged from below detection limits (BDL) to 42.3 mg/kg DW in the 15 samples collected nearby the Redstone Army Arsenal. The DW-normalized SEC of 1.17 mg/kg DW for SUM DDD was exceeded in 11 of the 15 sediment samples; hence, 11 samples were predicted to be toxic. The results of the toxicity tests indicated that all 11 samples were toxic to amphipods (statistical analyses of the mortality data were not performed by these investigators; samples with mortality of >20% were defined as toxic in this evaluation of the predictability of the SECs). In addition, all 11 of the samples that were predicted to be toxic using the OC-normalized SEC (0.299 mg/kg $DW_{1\%OC}$) were toxic to amphipods. Therefore, the predictability of both the DW-normalized and OC-normalized SECs for SUM DDD was calculated to be 100%.

3.5 Toxic Effects of Total DDT

3.5.1 Spiked-Sediment Bioassay Data

The data from four spiked-sediment toxicity investigations (McLeese and Metcalfe 1980; McLeese *et al.* 1982; Plesha *et al.* 1988; Bay *et al.* 1994) indicate that median lethal concentrations of tDDT ranged from 0.031 to >16.5 mg/kg DW (0.111 to >8.7 mg/kg $DW_{1\%OC}$). While these studies provide important information for assessing the toxic effects of specific DDT isomers, they may not

be directly relevant for evaluating the toxicity of tDDT. For example, it is likely that three of these studies utilized technical or reagent grade DDT in the toxicity tests. Both of these formulations are comprised primarily (i.e., >90%) of the *p,p'*-DDT and *o,p'*-DDT isomers (USEPA 1980a). However, Bay *et al.* (1994) reported that SUM DDE represented, on average, 88.4 ± 7.86% of the tDDT in the Palos Verdes sediments sampled in 1992; SUM DDT represented, on average, only 3.7 ± 3.89% of the tDDT in these samples. As there is some evidence (from water-only exposure studies) to suggest that *p,p'*-DDT and *o,p'*-DDT (i.e., SUM DDT) are more toxic to marine organisms than DDE or DDD (USEPA 1980a), consideration of data on SUM DDT alone could overestimate the toxicity of tDDT in the Southern California Bight. Likewise, data on the toxic effects of SUM DDE alone could underestimate the toxicity of tDDT, if DDE was significantly less toxic than the other DDT isomers. Therefore, the available spiked-sediment bioassay data were not used directly to determine SECs for tDDT in the Southern California Bight. However, these data were incorporated into the toxicological database and used to derive SECs using the WEA.

3.5.2 Field Data

In 1977, Word and Mearns (1979) collected sediment samples from a total of 70 stations between Point Conception and the United States-Mexico border. At each station, two samples were collected for assessing benthic invertebrate community characteristics and one sample was collected for chemical analysis. Total DDT concentrations were measured in the samples collected at each station. All of these samples were collected from a water depth of approximately 60 meters.

The results of the Word and Mearns (1979) study suggest that several benthic invertebrate community metrics are correlated with the concentration of tDDT in the Southern California Bight. For example, sites with an average of 70.2 ± 70.7 mg tDDT/kg DW had low densities of arthropods (4 ± 3.45 N/0.1 m^2). Higher arthropod densities (48.8 ± 19.5 N/0.1 m^2) were observed at sites with, on average, 3.2 ± 11.3 mg/kg DW of tDDT. The highest densities of arthropods (144 ± 42.7 N/0.1 m^2) were observed at the sites with the lowest concentrations of tDDT (0.101 ± 0.151 mg/kg DW). While echinoderm abundance demonstrated similar patterns relative to tDDT concentrations, species richness and total invertebrate abundance were not strongly linked to tDDT concentrations. As OC concentrations were not reported in this study, it was not possible to normalize the results to 1%OC.

In the 1980 study conducted in the vicinity of the Los Angeles County Sanitation District's sewage outfalls, Swartz *et al.* (1985) examined sediment toxicity, contamination, and benthic macroinvertebrate community structure at seven sites on the Palos Verdes Shelf. The results of this study indicated that the sediments from three sites were acutely toxic to amphipods during 10-day exposures. Benthic invertebrate community structure was also altered at these sites (as indicated by infaunal index and total biomass). Sediments from the other four sites were not toxic. At the toxic sites, the concentration of tDDT averaged 7.15 ± 1.89 mg/kg DW or 1.81 ± 0.55 mg/kg $DW_{1\%OC}$. The mean concentration of this group of substances at the non-toxic sites was 3.21 ± 4.46 mg/kg DW or 0.94 ± 1.12 mg/kg $DW_{1\%OC}$.

In a follow-up survey conducted in 1983, Swartz *et al.* (1986) collected sediment and macrobenthos samples from a total of nine sites on the Palos Verdes Shelf and in Santa Monica Bay. Matching sediment chemistry and biological effects (including acute toxicity bioassays and benthic invertebrate community structure) data were reported for six of these sites. These stations were considered to be the same locations as those sampled in the 1980 survey. The results of 10-day tests on the amphipod, *Rhepoxynius abronius*, indicated that the sediments collected from only one station (#6) were acutely toxic (Ferraro *et al.* 1991). The concentration of tDDT at this station was 3.55 mg/kg DW or 1.48 mg/kg $DW_{1\%OC}$. The mean concentration of tDDT at the non-toxic sites was 5.25 ± 4.31 mg/kg DW or 1.80 ± 1.29 mg/kg $DW_{1\%OC}$. The lack of concordance between the amphipod survival and tDDT concentrations indicates that this group of substances was not responsible for observed biological effects.

In the 1983 study (Swartz *et al.* 1986), benthic invertebrate community structure was altered at several sites with elevated levels of tDDT. For example, low echinoderm densities were observed at sites with mean concentrations of tDDT of 5.92 ± 3.49 mg/kg DW or 2.08 ± 0.934 mg/kg $DW_{1\%OC}$. In contrast, high densities of echinoderms were observed at a site with 0.140 mg tDDT/kg DW or 0.107 mg tDDT/kg $DW_{1\%OC}$. Similarly, low amphipod densities were observed at sites with mean concentrations of tDDT of 8.25 ± 1.70 mg/kg DW or 2.65 ± 0.659 mg/kg $DW_{1\%OC}$. Higher densities of amphipods were observed at sites with 1.68 ± 1.73 mg tDDT/kg DW or 0.846 ± 0.691 mg/kg $DW_{1\%OC}$. Similar results were observed when total benthic invertebrate density, species richness, and infaunal index were considered.

In 1985, Swartz *et al.* (1991) collected sediment cores from four stations on the Palos Verdes Shelf and in Santa Monica Bay. Two cores (up to 50 cm in depth) were collected from each station and cut into 5 cm vertical sections. Acute (10

day) toxicity tests using amphipods, *Rhepoxynius abronius*, were conducted on each of the core sections. The results of this investigation indicated that the mid-depth (12.5 - 32.5 cm) sediments from the stations located nearby the Los Angeles County outfalls were the most toxic to amphipods (78.6 ± 8.7% mortality). The mean concentration of tDDT in these sediment samples was 143 ± 52.3 mg/kg DW or 17.2 ± 3.13 mg/kg $DW_{1\%OC}$. Moderate toxicity to amphipods (35.9 ± 12.1% mortality) was observed in shallower and deeper sediments (2.5 - 12.5 cm and 37.5 to 47.5 cm); these samples had, on average, 23.9 ± 17.5 mg/kg DW (4.59 ± 3.10 mg/kg $DW_{1\%OC}$) of tDDT. The samples that were the least toxic to amphipods (8.7 ± 3.3% mortality) had average tDDT concentrations of 1.94 ± 4.85 mg/kg DW (0.580 ± 0.835 mg/kg $DW_{1\%OC}$).

One year later (1986), another follow-up survey was conducted to evaluate trends in sediment contamination and benthic macroinvertebrate community structure on the Palos Verdes Shelf and in Santa Monica Bay (Ferraro *et al.* 1991). A total of eight sites were sampled in this survey; none of the sediments tested were acutely toxic to the amphipod, *Rhepoxynius abronius*, during 10-day exposures. The mean concentration of tDDT at the eight sites was approximately 6.94 ± 4.69 mg/kg DW or 1.83 ± 0.922 mg/kg $DW_{1\%OC}$.

Data on benthic invertebrate community structure, which reflects continuous exposure to sediment-associated contaminants, indicates that adverse effects on sediment-dwelling organisms occur at elevated levels of tDDT (Ferraro *et al.* 1991). For example, low densities of amphipods (4.1 ± 2.5 N/0.1 m^2) were observed at several sites sampled on the Palos Verdes Shelf. At these sites, concentrations of tDDT averaged 10.7 ± 4.55 mg/kg DW or 2.66 ± 0.253 mg/kg $DW_{1\%OC}$. Moderate amphipod densities (23.5 ± 5.9 N/0.1 m^2) were observed at the sites with lower concentrations of tDDT (7.12 ± 0.695 mg/kg DW or 1.90 ± 0.238 mg/kg $DW_{1\%OC}$). The highest amphipod densities (54.6 ± 5.1 N/0.1 m^2) were observed at the sites with the lowest tDDT concentrations (1.10 ± 1.23 mg/kg DW or 0.494 ± 0.295 mg/kg $DW_{1\%OC}$). Similarly, low echinoderms densities (2.4 ± 5.7 N/0.1 m^2) were observed at seven of the eight sites sampled during this survey, with tDDT concentrations averaging 7.90 ± 4.13 mg/kg DW or 2.05 ± 0.732 mg/kg $DW_{1\%OC}$ at these sites. The density of echinoderms (208 N/0.1 m^2) was higher at a site with lower concentrations of tDDT (0.229 mg/kg DW or 0.286 mg/kg $DW_{1\%OC}$). Species richness, total benthic invertebrate density, and total benthic invertebrate biomass were not correlated with tDDT concentrations, however.

Matching sediment chemistry and biological effects data were collected at seven sites in the Southern California Bight during 1987 (Anderson *et al.* 1988). While

this study was conducted primarily to evaluate the effects associated with PAH-contaminated sediments, it also provides some information for assessing the potential effects of mixtures of tDDT and other substances. In this study, the survival and reburial of the amphipod, *Grandidierella japonica*, (in 10-day acute toxicity tests) were not linked with concentrations of tDDT. The mean concentration of tDDT was 0.104 ± 0.094 mg/kg DW or 0.042 ± 0.044 mg/kg $DW_{1\%OC}$ in sediments that were significantly toxic to this species. The average concentration of tDDT in sediments that did not affect survival was 1.04 ± 2.45 mg/kg DW or 0.259 ± 0.585 mg/kg $DW_{1\%OC}$. As the concentration of this substance was lower at the toxic sites than it was at the non-toxic sites, something other than the concentrations of tDDT must have been responsible for the observed effects.

The survival, sediment preference (i.e., avoidance behavior), and gonad growth of the sea urchin, *Lytechinus pictus*, (in 35-day chronic exposure tests) were not correlated with the concentrations of sediment-associated tDDT measured in Palos Verdes sediments (i.e., there was no concordance between sediment chemistry and the biological effects; Anderson *et al.* 1988). However, effects on sea urchin growth were associated with elevated concentrations of DDTs. Reduced growth rates were observed in sediments with mean concentrations of 3.12 ± 4.13 mg/kg DW or 0.736 ± 1.01 mg/kg $DW_{1\%OC}$ of tDDT. It should be noted that this analysis was significantly affected by one sample (Palos Verdes) that had concentrations of DDTs that were more than an order of magnitude higher than those measured at other sites.

In a study commissioned by the Santa Monica Bay Restoration Project, Bay *et al.* (1994) collected sediments from 12 sites located in the vicinity of the Palos Verdes Peninsula and one reference site near Dana Point. Acute toxicity bioassays were conducted using sediments from five of the 13 sites sampled in the 1992 survey; none on these sediments were toxic to amphipods (*Rhepoxynius abronius*; Bay *et al.* 1994). The mean concentrations of tDDT at these sites were 7.09 ± 6.96 mg/kg DW or 2.71 ± 2.09 mg/kg $DW_{1\%OC}$. Similarly, the survival, avoidance behavior, gonad growth and growth (as indicated by diameter) of white sea urchins (*Lytechinus pictus*) were not affected at mean tDDT concentrations of 5.61 ± 5.83 mg/kg DW or 1.97 ± 1.57 mg/kg $DW_{1\%OC}$.

The growth rate (as measured by wet weight change over the 35-day exposure period) of white sea urchins was influenced by exposure to Palos Verdes sediments (Bay *et al.* 1994). Reduced growth rates were observed at sites with mean concentrations of tDDT of 10.7 ± 7.32 mg/kg DW or 3.09 ± 2.10 mg/kg $DW_{1\%OC}$. The concentrations of this group of substances were lower in the

sediments that were not associated with growth effects (3.36 ± 3.52 mg/kg DW or 1.48 ± 1.07 mg/kg $DW_{1\%OC}$). Similar results were obtained when the fertilization of sea urchin, *Strongylocentrotus purpuratus*, gametes was the experimental endpoint considered in the bioassay. The results of this short-term (< 2 hours) test indicated that low fertilization rates (9.4 ± 16.2%) were associated with exposure to porewater from sediments that had mean tDDT concentrations of 10.3 ± 5.83 mg/kg DW or 3.15 ± 1.61 mg/kg $DW_{1\%OC}$. Higher fertilization rates were associated with exposure to porewater from sediments with 3.02 ± 3.88 mg tDDT/kg DW or 1.31 ± 1.14 mg tDDT/kg $DW_{1\%OC}$.

Under the Bay Protection and Toxics Cleanup Program, sediment samples were collected from a number of locations in the vicinity of Los Angeles and Long Beach Harbours in 1992 (i.e., San Pedro Bay; Sapudar *et al.* 1994). The toxicity of each sample was evaluated using two toxicity tests, including 48-hour red abalone (*Haliotus rufescens*) larval development test (using pore water) and 10-day amphipod (*Rhepoxynius abronius*) survival test (using bulk sediments). The data on the effects of pore water on abalone larval development were not used in this evaluation because they provided little ability to discriminate between sampling sites (i.e., nearly 90% of the samples were shown to be toxicity based on the results of this test).

Based on the results of the amphipod tests, Sapudar *et al.* (1994) showed that sediments from Los Angeles Inner Harbour, Inner Fish Harbour, East Basin, and Alamitos Bay tended to be the most toxic. In this assessment, toxic samples were identified as those in which amphipod survival was more than 20% lower than the average survival in the control treatments (Long *et al.* In review). In the toxic samples from San Pedro Bay, the concentrations of tDDT averaged 0.161 ± 0.147 mg/kg DW or 0.081 ± 0.064 mg/kg $DW_{1\%OC}$. By comparison, tDDT concentrations averaged 0.111 ± 0.086 mg/kg DW or 0.113 ± 0.116 mg/kg $DW_{1\%OC}$ in the non-toxic samples. The limited concordance between amphipod survival and tDDT concentrations indicates that this group of substances likely contributed minimally to the amphipod mortality that was observed in Los Angeles and Long Beach Harbours.

During 1992 and 1993, sediment sampling was conducted at several locations on the Palos Verdes Shelf and in Santa Monica Bay (Fairey 1997). Matching sediment chemistry and toxicity data were reported for 19 sites in this area. The results of 10-day acute toxicity tests with the amphipod, *Rhepoxynius abronius*, indicated that the sediments from 11 of these sites were acutely toxic. The average concentrations of tDDT at these sites were 0.683 ± 1.28 mg/kg DW or 0.495 ± 1.04 mg/kg $DW_{1\%OC}$. At the non-toxic sites, tDDT concentrations

averaged 2.83 ± 0.521 mg/kg DW or 1.73 ± 1.07 mg/kg $DW_{1\%OC}$. The lack of concordance between amphipod survival and tDDT concentrations indicates that this group of substances was not responsible for the observed biological effects. While polychaete survival and growth tests were also conducted in this study, the data were not used in this evaluation because only four sediment samples were tested.

Between October, 1992 and May, 1994, a total of 350 samples were collected under the Bay Protection and Toxics Cleanup Program to evaluate sediment quality conditions in San Diego (Fairey *et al.* 1996). A portion of these data (i.e., the samples from the middle portion of San Diego Bay near the naval shipyards) were included in the data set assembled for this investigation because substantial concentration gradients existed for several of the contaminants of concern. The porewater and solid phase sediment toxicity tests conducted on each of the samples included: amphipod (*Rhepoxynius abronius*) survival; sea urchin (*Strongylocentrotus purpuratus*) fertilization; and, sea urchin (*S. purpuratus*) larval development. The results of the polychaete growth and survival test, the bay mussel larval development test, and the red abalone larval development tests were not used due to incomplete designation of toxic samples. The results of the power analyses conducted by Long *et al.* (In review) were used to designate toxic samples for the amphipod and sea urchin tests (i.e., samples were designated as toxic if the response measured differed by more than 20% from that of the control samples).

Based on the results of the 10-day acute lethality tests, sediments from the eastern portion of middle San Diego Bay were generally found to be the most toxic to amphipods. The concentration of tDDT at the toxic sites averaged 0.022 ± 0.049 mg/kg DW (0.028 ± 0.123 mg/kg $DW_{1\%OC}$). Similar concentrations of tDDT (0.022 ± 0.021 mg/kg DW or 0.013 ± 0.013 mg/kg $DW_{1\%OC}$) were observed in the samples that were not acutely toxic to amphipods, indicating that tDDT probably contributed little to amphipod mortality in the middle portion of San Diego Bay. Better concordance between the results of two of the toxicity tests (i.e., amphipod mortality and sea urchin larval development) and tDDT concentrations was observed when organic carbon-normalized values were considered, however.

In 1993, sediment samples were collected from 10 sites along the 60 meter contour on the Palos Verdes Shelf (Murdoch *et al.* In press). Acute (10 day) and short-term chronic (20 day) toxicity tests using the marine polychaete, *Neanthes arenaceodentata*, were conducted on sediments from all of these locations. In addition, a 120 day chronic toxicity test was conducted using the same species to

determine the effects on reproduction associated with long-term exposure to PCBs and DDTs. The results of this study indicated that acute and short-term chronic exposure to tDDT concentrations as high as 267 mg/kg DW (33.2 mg/kg $DW_{1\%OC}$) did not adversely affect polychaete survival or growth. The concentrations of tDDT averaged 49.4 ± 107 mg/kg DW (7.56 ± 12.6 mg/kg $DW_{1\%OC}$) in these non-toxic samples. However, polychaete reproductive success, as indicated by the number of emergent juveniles, was compromised in the sediments that had the highest concentrations of tDDTs (140 ± 180 mg/kg DW or 18.3 ± 21 mg/kg $DW_{1\%OC}$). In contrast, polychaete reproduction was not impaired in sediments that contained 4.14 ± 3.38 mg/kg DW (2.18 ± 1.23 mg/kg $DW_{1\%OC}$).

3.5.3 SECs for Total DDT

Using the weight-of-evidence approach, SECs of 7.15 mg/kg DW and 2.00 mg/kg $DW_{1\%OC}$ were derived for tDDT (i.e., the sum of the concentrations of *p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *o,p'*-DDE, *p,p'*-DDD, *o,p'*-DDD).

Rationale: As indicated previously, data on the toxicity of tDDT are available from four spiked-sediment bioassays. Two of the four studies included dose-response information on a benthic arthropod species, but both of these investigations were conducted using the technical or reagent grade DDT. As the tDDT in Southern California Bight sediment consists primarily of DDE, the data from these spiked-sediment bioassays could overestimate the toxicity of tDDT. For this reason, SECs were derived using the WEA rather than the SSBA.

The summarized and unsummarized toxicological data sets for tDDT (mg/kg DW) contained a total of 36 and 149 effects data records, respectively (hits; designated by an *; Tables A4-13 and A4-14). Evaluation of these data sets, using the procedures described in Section 2.4, resulted in the calculation of ER-Ms (effects range median) of 7.15 and 8.22 mg/kg DW using the summarized and unsummarized data sets, respectively, for tDDT. The lower of these two values was identified as the SEC.

Similarly, the summarized and unsummarized toxicological data sets for tDDT, expressed on an OC-normalized basis (mg/kg

$DW_{1\%OC}$) contained 28 and 100 effects data entries, respectively (Tables A4-15 and A4-16). The ER-Ms derived from these two data sets were 2.00 and 2.21 mg/kg $DW_{1\%OC}$, respectively. The lower of these two values was identified as the SEC.

3.5.4 Evaluation of the SECs for Total DDT

Reliability:

The reliability of the SECs for tDDTs was evaluated using the procedures described in Section 2.5. To support this evaluation, matching sediment chemistry and biological effects data were compiled from 11 studies that were conducted in the Southern California Bight. The results of an evaluation of the SECs derived in this study indicate that these assessment values provide a reliable basis for evaluating the toxic effects of sediment-associated tDDTs.

In the Southern California Bight, 40 sediment samples had concentrations of tDDTs that equaled or exceeded the SEC of 7.15 mg/kg DW (Table 14). Based on the results of various toxicity tests and benthic invertebrate community assessments, 38 of these samples (95%) were found to be toxic. This assessment indicates that a high degree of confidence should be placed in the SEC for tDDT.

A lower value was found to be less reliable than the SEC for tDDT. Of the 62 sediment samples with tDDT concentrations at or in excess of 2.0 mg/kg DW, 47 (76%) were found to be toxic. A higher incidence of toxicity (96%) was observed in sediment samples with tDDT concentrations at or in excess of 10 mg/kg DW. The increasing incidence of toxicity with increasing concentrations of tDDTs raises the level of confidence that can be placed in the SEC.

Based on the information contained in the toxicological data sets, the OC-normalized SEC is also provides a reliable basis for classifying sediment samples from the Southern California Bight (Table 15). Thirty-two of the 39 sediment samples (82%) with tDDT concentrations at or above the SEC were found to be toxic. A lower value (0.5 mg/kg $DW_{1\%\ OC}$) was found to be much less reliable, as only 63% of the samples with concentrations at or above this level

were toxic. A higher value, 3.0 mg/kg $DW_{1\% OC}$, was found to be slightly more reliable than the SEC [i.e., 21 of 25 (84%) of the sediment samples were correctly classified].

Predictability:

The predictability of the SECs for tDDT was evaluated using data from nine studies that were conducted elsewhere in the United States (i.e., outside the Southern California Bight; Chapman *et al.* 1987; Pastorok and Becker 1990; Munns *et al.* 1991; Casillas *et al.* 1992; Swartz *et al.* 1994; Long *et al.* 1994; Rice *et al.* 1995; Long *et al.* 1995b; Long 1997; Table A5-4). This data set included matching sediment chemistry and biological effects data on more than 300 sediment samples. Only three of these samples had concentrations of tDDTs that exceeded the dry weight-normalized SECs; all three of these sediment samples were toxic (Table 16). Notwithstanding the limitations on the data set, these results suggest that the SEC provides an accurate basis for classifying sediment samples with elevated levels of tDDTs. A somewhat lower level of predictability (83%; 5 of 6 samples were correctly classified) was achieved using a lower value of tDDTs (2.0 mg/kg DW).

Evaluation of the organic carbon-normalized SEC for tDDT was also limited by the available data (Table 17). That is, few sediment samples from sites outside the Southern California Bight had tDDT concentrations that exceeded the SEC. Nonetheless, all of the sediment samples with tDDT levels above 2.0 mg/kg $DW_{1\% OC}$ (i.e., 3 of 3 samples) were found to be toxic, suggesting that the SEC provided an accurate predictor of sediment toxicity. A lower value (0.050 mg/kg $DW_{1\%OC}$) also accurately classified sediments with elevated levels of tDDTs (predictability = 86%, 6 of 7 samples).

The results of independent study conducted in a freshwater ecosystem provide additional information for evaluating the predictability of the SEC that was developed for tDDT in the Southern California Bight. In 1991, Hoke *et al.* (1994) evaluated the acute toxicity of field-collected sediments from the Huntsville Spring Branch-Indian Creek system in Alabama. In this study, amphipods (*Hyalella azteca*) were exposed for a period of 10 days to sediments (15 samples) collected nearby the Redstone Army Arsenal. The concentrations of tDDT

ranged from below detection limits (BDL) to 199 mg/kg DW (BDL to 78.6 mg/kg $DW_{1\%OC}$) in these samples. The SEC of 7.15 mg/kg DW for tDDT was exceeded in 10 of the sediment samples; all 10 samples were predicted to be toxic. The results of the toxicity tests that were performed indicated that all 10 samples were toxic to amphipods (statistical analyses of the mortality data were not performed by these investigators; samples with mortality of >20% were defined as toxic in this evaluation of the predictability of the SECs). All 11 of the samples that were predicted to be toxic using the OC-normalized SEC (2.00 mg/kg $DW_{1\%OC}$) were toxic to amphipods. Therefore, the predictability of both the DW-normalized and OC-normalized SECs for tDDT was calculated to b 100%.

3.6 Discussion of the Toxic Effects of DDTs

There are a number of factors that could, potentially, affect the toxicity of sediment-associated DDTs. These factors include species and life stage tested, exposure route(s) considered, duration of exposure, endpoint measured, DDT isomers present, and the characteristics of the sediments under investigation. While it is difficult to evaluate the influence of these factors directly (due to the limitations of the available data), the following discussion is provided to identify the potential effects of these factors on the toxicity of DDTs.

Marine organisms exhibit a broad range of sensitivities to environmental contaminants. Therefore, the species and life stage used in a toxicity test can influence the apparent toxicity of a substance. No information was located that would directly support an evaluation of the relative sensitivities, to sediment-associated DDTs, of the biota that would normally occur in association with Southern California Bight sediments. However, data from water column exposure studies appear to corroborate the premise that aquatic organisms exhibit a broad range of sensitivities to DDTs. For example, USEPA (1980a) reported that acutely (96 hour) lethal (LC_{50}) or effective (EC_{50}) concentrations of DDT to marine biota ranged from 0.00014 mg/L for the brown shrimp (*Penaeus aztecus*) to 0.089 mg/L for the northern puffer (*Sphaeroides maculatus*). **Variability in species and life stage sensitivities to DDTs means that SECs established using limited data only may not accurately reflect the range of sensitivities that exist among the species that would normally occur in the Southern California**

Bight. Hence, adverse biological effects on important and sensitive species could occur below the SECs of DDTs developed in this study.

In coastal ecosystems, aquatic organisms may be exposed to DDTs via a number of routes. First, epibenthic species may be exposed to DDTs through direct contact with the sediments (i.e., dermal exposure) and in their diet (i.e., oral exposure). Contact with the overlying water is expected to be a minor exposure route for these species. Infaunal organisms may be exposed to DDTs by direct contact with sediment particles and porewater, as well as in their diet. However, dermal exposure may be reduced in tube-dwelling species. Lastly, benthic invertebrates that process sediments are likely to have the highest exposure to DDTs, as they may extract DDTs directly from sediment particles or from microorganisms that they ingest. In addition, they are likely to be exposed by direct contact with sediments and porewater. Therefore, it is important for the toxicological database to include data on species that are exposed to DDTs via various routes to increase the ecological applicability of the sediment effect concentrations subsequently developed. For example, SECs based on data for epibenthic species only could underestimate the toxicity of sediment-associated DDTs.

Duration of exposure is an important factor that affects the results of toxicity tests. Typically, high concentrations of a contaminant are required to elicit significant effects in short-term exposure tests (e.g., 96 hours), while lower effect concentrations are reported in longer tests on the same species and life stage. MacDonald (1993) evaluated toxicity data on over forty substances from water-only exposures and reported that short-term LC_{50}s were, on average, 7.7 times higher than long-term LC_{50}s. It is likely that biological responses to sediment-associated contaminants would also be affected by exposure duration. As most of the available toxicity data on DDTs are from relatively short-term studies in which lethality was the endpoint measured, threshold effect concentrations of DDTs (i.e., the levels that are associated with adverse effects) in the Southern California Bight could be lower than those indicated in this assessment.

The experimental endpoint measured in toxicity tests can also influence the apparent toxicity of DDTs to sediment-dwelling organisms. Exposure to DDTs has been associated with a diverse range of adverse effects in fish and other aquatic biota, including mortality, reproductive impairment, enzyme activity inhibition, hyperactivity, loss of equilibrium, and behavioral alterations (USEPA 1980a). No evidence of carcinogenicity in aquatic organisms was located in this review; however, inconclusive evidence of carcinogenicity in mammalian receptors has been reported (USEPA 1980a). MacDonald (1993) reported that effective

concentrations of water-borne contaminants can vary by as much as two orders of magnitude depending on the endpoint that was measured in the bioassay. Similar patterns of toxicity are likely to occur for sediment-associated contaminants, as well. As more sensitive effects are likely to occur at lower concentrations of DDTs, sediment effect concentrations derived from acute lethality data could underestimate the toxicity of DDTs in the Southern California Bight.

Evaluation of the toxicity of DDTs is further complicated by the availability of dose-response data (i.e., from spiked-sediment bioassays) for tDDT and the individual DDT isomers. For this reason, associative (or co-occurrence) information that links contaminant concentrations to adverse biological effects has also been used in this review. However, interpretation of associative data is complicated by the presence of multiple contaminants in each sediment sample, frequently including metals, PAHs, PCBs, and other substances. While the methodology used in this review provides a means of identifying the contaminants that are implicated in the toxic response, it is difficult to conclusively desegregate the effects of individual chemical contaminants. As the SECs reflect the effects of DDTs when they are present in mixtures, the toxicity of individual sediment-associated DDTs could be overestimated if they occurred in the Southern California Bight by themselves.

The toxicity of sediment-associated DDTs may also be affected by the mixture of DDTs present. Sediments in the Southern California Bight frequently contain the parent compounds and several degradation products. While few data are available to evaluate the relative toxicity of these substances in sediments, information on the effects of water-borne DDTs indicates that there could be significant differences in toxicity. For example, USEPA (1980a) reported data which indicated that the species mean acute values of water-borne DDT, DDE, and DDD for the eastern oyster (*Crassostrea virginica*) were 0.0079 mg/L, 0.014 mg/L, and 0.025 mg/L, respectively. In another species, the Korean shrimp (*Palaemon macrodactylus*), water-borne DDT was roughly ten times more toxic than DDD (when acute lethality was the endpoint measured). These data appear to indicate that DDT is more toxic than either of the two major metabolites, DDE and DDD. This is important when the toxicity of tDDT is being evaluated because reliance on toxicological information on one of the more toxic forms of DDT could bias the overall assessment. Likewise, reliance on toxicological data on the least toxic forms could result in SECs that underestimate toxicity.

The results of the evaluations presented in this review indicate that the SECs for DDT are generally reliable. That is, the dry weight- and organic carbon-normalized SECs for all four groups of DDTs can be used to accurately classify sediments

from the Southern California Bight. For SUM DDT, reliability could have been improved to 85% if an SEC of 0.06 mg/kg DW had been selected.

The evaluation of the predictability of the SECs that were developed for DDTs in this study was limited by the matching sediment chemistry and biological effects data that were available for sites located outside the Southern California Bight. That is, most of the sediment samples obtained from sites located elsewhere in the United States had concentrations of DDTs that were below the SECs. As such, it was not possible to evaluate the predictability of the SECs for SUM DDE in marine and estuarine sediments. Nonetheless, evaluation of the data that were compiled showed that most of the dry weight- and organic carbon-normalized SECs can be used to accurately classify sediments from outside the Southern California Bight. A higher SEC for SUM DDD (e.g., 0.4 mg/kg $DW_{1\%OC}$) would have been more predictive, however. The general agreement between the results of the reliability and predictability evaluations substantially increases the confidence that can be placed in the SECs.

The DW-normalized SECs for three of the four groups of DDTs accurately predicted toxicity in field-collected sediments. However, the SEC for SUM DDT would have predicted toxicity more accurately if it were higher (eg., 0.060 mg/kg $DW_{1\%OC}$). All of the OC-normalized SECs provided an accurate basis for predicting the toxicity of Southern California Bight sediments. While data from the Southern California Bight provide essential information for evaluating the SECs, data from other geographic areas provides an independent basis for assessing their predictability. Two independent data sets were used to evaluate the predicability of the SECs for DDTs (Swartz *et al.* 1994; Hoke *et al.* 1994). The results of this assessment indicate that the SECs provide an accurate basis for predicting sediment toxicity. However, a higher SEC for SUM DDT (e.g., 0.200 mg/kg DW) would have predicted sediment toxicity more accurately.

4.0 Evaluation of the Toxicity of Sediment-Associated PCBs

4.1 Identity and Nomenclature of PCBs

Polychlorinated biphenyls (PCBs) is the generic term that is applied to a group of 209 congeners that contain between one and 10 chlorine atoms on a biphenyl ring. The potential positions for chlorine substitution are numbered according to the American Chemical Society standard notation. PCB congeners with the same number of chlorine atoms on the biphenyl rings are grouped into a specific class (e.g., tetrachlorobiphenyl), with each congener in the class assigned a numeric prefix that describes the position of the chlorine atoms (e.g., 3,4,4',5-tetrachlorobiphenyl). The ten classes of PCBs, the empirical formulas for each class, and the number of possible congeners for each class are listed in Table 18.

Table 18. Empirical formulae and number of congeners for each class of PCBs.

PCB	Empirical Formula	Number of Possible Congeners
Monochlorobiphenyl	$C_{12}H_9Cl$	3
Dichlorobiphenyl	$C_{12}H_8Cl_2$	12
Trichlorobiphenyl	$C_{12}H_7Cl_3$	24
Tetrachlorobiphenyl	$C_{12}H_6Cl_4$	42
Pentachlorobiphenyl	$C_{12}H_5Cl_5$	46
Hexachlorobiphenyl	$C_{12}H_4Cl_6$	42
Heptachlorobiphenyl	$C_{12}H_3Cl_7$	24
Octachlorobiphenyl	$C_{12}H_2Cl_8$	12
Nonachlorobiphenyl	$C_{12}HCl_9$	3
Decachlorobiphenyl	$C_{12}Cl_{10}$	1

Commercially, PCBs have been produced as complex mixtures of many chlorobiphenyl congeners, whose usages depend primarily on the percentage of chlorine in the mixture. For example, mixtures of PCBs that contain between 21% and 54% chlorine (by weight) have been used extensively as dielectric fluids in closed electrical systems. In addition, PCB mixtures have been used as

plasticizers, heat transfer liquids, hydraulic fluids, fluids in vacuum pumps and compressors, lubricants, wax extenders, special adhesives, and surface coatings for carbonless copy paper (CCREM 1986). All of these latter uses were curtailed in 1971 in the United States (USEPA 1980b).

Polychlorinated biphenyls have been marketed under a number of trade names worldwide (e.g., Askerel, Eucarel, Sovol; McDonald and Tourangeau 1986); however, all of the PCBs manufactured in North America were produced under the trade name Aroclor (Moore and Walker 1991). The commercially available Aroclor mixtures are designated with a four digit number, which typically indicates the molecular structure and the percent chlorine by weight. For example, Aroclor 1254 is a chlorinated biphenyl which contains 54% chlorine by weight (which is designated by the '54'; Kalmaz and Kalmaz 1979). The lower chlorinated Aroclor formulations (e.g., 1221 and 1232) are primarily composed of mono-, di-, and trichlorobiphenyls, whereas the higher chlorinated Aroclor mixtures (e.g., 1254 and 1260) are dominated by tetra-, hexa-, and hepta-chlorobiphenyls (see Table 19; Rappe and Buser 1980; USEPA 1980b).

Table 19. Approximate molecular composition of Aroclor mixtures.

PCB	Percent Chlorine (by weight) of Aroclor Formulations					
	1221	1232	1242	1248	1254	1260
Biphenyl	11.0	6.0	-	-	-	-
Monochlorobiphenyl	51.0	26.0	1.0	-	-	-
Dichlorobiphenyl	32.0	29.0	17.0	1.0	-	-
Trichlorobiphenyl	4.0	24.0	40.0	23.0	-	-
Tetrachlorobiphenyl	2.0	15.0	32.0	50.0	16.0	-
Pentachlorobiphenyl	0.5	0.5	10.0	20.0	60.0	12.0
Hexachlorobiphenyl	-	-	0.5	1.0	23.0	46.0
Heptachlorobiphenyl	-	-	-	-	1.0	36.0
Octachlorobiphenyl	-	-	-	-	-	6.0
Nonachlorobiphenyl	-	-	-	-	-	-
Decachlorobiphenyl	-	-	-	-	-	-

Evaluation of the toxic effects of PCBs is complicated for a number of reasons. First, this group of compounds consists of 209 different congeners, each of which may have unique toxicological characteristics. However, dose-response data from spiked-sediment bioassays were not located on any of these substances. Therefore, it was not possible to assess the toxicity of individual PCB congeners to sediment-dwelling organisms.

Second, much of the available data on the toxicity of sediment-associated PCBs have been generated on several formulated PCB mixtures, including Aroclor 1242 and Aroclor 1254. These data are essential for evaluating the toxicity of these formulations in field-collected sediments. In the Southern California Bight, however, sediments are likely to contain many more PCB congeners than would be represented by measurements of Aroclor 1242 and/or Aroclor 1254 concentrations (i.e., mono-, di-, hepta-chlorobiphenyls may not be fully represented by these measurements). Hence, field-collected sediments could be more toxic than would be indicated by, for example, Aroclor 1254 concentrations alone.

Finally, the majority of field studies have reported the concentrations of total PCBs in sediments. However, a variety of procedures have been used to calculate these concentrations. For example, Bay *et al.* (1994) measured the concentrations of 80 PCB congeners and calculated total PCBs as the sum of these measurements. In other studies, total PCBs has been calculated as the sum of the concentrations of Aroclor 1242 and Aroclor 1254 (e.g., Anderson *et al.* 1988). In other cases, the concentration of total PCBs has been reported, but no information was provided on the procedures that were used to calculate the value. Therefore, measurements of total PCBs in sediment samples may vary depending on which procedure has been used to calculate the concentrations.

In this review, data were compiled separately for Aroclor 1254 and total PCBs in bed sediments. No attempt was made to determine the relationship between these two variables in the Southern California Bight. As such, total PCBs were not estimated from Aroclor 1254 measurements or vice versa. Instead, data from studies which reported Aroclor 1254 concentrations were compiled together. Likewise, data on the effects of total PCBs were compiled together, regardless of which procedure was used to calculate these values. The SECs for each group of substances were derived separately from the appropriate toxicological data sets.

4.2 Toxic Effects of Aroclor 1254

4.2.1 Spiked-Sediment Bioassay Data

A total of five studies were located which examined the effects of Aroclor 1254 in spiked-sediment bioassays. While these studies involved three different species which occur, or are closely related to species that occur, in the Southern California Bight, the experimental protocols used and ancillary information reported in several of these studies limit their application in this review. Nonetheless, the results of all of these studies are discussed below to provide the reader with the information needed to evaluate the results.

The results of a study on the effects of Aroclor 1254 indicate that the sand shrimp, *Crangon septemspinosa*, is relatively insensitive to sediment-associated PCB mixtures (McLeese and Metcalfe 1980). In this experiment, adult sand shrimp were exposed to two different PCB mixtures, Aroclor 1242 and 1254, for a period of 96 hours. As no mortalities were observed during the course of this test, it was not possible to calculate definitive median lethal concentrations for either of these formulated PCB products. Therefore, 96-hour LC_{50}s of >0.78 and >3.4 mg/kg DW were reported for Aroclor 1242 and 1254, respectively (at 0.28% TOC DW). Normalization of these values to 1%OC results in the calculation of 96-hour LC_{50}s of >2.79 and >12.1 mg/kg $DW_{1\%OC}$ for these formulated PCBs, respectively. It should be noted that no information was provided to assess whether or not equilibrium conditions were achieved in the test chambers and that only three organisms per treatment were tested in this study.

The results of two long-term experiments conducted on the sandworm, *Nereis diversicolor*, suggest that relatively high concentrations of a PCB mixture are required to affect this species. In the first test, Polikarpov *et al.* (1983) exposed sandworms to concentrations of a PCB, identified as DP5 (which is a formulated PCB product; B. Dexter. E.V.S. Consultants. Seattle, Washington. Personal communication), ranging from 18.7 to 89.6 mg/kg DW for 128 days. The concentration of DP5 in reference sediments was 0.19 mg/kg DW. High mortality was observed in all of the test groups, with 50% mortality occurring over 31.5 to 48.5 days at the various treatment concentrations. By comparison, 50% mortality occurred in reference sediments after 62.5 days. In the second test, significant adverse effects on survival were observed at 14.7 mg DP5/kg DW, but not at 1.7 mg/kg DP5 DW. The authors reported that sediments with 3.9 and 6.5 mg DP5/kg DW were only slightly toxic. Growth rate (as indicated by changes in body weight) was not a useful indicator of the toxic effects of the DP5 in either of these tests. It is important to note that no information was provided on

the composition of this PCB mixture, the experimental methods in the bioassays, or the characteristics of the sediments that were used in this study. Therefore, these data were not used to derive sediment effect concentrations of PCBs.

In a more recent study, Plesha *et al.* (1988) examined the toxicity of a mixture of four chlorinated hydrocarbons to the infaunal amphipod, *Rhepoxynius abronius*. The chlorinated hydrocarbons used in this investigation included Aroclor 1254, hexachlorobutadiene, 2,2-bis(*p*-chlorophenyl)-1,1,1-trichloroethane (*p,p'*-DDT), and hexachlorobenzene, at nominal concentrations of 1.0, 0.10, 0.20, and 0.05 mg/kg DW. The results of acute toxicity bioassays, in which mortality was the endpoint measured, indicated that the sediments with 1.0 mg/kg DW of Aroclor 1254 (at 0.9% OC) were significantly toxic to amphipods. Much lower survival rates were observed when the amphipods were exposed to sediments that had higher nominal concentrations of chlorinated hydrocarbons (5.0 mg/kg DW of Aroclor 1254). The results of this study suggest that Aroclor 1254 is toxic in the 1 mg/kg DW range, when it is present in mixtures of chlorinated hydrocarbons.

Swartz *et al.* (1988) conducted acute lethality bioassays on the infaunal amphipod, *Rhepoxynius abronius*, to assess the toxicity of Aroclor 1254, both alone and in mixtures with other substances. These investigators reported a 10 day LC_{50} of 8.8 mg/kg DW and a 10 day LC_{10} of 5.45 mg/kg DW for this formulated mixture of PCBs (at 0.41% OC; R. Swartz. USEPA. Newport, Oregon. Personal communication). Normalization of these results to 1%OC results in the calculation of a 10 day LC_{50} of 21.5 mg/kg $DW_{1\%OC}$ and a 10 day LC_{10} of 13.3 mg/kg $DW_{1\%OC}$ for Aroclor 1254.

A significant increase in mortality (to 55% in a 10 day test) was observed when amphipods were exposed to sediments (0.39% OC DW) containing fluoranthene (2.10 mg/kg DW) in combination with Aroclor 1254 (2.1 mg/kg DW; Swartz *et al.* 1988). However, significant mortality did not occur when Aroclor 1254 was present alone at this concentration (mortality <10%) or in combination with zinc (at 138 mg/kg DW; mortality <10%). These results indicate that the toxicity of Aroclor 1254 is enhanced by the presence of fluoranthene. Normalization of these results to 1%OC yields a calculated 10 day LC_{50} of <5.38 mg/kg $DW_{1\%OC}$ for Aroclor 1254 in the presence of 5.38 mg/kg $DW_{1\%OC}$ of fluoranthene.

More recently, the lethal and sublethal effects of Aroclor 1254 on the sediment-dwelling copepod, *Microarthridion littorale*, were investigated in a study that employed Aroclor 1254 spiked-sediments (DiPinto *et al.* 1993). In the initial acute toxicity bioassays, male and female copepods were exposed, separately, to concentrations ranging from 21 to 333 mg/kg of Aroclor 1254 for a period of 96

hours. The results of this study indicated male copepods were more sensitive to this PCB mixture than were female copepods, with 96 hour LC_{50}s of 117 and 251 mg/kg DW reported, respectively (at 3.8 to 4.0% OC). Normalization of these median lethal concentrations to 1%OC results in the calculation of 96 hour LC_{50} of 30.0 and 64.4 mg Aroclor 1254/kg $DW_{1\%OC}$ for male and female copepods, respectively. The lowest observed effect level (LOEL) for acute lethality was 83 mg/kg DW for Aroclor 1254 or 21.3 mg Aroclor 1254/kg $DW_{1\%OC}$.

In a related experiment, DiPinto *et al.* (1993) conducted short-term chronic bioassays to evaluate the effects of Aroclor 1254 on copepod reproduction. In these tests, copulating pairs of copepods were allowed to reproduce in PCB-contaminated sediments, in which Aroclor 1254 concentrations ranged between 4 and 83 mg/kg. The results of these tests, which were 12 days in duration, indicated that reproductive impairment can occur at relative low concentrations of sediment-associated Aroclor 1254. In the first of two experiments, the production of eggs and total reproductive capacity was significantly reduced when the adult copepods were exposed to Aroclor 1254 concentrations as low as 4.2 mg/kg DW. Reduced nauplii (i.e., larval copepods) production was observed in copepods exposed to 8.3 mg/kg DW. Similar trends of decreasing nauplii production and total reproductive capacity with increasing Aroclor 1254 concentrations were also observed in the second experiment, although these latter results were not statistically significant. Normalization of the lowest effective treatment concentration to 1%OC results in a calculated LOEL of 1.08 mg Aroclor 1254/kg $DW_{1\%OC}$. It should be noted that the shallow layer of sediment used in these bioassays tended to minimize contaminant exposure (DiPinto *et al.* 1993). Consequently, these data may underestimate the toxicity of Aroclor 1254 to this organism.

4.2.2 Field Studies

In the past 15 years, several studies have been conducted in the Southern California Bight to evaluate the environmental concerns associated with contaminated sediments. In three of these investigations, matching data on biological effects and the concentrations of Aroclor 1254 were collected (Word and Mearns 1979; Anderson *et al.* 1988; Swartz *et al.* 1991). These three studies on the Southern California Bight were reviewed to support the evaluation of sediment effect concentration for PCBs.

In 1977, Word and Mearns (1979) collected sediment samples from a total of 70 stations between Point Conception and the United States-Mexico border. At each station, two samples were collected for analysis of benthic invertebrate community characteristics and one sample was collected for sediment chemistry. Total PCB and Aroclor 1254 concentrations were measured in the samples collected at each station. All of these samples were collected from a water depth of approximately 60 metres.

The results of this study indicate that benthic invertebrate community structure may be affected by sediment-associated Aroclor 1254 (Word and Mearns 1979). For example, low arthropod abundance (4.0 ± 2.5 N/0.1 m^2) was observed in sediments that had, on average, 3.31 ± 2.27 mg/kg DW of Aroclor 1254. Higher densities of arthropods (144 ± 42.7 N/0.1 m^2) were observed at sites with 0.052 ± 0.070 mg Aroclor 1254/kg DW. Several other benthic invertebrate community metrics including species richness, infaunal index, and echinoderm abundance, were influenced by the concentrations of Aroclor 1254 in sediments. Neither polychaete abundance nor total benthic invertebrate abundance were reduced at the sites with elevated levels of Aroclor 1254. It was not possible to OC-normalize these results, as TOC was not reported in this study.

In 1985, Swartz *et al.* (1991) collected sediment cores from four stations on the Palos Verdes Shelf and in Santa Monica Bay. Two cores (up to 50 cm in depth) were collected from each station and cut into 5 cm vertical sections. Acute (10 day) toxicity tests using amphipods, *Rhepoxynius abronius*, were conducted on each of the core sections. The results of this investigation indicated that the mid-depth (12.5 - 32.5 cm) sediments from the stations located nearby the Los Angeles County outfalls were the most toxic to amphipods (78.6 ± 8.7% mortality). The mean concentration of Aroclor 1254 in these sediment samples was 10.6 ± 5.34 mg/kg DW or 1.24 ± 0.437 mg/kg $DW_{1\%OC}$. Moderate toxicity to amphipods (35.9 ± 12.1% mortality) was observed in shallower and deeper sediments (2.5 - 12.5 cm and 37.5 to 47.5 cm); these samples had, on average, 2.61 ± 6.10 mg/kg DW (0.456 ± 0.245 mg/kg $DW_{1\%OC}$) of Aroclor 1254. The samples that were the least toxic to amphipods (8.7 ± 3.3% mortality) had average Aroclor 1254 concentrations of 0.322 ± 0.731 mg/kg DW (0.110 ± 0.112 mg/kg $DW_{1\%OC}$).

In 1987, Anderson *et al.* (1988) sampled sediments from seven sites in the vicinity of Palos Verdes and three sites in San Diego Harbor. Matching sediment chemistry and biological effects data were generated for each of these sites. The sediment chemistry data consisted of information on over 50 substances, including Aroclor 1254. The biological effects information collected during this survey were

generated using three laboratory bioassays (Microtox, amphipod, and sea urchin), as well as benthic invertebrate community analyses. The Microtox data (which are based on measurements of bacterial luminescence) were not considered because the ecological relevance of this test is uncertain. Only the data from the Palos Verdes area was used in this assessment.

The survival and reburial of the amphipod, *Grandidierella japonica*, in Southern California Bight sediments (in 10 day acute toxicity tests) was not correlated with concentrations of Aroclor 1254 in the Anderson *et al.* (1988) study. For example, the mean concentration of Aroclor 1254 in sediments that were toxic to amphipods was 0.238 ± 0.237 mg/kg DW (0.085 ± 0.097 mg/kg $DW_{1\%OC}$). By comparison, the mean concentration of Aroclor 1254 was 0.240 ± 0.455 mg/kg DW (0.075 ± 0.097 mg/kg $DW_{1\%OC}$) in sediments that did not affect the survival of this species. As the concentrations of Aroclor 1254 were similar at the toxic and the non-toxic sites, something other than the concentrations of this PCB formulation must have been responsible for the observed effects.

While amphipods were apparently unaffected by concentrations of Aroclor 1254 in Southern California Bight sediments, the survival, sediment preference (i.e., avoidance behavior), and gonad growth of the sea urchin, *Lytechinus pictus*, (in 35-day chronic exposure tests) were linked to the concentrations of sediment-associated Aroclor 1254 (i.e., there was concordance between sediment chemistry and the biological effects). The concentration of Aroclor 1254 was 0.484 mg/kg DW at the site that was associated with these biological effects. However, the linkages between these effects and Aroclor 1254 were weaker when the concentrations of this PCB mixture were expressed on an OC-normalized basis. Impairment of sea urchin growth was also observed at sites with elevated concentrations of Aroclor 1254 (0.817 ± 0.472 mg/kg DW or 0.161 ± 0.163 mg/kg $DW_{1\%OC}$).

4.2.3 SECs for Aroclor 1254

Using the spiked-sediment bioassay approach, SECs of 2.1 mg/kg DW and 1.08 mg/kg $DW_{1\%OC}$ were derived for Aroclor 1254.

Rationale: The available spiked-sediment bioassay data include toxicological information on three sediment-resident invertebrate species (including one amphipod species) and, therefore, satisfy the minimum data criteria established in this study. Data from four

spiked-sediment toxicity investigations (McLeese and Metcalfe 1980; Plesha *et al.* 1988; Swartz *et al.* 1988; DiPinto *et al.* 1993) were considered to be acceptable for deriving sediment effect concentrations of Aroclor 1254 in bed sediments. The results of these tests indicated that Aroclor 1254, alone, is acutely toxic to aquatic organisms at concentrations ranging from 8.8 to 251 mg/kg DW. Acutely toxic concentrations of Aroclor 1254 alone, expressed on a dry weight basis at 1%OC, ranged from 21.5 to 64.4 mg/kg $DW_{1\%OC}$.

Few data were available to evaluate the chronic toxicity of Aroclor 1254. However, the short-term chronic toxicity tests on copepod reproduction are relevant to the development of SECs. In the first of two experiments, reductions in the total reproductive capacity and egg production of copepods were observed at concentrations of Aroclor 1254 as low as 4.20 mg/kg DW (1.08 mg/kg $DW_{1\%OC}$; DiPinto *et al.* 1993). In the second experiment, exposure to Aroclor 1254 significantly reduced naupliar output and, perhaps, total reproductive capacity per live female. Although greater variability in the data reduced the statistical power of the second experiment, the trends of decreasing reproductive success with increasing Aroclor 1254 concentrations were similar in the two experiments.

Aroclor 1254 is more toxic to amphipods when it is present in complex mixtures than when it occurs alone. Swartz *et al.* (1988) observed significant mortality (55%) when amphipods were exposed to 2.10 mg Aroclor 1254/kg DW (5.38 mg/kg $DW_{1\%OC}$), in the presence of fluoranthene (at 2.10 mg/kg DW or 5.38 mg/kg $DW_{1\%OC}$). Fluoranthene was the least toxic of the PAHs evaluated by Long *et al.* (1995a; i.e., it had the highest ER-M). Therefore, Aroclor 1254 would be expected to be more toxic in mixtures with other PAHs at 2.1 mg tPAH/kg DW than in mixtures with fluoranthene alone. Bay *et al.* (1994) reported that tPAH concentrations ranged from 0.756 to 10.6 mg/kg DW in Southern California Bight sediments. Anderson *et al.* (1988) observed tPAH concentrations as high as 20.4 mg/kg DW. Therefore, PAHs occur in Southern California Bight sediments at concentrations that would be expected to enhance the toxicity of Aroclor 1254. Together, these data suggest that Aroclor 1254

may be acutely toxic to amphipods at concentrations as low as 2.10 mg/kg DW (5.38 mg/kg $DW_{1\%OC}$).

The lowest observed effect level (2.10 mg/kg DW) of Aroclor 1254 from the acute toxicity tests on amphipod survival was adopted as the DW-normalized SEC (Swartz *et al.* 1988). The OC-normalized SEC for Aroclor 1254 was the LOEL (1.08 mg/kg $DW_{1\%OC}$) obtained from the short-term chronic toxicity tests on copepod reproduction (DiPinto *et al.* 1993).

The SECs for Aroclor 1254 are supported by the results of additional spiked-sediment bioassays which indicate toxic effects at similar concentrations of this PCB mixture. For example, Swartz *et al.* (1988) reported a 10-day lethal threshold concentration (LC_{10}) of 5.45 mg/kg DW or 13.3 mg/kg $DW_{1\%OC}$ for the amphipod, *Rhepoxynius abronius*. In mixtures with other organic (fluoranthene) and inorganic (zinc and mercury) substances, significant toxicity to this amphipod species was observed at 2.10 to 4.60 mg/kg DW (5.38 to 9.02 mg/kg $DW_{1\%OC}$). Similarly, Plesha *et al.* (1988) reported significant toxicity to amphipods in 10 day toxicity tests at concentrations of Aroclor 1254 as low as 1.00 mg/kg DW or 1.11 mg/kg $DW_{1\%OC}$, when it was present in mixtures of chlorinated hydrocarbons. Greater than 80% mortality to amphipods was observed at 5.00 mg/kg DW (5.56 mg/kg $DW_{1\%OC}$) of Aroclor 1254 in the same mixtures of chlorinated hydrocarbons. As sediments on the Palos Verdes Shelf also contain complex mixtures of chlorinated hydrocarbons (e.g., DDTs; Swartz *et al.* 1991), PAHs (Anderson *et al.* 1988), and metals (Mearns *et al.* 1991), the data from spiked-sediment bioassays for mixtures of contaminants are likely to be relevant for establishing the SECs.

4.2.4 Evaluation of the SECs for Aroclor 1254

Reliability:

The reliability of the SECs for Aroclor 1254 were evaluated using the toxicological data sets that were assembled for the Southern California Bight. The results of this assessment indicate that the dry-weight

normalized SEC for Aroclor 1254 provides a reliable basis for classifying sediment samples as toxic or non-toxic (Table 20). Thirteen of the 14 samples with Aroclor 1254 concentrations at or above the SEC were found to be toxic, based on the results of laboratory toxicity tests and benthic invertebrate community assessments. Importantly, lower values of Aroclor 1254 would also have provided reliable SECs; the incidence of toxicity was 95% and 94% in sediment samples with Aroclor 1254 concentrations at or in excess of 0.4 and 1.15 mg/kg DW, respectively. These results indicate that adverse effects on sediment-dwelling organisms are likely to occur at Aroclor 1254 concentrations well below the SEC. Therefore, it would be appropriate to establish the SEC at a lower level for Aroclor 1254.

Although the data are limited, the results of this assessment show that the OC-normalized SEC also provides a reliable basis for classifying sediment samples in the Southern California Bight (Table 21). All of the sediment samples with Aroclor 1254 concentrations at or in excess of 1.08 mg/kg $DW_{1\% OC}$ (i.e. 5 of 5 samples) were found to be toxic to sediment-dwelling organisms. These results also indicate that a lower SEC could have been established for Aroclor 1254. For example, 18 of the 19 (95%) sediment samples with Aroclor 1254 concentrations at or above 0.20 mg/kg $DW_{1\% OC}$ were toxic. Therefore, the lower value would have provided a reliable SEC for Aroclor 1254.

Predictability:

No data were located for evaluating the predictability of the dry weight-normalized or organic carbon-normalized SECs for Aroclor 1254. All of the data sets compiled for marine and estuarine sites outside the Southern California Bight had Aroclor 1254 concentrations well below the recommended SECs (Table A5-5). However, a few of the samples collected in two of these studies (Word *et al.* 1988; Munns *et al.* 1991) had Aroclor 1254 levels that exceeded the lower values that were evaluated above. Only one toxicity test was conducted in each of these studies, an acute lethality test with amphipods. The results shown in Tables 22 and 23 indicate that neither of the values (i.e., 0.4 mg/kg DW and 0.2 mg/kg $DW_{1\% OC}$) provided an accurate basis for classifying sediment samples based on

Aroclor 1254 concentrations. However, these results should not be considered to be definitive due to the limited number of samples that were considered.

4.3 Toxic Effects of tPCBs

4.3.1 Spiked-Sediment Bioassay Data

While data from five spiked-sediment bioassays provide information for evaluating the toxic effects of Aroclor 1254, no dose-response data from controlled laboratory studies were located on tPCBs.

4.3.2 Field Studies

In the past 15 years, several studies have been conducted in the Southern California Bight to evaluate the environmental concerns associated with contaminated sediments. One of these studies was conducted in the late 1970's (Word and Mearns 1979) and several follow-up surveys have been implemented to assess trends in contamination or toxicity (Anderson *et al.* 1988; Swartz *et al.* 1991; Bay *et al.* 1994; Murdoch *et al.* In press; Sapudar *et al.* 1994; Fairey *et al.* 1996; Fairey 1997). A total of eight studies with matching chemistry and biological effects data from the Southern California Bight were reviewed to support the evaluation of sediment effect concentration for PCBs. It should be noted that data from field surveys provide information that can be used to link contaminant concentrations to adverse biological effects; however, these data do not provide dose-response information for definitively identifying causality. A variety of factors, other than the concentration of PCBs, could also have contributed to, or been responsible for, the effects observed in these investigations.

In 1977, Word and Mearns (1979) collected sediment samples from a total of 70 stations between Point Conception and the United States-Mexico border. At each station, two samples were collected for analysis of benthic invertebrate community characteristics and one sample was collected for sediment chemistry. Total PCB concentrations were measured in the samples collected at each station. All of these samples were collected from a water depth of approximately 60 metres.

The results of this study suggest that several benthic invertebrate community metrics are correlated with the concentration of sediment-associated tPCB in the Southern California Bight. For example, high (229 ± 60.3/0.1 m^2) and moderate (73.8 ± 40.9/0.1 m^2) densities of echinoderms were present at sites with mean concentrations of 0.015 ± 0.017 and 0.032 ± 0.040 mg tPCB/kg DW, respectively. In contrast, much lower densities of echinoderms (3.1 ± 4.5/m^2) were observed at sites with tPCB concentrations of 1.48 ± 2.77 mg/kg DW. Similarly, low densities of arthropods and low species richness were observed at sites with 4.88 ± 4.09 and 1.05 ± 2.50 mg tPCB/kg DW, respectively. However the densities of polychaetes and total invertebrates were not reduced at elevated tPCB concentrations (2.28 ± 4.29 and 3.38 ± 5.08 mg/kg DW, respectively). As OC concentrations were not reported in this study, it was not possible to normalize the results to 1%OC.

In 1985, Swartz *et al.* (1991) collected sediment cores from four stations on the Palos Verdes Shelf and in Santa Monica Bay. Two cores (up to 50 cm in depth) were collected from each station and cut into 5 cm vertical sections. Acute (10 day) toxicity tests using amphipods, *Rhepoxynius abronius*, were conducted on each of the core sections. The results of this investigation indicated that the mid-depth (12.5 - 32.5 cm) sediments from the stations located nearby the Los Angeles County outfalls were the most toxic to amphipods (78.6 ± 8.7% mortality). The mean concentration of tPCB in these sediment samples was 20.7 ± 13.1 mg/kg DW or 2.37 ± 1.20 mg/kg $DW_{1\%OC}$. Moderate toxicity to amphipods (35.9 ± 12.1% mortality) was observed in shallower and deeper sediments (2.5 - 12.5 cm and 37.5 to 47.5 cm); these samples had, on average, 4.40 ± 9.21 mg/kg DW (0.693 ± 0.575 mg/kg $DW_{1\%OC}$) of tPCB. The samples that were the least toxic to amphipods (8.7 ± 3.3% mortality) had average tPCB concentrations of 0.429 ± 1.02 mg/kg DW (0.140 ± 0.157 mg/kg $DW_{1\%OC}$).

In 1987, Anderson *et al.* (1988) sampled sediments from seven sites in the vicinity of Palos Verdes and three sites in San Diego Harbor. Matching sediment chemistry and biological effects data were generated for each of these sites. The sediment chemistry data consisted of information on over 50 substances, including Aroclor 1242, Aroclor 1254, and tPCBs. Although it was not explicitly stated, it appears as though tPCB concentrations were calculated as the sum of the concentrations of Aroclor 1242 and Aroclor 1254. The biological effects information collected during this survey were generated using three laboratory bioassays (Microtox, amphipod, and sea urchin), as well as benthic invertebrate community analyses. The Microtox data (which are based on measurements of bacterial luminescence) were not considered because the ecological relevance of

this test is uncertain. Only the data from the Palos Verdes area were used in this assessment.

The survival and reburial of the amphipod, *Grandidierella japonica*, in Southern California Bight sediments (in 10 day acute toxicity tests) was not correlated with concentrations of tPCB in the Anderson *et al.* (1988) study. For example, the mean concentration of tPCB was 0.320 ± 0.340 mg/kg DW (0.105 ± 0.109 mg/kg $DW_{1\%OC}$) in sediments that were significantly toxic to this species. The mean concentrations of tPCB in sediments that did not affect amphipod survival was 0.314 ± 0.588 mg/kg DW (0.089 ± 0.135 mg/kg $DW_{1\%OC}$). As the concentrations of these substances were similar at the toxic and the non-toxic sites, something other than the concentrations of PCBs was likely responsible for the observed effects.

The survival, sediment preference (i.e., avoidance behavior), and gonad growth of the sea urchin, *Lytechinus pictus*, (in 35-day chronic exposure tests) were not correlated with the concentrations of sediment-associated tPCBs (i.e., there was no concordance between sediment chemistry and the biological effects). However, sea urchin growth was correlated with concentrations of tPCBs, with significant reductions in growth observed in sediments with mean concentrations of 1.09 ± 0.57 mg/kg DW or 0.211 ± 0.207 mg/kg $DW_{1\%OC}$ of tPCB. The growth of sea urchins was not affected by sediments with 0.096 ± 0.137 mg tPCB/kg DW or 0.061 ± 0.079 mg tPCB/kg $DW_{1\%OC}$.

In a study commissioned by the Santa Monica Bay Restoration Project, Bay *et al.* (1994) collected sediments from 12 sites located off the Palos Verdes Peninsula during June and July, 1992. A station located near Dana Point in Orange County was used as a reference site in this study. This study was designed to evaluate the toxicity of Palos Verdes sediments to infaunal and epibenthic organisms, and included both bulk sediment and porewater bioassays. The toxicity of bulk sediments was assessed in acute (10 day) tests on the amphipod, *Rhepoxynius abronius*, and chronic (28 day and 35 day) tests on the amphipod, *Grandidierella japonica*, and the white sea urchin, *Lytechinus pictus*. As poor survival was observed among all of the treatment groups (including controls) in the amphipod growth bioassay, these data were not considered for identifying sediment effect concentrations of tPCBs. In this survey, the toxicity of porewater was evaluated in short-term (< 2 hour) bioassays using purple sea urchin, *Strongylocentrotus purpuratus*, gametes.

Acute toxicity bioassays were conducted using sediments from five of the 13 sites sampled in the 1992 survey; none on these sediments were toxic to amphipods

(Bay *et al.* 1994). The mean concentration of tPCB at these sites was 1.31 ± 1.35 mg/kg DW or 0.497 ± 0.404 mg/kg $DW_{1\%OC}$. Likewise, avoidance behavior and growth of white sea urchins (as measured by test width; the test is the hard outer covering of the sea urchin) was not affected by any of the sediments tested in this study. However, the weight gain of white sea urchins was affected by exposure to Palos Verdes sediments. Low growth rates (0.002 ± 0.0002 g WW/d) were observed at sites with a mean concentration of 1.94 ± 1.39 mg tPCB/kg DW (0.565 ± 0.407 mg/kg $DW_{1\%OC}$). Higher growth rates (0.005 ± 0.001 g WW/d) were measured in sediments containing lower tPCB concentrations (0.645 ± 0.699 mg/kg DW or 0.281 ± 0.193 mg/kg $DW_{1\%OC}$).

As part of the Bay Protection and Toxics Cleanup Program, sediment samples were collected from a number of locations in San Pedro Bay in 1992, including Los Angeles and Long Beach Harbours (Sapudar *et al.* 1994). The toxicity of each sample was evaluated using two toxicity tests, including 48-hour red abalone (*Haliotus rufescens*) larval development test (using pore water) and 10-day amphipod (*Rhepoxynius abronius*) survival test (using bulk sediments). The data on the effects of pore water on abalone larval development were not used in this evaluation because they provided little ability to discriminate between sampling sites (i.e., nearly 90% of the samples were shown to be toxicity based on the results of this test).

The results of this investigation indicated that sediments from Los Angeles Inner Harbour, Inner Fish Harbour, East Basin, and Alamitos Bay were the most toxic to amphipods. In this study, toxic samples were identified as those in which amphipod survival was more than 20% lower than the average survival in the control treatments (Long *et al.* In review). The average concentration of tPCB in the toxic samples was 0.177 ± 0.152 mg/kg DW or 0.089 ± 0.059 mg/kg $DW_{1\%OC}$. By comparison, tPCB concentrations averaged 0.088 ± 0.092 mg/kg DW or 0.074 ± 0.046 mg/kg $DW_{1\%OC}$ at the non-toxic sites in this survey. These results indicate that amphipod survival was linked to the dry weight-normalized concentrations of tPCB. However, limited concordance was evident between amphipod survival and organic carbon-normalized concentrations of tPCB.

In a related study, sediments were collected from several locations on the Palos Verdes Shelf and in Santa Monica Bay during 1992 and 1993 (Fairey 1997). Matching sediment chemistry and toxicity data were reported for 19 sites in this area. The results of 10-day acute toxicity tests with the amphipod, *Rhepoxynius abronius*, indicated that the sediments from 11 of these sites were acutely toxic. The average concentration of tPCB at these sites was 0.241 ± 0.126 mg/kg DW or 0.104 ± 0.080 mg/kg $DW_{1\%OC}$. At the non-toxic sites, tPCB concentrations

averaged 0.265 ± 0.050 mg/kg DW or 0.158 ± 0.092 mg/kg $DW_{1\%OC}$. The lack of concordance between amphipod survival and tPCB concentrations indicates that this group of substances was not responsible for the observed biological effects. While polychaete survival and growth tests were also conducted in this study, the data were not used in this evaluation because only four sediment samples were tested.

Sediments were also collected at a total of 350 stations in the vicinity of San Diego as part of the Bay Protection and Toxics Cleanup Program between October, 1992 and May, 1994 (Fairey *et al.* 1996). The results of chemical analyses indicated that the sediments in San Diego Bay, Mission Bay, the San Diego River Estuary, and the Tijuana River Estuary contained a variety of contaminants. While most of the areas within San Diego Bay had relatively low levels of PCBs, some of the stations in the middle portion of the bay had relatively elevated PCBs concentrations. In particular, sediment samples collected in the vicinity of the naval shipyards had substantial PCB concentrations gradients and were, therefore, considered to be the most relevant for evaluating the toxicity effects of PCBs. In this study, total PCB concentrations were estimated from the sum of the 18 PCB congeners that are typically measured under the NOAA National Status and Trends Program (NOAA 1991).

Several porewater and solid phase sediment toxicity tests were conducted on each of the samples collected in the vicinity of the naval shipyards in San Diego Bay. Data on amphipod (*Rhepoxynius abronius*) survival, sea urchin (*Strongylocentrotus purpuratus*) fertilization, and sea urchin (*S. purpuratus*) larval development were obtained and used to evaluate the toxicity of sediment-associated PCBs. The results of the polychaete growth and survival test, the bay mussel larval development test, and the red abalone larval development tests were not used due to incomplete designation of toxic samples. The results of the power analyses conducted by Long *et al.* (In review) were used to designate toxic samples for the amphipod and sea urchin tests (i.e., samples were designated as toxic if the response measured differed by more than 20% from that of the control samples).

The results of acute toxicity test showed that sediments taken from the eastern portion of middle San Diego Bay (i.e., nearby the naval shipyards) were generally the most toxic to amphipods. The average concentration of tPCBs at the toxic sites was 0.281 ± 0.395 mg/kg DW (0.228 ± 0.459 mg/kg $DW_{1\%OC}$). By comparison, the average concentration of tPCB in the samples that were not acutely toxic to amphipods was 0.244 ± 0.360 mg/kg DW (0.218 ± 0.350 mg/kg $DW_{1\%OC}$). Because tPCB concentrations were similar in the toxic and non-toxic samples, it is unlikely that tPCBs contributed significantly to the biological effects

that were observed in the middle portion of San Diego Bay. This conclusion is supported by the analyses of the sea urchin fertilization and larval development tests, which showed no clear linkage between toxicity test results and tPCB concentrations.

As part of an investigation to evaluate the effects of organochlorines on the survival, growth, and reproduction of a marine polychaete, Murdoch *et al.* (In press) collected sediment samples from 10 sites along the 60 meter contour on the Palos Verdes Shelf in 1993. The toxicity tests conducted on these sediment samples included acute (10 day) and short-term chronic (20 day) survival and growth tests and a chronic (120 day) reproduction test using the marine polychaete, *Neanthes arenaceodentata*. The results of this study indicated that acute and short-term chronic exposure to tPCB concentrations as high as 31.8 mg/kg DW (3.95 mg/kg $DW_{1\%OC}$) did not adversely affect polychaete survival or growth. The concentration of tPCB averaged 5.85 ± 12.7 mg/kg DW (0.89 ± 1.51 mg/kg $DW_{1\%OC}$) in these non-toxic samples. However, polychaete reproductive success, as indicated by the number of emergent juveniles, was compromised in the sediments that had the highest concentrations of tPCB (16.6 ± 21.5 mg/kg DW; 2.16 ± 2.54 mg/kg $DW_{1\%OC}$). Polychaete reproduction was not impaired in sediments that contained 0.49 ± 0.42 mg/kg DW (0.26 ± 0.13 mg/kg $DW_{1\%OC}$), however.

4.3.3 SECs for tPCBs

Using the weight-of-evidence, SECs of 0.835 mg/kg DW and 0.577 mg/kg $DW_{1\%OC}$ were derived for tPCBs.

Rationale: As indicated previously, no spiked-sediment bioassay data were located that applied directly to tPCB. For this reason, the SECs for tPCB were derived using the WEA.

The summarized toxicological data set on tPCB had 18 effects data records (Table A4-21). The 50th percentile concentration of this data distribution was 1.086 mg/kg DW. There were a total of 110 effects data records in the unsummarized toxicological data set assembled for this group of substances (Table A4-22). Evaluation of these data using the procedures described in Appendix 3 results in an ER-M of 0.835 mg/kg DW.

The lower of these two values was selected as the SEC for tPCB.

Using the summarized and unsummarized data sets assembled on the biological effects of sediment-associated tPCB (OC-normalized), ER-Ms of 0.606 and 0.577 mg/kg $DW_{1\%OC}$ were derived (Table A4-23 and A4-24). The lower of these two values was identified as the SEC for tPCBs.

4.3.4 *Evaluation of the SECs for PCBs*

Reliability:

The reliability of the recommended SECs were evaluated using the matching sediment chemistry and biological effects data for the Southern California Bight that were assembled during this study. The results of this evaluation indicate that the SEC of 0.835 mg/kg DW provides a reliable basis for assessing PCB-contaminated sediments (Table 24). Eighty-seven percent of the sediment samples with tPCB concentrations at or above the SEC were found to be toxic to benthic invertebrates (34 of 39 samples).

Both lower and higher values of tPCBs would also provide a reliable basis for predicting sediment toxicity in the southern California Bight. For example, the incidence of toxicity was 87% (52 of 60 samples) in sediments with tPCB concentrations at or above 0.4 mg/kg DW, suggesting that a lower SEC would be just as reliable as the recommended SEC. Similarly, a higher level of tPCBs also correctly predicted toxicity in 20 of the 21 (95%) sediment samples with tPCB concentrations at or in excess of 2.0 mg/kg DW. The increasing incidence of toxicity with increasing concentrations of tPCB generates additional confidence in the SEC.

The results of this evaluation indicate that the OC-normalized SEC for tPCBs (0.577 mg/kg $DW_{1\%OC}$) is also reliable (Table 25). In the data set for the Southern California Bight, 20 of the 25 (80%) samples with tPCB concentrations at or in excess of the SEC were found to be toxic. However, a lower value was shown to be less reliable, as

Table 24. An evaluation of the reliability of the dry weight-normalized SECs for tPCBs.

SEC	Study	Total Number of Samples Collected	Number of Samples Predicted to be Toxic (tPCB > SEC)	Number of Toxic Samples	Predictability of SEC (% Correct)

indicated by the lower incidence of toxicity (71%; 47 of 66 samples) at tPCB concentrations at or in excess of 0.20 mg/kg $DW_{1\%OC}$. In contrast, a somewhat higher value (1.0 mg/kg $DW_{1\%OC}$) provided a more reliable basis for classifying sediment samples with elevated concentrations of tPCBs (i.e., 94% correct classification; 15 of 16 samples). Once again, the increasing incidence of toxicity with increasing concentrations of tPCB indicates that the SEC is reliable.

Predictability:

The predictability of the SECs for tPCBs was evaluated using matching sediment chemistry and biological effects data from sites located outside of the Southern California Bight (i.e., elsewhere in the United States; Table A5-6). The results of this evaluation indicate that the SEC of 0.835 mg/kg DW provides an accurate basis for predicting the toxicity of tPCBs. Of the 43 sediment samples that had tPCB concentrations equal or greater than the SEC, 42 were found to be toxic. Therefore, 98% of the sediment samples were correctly classified using the recommended SEC (Table 26).

The predictability of higher and lower values were also evaluated to provide a basis for comparison with the SEC. The results of this assessment indicated that a lower value could also be used to accurately classify sediment samples collected outside the Southern California Bight. For example, the incidence of toxicity was 87% in sediment samples with tPCB concentrations at or above 0.4 mg/kg DW (67 of 77 samples were toxic). A higher value was also predictive of sediment toxicity, as indicated by the high incidence of effects (100%; 7 of 7 samples) in sediment samples with tPCB concentrations at or above 2.00 mg/kg DW.

The SEC of 0.577 mg/kg $DW_{1\%OC}$ accurately predicted the toxicity of tPCBs in sediments outside the Southern California Bight. Based on information from laboratory toxicity tests and benthic invertebrate community assessments, all ten of the sediment samples with tPCB concentrations at or above the SEC were found to be toxic (predictability = 100%; 10 of 10 samples; Table 27). An SEC of 0.2 mg/kg $DW_{1\%OC}$ would provide a slighty less accurate basis for predicting the toxicity of tPCB. Forty-nine of the 59 (83%) of the sediment samples that had tPCB concentrations equal to or greater

than 0.2 mg/kg $DW_{1\%OC}$ were toxic. These results indicate that a lower SEC could be used to accurately classify sediment samples with elevated levels of tPCBs. As was the case in the Southern California Bight, the incidence of toxicity increased with increasing concentrations of tPCB elsewhere in the United States.

4.4 Discussion of the Toxic Effects of PCBs

There are a number of factors that could, potentially, affect the toxicity of sediment-associated PCBs. These factors include species and life stage tested, exposure route(s), duration of exposure, endpoint measured, PCB congeners present, and the characteristics of the sediments under consideration. While it is difficult to evaluate the influence of these factors directly (due to limitations on the available data), the following discussion is provided to identify the potential effects of these factors on the toxicity of PCBs.

No information was located that would directly support an evaluation of the relative sensitivities, to sediment-associated PCBs, of the biota that would normally occur in association with Southern California Bight sediments. However, data from acute toxicity tests (24 to 96 hours in duration) in which aquatic organisms were exposed to water-borne Aroclor 1254 indicate that sensitivities can span several orders of magnitude. For example, the concentrations of Aroclor 1254 causing biological effects ranged from 0.015 mg/L for a natural phytoplankton assemblage (Moore and Harriss 1972) to 9.00 mg/L for the green alga, *Dunaliella tertiolecta* (Luard 1973), when photosynthetic rate was the experimental endpoint measured. In general, invertebrates appear to be somewhat more sensitive than phytoplankton, with median lethal concentrations (LC_{50}s) of Aroclor 1254 ranging from 0.0078 mg/L for the grass shrimp, *Palaemonetes pugio* (Roesijadi *et al.* 1976) to >0.100 mg/L for the oyster, *Crassostrea virginica* (Duke *et al.* 1970). By comparison, no mortality was observed when pinfish, *Lagodon rhomboides*, were exposed to 0.100 mg/L of Aroclor 1254 for a period of 48 hours. Together, these data suggest that aquatic organisms exhibit a wide range of sensitivities to PCBs.

Few data were located with which to evaluate the relative sensitivities of various life stages of marine organisms to PCBs. However, the available information from acute lethality tests indicates that the sensitivities of various life stages can span more than an order of magnitude. For example, the 96 hour LC_{50}s of Aroclor

1254 were 0.0078 mg/L for juvenile grass shrimp and 0.041 mg/L for adults of the same species (Roesijadi *et al.* 1976). Likewise, juvenile fiddler crabs, *Uca pugilator*, were much more sensitive to Aroclor 1254 than the adults of the same species, with LC_{50}s of 0.010 and >0.100 mg/L reported for these life stages, respectively. **This variability in species and life stage sensitivities means that SECs of PCBs, established using limited data only, may not accurately reflect the range of sensitivities that exist among the species that would normally occur in the Southern California Bight. Hence, adverse biological effects on important and sensitive species could occur below the SECs of PCBs developed in this study.**

In coastal ecosystems, aquatic organisms may be exposed to PCBs via a number of routes. First, epibenthic species may be exposed to PCBs through direct contact with the sediments (i.e., dermal exposure) and in their diet (i.e., oral exposure). Contact with the overlying water is expected to be a minor exposure route for these species. Sediment resident organisms may be exposed to PCBs by direct contact with sediment particles and porewater, as well as in their diet. However, dermal exposure may be reduced in tube-dwelling species. Lastly, benthic invertebrates that process sediments are likely to have the highest exposure to PCBs, as they may extract PCBs directly from sediment particles or from microorganisms that they ingest. In addition, they are likely to be exposed by direct contact with sediments and porewater. Therefore, it is important for the toxicological database to include data on species that are exposed to PCBs via various routes to increase the ecological applicability of the SECs subsequently developed.

Duration of exposure is an important factor that affects the results of toxicity tests. Typically, higher concentrations of a contaminant are required to elicit significant effects in short-term exposure tests (e.g., 96 hours) than would be required in longer term tests (e.g., ≥ 10 days). For example, MacDonald (1993) evaluated toxicity data on over forty substances from water-only exposures and reported that short-term LC_{50}s were, on average, 7.7 times higher than long-term LC_{50}s. Therefore, SECs of PCBs derived using data from short-term studies are likely to be higher than those that are based on chronic toxicity studies.

The experimental endpoint measured is an important factor in the evaluation of the toxic effects of PCBs. Exposure to PCBs has been associated with a diverse range of adverse effects in fish and other aquatic biota, including changes in community structure, mortality, reproductive impairment, inhibition of growth and photosynthesis, alteration of metabolic rates, and changes in gross morphology (Moore and Walker 1991). MacDonald (1993) reported that the concentrations of water-borne contaminants that cause adverse biological effects can vary over

several orders of magnitude depending on the endpoint that was measured in the bioassay. Similar patterns of toxicity are likely to occur for sediment-associated contaminants, as well. As more sensitive biological processes are likely to be affected by lower concentrations of PCBs, SECs derived from lethality data could underestimate the toxicity of PCBs in the Southern California Bight.

The analytical procedures used to generate data on PCB concentrations in the field could affect the SECs derived in this study. Derivation of an reliable SEC for PCBs from field data alone is contingent on the use of accurate and precise analytical procedures. Historically, the analytical methods for quantifying PCBs from field samples have been variable (i.e., different extraction and quantification procedures have been used). Therefore, it is likely that the precision and accuracy of these methods were also variable. This variability has the potential to influence the SECs that are derived from these data. However, it is unknown if this variability would result in under- or over-estimates of PCB concentrations. It should be noted, however, that measurements of formulated PCBs or individual congeners are likely to underestimate the concentrations of tPCBs.

Evaluation of the toxicity of PCBs is further complicated by limitations on the availability of dose-response data (i.e., from spiked-sediment bioassays) for most PCB mixtures. For this reason, associative (or co-occurrence) information that links contaminant concentrations to adverse biological effects has also been used in this review. However, interpretation of associative data is complicated by the presence of multiple contaminants in each sediment sample, frequently including metals, PAHs, PCBs, and other substances. While the methodology used in this review provides a means of identifying the contaminants that are implicated in the toxic response, it is difficult to conclusively desegregate the effects of individual chemical contaminants. Hence, the weight-of-evidence approach could overestimate or underestimate the toxicity of individual sediment-associated PCBs in the Southern California Bight. Nonetheless, this approach is considered to be applicable because the PCBs in the Southern California Bight do not occur in isolation; rather they are present in complex mixtures of organic and inorganic contaminants.

Lastly, differences in the toxicity of individual PCB congeners has the potential to affect the SECs for this group of substances. It is difficult to determine the influence of this factor because no data were located on the relative toxicity of the various PCB congeners or mixtures in sediments. Data from water-only exposure studies revealed no clear trends in the relative toxicity of water-borne PCB formulations (Aroclor 1220, 1224, 1248, 1254, and 1260; USEPA 1980b), which suggests that degree of chlorination is not a major determinant in PCB toxicity.

However, it is possible that coplanar PCBs may be the most toxic congeners. If their mode of toxicity is similar to that of dioxins (e.g., 2,3,7,8-tetrachlorodibenzo-*p*-dioxin), then toxic effects on sensitive endpoints, like reproduction and growth, would be expected to occur at concentrations that are much lower than acutely toxic concentrations. Moreover, extended exposure and observation periods would be required to detect these responses. Therefore, data from short-term lethality studies would underestimate the toxicity of these congeners and, hence, underestimate the toxicity of PCB mixtures in the field.

Consideration of all the factors discussed above suggests that the SECs for PCBs are more likely to underestimate than to overestimate the toxicity of these substances. Because the SECs for Aroclor 1254 are based on data from relatively short-term studies (i.e., ≤ 12 days), they probably underestimate the chronic toxicity of this formulation. This would be even more likely if this formulation contained a significant quantity of coplanar PCBs.

Evaluations of both the reliability and predictability indicate that the SECs for Aroclor 1254 are probably too high. For example, SECs of 0.400 mg/kg DW and 0.200 mg/kg $DW_{1\%OC}$ would have been approximately as reliable as the recommended values. These lower values predicted toxicity in Southern California Bight sediments with a high degree of accuracy (95% and 95%, respectively). The SECs for tPCBs provide a reliable basis for evaluating biological effects in field-collected sediments from the Southern California Bight. In addition, the SECs for tPCBs can be used to accurately classify sediment samples from elsewhere in the United States. This agreement between the evaluations of reliability and predictability increase the confidence that can be placed in the SECs.

5.0 Summary and Conclusions

A review of the published and unpublished literature was conducted to evaluate the toxic effects of DDTs and PCBs in sediments. The primary objective of this review was to determine sediment effect concentrations (SECs) of DDTs and PCBs in Southern California Bight sediments. The secondary objective of this study was to determine if the concentrations of DDTs and PCBs in the sediments of the Southern California Bight would cause injury to one or more sediment-dwelling species that occur or would be expected to occur in this area. Injurious effects were considered to include any impairments to benthic organisms or habitats caused by DDTs or PCBs acting alone, or in any combination with other contaminants.

In this review, DDTs were defined as *p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *o,p'*-DDE, *p,p'*-DDD, *o,p'*-DDD, and any metabolite or degradation product of these chemicals. The term "PCBs" is defined as all of the polychlorinated biphenyls found in Southern California Bight, plus the degradation products and metabolites of these chemicals.

A tiered strategy was used to derive SECs for DDTs and PCBs in the Southern California Bight. This strategy relied preferentially on data from controlled laboratory studies to establish SECs for these substances (i.e., using the spiked-sediment bioassay approach; SSBA). Information from field studies and other sources were utilized when acceptable data from spiked-sediment bioassays were not available (i.e., SECs were derived using the weight-of evidence approach; WEA). These two approaches were considered to be complementary because cause-and-effect relationships between contaminant concentrations and toxic effects can be established from controlled laboratory experiments. While it is difficult to definitively identify the causes of toxic effects in field studies, SECs derived using the weight-of evidence approach may be more accurate because they reflect the toxicity of complex mixtures of contaminants. This is important in the Southern California Bight because DDTs, PCBs, and other substances occur in complex mixtures.

The SECs developed in this review were evaluated to determine their reliability and predictability. The reliability of the SECs was evaluated to determine if toxic effects could be accurately predicted in sediments from the Southern California Bight. The predictability of the SECs was evaluated to determine if toxic effects could be accurately predicted in sediments from elsewhere in the United States using data on concentrations of DDTs and PCBs alone.

The available data on the toxic effects of SUM DDT (*p,p'*-DDT + *o,p'*-DDT), SUM DDE (*p,p'*-DDE + *o,p'*-DDE), SUM DDD (*p,p'*-DDD + *o,p'*-DDD), total DDT (sum of all six DDT compounds), Aroclor 1254, and total PCBs were summarized in this review. These groups of substances were the focus of this review because there was no evidence to suggest that there were significant differences in the toxicity of the o,p'- and p,p'-isomers of DDT, DDE, or DDD. In addition, insufficient toxicological information was available on the o,p'-isomers of DDTs and the individual PCB congeners to derive SECs. Acceptable dose-response data from controlled laboratory studies (i.e., spiked-sediment bioassays on sediment-dwelling arthropod species) were located for SUM DDT and Aroclor 1254. Therefore, the SECs for these groups of substances were derived using the SSBA. The SECs for the other groups of substances were derived using the WEA. The SECs for DDTs and PCBs were derived using both summarized and unsummarized field data; both values have been reported. The SECs of DDTs and PCBs that were derived in this study are presented in Table 28. The SECs are reported on a dry weight basis and on an OC-normalized basis at three levels of organic carbon to simplify their use.

The results of the evaluations of reliability and predictability indicate that a high degree of confidence can be placed on the SECs that were derived in this study. Importantly, the dry weight-normalized SECs for all six groups of substances (SUM DDT, SUM DDE, SUM DDD, tDDT, Aroclor 1254, and tPCB) were considered to be reliable. That is, the recommended SECs can be used to accurately predict toxic effects in sediments from the Southern California Bight. The SECs for SUM DDT, SUM DDD, tDDTs, and tPCBs all had high predictability (i.e., >80%); insufficient data were available to evaluate the predictability of the SECs for SUM DDE and Aroclor 1254. Therefore, most of the SECs can be used to accurately predict toxic effects in sediments from elsewhere in the United States. The agreement between the results of the reliability and predictability evaluations increase the confidence that can be placed on the SECs. Higher reliability (i.e., 85%) and similar predictability (82%) were obtained for a somewhat higher SEC for SUM DDT (i.e., 0.06 mg/kg DW). A lower SEC for Aroclor 1254 (i.e., 0.4 mg/kg DW) would have been just as reliable (i.e., 95%) and could be used to classify more sediment samples from the Southern California Bight.

The results of these evaluations indicate that the organic carbon-normalized SECs are reliable. The incidence of toxicity was ≥ 80% when any of these SECs were equalled or exceeded in sediments from the Southern California Bight, which indicates that the SECs provide effective tools for assessing sediments from this geographic area. Most of the SECs can also be used to accurately predict toxic

Table 28. A summary of the sediment effect concentrations (SECs) for DDTs and PCBs in in the Southern California Bight.

Substance	Sediment Effect Concentration	Reliability	Predictability

	5.40 mg/kg DW (5% OC)	80%	100%

The most highly recommended SECs are shown in bold italics..
NA - Insufficient data available to evaluate predictability.

effects in sediments from elsewhere in the United States. The predictability of the SECs for SUM DDT, tDDTs, and tPCBs ranged between 82% and 100%. Lower predictability (71%) was observed for the SEC for SUM DDD; a higher SEC (0.40 mg/kg $DW_{1\%OC}$) would have been more predictive of toxicity in the independent data set (i.e., 100% predictability). Insufficient data were available to evaluate the predictability of the SECs for SUM DDE and Aroclor 1254, indicating the the concentrations of these substances tend to be much lower elsewhere in the United States than they are in the Southern California Bight. The general agreement between the results of the reliability and predictability evaluations increases the confidence that can be placed on the SECs.

Based on a review of the existing information, it was concluded that the concentrations of DDTs and PCBs in the sediments of the Southern California Bight were sufficient to cause injury to sediment-dwelling organisms. While much of the information reviewed was from studies conducted in the 1970's and 1980's, the most recent data examined indicate that the concentrations of SUM DDT, SUM DDE, SUM DDD, tDDT, and tPCB in surficial sediments (0 to 2 cm) exceeded the SECs derived in this study at many sites (Bay *et al.* 1994; Sapudar *et al.* 1994; Fairey *et al.* 1996; Fairey 1997). Higher concentrations of these groups of substances were observed in deeper sediments (e.g., 7.5 to 47.5 cm) collected from the Palos Verdes Shelf in 1985 (Swartz *et al.* 1991). The concentrations of Aroclor 1254 in deeper sediments also exceeded the SECs derived in this study. The majority of the samples that exceeded the SECs were also toxic, considering amphipod survival, amphipod abundance, or the sea urchin fertilization. These data indicate that the concentrations of DDTs and PCBs in the Southern California Bight were sufficient to cause injury to sediment-dwelling organisms.

A number of limitations on the SECs have been identified throughout this review. It is important to consider these limitations when the SECs are utilized for assessing sediment injury in the Southern California Bight, including:

- The recommended SECs define contaminant concentrations which, if exceeded, have a high probability (i.e., >75%) of adversely affecting sediment-dwelling organisms in the Southern California Bight;

- The recommended SECs do not consider the potential effects of sediment-associated contaminants on fish and other species that reside in the water column;

- The recommended SECs do not consider the potential for adverse effects on higher trophic levels in the food web that could occur due to bioaccumulation;

- The recommended SEC for SUM DDT do not explicitly consider information on the toxicity of SUM DDT when it occurs in mixtures with other contaminants. It is likely that this group of substances would be more toxic when it is present in sediments with other contaminants;

- Because the SECs define contaminant concentrations that are likely to elicit adverse biological effects, remediation objectives would have to be lower to adequately protect sediment-dwelling organisms. Therefore, the recommended SECs should not be used directly as sediment quality remediation objectives or target clean-up levels;

- The recommended SECs were derived using data on a limited number of species and life stages of marine organisms, and, in some cases, using data from short-term tests in which lethality was the endpoint measured. The SECs would likely be lower if additional toxicological data on more sensitive species, more sensitive life stages, more sensitive endpoint, or longer exposure durations were available.

Appendix 1

Glossary of Terms

Appendix 1

Glossary of Terms

Amphipod - any crustacean of the order Amphipoda (e.g., sand hoppers).

Arthropod - any member of the phyllum arthropoda, which includes crustaceans, insects, arachnids, and centipedes.

Approach - the philosophy and procedures used by a regulatory agency to establish criteria. The components of the approach can include the types of information considered, the management goal underlying the criteria (e.g., protection of aquatic life), relative priorities assigned to various types of information, and the ways that information is combined to set the criteria.

Background concentration - the concentration of a chemical substance that is present in water, sediment, or soil at a site or area that is considered to be relatively unaffected by industrial activity.

Benthic - is a term that refers to an organism that is generally associated with the sediments.

Community metrics - a group of parameters that are calculated to describe the structure of the benthic macroinvertebrate community.

Contact - a term that is used to describe pesticides that act on direct contact with the outside surface of the plant or animal (i.e., it does not have to be ingested).

Contaminant - any chemical substance whose concentration exceeds background concentrations or which is not naturally occurring in the environment.

Criteria - the numerical limits or narrative statements that are recommended to protect and maintain the specified uses of water, sediment, or soil.

Decapod - any crustacean of the order Decapoda (e.g., crabs, lobsters, shrimps, prawns).

Degradation product - a simpler substance that is formed as a result of the breakdown (or degradation) of a chemical.

Dry weight - is the weight of a sediment sample after it has been dried to remove moisture.

Echinoderm - any member of the phylum Echinodermata (e.g., sea urchin).

Epibenthic - a term that refers to an organism that generally lives on the surface of the sediments.

Equilibrium - a term that refers to sediments in which there is no net movement of a substance between the water and the sediments (i.e., the concentrations of the substance in water and sediments are constant over time).

Gonad - ovary or testes.

Guidelines - the numerical limits or narrative statements that are recommended to protect and maintain the specified uses of water, sediment, or soil.

Infaunal - is a term that refers to an organism that generally lives in the sediments.

Invertebrate - an animal without a backbone; with or without a hard external skeleton (e.g., shrimp, worm).

Lipid - fatty substances that are not soluble in water. Certain toxic chemicals are soluble in the lipids of organisms.

Macroinvertebrate - an invertebrate that is visible with the naked eye.

Metabolite - a simpler substance that is formed as a result of the breakdown (metabolism) of a chemical in an organism.

Microorganisms - animals and plants that are not visible to the naked eye.

Microtox™ - a toxicity test that is performed with a bacterium of the genus *Photobacterium*.

Northern puffer - a species of fish (vertebrate).

Objectives - the numerical limits or narrative statements that are established to protect and maintain the specified uses of water, sediment, or soil at a particular site. Objectives may be adopted directly from generic criteria or formulated to account for site-specific conditions.

Organic carbon - includes the nonvolatile organic compounds (sugars), volatile organic compounds (mercaptans, partially volatile compounds (oils), and particulate carbonaceous materials (cellulose) that are contained in sediments. Organic carbon is important because non-ionic compounds tend to partition into it and because it bears surface charges which can interact with other types of contaminants (e.g., ionic compounds). These interactions can affect the toxicity of sediment-associated contaminants.

Polychaete - marine worm.

Porewater - is a term that refers to water that surrounds the sediment particles and fills the voids between sediment particles (also known as interstitial water).

Process sediments - to ingest sediments to obtain the edible material that is present; the sediment is extruded after processing (e.g., worm casts).

Remediation - the management of a contaminated site so as to prevent, minimize, or mitigate damage to human health or the environment. Remediation options may include both direct physical actions (such as removal, destruction, and containment) and institutional controls (such as zoning designations or orders).

Safety factors - unitless digits which are applied to effective concentrations of a contaminant to account for a number of uncertainties associated with the derivation of sediment quality criteria from limited toxicological data sets. Safety factors are used to estimate "safe concentrations" of a substance in sediments to protect sensitive species that are not represented in the toxicological data set or for which the available data are not directly applicable.

Spiked-sediment bioassay - toxicity test in which a contaminant has been added to clean sediments at different concentrations to determine its toxicity to a test organism. Typically the sediments are thoroughly mixed and left to equilibrate before adding the test organism.

Standards - the numerical limits or narrative statements, which are usually adopted from criteria or objectives, that are recognized in the enforceable environmental control laws of one or more levels of government. Standards may be specified in a regulation, statute, contract, or any other legally binding document.

Steady State - a term that refers to sediments in which there is little net movement of a substance between the water and the sediments (i.e., the concentrations of the substance in water and sediments are relatively constant over time; equilibrium conditions have almost been achieved).

Wet weight - is the weight of a sediment sample before it has been dried to remove moisture.

Appendix 2

Glossary of Acronyms

Appendix 2

Glossary of Acronyms

+/-	=	Is the shorthand used when the mean plus or minus one standard deviation is reported
>, <, =	=	Greater than, Less than, Equal to
-	=	Indeterminate
*	=	Hit; see Methods-Appendix 3
µg/kg	=	Micrograms Per Kilogram; Parts Per Billion
µg/L	=	Micrograms Per Liter; Parts Per Billion
ACOE	=	Army Corps of Engineers
ADT	=	Adult
ADT/JUV	=	Adult and/or Juvenile
AET	=	Apparent Effects Threshold
AETA	=	Apparent Effects Threshold Approach
AVS	=	Acid Volatile Sulphides
BEDS	=	Biological Effects Database for Sediments
BDL	=	Below Detection Limit
CAS RN	=	Chemical Abstracts Service Registry Number
CCME	=	Canadian Council of Ministers of the Environment
C.L.	=	Confidence Limit
COA	=	Co-occurrence Analysis
CWA	=	Clear Water Act
d	=	Day
DDTs	=	*p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *o,p'*-DDE, *p,p'*-DDD, *o,p'*-DDD and any metabolite or degradation product
DW	=	Dry Weight
EC_{50}	=	Effective Concentration to 50% of the tested organisms
EPA	=	Environmental Protection Agency
EqP	=	Equilibrium Partitioning
EqPA	=	Equilibrium Partitioning Approach
ER-L	=	Effects Range-Low
ER-M	=	Effects Range-Median
ej/prod.	=	Emergent Juveniles per Production
FCV	=	Final Chronic Value
FT	=	Flow-through Test
g	=	Gram
GAM	=	Gamete
h	=	Hour
HAT	=	Hatchlings
I	=	Instar

JUV	=	Juvenile
kg	=	Kilogram
L	=	Liter
LAR	=	Larval
LOEL	=	Lowest Observed Effect Level
LC_0	=	Lethal Concentration to 0% of the tested organisms
LC_{50}	=	Lethal Concentration to 50% of the tested organisms
LPL	=	Lower Prediction Limit
m	=	Month
20-m	=	20 minutes
MFO	=	Mixed-Function Oxidase
mg/kg	=	Milligrams Per Kilogram; Parts Per Million
mm/d	=	Millimeters Per Day; Growth Rate
N	=	Number of Organisms
NC	=	No Concordance
ND	=	Not Detected
NE	=	No Effect
NEO	=	Neonate
NG	=	No Gradient
NOAA	=	National Oceanic and Atmospheric Administration
NRDA	=	Natural Resources Damage Assessments
NSLC	=	National Screening Level Concentration
NSTP	=	National Status and Trends Program
NSTPA	=	National Status and Trends Program Approach
NYM	=	Nymph
OC	=	Organic Carbon
PAHs	=	Polycyclic Aromatic Hydrocarbons
PCBs	=	Polychlorinated Biphenyls plus degradation products and metabolites of these chemicals
ppb	=	Parts Per Billion
ppm	=	Parts Per Million
PSDDA	=	Puget Sound Dredge Disposal Analysis
S	=	Species
SAB	=	Science Advisory Board
SBA	=	Sediment Background Approach
SD	=	Standard Deviation
SDUs	=	Species Diversity Units
SDWA	=	Safe Drinking Water Act
SEC	=	Sediment Effect Concentration
SG	=	Small Gradient
SLCA	=	Screening Level Concentration Approach
sp.	=	Species
spp.	=	Species (plural)

SQ Criteria	=	Sediment Quality Criteria
sq.m.	=	Square meter
SQAGs	=	Sediment Quality Assessment Guidelines
SQO	=	Sediment Quality Objective
SRUs	=	Species Richness Units
SSBA	=	Spike Sediment Bioassay Approach
ST	=	Static Test
SUBADT	=	Sub Adult
SUM DDT	=	*p,p'*-DDT, *o,p'*-DDT
SUM DDD	=	*p,p'*-DDD, *o,p'*-DDD
SUM DDE	=	*p,p'*-DDE, *o,p'*-DDE
TC	=	Threshold Concentration
TLm	=	Median Tolerant Levels
TOC	=	Total Organic Carbon
Total DDT (or tDDT)	=	*p,p'*-DDT, *o,p'*-DDT, *p,p'*-DDE, *o,p'*-DDE, *p,p'*-DDD, *o,p'*-DDD
Total PCBs (or tPCBs)	=	Sum of the concentrations of 209 individual PCB congeners; tPCBs may be estimated from the sum of the concentrations of a subset of the 209 individual congeners
TU/g	=	Toxic Units / gram
USEPA	=	United States Environmental Protection Agency
WEA	=	Weight of Evidence Approach
wk	=	Week
WW	=	Wet Weight

Appendix 3

Methods for Deriving SECs

Appendix 3

Description of the Methods Used to Derive Sediment Effect Concentrations for DDTs and PCBs

A3.1 Spiked-Sediment Bioassay Approach

In the spiked-sediment bioassay approach (SSBA), sediment quality guidelines (SQGs) are derived using empirically generated information on the responses of test organisms to specific contaminant challenges under controlled laboratory conditions. The information that supports this approach is obtained from studies in which uncontaminated sediments are spiked with a range of known contaminant concentrations. By exposing test organisms to these spiked sediments, it is possible to establish quantitative cause-and-effect relationships between chemical concentrations and adverse biological responses. The preferred experimental endpoints in these studies include (Lamberson and Swartz 1992):

(i) mortality;
(ii) growth
(iii) reproduction;
(iv) physiological alterations; and,
(iv) other responses that have demonstrated ecological relevance (see Appendix 4).

Typically, the results of these tests are expressed as the concentrations that cause mortality (LC_{50}) or another effect (EC_{50}) to 50% of the organisms tested over a specific time period (e.g., 10 days). Chemicals may be tested alone or in combination to determine the effects of various concentrations of contaminants in sediment.

In this review, sediment effect concentrations (SECs) have been established preferentially from spiked-sediment bioassay data. Specifically, the lowest observed effect level (LOEL) for the most sensitive species represented in the toxicological database was identified as the SEC (CCME 1994). The LOEL is defined as the lowest concentration of a substance that has been demonstrated to cause an adverse biological effect on a sediment-dwelling organism. Where possible, the results of chronic (i.e., long-term) toxicity tests which measured non-lethal endpoints (such as growth or reproduction) were used in this review. If such data were not available, the results of

acute toxicity tests were used directly to define SECs for DDTs and PCBs.

To ensure that only the highest quality data were used to derive the SECs, the spiked-sediment bioassay data were evaluated prior to incorporation into the toxicological data sets. Data were included in the spiked-sediment bioassay database if:

(i) the contaminant concentrations in the various treatment groups were measured (i.e., estimated concentrations were not used);
(ii) the equilibrium adjustment period (i.e., the time between sediment spiking and toxicity testing) was reported or information was reported to determine how concentrations of the contaminant changed over time;
(iii) adequate environmental conditions were maintained in the test chambers;
(iv) the responses in the control treatments were within accepted limits (e.g., at least 90% for the amphipod, *Rhepoxynius abronius*; ASTM 1994a; 1994b);
(v) the endpoint(s) measured were ecologically-relevant (i.e., likely to influence the organism's viability in the field); and,
(vi) the organism tested was identified and representative of sediment-dwelling species that occur in the Southern California Bight. A test organism was considered to be representative of species that occur in the Southern California Bight if:
    - that species is known to occur in the Southern California Bight; or,
    - similar species are known to occur in the Southern California Bight (SCAMIT 1994).

Only data that met all of these criteria were incorporated into the toxicological data sets that were used to derive the SECs. SECs were derived using this approach only if acceptable data were available from at least one solid phase test on an epibenthic or infaunal arthropod species. This criterion was established to increase the likelihood that SECs would be applicable to sensitive sediment-dwelling species (i.e., species that are exposed to DDTs and PCBs from multiple routes, including direct contact with sediments, direct contact with porewater, and/or processing of sediments to obtain food). The LOEL for the most sensitive life stage of the most sensitive species represented in the toxicological data set was adopted as the SEC for the substance under consideration. This procedure was used to ensure that the SECs would

be as protective as possible. These SECs were expressed on a dry weight basis (mg/kg DW) and on a dry weight basis at various levels of organic carbon (e.g., mg/kg $DW_{1\%OC}$). If insufficient data were available to support the derivation of SECs using the SSBA (i.e., acceptable data on at least one sediment-dwelling arthropod species), then the weight-of-evidence (WEA) was used to derive the SECs.

A3.2 Weight-of-Evidence Approach

When acceptable spiked-sediment bioassay data were not available, SECs were derived using the weight-of-evidence approach (WEA; Long and Morgan 1990; Long 1992; Long *et al.* 1995a; MacDonald 1994). The derivation of SECs using the WEA involved four main steps. First, the available information on the effects of sediment-associated contaminants was identified and retrieved. Next, the available data were evaluated to determine their applicability to the SEC process. Data which met the screening criteria were either incorporated directly or further analyzed prior to incorporation into the appropriate toxicological data sets. Lastly, the information in the various toxicological data sets was evaluated to identify SECs for DDTs and PCBs. The procedures used to derive SECs using the weight-of-evidence approach (MacDonald 1994; Long *et al.* 1995a; MacDonald *et al.* 1996) are described below.

The first step in the SEC derivation process involved the collation of information on the effects of sediment-associated contaminants. To this end, more than ten bibliographic databases were searched for relevant published information. In addition, over 300 scientists were contacted by telephone or letter to obtain additional publications. In total, more that 800 potentially-relevant references were identified and retrieved. These references included data from spiked-sediment bioassays and field studies of sediment toxicity.

To ensure that only the highest quality data were used to derive the SECs, all of the data that were retrieved during this study were critically evaluated. Data from individual studies were considered to be acceptable for deriving SECs if:

(i) the study was conducted in a marine or estuarine area within the Southern California Bight (i.e., Point Conception to the US-Mexico Border);

(ii) matching (i.e., synoptically-collected) biological and chemical data were collected and reported;

(iii) appropriate procedures for collecting, handling, and storing sediments were utilized (ASTM 1994c);

(iv) sediment contaminant concentrations in each sample or treatment group were measured (estimated values were not used;

(v) the concentrations of the contaminants of concern differed by at least a factor of ten among sampling stations (Long and Morgan 1990; Long and MacDonald 1992; Long *et al.* 1995a). This criterion was established to ensure that the data utilized were from areas that had significant gradients in DDT or PCB concentrations. As such, DDTs and PCBs were more likely to be directly associated with the adverse effects reported in the study;

(vi) sediments were not frozen before toxicity tests were initiated (ASTM 1994a; 1994b);

(vii) the responses in the control treatments were within commonly accepted limits (e.g., at least 90% for the amphipod, *Rhepoxynius abronius* ASTM 1994a; 1994b);

(viii) adequate environmental conditions were maintained in test chambers during toxicity testing (ASTM 1994a; 1994b). This criterion was included to ensure that the biological responses were not caused by, for example, low dissolved oxygen levels or elevated water temperatures;

(ix) the endpoint(s) measured were ecologically-relevant (i.e., likely to influence the organism's viability in the field); and,

(x) the organism tested was identified and representative of sediment-dwelling species that occur in the Southern California Bight. A test organism was considered to be representative of species that occur in the Southern California Bight if:

- that species is known to occur in the Southern California Bight; or,
- similar species are known to occur in the Southern California Bight (SCAMIT 1994).

To ensure that the SECs considered a broad range of biological effects, the toxicological information considered in this review included:

(i) measurements of altered benthic communities (depressed species richness or total abundance) in field studies;

(ii) significantly or relatively elevated sediment toxicity in field studies; and,

(iii) effective (e.g. EC_{50}) or lethal (e.g. LC_{50}) concentrations determined in laboratory bioassays of sediments spiked with single chemicals or mixtures of chemicals.

The raw data that passed the initial screening steps were further evaluated and incorporated into the toxicological data sets that were developed for this project. A total of four toxicological data sets were created for each group of chemicals that was considered in this study. Two of the data sets included "summarized" toxicological data, one of which included data expressed on a dry weight basis and the other included data expressed on an dry weight basis at 1% OC. The other two data sets incorporated raw or "unsummarized" toxicological data, one of which included data expressed on a dry weight basis and the other included data expressed on an dry weight basis at 1% OC.

The summarized data sets listed the mean concentrations of DDTs or PCBs in the toxic and non-toxic samples for each endpoint measured in each study. By contrast, the "unsummarized" data sets listed all the concentrations of DDTs or PCBs in the toxic and non-toxic samples for each endpoint reported for each study. Both "summarized" and "unsummarized" data were utilized in this study to optimize the use of the available information. In addition, derivation of SECs using both types of data sets provided a means of assessing the influence of the data analysis procedures on the resultant SECs.

Chemical concentrations were normalized to 1% OC by dividing the original dry weight concentrations by the OC (%) content of the sediment. As such, the OC-normalized contaminant concentrations were reported as mg/kg $DW_{1\%\ OC}$. Organic carbon normalization of non-polar organic contaminant concentrations is considered to account for the influence of organic matter on contaminant bioavailability (Di Toro *et al.* 1991).

Raw data from individual field surveys that passed the initial screening steps were evaluated in "co-occurrence analyses" with either of two methods (Long 1992; Long and MacDonald 1992) prior to incorporation into the "summarized" toxicological data sets. If the statistical significance of the data was reported, then the mean chemical concentrations in the statistical groups (i.e., toxic and non-toxic) were calculated and compared. In some cases, the results of power analyses

conducted for various toxicity tests were used to identify toxic samples [i.e., when the minimum significant difference (MSD) from controls was exceeded; Thursby In prep.; Long *et al.* 1996]. If no such statistical evaluations were reported, the frequency distributions of the biological data were examined and mean concentrations in subjectively determined groups of samples were calculated and compared (e.g., most toxic versus least toxic). The available data from spiked-sediment bioassays were also included in the summarized toxicological data sets.

The raw data from individual field surveys were also evaluated in co-occurrence analyses prior to inclusion in the "unsummarized" toxicological data sets. If the statistical significance of the data was reported, then the concentration of the analyte in each "toxic" sample was compared to the mean concentration of the analytes in the "non-toxic" samples. The calculated MSDs for the various toxicity tests were also used to assign toxic and non-toxic designations to individual sediment samples. If no such statistical evaluations were reported, the frequency distributions of the biological data were examined. Subsequently, the concentration of the analyte in each of the samples that were considered to be toxic was compared to the mean concentration of the substance in the non-toxic samples. The available data from spiked-sediment bioassays were also included in the unsummarized toxicological data sets.

Each entry in all of the data sets was assigned an 'effects/no-effects' descriptor (see Tables A4-1 to A4-24; Long *et al.* 1995a; MacDonald *et al.* 1996). An entry was assigned an 'effects' descriptor (*) if:

(i) an adverse biological effect, such as acute toxicity, was reported; and,

(ii) concordance was apparent between the observed biological response and the measured chemical concentration.

Concordance was apparent when adverse biological effects were observed in association with at least a two-fold elevation in the chemical concentration above reference concentrations. This two-fold criterion provided a consistent basis for identifying chemical concentrations that were associated with the adverse effect that was measured (Long and Morgan 1990; Long and MacDonald 1992; Long *et al.* 1995a). A 'no gradient' (NG) descriptor was assigned when no differences in the concentrations of the chemical of concern was reported between the toxic and non-toxic stations. A 'small gradient' (SG) descriptor was assigned when the concentrations of a substance differed by less than a factor of two between the toxic and non-toxic

samples. A 'no concordance' (NC) descriptor was assigned when there was no concordance between the severity of the effect and the chemical concentration that was measured (i.e., the concentration of a chemical in the toxic samples was lower than the concentration of that substance in the non-toxic samples). For samples that were assigned the NG, SG, and NC descriptors, it was assumed that other factors (whether measured or not) were more important in the etiology of the observed effect than the concentration of the contaminant considered. Finally, a 'no effects' (NE) descriptor was applied to biological data from unaffected, background, or reference samples. Data entries from spiked-sediment bioassays were also assigned an 'effects' descriptor if significant biological effects were reported.

Collectively, the 'effects' data entries from laboratory and field studies were used to derive the SECs. All of the 'effects' data were given equal weight in the derivation of SECs using the WEA. Collectively, data assigned 'no gradient', 'small gradient', 'no concordance', and 'no effects' descriptors were regarded as the 'no-effects' data set. These latter data entries were included in the 'no effects' data set because the concentrations of the substance were not associated with the observed biological effects. Hence, the substance was not considered to be harmful at the concentration that was measured. While the 'no effects' data were not used to derive the SECs, they were used to evaluate the reliability of the resultant SECs.

The distributions of the effects data sets for each substance were determined using percentiles (Byrkit 1975). The median, or 50th percentile, of the effects data was determined and referred to as the Effects Range-Median (ER-M; Long and Morgan 1990; Long *et al.* 1995a). The lower of the ER-Ms derived using the summarized and unsummarized data sets for each substance was adopted as the SEC, when insufficient data were available to support the SSBA. Percentiles of aquatic toxicity data were used by Klapow and Lewis (1979) to calculate marine water quality standards; the authors noted that this approach tended to minimize the influence of single (potentially outlier) data points on the development of guidelines. The SECs derived using the WEA are considered to be appropriate for evaluating sediment quality in the Southern California Bight because there is a high probability of observing adverse effects when this concentration is exceeded (see Long and Morgan 1990; Long 1992; Long and MacDonald 1992; MacDonald 1994; CCME 1994; Long *et al.* 1995a; MacDonald *et al.* 1996 for more complete descriptions of the WEA). Therefore, the SECs are likely to define concentrations of sediment-associated contaminants that would injure sediment-dwelling organisms.

[a]SUM DDT concentrations have been estimated from the concentrations of p,p'-DDT by dividing by 0.894 (conversion factor was determined from the data reported by Bay et al. 1994).
ND = not detected; detection limit was not reported.
See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Table A4-2. A summary of the available data on the biological effects associated with sediment-sorbed SUM DDT (mg/kg DW; unsummarized data set).

[a]SUM DDT concentrations have been estimated from the concentrations of p,p'-DDT by dividing by 0.894 (conversion factor was determined from the data reported by Bay et al. 1994).

ND = not detected; detection limit was not reported.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.

Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Where the concentration of the contaminant was less than detection limit (indicated by '<') in a toxic sample, 1/2 of the detection limit was used to compare to the mean concentration in the non-toxic samples.

[a]SUM DDT concentrations have been estimated from the concentrations of p,p'-DDT by dividing by 0.894 (conversion factor was determined from the data reported by Bay et al. 1994).
ND = not detected; detection limit was not reported
See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

[a]SUM DDE concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.886 (conversion factor was determined from the data reported by Bay et al. 1994).
See Appendix 2 for glossary of acronyms.
[b]Total DDT equals the sum of SUM DDT, SUM DDD and SUM DDE. SUM DDT concentrations were calculated by dividing p,p'-DDT by 0.894; SUM DDD concentrations were calculated by dividing p,p'-DDD by 0.863; (conversion factors were determined from the data reported by Bay et al. 1994). SUM DDE was calculated as the sum of the reported p,p'-DDE and o,p'-DDE concentrations.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Table A4-6. A summary of the available data on the biological effects associated with sediment-sorbed SUM DDE (mg/kg DW; unsummarized data set).

*SUM DDE concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.886 (conversion factor was determined from the data reported by Bay et al. 1994).

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.

Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Where the concentration of the contaminant was less than detection limit (indicated by '<') in a toxic sample, 1/2 of the detection limit was used to compare to the mean concentration in the non-toxic samples.

Table A4-7. A summary of the available data on the biological effects associated with sediment-sorbed SUM DDE (mg/kg DW at 1% OC; summarized data set).

[a]SUM DDE concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.886 (conversion factor was determined from the data reported by Bay et al. 1994).

[b]Total DDT equals the sum of SUM DDT, SUM DDD and SUM DDE. SUM DDT concentrations were calculated by dividing p,p'-DDT by 0.894; SUM DDD concentrations were calculated by dividing p,p'-DDD by 0.863; (conversion factors were determined from the data reported by Bay et al. 1994). SUM DDE was calculated as the sum of the reported p,p'-DDE and o,p'-DDE concentrations.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study. Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

[a]SUM DDE concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.886 (conversion factor was determined from the data reported by Bay et al. 1994).

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study. Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

[a]SUM DDD concentrations have been estimated from the concentrations of p,p'-DDD by dividing by 0.863 (conversion factor was determined from the data reported by Bay et al. 1994).

ND = not detected; detection limit was not reported.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study. Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Table A4-10. A summary of the available data on the biological effects associated with sediment-sorbed SUM DDD (mg/kg DW; unsummarized data set).

Sum DDD Conc.+/-SD	Ratio	Hit	Area	Analysis Type	Test Type	End-Point Measured	Species	Life Stage	TOC (%)	Reference

[a]SUM DDD concentrations have been estimated from the concentrations of p,p'-DDD by dividing by 0.863 (conversion factor was determined from the data reported by Bay et al. 1994).
ND = not detected; detection limit was not reported.
See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.
Where the concentration of the contaminant was less than detection limit (indicated by '<') in a toxic sample, 1/2 of the detection limit was used to compare to the mean concentration in the non-toxic samples.

[a]SUM DDD concentrations have been estimated from the concentrations of p,p'-DDD by dividing by 0.863 (conversion factor was determined from the data reported by Bay et al. 1994).
ND = not detected; detection limit was not reported.
See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

[a]Total DDT concentrations have been estimated from the concentrations of the p,p'-isomers (p,p'-DDT, p,p'-DDE, p,p'-DDD) by dividing by 0.889 (conversion factor was determined from the data reported by Bay et al. 1994).
[b]Total DDT concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.787 (conversion factor was determined from the data reported by Bay et al. 1994).
[c]Total DDT equals the sum of SUM DDT, SUM DDD and SUM DDE. SUM DDT concentrations were calculated by dividing p,p'-DDT by 0.894; SUM DDD concentrations were calculated by dividing p,p'-DDD by 0.863; SUM DDE was calculated as the sum of the reported p,p'-DDE and o,p'-DDE concentrations (conversion factors were determined from the data reported by Bay et al. 1994).
See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

[a]Total DDT concentrations have been estimated from the concentrations of the p,p'-isomers (p,p'-DDT, p,p'-DDE, p,p'-DDD) by dividing by 0.889 (conversion factor was determined from the data reported by Bay et al. 1994).
[b]Total DDT concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.787 (conversion factor was determined from the data reported by Bay et al. 1994).
[c]Total DDT equals the sum of SUM DDT, SUM DDD and SUM DDE. SUM DDT concentrations were calculated by dividing p,p'-DDT by 0.894; SUM DDD concentrations were calculated by dividing p,p'-DDD by 0.863; SUM DDE was calculated as the sum of the reported p,p'-DDE and o,p'-DDE concentrations (conversion factors were determined from the data reported by Bay et al. 1994).
See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.
Where the concentration of the contaminant was less than detection limit (indicated by '<') in a toxic sample, 1/2 of the detection limit was used to compare to the mean concentration in the non-toxic samples.

[a]Total DDT concentrations have been estimated from the concentrations of the p,p'-isomers (p,p'-DDT, p,p'-DDE, p,p'-DDD) by dividing by 0.889 (conversion factor was determined from the data reported by Bay et al. 1994).
[b]Total DDT concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.787 (conversion factor was determined from the data reported by Bay et al. 1994).
[c]Total DDT equals the sum of SUM DDT, SUM DDD and SUM DDE. SUM DDT concentrations were calculated by dividing p,p'-DDT by 0.894; SUM DDD concentrations were calculated by dividing p,p'-DDD by 0.863; (conversion factors were determined from the data reported by Bay et al. 1994). SUM DDE was calculated as the sum of the reported p,p'-DDE and o,p'-DDE concentrations.
See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Table A4-16. A summary of the available data on the biological effects associated with sediment-sorbed Total DDT (mg/kg DW at 1% OC; unsummarized data set).

[a]Total DDT concentrations have been estimated from the concentrations of the p,p'-isomers (p,p'-DDT, p,p'-DDE, p,p'-DDD) by dividing by 0.889 (conversion factor was determined from the data reported by Bay et al. 1994).
[b]Total DDT concentrations have been estimated from the concentrations of p,p'-DDE by dividing by 0.787 (conversion factor was determined from the data reported by Bay et al. 1994).
[c]Total DDT equals the sum of SUM DDT, SUM DDD and SUM DDE. SUM DDT concentrations were calculated by dividing p,p'-DDT by 0.894; SUM DDD concentrations were calculated by dividing p,p'-DDD by 0.863; (conversion factors were determined from the data reported by Bay et al. 1994). SUM DDE was calculated as the sum of the reported p,p'-DDE and o,p'-DDE concentrations.
See Appendix 2 for glossary of acronyms.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study. Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.

Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Where the concentration of the contaminant was less than detection limit (indicated by '<') in a toxic sample, 1/2 of the detection limit was used to compare to the mean concentration in the non-toxic samples.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.

Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Table A4-21. A summary of the available data on the biological effects associated with sediment-sorbed Total Polychlorinated Biphenyls (mg/kg DW; summarized data set).

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study. Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.

Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Where the concentration of the contaminant was less than detection limit (indicated by '<') in a toxic sample, 1/2 of the detection limit was used to compare to the mean concentration in the non-toxic samples.

Table A4-23. A summary of the available data on the biological effects associated with sediment-sorbed Total Polychlorinated Biphenyls (mg/kg DW at 1% OC; summarized data set).

See Appendix 2 for glossary of acronyms.
The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study.
Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

See Appendix 2 for glossary of acronyms.

The ratio was calculated by dividing the measured concentration of the substance in sediments at the toxic site by the mean concentration of that substance at the non-toxic sites for the same study. Information on the mean concentrations of the substance at the non-toxic sites can be found in the Summarized data tables.

Appendix 5

Independent Data Set for DDTs & PCBs

Appendix A5-1. A summary of the available information on the toxic effects of sediment-associated SUM DDT from locations outside the Southern California Bight.

Concentration			Endpoint Measured

26.0	15.0	San Francisco Bay, CA	36 % mort.	T										T	Swartz et al. 1994
47.8	26.9	San Francisco Bay, CA	43 % mort.	T										T	Swartz et al. 1994
77.7	32.7	San Francisco Bay, CA	66 % mort.	T										T	Swartz et al. 1994

Concentration: DW = dry weight; @1%OC = at 1% organic carbon.

Endpoint Measured: mort. = mortality; fert. = fertilization; norm. dev. = normal development; abnorm. dev. = abnormal development; inc. = increase.

NT = toxic; T = toxic.

Species tested included:

Casillas et al. 1992; Dendraster excentricus (sand dollar).

Chapman et al. 1987; Rhepoxynius abronius (amphipod).

Long et al. 1994; Ampelisca abdita (amphipod); Arbacia punctulata (sea urchin).

Long et al. 1995b; Ampelisca abdita (amphipod).

Long 1997; Ampelisca abdita (amphipod); Arbacia punctulata (sea urchin).

Munns et al. 1991; Ampelisca abdita (amphipod).

Pastorok & Becker 1990; Rhepoxynius abronius (amphipod), Dendraster excentricus (sand dollar), Neanthes arenaceodentata (polychaete).

Rice et al. 1995; Rhepoxynius abronius (amphipod), Dendraster excentricus (sand dollar), Armandia brevis (amphipod).

Swartz et al. 1994; Eohaustorius estuarius (amphipod).

0.7800	0.3662	Oakland Inner H., CA	24 % mort.	NT							NT	Word et al. 1988

Concentration: DW = dry weight; @1%OC = at 1% organic carbon.

Area: Est. = estuary; S. Francisco = San Francisco; Oakland Inner H. = Oakland Inner Harbor.

Endpoint Measured: mort. = mortality; fert. = fertilization; norm. dev. = normal development; abn. dev. = abnormal development; inc. len. = increase length; inc. d. = increase diameter.

NT = toxic; T = toxic.

Species tested included:

Casillas et al. 1992; Dendraster excentricus (sand dollar).

Chapman et al. 1987; Rhepoxynius abronius (amphipod).

Long et al. 1994; Ampelisca abdita (amphipod); Arbacia punctulata (sea urchin).

Long et al. 1995b; Ampelisca abdita (amphipod).

Long 1997; Ampelisca abdita (amphipod); Arbacia punctulata (sea urchin).

Munns et al. 1991; Ampelisca abdita (amphipod).

Pastorok & Becker 1990; Rhepoxynius abronius (amphipod), Dendraster excentricus (sand dollar), Neanthes arenaceodentata (polychaete).

Rice et al. 1995; Rhepoxynius abronius (amphipod), Dendraster excentricus (sand dollar), Armandia brevis (amphipod).

Swartz et al. 1994; Eohaustorius estuarius (amphipod).

Tietjen & Lee 1984; Chromadorina germanica and Diplolaimella punicea (nematodes).

Word et al. 1988; Rhepoxynius abronius (amphipod).

CV of Donald D. MacDonald

DONALD D. MACDONALD

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

EDUCATION:

Bachelor of Science, Zoology
(Fisheries Biology; Environmental Physiology, Comparative Biochemistry)
University of British Columbia, 1982

SPECIALIZATION:

Principal of MacDonald Environmental Sciences Limited, which was established to provide scientific consulting services in the fields of fisheries and aquatic resource management, stream ecology, environmental quality guidelines and policy development, environmental risk and hazard assessment, and information and technology transfer.

Specialist environmental toxicology and chemistry, ecosystem-based resource management, water quality/water use interactions, and sediment quality assessment.

PROFESSIONAL MEMBERSHIPS:

American Fisheries Society
Past-President, Canadian Aquatic Resources Section; Nominations Committee; Chair, Wetlands Conservation Committee; Newsletter Committee; Membership Committee.

Aquaculture Association of Canada

Association of Professional Biologists of British Columbia

Canadian Association on Water Pollution Research and Control

International Association on Water Pollution Research and Control

Pacific Fisheries Biologists

Society of Environmental Toxicology and Chemistry

DONALD D. MACDONALD

A6-2

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

EXPERIENCE:

AQUATIC BIOLOGIST - February, 1989 to Present

MacDonald Environmental Sciences Limited
2376 Yellow Point Road, RR #3, Ladysmith, B.C. V0R 2E0

Independent consulting on fisheries and aquatic resource management, environmental quality, stream ecology, computer data management, and information and technology transfer. Recent projects have been focused on the development of water quality guidelines, sediment quality guidelines, tissue residue guidelines, environmental quality monitoring programs, fisheries co-management programs, and the assessment of environmental quality.

WATER QUALITY OBJECTIVES OFFICER - September, 1984 to February, 1989

Water Quality Branch, Inland Waters, Environment Canada
502 - 1001 West Pender Street, Vancouver, B.C. V6E 2M9

Compilation, management and statistical analysis of existing and new information generated to support the formulation of water quality objectives in waters of significant federal interest; generation of water quality criteria information through toxicological, water quality, and other studies; design and implementation of monitoring programs to assess compliance with water quality objectives; preparation of reports and other publications on information developed to formulate water quality objectives; organization of workshops and information exchange sessions on water quality guidelines and objectives; provision of information and advice to technical committees established to resolve the International Joint Commission reference on the Flathead River.

Supervisor: Dr. D. Valiela, Head Water Quality Objectives Division

TECHNICAL PLANNING COORDINATOR - November, 1983 to September, 1984

Water Quality Branch, Inland Waters, Environment Canada
502 - 1001 West Pender Street, Vancouver, B.C. V6E 2M9

Planning and development of regional water quality programs, including long- and short-term logistics and budgetary requirements and inter-project coordination; planning, organization, expedition, and supervision of special field studies and sampling projects for water quality analysis; pollution surveillance and sediment sampling; planning and implementation on national water quality monitoring programs to assess national trends and conditions.

Supervisor: Dr. W.E. Erlebach, Chief Water Quality Branch

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

Volume 4: Supporting documentation - Regional biological effects database for sediments. Report prepared for Florida Department of Environmental Protection. Tallahassee, Florida.

Zeeman, A.J. and D.D. MacDonald. 1994. An evaluation of the relationship between lowest observed effect levels and no observed levels in aquatic toxicity tests. Prepared for Environment Canada. Hull, Quebec. 40 pp.

Christensen, E.V., D.D. MacDonald, and P. Quaw. 1994. A discussion paper on First Nations environmental assessment. Prepared for Dene Nation. Yellowknife, Northwest Territories. 43 pp.

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

Haines, M.L., K. Brydges, M.J. MacDonald, S.L. Smith, D.D. MacDonald. 1994. A review of environmental quality criteria and guidelines for priority substances in the Fraser River. Supporting Documentation. Prepared for Environment Canada. Pacific and Yukon Region. West Vancouver, British Columbia. 222 pp.

MacDonald, D.D. 1993. Canadian environmental quality guidelines for polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans. Report prepared for EcoHealth Branch, Environment Canada. Ottawa Canada. 212 pp.

MacDonald, D.D. 1993. A discussion paper on the development and use of safety, application, and uncertainty factors in the derivation of water quality guidelines for aquatic life. Technical Report. Report prepared for EcoHealth Branch, Environment Canada. Ottawa Canada. 18 pp.

MacDonald, D.D. and M.L. Haines 1993. A discussion paper on the development and use of safety, application, and uncertainty factors in the derivation of water quality guidelines for aquatic life. Supporting Documentation. Report prepared for EcoHealth Branch, Environment Canada. Ottawa Canada. 244 pp.

MacDonald, D.D. and A. Sobolewski. 1993. Recommended procedures for developing site-specific environmental quality remediation objectives for contaminated sites. Report prepared for EcoHealth Branch, Environment Canada. Ottawa Canada. 85 pp.

MacDonald, D.D., A. White, B. Charlish, M.L. Haines, and T. Wong. 1993. Compilation of toxicological information on sediment-associated contaminants and the development of freshwater sediment quality guidelines. Report prepared for EcoHealth Branch, Environment Canada. Ottawa Canada. 24 pp + Supporting Documentation.

Smith, S.L. and D.D. MacDonald. 1993. A protocol for the derivation of sediment quality guidelines for the protection of aquatic life. *In:* Canadian Sediment Quality Guidelines. Report prepared for the Task Group on Water Quality Guidelines. Canadian Council of Ministers of the Environment. Ottawa, Canada.

Smith, S.L. and D.D. MacDonald. 1993. Framework for the Implementation of sediment quality guidelines. *In:* Canadian Sediment Quality Guidelines. Report prepared for the Task Group on Water Quality Guidelines. Canadian Council of Ministers of the Environment. Ottawa, Canada.

MacDonald Environmental Sciences Ltd. 1993. Development of a First Nations fisheries management model - Phase II: Strategic planning in stock assessment and stewardship. Report prepared for Coast Salish Fisheries Working Group. Vancouver, British Columbia. 132 pp.

MacDonald Environmental Sciences Ltd. 1993. Development of a First Nations fisheries management model - Phase III: Formulation and implementation of a joint fisheries management strategy. Report prepared for Coast Salish Fisheries Working Group. Vancouver, British Columbia.

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

MacDonald Environmental Sciences Ltd. 1993. Proceedings of the Coast Salish Fisheries Working Group Harvest Monitoring Workshop. Report prepared for Coast Salish Fisheries Working Group. Vancouver, British Columbia. 69 pp.

MacDonald, D.D. 1992. Development of an approach to the assessment of sediment quality in Florida coastal waters. Report prepared for the Florida Department of Environmental Regulation. Tallahassee, Florida.

MacDonald, D.D. 1992. Canadian interim sediment quality guidelines for arsenic, cadmium, chromium, copper, lead, mercury, silver, and zinc. Report prepared for EcoHealth Branch. Environment Canada. Hull, Quebec. 81 pp.

MacDonald, D.D. and S.L. Walker. 1992. A discussion paper on the derivation and use of Canadian tissue residue guidelines for the protection of aquatic life and wildlife. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada.

MacDonald, D.D., K. Brydges, and M.L. Haines. 1992. Development of an approach to the assessment of sediment quality in Florida coastal waters: Supporting documentation. Report prepared for the Florida Department of Environmental Regulation. Tallahassee, Florida.

MacDonald, D.D., P.M. Outridge, and I.D. Cuthbert. 1992. Canadian soil quality criteria for contaminated sites: Cadmium. Report prepared for the CCME Subcommittee on Environmental Quality Criteria for Contaminated Sites. 76 pp.

MacDonald, D.D., I.D. Cuthbert, and P.M. Outridge. 1992. Sampling and analytical methods for monitoring and assessing the impacts of glycols in the Canadian environment. Report prepared for Environment Canada and Transport Canada. Ottawa, Canada. 27 pp.

MacDonald, D.D., I.D. Cuthbert, and P.M. Outridge. 1992. Canadian environmental quality guidelines for three glycols used in aircraft de-icing/anti-icing fluids. Report prepared for Environment Canada and Transport Canada. Ottawa, Canada. 140 pp.

MacDonald, D.D., S.L. Smith, M.P. Wong, and P. Mudroch. 1992. The development of Canadian marine environmental quality guidelines. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada.

MacDonald, D.D., I.D. Cuthbert, P.M. Outridge, and R.T. Ruthman. 1992. Canadian water quality guidelines for the protection of aquatic life for ethylene glycol, diethylene glycol, and propylene glycol. Report prepared for Environment Canada and Transport Canada. Ottawa, Canada. 70 pp.

Haines, M.L. and D.D. MacDonald. 1992. A guide to conducting on-line literature searches in support of CEPA-PSL assessments and Canadian EQGs development: Experience with two organic chemicals: DCM and TCE. Environment Canada. Ottawa, Ontario. 8 pp.

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffnesl@island.net

Isaac, T.D. and D.D. MacDonald. 1992. Willow River adult chinook salmon enumeration/carcass recovery program: 1992. Report prepared by Lheit-Lit'en Nation. Prince George, British Columbia.

Long, E.R. and D.D. MacDonald. 1992. National Status and Trends Program approach. *In:* Sediment Classification Methods Compendium. Sediment Oversight Technical Committee. United States Environmental Protection Agency. Washington, District of Columbia.

Outridge, P.O., D.D. MacDonald, and I.D. Cuthbert. 1992. Background supporting document for cadmium. Canadian Environmental Protection Act. Priority Substances List. Report prepared for EcoHealth Branch, Environment Canada. Ottawa, Canada. 202 pp.

MacDonald Environmental Sciences Ltd. 1992. Development of a First Nations fisheries management model - Phase I: Derivation of a generic model. Report prepared for Coast Salish Fisheries Working Group. Vancouver, British Columbia. 80 pp.

MacDonald Environmental Sciences Ltd. 1992. An assessment of ambient environmental conditions in the Liard River Basin, Northwest Territories. Report prepared for Water Resources Division. Indian and Northern Affairs Canada. Yellowknife, Northwest Territories. 89 pp.

MacDonald, D.D. 1991. Canadian water quality guidelines for polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada.

MacDonald, D.D. 1991. Canadian water quality guidelines for dimethoate. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 66 pp.

MacDonald, D.D. 1991. Canadian water quality guidelines for aldicarb. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 68 pp.

MacDonald, D.D. 1991. Canadian water quality guidelines for MCPA. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 64 pp.

MacDonald, D.D., L.E. Fidler, S.B. Miller, B.J. Moore, V.A. Wong, and S. Walker. 1991. Canadian water quality guidelines for polycyclic aromatic hydrocarbons. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 215 pp.

MacDonald, D.D. 1990. A discussion paper on the development of ecosystem guidelines for the Slave River, Northwest Territories. Report prepared for Indian and Northern Affairs Canada. Yellowknife, Northwest Territories. 63 pp.

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

MacDonald, D.D. 1990. Canadian water quality guidelines for bromoxynil. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 68 pp.

MacDonald, D.D. 1990. Canadian water quality guidelines for dicamba. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 81 pp.

MacDonald, D.D. 1990. Protocols for the derivation of water quality guidelines for the protection of agricultural water uses. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 36 pp.

MacDonald, D.D. 1990. A discussion paper on the derivation and use of action levels for pesticides in groundwater: Technical appendix. Report prepared for Environment Canada. Ottawa, Canada. 54 pp.

MacDonald, D.D. and J.E. Fairfield. 1990. A discussion paper on the derivation and use of action levels for pesticides in groundwater. Report prepared for Environment Canada. Ottawa, Canada. 45 pp.

MacDonald, D.D. and S.L. Smith. 1990. An approach to monitoring ambient environmental quality in the Slave River basin, Northwest Territories: Toward a consensus. Report prepared for Indian and Northern Affairs Canada. Yellowknife, NWT. 64 pp.

MacDonald, D.D. and S.L. Smith. 1990. A strategic approach to monitoring ambient environmental quality conditions in the Slave River basin, NWT. Report prepared for Indian and Northern Affairs Canada. Yellowknife, NWT. 60 pp.

MacDonald, D.D. and S.L. Smith. 1990. A strategic approach to the development and implementation of environmental quality guidelines and objectives in the territorial portion of the Slave River basin. Report prepared for Indian and Northern Affairs Canada. Yellowknife, NWT. 146 pp.

Fidler, L.E., B.J. Moore, and D.D. MacDonald. 1990. A review of the status of prophylaxis, pretreatment, and therapy of intoxications due to botulinal neurotoxins, staphylococcal enterotoxins and ricin in humans. Report prepared for National Defence Canada. Ralston, Alberta. 92 pp.

Fidler, L.E., B.J. Moore, and D.D. MacDonald. 1990. A survey of research groups in Canada and the United States capable of conducting research on botulinal neurotoxins, staphylococcal enterotoxins and ricin in humans. Report prepared for National Defence Canada. Ralston, Alberta. 34 pp + appendices.

Roch, M., D.D. MacDonald, C. Hilliar and W.E. McLean. 1990. Copper toxicity bioassays conducted at the Puntledge River salmon hatchery to assess the effects of acid mine drainage from Mt. Washington. Report prepared for the Steelhead Society. Campbell River, British Columbia.

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

Kistritz, R.U. and D.D. MacDonald. 1990. Procedure for deriving water quality guidelines for nutrients, algae and aquatic vascular plants in Canadian stream ecosystems. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada.

Sigma Engineering Limited. 1990. Keenleyside powerplant project: Assessment of water quality and use. Report prepared for BC Hydro and Power Authority. Vancouver, British Columbia. 119 pp + appendices.

Sigma Engineering Limited. 1990. Columbia River integrated environmental sampling program. Report prepared for BC Ministry of Environment, Cominco Metals, Celgar Pulp, and BC Power and Hydro Authority. Vancouver, British Columbia. 47 pp + appendices.

MacDonald, D.D. 1989. An assessment of ambient water quality conditions in the Slave River basin, NWT. Report prepared for Indian and Northern Affairs Canada. Yellowknife, NWT. 94 pp.

MacDonald, D.D. 1989. Proceedings of the Canada-British Columbia workshop on water quality guidelines and objectives: Focus on the Fraser. Water Quality Branch, Environment Canada. Vancouver, B.C. 151 pp.

MacDonald, D.D. 1989. Canadian water quality guidelines for dinoseb. Report prepared for the Canadian Council of Resource and Environment Ministers. Ottawa, Canada. 74 pp.

MacDonald, D.D. 1989. Development, implementation and use of site-specific water quality objectives: A conceptual model. Proceedings of the CCREM Workshop on the Development and Use of Water Quality Objectives. Environment Canada. Ottawa, Canada.

MacDonald, D.D. and R. Bocking. 1989. Rosette Creek: Assessment of potential impacts of bridge construction on sockeye salmon. Report prepared for the Carrier Sekani Tribal Council. MacDonald Environmental Sciences Ltd. and LGL Ltd. Vancouver, British Columbia. 28 pp.

MacDonald, D.D., W.T. Willingham, L.P. Parrish, G.J. Rodreguez, J.M. Lazorchak, and J.W. Love. 1989. Using *in situ* bioassays as a basis for the development of water quality guidelines: A case study of the Arkansas River. Proceedings of the CCREM Workshop on the Development and Use of Water Quality Objectives. Environment Canada. Ottawa, Canada.

Mah, F.T.S., D.D. MacDonald, S.W. Sheehan, T.N. Tuominen, and D. Valiela. 1989. Dioxins and furans in sediments and fish from the vicinity of ten inland pulp mills in British Columbia. Water Quality Branch. Environment Canada. Vancouver, B.C. 77 pp.

2376 Yellow Point Road, RR3 • Ladysmith, BC V0R 2E0 • 250-722-3631 • Fax: 250-722-3651 • E-mail: sffmesl@island.net

MacDonald, D.D. and D. Valiela. 1988. Site-specific water quality guidelines for fish and aquatic life: Deposited sediments. Water Quality Branch, Environment Canada. 84 pp. + appendices.

MacDonald, D.D., L.E. Fidler and D. Valiela. 1987. Site-specific water quality criteria for fish and aquatic life in the Canadian portion of the Flathead River basin: Nitrate, nitrite and ammonia. Water Quality Branch, Environment Canada, Vancouver, B.C. 119 + appendices.
