because the controls necessary to attain the use "would result in substantial and widespread economic and social impact." The reason for this provision is to avoid the type of situation evidenced by this proposed TMDL, namely to require the expenditure of resources in pursuit of small or nonexistent benefits.

Over many decades, economists have developed a rigorous methodology to assess the impacts of government actions. The approach derives from the basic principles of public finance and welfare economics. It takes a holistic perspective by considering many groups in society, and articulates the tradeoffs among policy alternatives. The economist's approach to assessing government actions also combines considerations of efficiency and equity, and has been widely applied to problems of environmental regulation. At its heart, economic analysis of regulation is an accounting of the consequences of a governmental action. This accounting is often quantitative, but many first-rate economic analyses also treat impacts qualitatively, especially for nonstandard commodities. Ideally, economic analysis will also give information on the distributional impacts of the intervention, or a description of which groups in society are affected by the action, and how much.

A requirement to "consider economics" is not the same as a directive to adopt only those regulations that pass a cost-benefit test. Agencies can use the results of economic analysis, but not be bound by "bottom-line" numbers. Most economists would not argue that quantified costs and benefits tell the whole story, or that precise measurements of either are always possible. But when economic analysis reveals low or nonexistent benefits and high costs, something seems amiss. Indeed, the California legislature sought to avoid just such a socially undesirable outcome by mandating a consideration of economics when setting water quality standards.

The federal government has maintained a decades-long commitment to economic analysis of regulation. This practice began in the Nixon Administration, which initiated Quality of Life Reviews of federal regulations in 1970. The two main events in the history of economic analysis at the federal level, however, occurred in the Reagan and Clinton Administrations. President Reagan issued Executive Order 12,291, perhaps the most decisive step in the cost-benefit record. This Executive Order established a set of principles for agencies to follow to the extent permitted by law, including a commitment to cost-benefit analysis. The order required Regulatory Impact Analysis of major rules, and also established a formal mechanism for OMB oversight of interventions. President Clinton issued Executive Order 12,866, which reaffirmed the basic commitments to economic analysis and conferred bipartisan legitimacy. This order also introduced some reforms to the economic analysis process that were designed primarily to assuage fears of industry capture. These reforms included procedures for conflict resolution and inclusion of equity considerations.

3. Implementation Costs

The Draft TMDL describes the proposed implementation plan to meet numeric targets for toxic pollutants in the Dominguez Channel and greater Los Angeles and Long Beach Harbor Waters. Compliance with the TMDL for metals and PAHs is based on achieving the load and waste load allocations and / or demonstrating attainment of the Sediment Quality Objectives (SQOs) as multiple lines of evidence. Compliance with the TMDLs for bioaccumulative compounds shall be based on achieving the assigned loads and waste load allocations or, alternatively, by meeting fish tissue targets.[2]

Proposed compliance measures include the elimination of toxic pollutants being loaded into Dominguez Channel and the harbors, and cleanup of contaminated sediments lying on the bottom of greater Los Angeles

[2] Draft TMDL, p. 102.

and Long Beach Harbors. In most areas of the harbors, contaminant concentrations in sediment are above the proposed numeric targets for sediment. WLAs and LAs may not be attainable without removal of contaminated sediment areas including identified hotspots within the Dominguez Channel Estuary and the Los Angeles and Long Beach Harbors. The Draft TMDL recommends the following implementation processes:

1. Implement (and evaluate effectiveness of) best management practices (BMPs) and source control in conjunction with the remediation actions to remove contaminated sediment as necessary;
2. Evaluate effectiveness of controlling sediment loading from Los Angeles River, San Gabriel River and Machado Lake through implementation of effective TMDLs.
3. Conduct monitoring to evaluate compliance with targets during implementation and after implementation actions are in place.
4. Determine if reductions in loadings from controllable sources from Los Angeles River and San Gabriel River will be required and addressed through revision of the TMDL.
5. Re-evaluate the WLAs and LAs, if necessary.[3]

Staff finds it may be feasible to dredge Harbors for contaminated sediment removal as part of the existing practices.

The Staff Report cites a 1998 study conducted for sediment contamination mitigation at the mouth of Ballona Creek and Marina del Rey. According to this study, the cost of dredging at that location ranges from $10.95 per cubic yard to $74.4 per cubic yard (Moffat & Nichol Engineers, 1998). The Staff Report estimates the unit cost of dredging by averaging these two bookend figures to arrive at a unit cost of $42.68 per cubic yard in 1998 dollars. Assuming an inflation rate of 3% each year, the Staff Report then adjusts the unit dredging cost to current dollars, arriving at a figure of $60.84 per cubic yard.

Based on the December 10, 2010 draft memorandum to the Regional Board Staff prepared by the Ports of Long Beach and Los Angeles, and its associated discussion, areas where dredging activities may be necessary to remove contaminated sediment to fulfill requirements of Effect Range Low (ERL) or SQOs were analyzed. The Draft TMDL cites five primary locations (see Table 9) as having concentrations exceeding ERLs.[4]

Staff Report Table 7-3: Estimated volume of dredged materials with respect to SQO and ERL

Waterbody	Estimated Volume of Dredged Materials (cy)	
	SQO	ERL
Fish Harbor	1,120	1,111,701
Los Angeles Harbor Cabrillo Marina	1,156,131	1,159,768
Los Angeles Harbor Consolidated Slip	475,910	478,294
Los Angeles Harbor Inner Cabrillo Beach Area	196,560	238,138
Los Angeles Harbor Beach Inner Harbor	6,692,551	21,864,948
Los Angeles Harbor Beach Outer Harbor	2,645,954	10,669,544
San Pedro Bay outside Harbors Outlet of Los Angeles River	4,840	4,840
Total	**11,173,066**	**35,527,233**

[3] Draft TMDL, p. 103.
[4] Draft TMDL, p. 124.

Staff estimates that the total cost of dredging at Harbors $679.8 million in present dollars. Given a compliance schedule of 20 years, and an assumed annual interest rate of 6%, the staff calculates that the amortized cost for each year is $59.3 million dollars. Basing the cost calculations instead on the Effect Range Low scenario, the total cost of dredging at Harbors is $2.16 billion, or $188.1 million annually.

Staff's quantification of dredging costs is flawed for several reasons. Most important, the use of a single study from a single location is not making use of the best available information, particularly when the study in question did not report actual dredging costs, but rather ex ante engineering estimates. Further, simply averaging the upper and lower cost estimates is crude in the extreme.

Staff's $60.84 per cy estimate of dredging is far lower than the actual cost of other similar remediation projects. We surveyed several similar soil removal sites in California to demonstrate that the cost of dredging is in the range of $120 - $1,320 per cy. The following discussion summarizes some of the available information on dredging costs in California.

United Heckathorn

This site, located in Richmond CA, consists of a former manufacturing site that was used from approximately 1947 to 1966 by a number of companies (collectively referred to as "United Heckathorn"). The primary contaminants of concern at this site are DDT and dieldrin. The 1994 Record of Decision (ROD) for this site proposed dredging 65,000 cy of pesticide-contaminated sediment. Mechanical dredging in the Lauritzen Canal started in September 1996 and finished in April 1997 and removal using long-stick excavators started in the Parr Canal in August 1996 and finished in April 1997. A total of 108,000 cy of sediment were actually removed, solidified, and disposed offsite by rail to landfills in Arizona and Utah. Dredged areas were backfilled with 18 inches of sand (15,700 cy). Actual costs have not been released; however the bid cost for the original target volume of 65,000 cy was reportedly $7.3 - $7.5 million ($112 - $115 per cy) in 1994 dollars. Actual combined transport and disposal cost to the ECDC landfill was about $48 per ton.[5] Using the same rate of inflation as the Draft TMDL, 3%, the estimated cost of dredging in 2010 dollars is $180 - $185 per cy.

Seaplane Lagoon

Seaplane Lagoon underwent a thorough examination in 2005 and, based on the 2007 ROD, the sediment remediation alternative chosen was a combination of dredging, monitoring, dewatering, and upland confinement. In addition, the 2005 feasibility study estimated the costs of this alternative to be between $7.6 million and $8.9 million.[6] However, according to the ROD the actual costs for the remediation alternative selected were $24.6 million (2007 dollars) which is approximately 30-35% higher than the totals estimated in the 2005 feasibility study.[7]

Moffett Field

The feasibility study for Moffett Field was completed in 2005. The remediation alternatives were different than the previously discussed sites, primarily due to the area being described as a tidal marsh or wetland. The remediation activities best suited to Moffett Field were determined to be in situ/ex situ treatment, excavation,

off-site disposal, restoration, and ecological monitoring. The costs associated with this suite of alternatives are estimated to be $6.7 million to $6.8 million (2007 dollars).[8]

Hunters Point

The final feasibility study for Hunters Point was finished in 2007. The sediment remediation alternatives developed were similar to Seaplane Lagoon but the actions suggested to best meet the desired remediation goal combined focused removal, off-site disposal, armored cap, monitored natural recovery, and institutional controls. The costs associated with this remediation alternative range from $26.9 to $29.0 million (2007 dollars).[9] The final costs of this cleanup have yet to be determined as this feasibility study is currently under review.

Oyster Point

This site remediation was completed in 2001 and significant sediment removal took place. Approximately two acres were removed at a depth of 2-3 feet with a twelve inch cap put in place for a total cost of $10 million.[10] According to the TMDL, there was at least one sample observed at some point in time with total PCB concentrations of greater than 1000µg/kg.[11] No post-remediation measurements were available to compare the effectiveness of the remediation activities.

San Diego Shipyard

The California Regional Water Quality Control Board, San Diego Region released a tentative cleanup and abatement order for the San Diego Shipyard Sediment Site on September 15, 2010. Proceedings, public comments, and public hearings are currently underway. Under the cleanup and abatement order, over 140,000 cubic yards of contaminated sediments will be removed from approximately 15.2 acres of the site with dredge buckets.[12] Dredging will involve stockpiling and dewatering the dredged material at an off-site sediment staging area in the vicinity of the project area and then transporting and disposing of the material at a regional hazardous waste landfill outside San Diego County (i.e. Copper Mountain, Nevada).[13]

In addition to the 15.2 acres targeted for dredging, approximately 2.3 acres of the project site are inaccessible or under-pier areas that will be remediated by other methods, most likely by sand cover. Sand capping would involve the transport of capping material to the site (possibly via truck or barge) and placement of the materials over contaminated sediment. Before the cleanup begins, an Environmental Impact Report (EIR) will be written to analyze the environmental impacts of sediment management, including the impacts of the

proposed dredging activities, handling of the dredged material, dewatering and potential treatment of the dredged material, and transport to the disposal site.[14]

The total cost of cleanup is estimated to be $58 million and includes the cost items in the table below.

Item	**Quantity**	**Unit**	**Unit Cost**	**Cost**
Design and Permitting				$2,323,000
Construction and Preparation				$1,400,000
Dredging subtotal	*178,670*	*cy*		*$3,900,000*
Unconstrained open-water dredging	17,925	cy	$10	$179,250
Constrained dredging from inner shipyard	125,475	cy	$18	$2,258,550
Dredging surface/subsurface debris	7,170	cy	$120	$860,400
Additional dredging	28,100	cy	$18	$505,800
Engineering controls				$96,000
Marine structures				$984,915
Sediment offloading and disposal				$24,781,250
Underpier remediation				$4,799,572
SW04 cleanout, BMP installation, investigation				$703,048
Other non-construction costs				$19,169,473
Total				**$58,061,258**
Total per cy dredged				***$325***

Source: California Water Resources Control Board - San Diego Region, "Revised Tentative Cleanup and Abatement Order and Draft Technical Report," September 15, 2010, Appendix for Section 32.

The following table summarizes dredging cost data for the locations listed above, including data from the Feasibility Studies and Records of Decision. These costs are all significantly larger than the $60.84/cy estimate provided in the Staff Report.

Summary of Remediation Costs for Selected Sites in California

Site	Sediment Removed in cy	Total Cost (2010 dollars)	Cost per cy (2010 dollars)
United Heckathorn	108,000	$19.1 - $19.4 M	$180 - $185
Sea Plane Lagoon	63,000	$27 M	$430
Moffett Air Field	47,400 - 61,500	$5.7 - $9.8 M	$120 - $160
Oyster Point[1]	9,860	$13 M	$1,320
Hunters Point Shipyard[2]	51,910 - 161,000	$12.8 - $112.4 M	$247 - $698
San Diego Shipyard	178,670	$58.1 M	$325

Notes:
(1) The costs per cubic yard for Oyster Point are for all dredging and capping activities
(2) Hunters Point Shipyard are composite costs that range from the complete dredging scenario to comparative unit cost of sediment removed for other alternatives.

[14] California Regional Water Quality Control Board, San Diego Region website, accessed at: http://www.waterboards.ca.gov/sandiego/water_issues/programs/shipyards_sediment/index.shtml on February 17, 2011.

The weighted average of dredging costs in this sample is roughly $200 per cy, which is over three times the unit cost assumed in the Staff Report. It is more appropriate to use this figure for estimating dredging costs since it is based on a sample of dredging projects in other locations, rather than a single, ex ante study.

4. Benefits

The Staff Report contains virtually no discussion of the incremental benefits of the TMDL relative to the status quo. The Regional Board staff have made no attempt to quantify the number of lives saved, illnesses avoided, improvements in wildlife populations, or other types of benefits that typically would be associated with major regulatory action. Indeed, there is no evidence in the Staff Report or other available documents that the actual benefits of implementing the TMDL would be commensurate with even the staff's low estimate of implementation costs.

The Draft TMDL cites the 1994 Water Quality Control Plan for the Los Angeles Region in defining the beneficial uses for the Dominguez Channel and greater Los Angeles and Long Beach Harbor waters. According to the Draft TMDL, Los Angeles and Long Beach harbor waters have designated uses to protect aquatic life including marine (MAR) and rare, threatened or endangered species habitat (RARE). There are also beneficial uses associated with human use of these waters, including recreational use for water contact (REC1), non-contact water recreation (REC2), navigation (NAV), industrial service supply (IND), commercial and sport fishing (COMM), and shellfish harvesting (SHELL). The estuaries (EST) are recognized as areas for spawning, reproduction and/or early development (SPWN), migration of aquatic organisms (MIGR) and wildlife habitat (WILD). Dominguez Channel also has an existing designated use of warm freshwater habitat (WARM) and the Los Angeles River estuary has the designated use of wetland habitat (WET).[15] There are also potential beneficial uses of the Dominguez Channel Estuary (MUNI, REC1, WARM, WILD), the Los Angeles River Estuary (SHELL), and Los Angeles – Long Beach Harbor (SHELL) and San Pedro Bay (SHELL). As noted in the Staff Report, recreation is listed as an actual or potential beneficial use of the Dominguez Channel Estuary even though access to it is currently prohibited by the Los Angeles County Department of Public Works.

The Staff Report does not adequately address the benefits of the proposed regulation. For example, although the Draft TMDL mentions recreational fishing as a beneficial use, it does not elaborate on how many anglers might be consuming fish in the greater Los Angeles and Long Beach Harbors area. Based on data of observed fish catches from the Pacific Recreational Fisheries Information Network, only a handful of species of fish are caught in any significant numbers from the Los Angeles Harbor. Those fish include barred sandbass, California scorpionfish, halfmoon, kelp bass, ocean whitefish, Pacific bonito, Pacific sanddab, and vermillion rockfish.

Number of fish caught at LA Harbor as compared to all of Los Angeles County, 2008

Fish Name	LA Harbor Site	LA County
Bank Rockfish	1	10
Barred Sandbass	**123**	2,502
Black Perch	3	331
Blacksmith	67	806
Boccaccio	93	826
Brown Rockfish	13	171
Cabezon	3	40

[15] Draft TMDL, p. 17.

Vermillion Rockfish	**183**	838
White Croaker	4	664
White Seaperch	2	106
Yellowfin Croaker	1	310
Yellowtail	14	52

Notes and Sources:

(1) 2008 was the most recent year for which complete data were available.

(2) If a fish is not shown in the table, it was not reported as being caught at LA Harbor in 2008.

(3) The Pacific Recreational Fisheries Information Network, accessed at: http://www.recfin.org/data/sampletools/tabulate-sample-data-refined-variable-choices on January 27, 2011.

Of the fish species most commonly mentioned in the Staff Report's survey of the limited fish tissue data available, there are only four reported instances of white croaker being caught in the Los Angeles Harbor in 2008, none for queenfish, none for spotted turbot, and none for halibut. Based on the best available survey data for recreational anglers, it is highly unlikely that there will be significant human health benefits relating to fish consumption as a result of implementing the TMDL.

As mentioned at the outset of this letter, the Staff Report does not contain any information on participation rates for any water-related activities. Thus, it is impossible to know whether staff actually considered the benefits of implementing the TMDL related to these activities.

Other parts of the Staff Report reinforce the conclusion that the TMDL will not produce benefits anywhere near commensurate with its costs. The analysis of pollutant loadings contained in the report shows that staff has concluded that air deposition of pollutants is a major contributor to water quality degradation. This observation calls into question the wisdom of a policy to require dredging since DDT and other contaminants removed by dredging will simply be redeposited by air.

Similarly, the Staff Report does not treat pollutant loading from the San Gabriel and Los Angeles Rivers, but rather calls for a series of "special studies" to analyze the impact of these inflows. As with air deposition, the likely influx of pollutants from an external source raises the potential that the area may be recontaminated after dredging has been completed. Such an outcome would be inefficient in the sense that tremendous resources would have been expended on dredging and other remediation activities as a result of the TMDL, but ongoing deposition would prevent its water quality targets from being attained.

In conclusion, the staff of the Regional Board has not met its burden under Porter-Cologne and U.S. EPA guidance to consider economics in the development of the TMDL. The Staff Report does not evaluate or consider the benefits of improving water quality relative to current water quality levels. The discussion of implementation costs fails to use the best available information, and contains important calculation errors. Actual costs of dredging are likely to be much higher than described. Finally, the Staff Report does not discuss benefits of the TMDL in relation to the costs of implementation, which is the only logical way to assess whether the action is reasonable.

Sincerely,
David Sunding

Professor, College of Natural Resources, UC Berkeley

Environ. Sci. Technol. **2000**, *34,* 709−713

Bioavailability to Earthworms of Aged DDT, DDE, DDD, and Dieldrin in Soil

DOUGLAS E. MORRISON, BOAKAI K. ROBERTSON,† AND MARTIN ALEXANDER*

Institute for Comparative and Environmental Toxicology and Department of Soil, Crop, and Atmospheric Sciences, Cornell University, Ithaca, New York 14853

A study was conducted to determine the bioavailability of several pesticides that have persisted for various periods in soils in the field and the laboratory. Based on the concentrations or the percentages of the compound in soil samples that were found in the earthworm *Eisenia foetida*, ca. 30, 12, 34, and 20% of DDT, DDE, DDD, and a total of the three compounds were bioavailable in a soil treated in the field with DDT 49 years earlier. Only 28 or 43% of dieldrin aged for 49 years was bioavailable based on concentrations in *E. foetida* or percentages of the compound assimilated by the worms, respectively. Comparably low percentages of DDT, DDE, and DDD but not dieldrin were assimilated by the worms from samples of soil from a waste-disposal site receiving the insecticide ca. 30 years earlier. Aging for 190 days in Kendaia loam in the laboratory markedly reduced the availability to *E. foetida* of DDT and DDE but not DDD. The amounts of aged or unaged DDT, DDE, and DDD but not dieldrin that were removed from the soils by solid-phase extraction with Tenax TA beads were generally greater with increasing amounts assimilated by the earthworms. The results show that aging markedly reduces the bioavailability of these compounds.

Considerable evidence exists that organic compounds may undergo a time-dependent sequestration in soil that results in a decline in bioavailability without a parallel decline in the concentration of the compounds determined by vigorous extraction with organic solvents. For example, the toxicity of DDT [1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane] and dieldrin to three species of insects (*1*), the inhibition of *Drosophila melanogaster* by lindane (*2*), the assimilation of phenanthrene by earthworms (*3*), the toxicity of atrazine to plants (*4*), and the biodegradability of phenanthrene by bacteria (*5*) decline with time in soil with either little or no diminution in the concentrations determined by vigorous extraction or decreases far less than are evident by biological tests. Such data suggest that current procedures for analyzing organic pollutants that have persisted in soil do not accurately predict the availability of those toxicants to living organisms.

DDT and dieldrin are highly persistent insecticides. For example, more than 50% of the initially applied DDT was present in some soils after more than 15 years (*6*), and DDT, DDE [1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane], and DDD [1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene] were still in the soil 24 years after addition of DDT (*7*). Similarly, dieldrin was still detected in soil after 15 years (*6*). A reexamination of the data from long-term monitoring of the persistence of these pesticides and a number of other organic compounds suggested that this aging led to a decline in their bioavailability to indigenous soil microorganisms (*8*). Although other studies have shown that the bioavailability of organic compounds to animals is reduced as result of their persistence in soil (*9*−*11*), few data are available that show the quantitative reduction in availability.

An investigation was therefore conducted to assess the decline in bioavailability as a result of aging of DDT, DDE, DDD, and dieldrin in soils in the laboratory and taken from the field. Because the availability to animals of chemicals in solvents is less, often appreciably so, than the same compounds added to soil even without aging (*8*), the assimilation of the unaged insecticides was measured using soil treated with the test chemicals shortly before the bioassays were conducted. This was not generally done in previous studies. The existence of experimental plots treated in 1949 with known concentrations of individual insecticies (*6*) provided a unique opportunity to measure the effect of aging in the field. In addition, data are presented to assess the feasibility of using a solid-phase extractant to determine bioavailability by a chemical assay.

Materials and Methods

Chemicals. DDT (75% *p,p′*-isomer, 18% *o,p′*-isomer), DDE (99.5% pure), DDD (99.5% pure), and dieldrin (99.5% pure) were obtained from ChemService (West Chester, PA). Hexane (HPLC grade), acetone (ACS grade), diethyl ether (reagent grade), and Florisil (60/100 mesh) were obtained from VWR Scientific Products (Bridgeport, NJ). Tenax TA 20/35 mesh, a porous polymer based on 2,6-diphenyl-*p*-phenylene oxide, was purchased from Alltech Associates (Deerfield, IL).

Soils. Samples of Chester loam (pH 5.5, 6.5% organic matter) and Sassafras silt loam (pH 5.2, 4.4% organic matter) that had been treated with DDT and dieldrin in 1949 or that did not receive the insecticides were obtained at depths of 0−25 cm from experimental plots at the Beltsville Agricultural Research Center (U.S. Department of Agriculture, Beltsville, MD). DDT and dieldrin initially had been mixed in separate plots at rates of 448 and 11.2 kg/ha of soil, respectively (*6*).

Samples of Kendaia loam (pH 6.6, 12.5% organic matter) were obtained from Aurora, NY. Samples of a sandy loam (pH 6.6, 6.0% organic matter) that had been contaminated with DDT and dieldrin approximately 30 years earlier and an adjacent uncontaminated silt loam (pH 6.4, 5.4% organic matter) from a remediation site at the U.S. Navy Surface Weapons Testing Center in Dahlgren, VA, were provided by Remediation Technologies.

Earthworms. Mature redworms (*Eisenia foetida*) from Carolina Biological Supply (Burlington, NC) were maintained in an aerated Styrofoam box containing a commercial worm bedding (Magic Products, Amherst Junction, WI), which was kept moist with Cl_2-free deionized water. The worms were fed a mixture of crude protein and carbohydrate (Magic Worm Food) and were active when introduced into the soils.

Determination of Pesticide Residues. Worms were frozen at −10 °C and ground with a mortar and pestle. The ground tissue (ca. 2 g) or 10 g of soil was subject to Soxhlet extraction by EPA Method 3540 (*12*) except that 150 mL of a 1:1 hexane: acetone mixture in a 25-mL round-bottom flask was used for the extraction. The tissues or soil samples were mixed with

Published on Web 01/07/2000

10 g of anhydrous Na_2SO_4 in paper extraction thimbles and then extracted for approximately 16 h. The extracts were concentrated to 10 mL in a vacuum evaporator and then cleaned on a Florisil column by EPA Method 3620 (*12*). The fractions containing DDT congeners or dieldrin were concentrated under vacuum to 2 mL and then diluted to 10 mL in hexanes.

The chemicals were analyzed with a gas chromatograph (model 5880, Hewlett-Packard) equipped with an electron-capture detector according to EPA Method 8080 (*12*) except that an HP-608 column (30 m, 0.53-mm i.d., 0.5-μm film thickness; Hewlett-Packard) was used, the N_2 (99.99% pure) flow rate was 10 mL/min, and the temperatures of the column, injector, and detector were 225, 275, and 275 °C, respectively. The retention times of DDT, DDE, DDD, and dieldrin were 4.7, 2.8, 4.0, and 3.0 min, respectively. The concentrations found in Chester loam treated in 1949 with DDT were 10.0 mg of DDT, 5.38 mg of DDE, and 4.10 mg of DDD/kg. Chester loam treated in 1949 with dieldrin contained 9.56 mg of the insecticide per kilogram. The soil from the Dahlgren remediation site contained 81.6 mg of DDT, 9.64 mg of DDE, 33.2 mg of DDD, and 9.35 mg of dieldrin per kg.

Aging of Chemicals in Laboratory. DDT, DDE, and DDD in hexanes were added to 2 kg of Chester loam that had not previously been treated and contained no pesticides. The final concentrations were 13.6, 5.28, and 3.26 mg/kg of soil, respectively. The soil was thoroughly mixed with a Teflon-coated spatula and stored in an EPA-certified ultraclean 1-L glass jar with a Teflon-lined screwcap. The height of the headspace above the soil was 5 cm. The soil was stored in the dark for 90 days at approximately 22 °C, and then earthworm uptake of the compounds was determined.

Prior to aging, 3.0−3.2 kg of Kendaia loam (in a 4-L glass jar with a Teflon-lined cap), which had been sterilized by 2.5 Mrad of γ-irradiation, was amended with DDT, DDD, DDE, or dieldrin under aseptic conditions. The first three compounds dissolved in hexane or dieldrin dissolved in acetone were added to soil, which was then mixed thoroughly with a Teflon-coated spatula. The final concentrations of DDT, DDD, DDE, and dieldrin were 46.6, 11.2, 19.8, and 13.6 mg/kg, respectively. The soils were placed in a hood for 2−3 days with the caps of the jars slightly loosened to allow the solvent to evaporate. The moisture content was then adjusted to 80% of field capacity. The bottles were stored at approximately 22 °C in the dark for aging. No microbial growth was observed in 7 days on nutrient agar to which 0.1-g samples of soil were added prior to and after the aging period.

Bioavailability. Six redworms were placed in 60 g (dry wt) of pesticide-amended soil contained in 250-mL glass jars. The soil had been adjusted to 90% of field capacity with Cl_2-free deionized water before the worms were added, and the jars were covered with Saran wrap bearing holes for air entry. The soils were kept under constant room lighting, and after 8 days, the worms were carefully removed, rinsed, and allowed to purge their gut contents for 24 h on moistened filter paper. All worms were active after the 8-day period. The worms in each soil sample were then weighed, the mass varying from 1.5 to 2.5 g of fresh weight per replicate. The worms were sealed in glass Petri dishes, frozen at −10 °C for 25−48 h, and ground with approximately 10 g of anhydrous Na_2SO_4 with a mortar and pestle. The tissue was transferred to paper thimbles and subject to Soxhlet extraction, and the extracts were cleaned with a Florisil column and analyzed.

To compare the bioavailabilities of compounds that had aged in Chester loam for 49 years in the field or 90 days in the laboratory relative to the bioavailabilities of these pesticides when freshly added to soil, DDT, DDE, and DDD were thoroughly mixed into pesticide-free soil to give 13.6, 5.28, and 3.26 mg/kg of soil, respectively. These were the concentrations found after 49 years in the soil. Each treatment was replicated four times.

In a study of the relative bioavailabilities of compounds aged in Kendaia loam in the laboratory for 0 and 190 days, triplicate soil samples were amended with DDT, DDE, or DDD to give 46.6, 19.8, and 11.2 mg/kg.

A determination was also made of the uptake by worms of dieldrin that had aged for 49 years in the field and that had been freshly added. The labels in the experimental plots that gave the original soil types had deteriorated, and sometimes were illegible. Consequently, although the aged dieldrin was in Chester loam, Sassafras silt loam was inadvertently used for the unaged dieldrin. The soil in which the dieldrin was not aged was amended to give 9.56 mg/kg, which was the concentration of aged dieldrin that was found in the field. Four replicate samples were used.

Measurements were also made of the bioavailabilities of DDT, DDE, DDD, and dieldrin present for approximately 30 years in soil from the remediation site in Dahlgren and in an adjacent soil to which the compounds were freshly added. DDT, DDE, DDD, and dieldrin were added to the uncontaminated soil to give 45.9, 11.0, 15.6, and 13.6 mg/kg, respectively.

The data for earthworm uptake are expressed on the basis of fresh weight of tissue.

Solid-Phase Extraction. Tenax TA was used by the method of Cornelissen et al. (*13*) with slight modification. A single extraction rather than consecutive extractions was performed. Soil (0.2 or 0.5 g) was placed in a 30-mL glass separatory funnel equipped with a Teflon stopcock and stopper. Sterile inorganic salts solution (25 mL) containing 10 mg of Na azide to prevent biodegradation and 0.1 or 0.2 g of Tenax TA beads were then added to the funnels. The salts solution contained 0.8 g each of K_2HPO_4 and NH_4NO_3, 0.1 g each of $MgSO_4 \cdot 7H_2O$ and $CaCl_2 \cdot 2H_2O$, and 0.1 g of $FeCl_3 \cdot 6H_2O$/L. The beads had been initially conditioned by washing with acetone (1 g in 10 mL solvent) followed by rinsing three times in hexane (1 g in 10 mL solvent) and then drying. The funnel was placed inside a rotary extractor designed in accordance with EPA specifications (*12*). The sample was shaken end-over-end at 20 rpm for 14−16 h. Tenax TA beads were found to be an adequate sink for organic pollutants in sediments (*14*). Subsequent extractions did not show a detectable level of the compounds. The single extractions appeared to be complete in <14 h.

The soil particles were allowed to settle, and the Tenax beads, which floated at the top of the liquid or adhered to the walls of the funnel, were removed and extracted with 10 mL of hexane. Because the beads float in aqueous solution, they were easily separated from the solids and surfaces, and all were recovered. The extracts were concentrated under N_2 to 1 mL and analyzed by gas chromatography using an electron-capture detector.

To ascertain the recovery by the beads of unaged DDT or dieldrin in soil, known amounts of the compounds were added to Kendaia loam, and 1 g of amended soil was mixed with various amounts of beads in 25 mL of inorganic salts solution contained in separatory funnels as previously described. The beads were separated from the water and extracted with hexane or acetone. The recoveries of the two compounds from soil ranged from 90 to 95%.

The results showed that 0.1 to 0.2 g of Tenax TA beads had sufficient sorption capacity to extract DDT or dieldrin from 0.2 to 0.5 g of soil containing up to 12% organic matter.

Results

Earthworm Bioassays. A determination was made of the availabilities to redworms of DDT, DDE, DDD, and dieldrin aged in soil for 49 years, 90 days, or 0 days. The concentrations of DDT, DDE, DDD, total of DDT and metabolites (including

DDE and DDD), and dieldrin were consistently lower in earthworms exposed to compounds that had persisted for 49 years than in worms exposed to soil containing the insecticides freshly added at the same concentrations (Table 1). If percentage sequestered is calculated as the difference in concentration between worms exposed to unaged and aged compound divided by the former concentration, then the percentages of DDT, DDE, DDD, DDT plus metabolites, and dieldrin sequestered are 68, 87, 63, 78, and 72%, respectively. The percentage of each of the compounds in soil that was assimilated by the worms was consistently and significantly lower for each of the aged than for the unaged insecticides. No such effect was evident with the compounds aged for 90 days, except for DDE. The lack of a detectable aging effect in these instances may be a result of the short time period, especially since aging of DDT sometimes is quite slow (*8*). The reason for greater uptake of DDT aged for 90 days than of unaged DDT is unknown. Based on the percentage of the compound assimilated by the animals, 72, 89, 68, 79, and 57% of the DDT, DDE, DDD, DDT plus metabolites, and dieldrin had been sequestered in the 49-year period. If the percentage sequestered in samples aged for 49 years was calculated for the data from the Tenax extractions following the procedure used for the data on earthworm uptake, the percentages of DDT, DDE, DDD, and total DDT and metabolites sequestered are 67, 74, 75, and 70%, respectively. The amount of the aged compound that was extracted by the Tenax beads was consistently less than the amount of the unaged compound. An aging effect was not evident for dieldrin.

A marked aging effect was observed when DDT and DDE were aged for 190 days in Kendaia loam (Table 2). The decline in bioavailability of DDT, DDE, and DDT plus metabolites was evident in measurements of concentration in the worm tissue and percentage of the compound assimilated. Aging of DDD was not evident by measurement of tissue concentration or percentage of the compound assimilated; indeed, the concentration of DDD aged for 190 days was higher in the worms in Kendaia loam. The percentage of DDT, DDE, and DDT plus metabolites sequestered were 46, 82, and 36%, respectively, based on tissue concentrations and 85, 73, and 74%, respectively, based on percentage of the compound assimilated.

The bioavailability of the insecticides after approximately 30 years of aging in the Dahlgren soil is shown in Table 3. Because the texture and organic matter and clay contents of

the two soils from the Dahlgren site differed appreciably, a comparison could not be made of the effect of aging in the contaminated soil, although the data from both soils were used to determine the utility of Tenax TA beads for assessing bioavailability. Nevertheless, a comparison of the data from this soil with the data in Table 1 from the soil samples aged for 49 years in Chester loam shows uniformly low values for percentages of the compound assimilated for the DDT species but not dieldrin. In contrast, the concentrations in the worm tissue were consistently higher for samples of Dahlgren soil, but this is not unexpected because the total concentrations of the various DDT species (but not dieldrin) were higher in the Dahlgren soil.

Assay with Tenax Beads. The quantity of aged and unaged DDT, DDE, and DDD extracted in triplicate by the beads from Chester loam, Sassafras silt loam, Kendaia loam, and the two soils from the Dahlgren site was determined. The standard errors for the values for all soils were <4% except that the standard errors for DDT aged in Chester loam were up to 14%. An analysis of variance ($P < 0.05$) showed that the values from soils containing aged DDT and metabolites were significantly different from the values from soils in which the compounds were freshly added except the values were not significantly different for DDD in Dahlgren soil and DDE in Kendaia loam.

A comparison was made of the quantities of DDT, DDE, DDD, and a total of the three compounds assimilated by the worms with the amounts retained by the Tenax TA beads (Figure 1). In soils from which the animals assimilated only small amounts of each compound, little was sorbed by the beads. Similarly, when worm uptake was high, a large amount was retained by the beads. As a result, the values for linear regression were high; i.e., the correlation coefficients (r) for the assays for DDT, DDE, and DDD were 0.933, 0.980, and

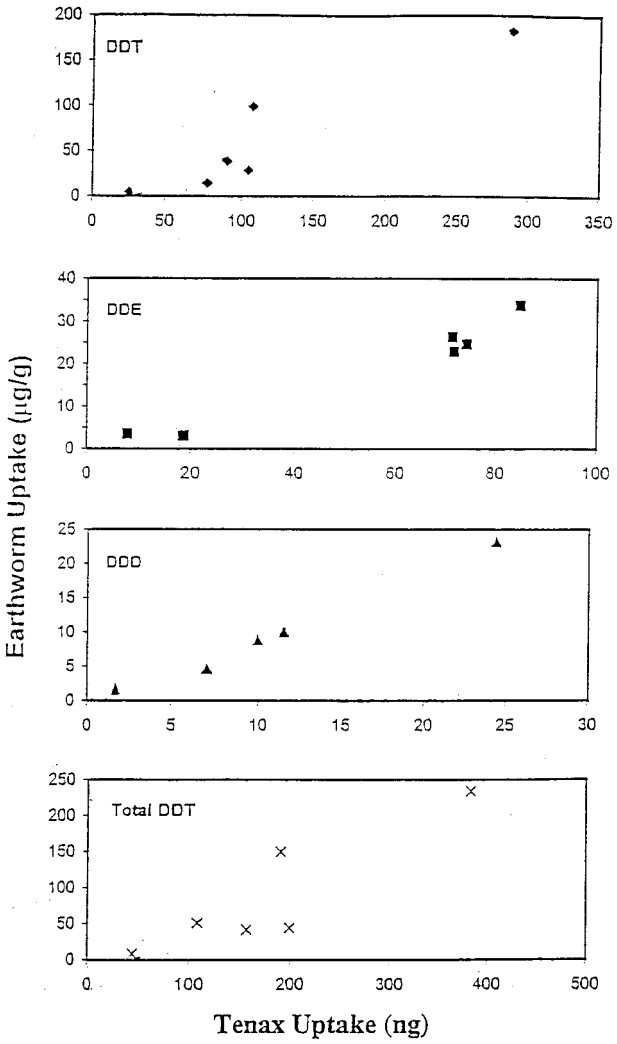

FIGURE 1. Correlation between earthworm uptake of DDT, DDE, DDD, and total of the three compounds from soil and the quantities extracted by Tenax TA beads.

0.995, respectively. The corresponding values for the adjusted R^2 were 0.850, 0.954, and 0.982, respectively. The results of the Tenax assay for DDT plus metabolites were also correlated ($r = 0.960$) with the concentration in earthworms. The corresponding value for the adjusted R^2 was 0.855. The value for total DDT species extracted was based upon three results from a single replicate set of beads that was assayed for DDT, DDE, and DDD. Nevertheless, a relationship between worm uptake and bead retention of DDT is not evident at the intermediate levels of assimilation. This is also evident in the totals of the three compounds since the values for totals are dominated by DDT as the major substance being analyzed. A clear correlation is shown between worm assimilation and bead retention of DDD, but it was not the major substance in these soils.

In contrast, the amount of dieldrin extracted from the soils by the Tenax resins was not correlated ($r = -0.215$) with the concentration of the insecticide in the earthworms after assimilation. The corresponding value for the adjusted R^2 was 0.036. The data are from analyses of Chester loam, Sassafras silt loam, and the two soils from the Dahlgren site.

Discussion

The results demonstrate the extensive decline in bioavailability to earthworms as a result of the aging of DDT, DDE, DDD, and dieldrin in field soils. The finding that more than half to >85% of the pesticides was not in a form accessible to the test species is of considerable importance in assessing the exposure and risk from these compounds. The observations that the availability to animals in field soils has diminished as a result of aging agree with laboratory studies of the decline in acute toxicity. Thus, as early as 1971, Peterson et al. (*15*) reported that the toxicity of DDT to *Drosophila melanogaster* declined as a soil was stored for a 108-day period, and recent tests with three insect species revealed the marked diminution in toxicity of both DDT and dieldrin as a result of aging, although the concentration of the two insecticides determined following vigorous extraction of the soils changed only slightly (*1*). The decline in bioavailabilty to animals is also consistent with the apparent reduced accessibility for biodegradation by the indigenous microflora of soils, as suggested by a reevaluation (*8*) of the patterns of disappearance in the field shown by repeated measurements of the concentrations of DDT (*6, 7, 16, 17*), DDE, DDD (*7*), dieldrin (*6*), and dieldrin and its aldrin precursor (*17*−*19*). Unavailability for microbial utilization is also shown by the resistance to bioremediation of 25% of the DDT and 65% of a breakdown product in a contaminated soil (*20*).

Although the bioavailability of each of the compounds was low after aging, some was still assimilated by *E. foetida* even after an aging period of 49 years. Thus, despite the fact that the accessibility has fallen sharply, the insecticides still can enter the animal and some exposure and risk remain. This view is consistent with the observation that DDT used in the field for termite control was still suppressing the termites after 33 years (*21*) and that the pesticide was still assimilated by aquatic animals many years after it entered coastal sediments (*22*). In addition, dieldrin present in a field site contaminated many years earlier was assimilated by rats that were given the contaminated soil by gavage (*23*).

Inasmuch as the data show differences in bioavailability among different soils, it is important to devise a useful method to assess bioavailability. Biological assays would serve this purpose, but they are typically slow, expensive, and lack precision. Thus, a chemical assay would be useful. A number of procedures have been proposed, including organic extractants (*24*), equilibrium partitioning (*25, 26*), high-temperature desorption (*13*), and analyses of pore water (*27*). In only some of the studies have correlations been made with bioavailability; for example, to earthworms (*24, 26*), nematodes (*27*), and microorganisms (*24*). The present investigation considered a different procedure, and it includes testing of soils with dissimilar properties as well as compounds that had been freshly added to soil or sequestered under both field and laboratory conditions for varying time periods.

The data show that the values for uptake by worms from soils with low or high bioavailability percentages of DDT, DDE, and DDD were correlated with retention with Tenax TA beads. However, a correlation was not evident at intermediate bioavailability percentages. It is not clear whether this lack of relationship is a result of soil properties, aging time, or some other factor. Although Tenax TA beads might thus be useful to distinguish among soils with low and high bioavailabilities, a more useful procedure appears to be our recently described technique using C18 membrane disks (*28*). With certain test conditions, this method gave correlations with *r* values of 0.967, 0.984, and 0.940 for DDT, DDE, and DDE, respectively, and the relationship between bioavailability and retention by the disks was clear even at intermediate bioavailabilities.

How Toxic Are Toxic Chemicals in Soil?

MARTIN ALEXANDER

Department of Soil, Crop, and Atmospheric Sciences, Cornell University, Ithaca, New York 14853

Assessments of the hazard of toxic chemicals in soil are made without concern about the possibility that their bioavailability may change with time. The patterns of disappearance of persistent compounds in the field and laboratory studies show a declining availability to microorganisms with residence time in soil. Changes in extractability with residence time and the kinetics of sorption and desorption suggest that the compounds are becoming sequestered in inaccessible microsites within the soil matrix. Diminishing toxicity as chemicals age in soil is evident in a limited number of assessments. Such findings suggest that the hazard and risk from toxic chemicals diminish as the compounds persist in soil.

Most polluted soils or subsoils that are currently being considered for remediation were contaminated many years ago. These soils were contaminated before there was widespread concern with environmental deterioration and before strict regulations were established and the high cost of remediation became evident. Nevertheless, assessments of the hazards from those sites have not taken into account slow processes that may take place and possibly reduce the impact of toxic compounds deposited in the soil, particularly those compounds that do not leach out to contaminate underlying aquifers. In recent years, evidence has accumulated that the availability of certain organic compounds changes as the compounds reside in soil for some time, a process that has been termed aging. Data have also been collected suggesting that organic molecules slowly become sequestered within the soil matrix. The declining availability and sequestration appear to be related, and a consideration of the declining bioavailability and the occurrence of chemical sequestration has great relevance to assessing toxicity, determining risk, and establishing meaningful regulations for the cleanup of sites containing hazardous wastes.

Three lines of evidence point to the sequestration of organic molecules that persist in soil: (a) field and laboratory studies demonstrating a diminishing availability to microorganisms; (b) investigations of the extractability of aged chemicals and the kinetics of sorption and desorption; and (c) assessments of toxicity. Although the issue of toxicity is the most relevant for decisions on risk and for environmental regulations, that line of evidence is based on few studies. However, all three lines of evidence are consistent and point to the need for a modified approach to assessing risk.

Diminishing Availability to Microorganisms

Long-term monitoring of organic compounds in soils has been chiefly restricted to pesticides, especially the chlorinated hydrocarbons that were once widely used as insecticides. These field measurements do not distinguish among losses resulting from biodegradation, volatilization, or abiotic decomposition. However, all the pesticides are biodegradable so that a chemical which disappeared initially but not in later periods must be less susceptible to all loss mechanisms, including degradation by microorganisms in the soil. The disappearance of appreciable amounts of these insecticides from the field sites was not a result of leaching because all are extensively sorbed and little vertical movement has been detected even after many years.

These persistent pesticides initially disappear from soil at reasonable rates, but frequently the rate subsequently slows markedly. A typical example is DDT [1,1,1-trichloro-2,2-*bis*(*p*-chlorophenyl)ethane]. Almost three decades ago, Nash and Woolson (*1*) reported a slow but continuous disappearance of the compound in the 10 years after its addition, but little or none of the compound was lost in subsequent years (Figure 1). Because this insecticide is metabolized by many microorganisms and microbial activity is a major contributor to its disappearance (*2*, *3*), prevailing conditions were conducive to their activity. However, some slow change occurred with the passage of time that rendered the compound increasingly less available to the microflora. Low winter temperatures and occasional drought periods can be ruled out for the lack of detectable biodegradation because the persistence curve extends for numerous seasons and many years. Similar curves, each with an initial phase of loss followed a period of little or no detectable loss, have been reported for DDT added to many soils in many areas of the world from the 1960s to the present time (*3*–*6*).

Field monitoring has shown analogous "hockey-stick" shaped curves for a variety of other chlorinated hydrocarbons; e.g., aldrin and its epoxide, dieldrin (*1*, *4*, *7*, *8*), heptachlor and its epoxide (*1*, *9*, *10*), chlordane (*1*, *4*), kepone (*11*), nonylphenol, and a linear alkylbenzene sulfonate (*12*). Examination of the data from these field monitoring

0013-936X/95/0929-2713$09.00/0

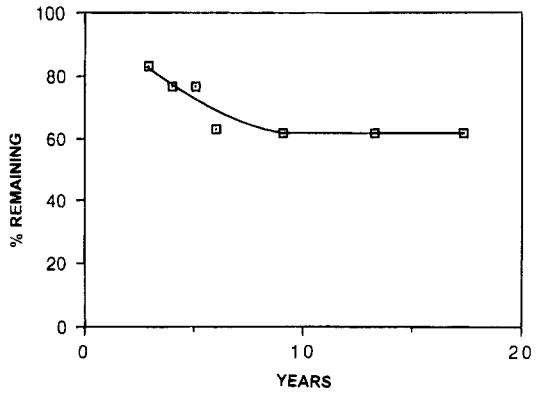

FIGURE 1. Concentration of DDT in Chester loam amended with 200 mg of the insecticide/kg of soil. Replotted from the data of Nash and Woolson (*1*).

programs reveals enormous differences in the time at which the initial phase of decline ends and the percentage of the original compound that remains following that decline. The time is sometimes as short as 1 year, but it may be longer than 10 years. From 10 to about 60% of the original compound remains in the soil during the period when there is little or no loss. Even with a single compound, the times and percentages may vary greatly; e.g., for DDT, aldrin, and dieldrin. A relationship to soil type or climate is not evident from the available data, but a systematic study was never conducted to establish such a relationship. It is possible that these differences in times and percentages can be attributed to the relative rates of degradation (or loss by volatilization) and the sequestration of the compounds in unavailable forms. If the loss is rapid compared to sequestration, little will remain. If the loss is slow and sequestration is rapid, a higher percentage will remain. Moreover, if the loss is so rapid that little time elapses for the slow sequestration, a residual, persistent amount will not be detected; this is the case for the many pesticides and other organic compounds that rapidly disappear from soil because of their degradation, volatilization, or leaching.

Laboratory studies confirm the unavailability to microorganisms of molecules that have been in soil for long periods. Thus, little or no loss was detected of 1,2-dibromoethane in a soil treated in the field 3 years earlier and of simazine [2-chloro-4,6-*bis*(ethylamino)-*s*-triazine] from a field that received the herbicide for 20 consecutive years, although newly added ^{14}C-labeled 1,2-dibromoethane and simazine were extensively metabolized in several weeks (*13*, *14*). Similarly, polycyclic aromatic hydrocarbons present in a soil at a manufactured gas site did not disappear in a 3-month period in the laboratory, but naphthalene and phenanthrene freshly added to the soil were rapidly metabolized (*15*).

A somewhat different approach to demonstrate aging was used by Hatzinger and Alexander (*16*). They introduced phenanthrene, a hydrocarbon that is not readily lost by abiotic mechanisms, into sterile soil and added a phenanthrene-degrading bacterium after the hydrocarbon had aged for different periods of time. The data with a soil rich in organic matter show that the extent of microbial conversion of phenanthrene to CO_2 and the rate of biodegradation decline with increasing time of contact with the soil (Figure 2). Similar observations were made with a soil with a lower level of organic matter, although aging appeared to be slower.

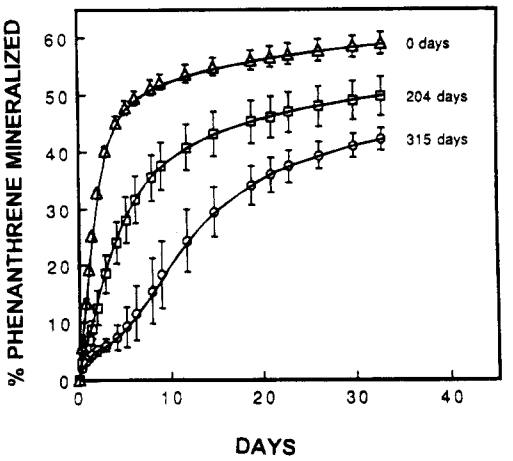

FIGURE 2. Biodegradation by a strain of *Pseudomonas* of phenanthrene at 10 mg/kg that had aged for 0, 204, or 315 days in Edwards muck. The error bars represent the standard deviations (*16*).

These field and laboratory investigations show that some abiotic process(es) make(s) organic compounds less readily available to microorganisms. The impact of that process or those processes becomes greater as the residence time of the chemicals increases. The fact that such a change in bioavailability affects microorganisms is of relevance to higher organisms because presumably bacteria are more able than plants and animals to assimilate chemicals in soil in view of their small size, their high population densities, and the physiological versatility of the indigenous microflora.

Extractability, Sorption, and Desorption

Little difficulty is usually encountered in finding an extractant that gives quantitative recoveries of organic compounds shortly after their introduction into soil. However, if a chemical persists and thus remains in contact with the particulate matter for some time, it becomes more and more resistant to extraction by many solvents. This has been known for many years by chemists endeavoring to obtain quantitative recoveries of insecticides and herbicides used for pest control (*17–19*). A diminished availability for solvent removal also has been noted in a sterile organic matter-rich soil and a loam that was incubated with phenanthrene under aseptic conditions (*16*). The organic solvents that extracted all of the newly added compound removed increasingly smaller amounts as the chemical persisted. More recent studies show that phenanthrene aged in sterile soil similarly becomes, with time, progressively less extractable with acetonitrile/water (1:1) and various ethanol/water mixtures (B. D. Kottler, J. W. Kelsey and M. Alexander, unpublished data). This represents another line of evidence that a change is occurring that renders persistent molecules less accessible, whether accessibility is assessed in microbiological or chemical terms.

Molecules that behave in this way are not to be confused with bound residues. Such bound residues, which have been well studied for pesticides, are those residual fractions that are not extracted by procedures that do not appreciably alter the nature of those residues; these molecules are changed in some manner and are usually converted to the original compound by vigorous hydrolysis. In contrast, aged compounds can be extracted by some organic solvents, often under vigorous conditions, and are thus subject to regulation if the original compounds are toxic in solution.

Studies of kinetics of sorption and desorption provide another perspective on the behavior of toxicants that is relevant to issues of risk. For hydrophobic as well as some other compounds, the attainment of apparent equilibrium in sorption may require weeks, months, and sometimes possibly even years; i.e., more and more of the organic compound is sorbed by soil particles with the passage of time. The initial phase of sorption is rapid, and frequently about half the chemical in aqueous solution is removed by the soil in a few minutes or hours. This first phase is followed by a considerably slower uptake, which can be of prolonged duration. Such kinetics have been observed not only with soil but also with aquifer solids (*20–24*), and they suggest that the sorption involves not only the external surface of the particles but also a slow and continuing diffusion of the molecules to sites within the particles. The internal and more remote sites continue to bind more of the compound with increasing time.

The desorption of many chemicals similarly shows a rapid phase followed by a period of slow desorption. Such behavior has been noted for polychlorinated biphenyls, trichloroethylene, tetrachloroethylene, toluene, xylene, picloram (4-amino-3,5,6-trichloropicolinic acid), and atrazine (2-chloro-4-ethylamino-6-isopropylamino-*s*-triazine). Furthermore, the longer the compound remains in soil, the less is the amount released (*24–27*). Such data suggest that, following the initially rapid release from sites very near to the particle–water interface, the slow appearance of the chemical in solution results from molecules originating from sites at some distance from the interface. The longer aging time allows more of the molecules to diffuse to ever more remote sites. Furthermore, the fraction of a compound that is not readily desorbed under natural conditions will increase with time because that is the fraction that will be less readily biodegraded, leached, or volatilized.

Sorption of nonionic compounds in soil is viewed as a three-dimensional process. The longer a chemical remains in the soil, the greater is the amount present in remote sites and the further is the bulk of the molecules from the more accessible, outer sites (*28*). Aging thus is presumably associated with a continuous diffusion into more remote sites, where the molecules are retained. Such a conceptualization is consistent with the findings of initially rapid followed by slow phases of both sorption and desorption. Furthermore, this view may explain the decreasing availability to microorganisms of organic compounds as they undergo aging, and it is of direct relevancy to the issue of toxicity to higher organisms of chemicals that have been in soil for extended periods.

Intraparticle or intraorganic matter diffusion is believed to account for the slow phases of sorption and desorption of nonionic molecules. According to the intraparticle diffusion model, the solute is within micropores inside of soil particles. Diffusion is greatly retarded by (a) the partitioning of the compound between the liquid in the pore and the pore wall and (b) the tortuous path between micropores before the compound reaches the outer surface of the micropore-filled soil particle (*29, 30*). Although the diameters of micropores within soil particles extend over a wide range, a considerable part of the pore volume is made up of pores with effective diameters of $<1.0\ \mu$m, and examination of several soils and solids from aquifers reveals an abundance of pores with diameters of 20 nm or smaller (*31–34*). Such pores are so small that even the smallest bacterium, animal, root, or root hair could not penetrate.

Intraorganic matter diffusion of hydrophobic molecules may essentially reflect a partitioning into the native organic matter of soil, the molecules moving into the amorphous humic polymers in a fashion similar to the movement of a hydrophobic compound from water to an organic solvent. However, the importance of partitioning into soil organic matter to slow sorption and desorption has been questioned (*35, 36*). Nevertheless, intraorganic matter diffusion is cited as being important for the slow sorption of a number of hydrophobic compounds by soil (*35*).

Regardless of which mechanism applies to a particular site or which is more important for a given soil, the outcome for bioavailability and toxicity of molecules is, for all intents and purposes, the same. Whether the molecule is present in a remote micropore, has partitioned into some solid organic phase in the soil, or both, it has become sequestered. In this sequestered state, it is inaccessible to microorganisms, plants, and animals. This physical remoteness of aged compounds and their very slow diffusion to locations that are biologically inaccessible are key considerations in assessing risk of toxicants in soil.

Assessments of Toxicity

The line of argumentation presented above—which follows from knowledge of the chemistry of sorption and the effect of aging on the availability of biodegradable substrates to microorganisms—is scarcely reflected in the literature of toxicology. Indeed, not a single investigation has been conducted of the possibly diminishing effect on mammals as toxicants age in soil, although in several studies, samples were taken from soils that were contaminated long before the assay was conducted. The difficulty in interpreting these investigations in terms of an aging effect is the inability to determine whether the diminished toxicity occurred only immediately after the compound came into contact with soil or whether there was an increased diminution of toxicity as the compound became sequestered in soil. Many toxicants become less hazardous to test mammals within a short time after they are added to soil or aquifer solids, regardless of whether exposure is by oral or dermal routes; e.g., trichloroethylene, benzo[*a*]pyrene, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), and *m*-xylene (*37–40*).

Such reservations on the possible involvement of aging must thus be considered in interpreting data showing that compounds present in soil for long periods are less toxic than the same compounds provided to test animals in the absence of soil. For example, less TCDD was taken up by rabbits and guinea pigs and far fewer of the guinea pigs were killed following their oral exposure to soils that had been contaminated years earlier than following exposure to newly treated soils (*41, 42*). A surprising effect of short-term aging was noted by Poiger and Schlatter (*40*), who found that less TCDD was absorbed by mammals from soil that had been in contact with this dioxin for 8 days than for 10–15 h. The work of Edwards et al. (*43*), although with insects rather than mammals, is noteworthy. Chemical determination and quantitative bioassays of the toxicity of lindane (γ-isomer of hexachlorocyclohexane) to *Drosophila melanogaster* were in good agreement shortly after adding this insecticide to the soil, but the results of the bioassays suggested that less of the toxicant was present after 22 months than shown by chemical analysis; i.e., although all of the compound was initially bioavailable, only a part was affecting the fruit flies in soil in which the molecule had

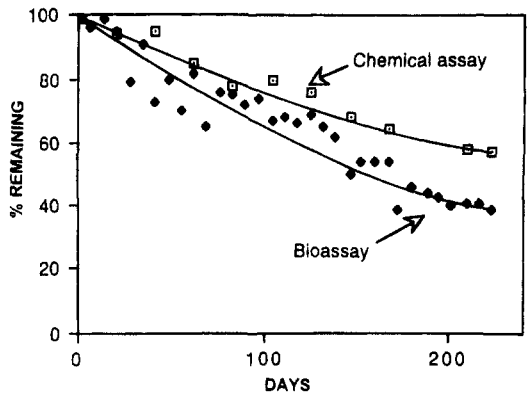

FIGURE 3. Changes with time in concentration of napropamide in soil as measured by bioassay and by extraction followed by gas chromatogrpahy. Calculated from the data of Hurle (45).

persisted for almost 2 years. An effect of aging also is suggested by a report that sugarbeet (*Beta vulgaris*) seedlings were not inhibited when grown in a fine loam that contained 0.22 mg of simazine/kg of soil derived from a field that was amended with the herbicide for 20 consecutive years, although 26 of 51 sugarbeet seedlings when grown in the same soil freshly amended with simazine at 0.22 mg/kg were injured by the newly introduced chemical (*14*).

Additional evidence that some compounds become progressively less toxic with increasing residence time comes from several old and largely forgotten studies. In one, the toxicity of DDT was found to decrease with an increase in the time during which the compound remained in soil (*44*). In another study, the rate of disappearance of napropamide [2-(α-naphthoxy)-*N,N*-diethylpropionamide] was faster when measured by quantitative bioassays of toxicity of the herbicide-treated soil to oats (*Avena sativa*) than when determined by gas chromatography (Figure 3); i.e., decreasing percentages of the herbicide were toxic with time (*45*). Similarly, bioassays with *Sinapis arvensis* (mustard) of soil to which was applied chlorbromuron [1-(3-chloro-4-bromophenyl)-3-methoxy-3-methylurea] gave higher values at approximately 30 days, the same values at approximately 60 days, and lower values at 85, 110, and 140 days, thereby showing that not all of the herbicide was available for toxicity (*46*). Aging also appears to occur in lake sediments, as witnessed by the decline in the rate of uptake of pyrene by the amphipod *Diporeia* sp. (*47*). Furthermore, we have recently found that phenanthrene aged for up to 150 days in samples of two sterile soils becomes progressively less available to earthworms subsequently added to these soils (J. W. Kelsey and M. Alexander, unpublished data).

A diminishing or reduced bioavailability with time is not always evident. The absence of an aging effect has been noted in investigations of the dermal availability to rats of TCDD (*48*), the toxicity of some herbicides to plants (*46*), and the biodegradation of a number of persistent pesticides by microorganisms (*14*). The reasons for the absence of an effect are as yet unknown, but they may be related to such properties of the soil as organic matter content or abundance of micropores or to such properties of the compound as hydrophobicity.

Perspective

The information that has been presented shows that (a) the availability of long-lived organic chemicals to microorganisms in soil in the field declines markedly with time, (b) some freshly added chemicals are readily available to microorganisms in soil in which the identical but aged compounds are not metabolized by indigenous microorganisms, (c) organic compounds incubated in sterile soil become increasingly less available to subsequently added microorganisms, (d) some compounds become increasingly resistant with time to extraction, and (e) sorption and desorption of hydrophobic compounds often require long time periods to reach equilibrium. These five lines of evidence are consistent with a sequestration of the molecules within particulate matter, presumably because the molecules diffuse into internal micropores or sites that are spatially remote. Because of their unavailability to even minute organisms and many extractants, it is likely that the compounds are also unavailable to humans, animals, and plants. These five lines of evidence are also consistent with a small but growing body of information showing that bioremediation of hydrocarbon-contaminated soils markedly reduces their toxicity to test species, despite the presence of presumably toxic concentrations of hydrocarbons as determined by exhaustive extraction (*49*).

Such a conclusion in regard to sequestration has major implications for assessments of the toxicity of compounds in soil that are known to be harmful in the absence of soil. The small base of information cited above shows that, at least for a few organic compounds, the toxicity to animals and plants disappears faster than the chemical itself. Thus, sequestration appears to alter the hazard to higher organisms. Indeed, the current views of the processes underlying slow sorption and desorption and those that give rise to ever increasing resistance to extraction implicitly suggest that toxic molecules will be less hazardous because they move to internal sites in soil particles that are too remote to impact living organisms.

The processes occurring may be envisioned in the following fashion. A toxic compound in solution is initially sorbed rapidly to the external surfaces of soil. This fraction is available for rapid desorption, to many organic solvents, to microorganisms for biodegradation, and to have some detrimental effect on susceptible organisms. That available fraction is slowly converted to an unavailable fraction, which is remote from the external surface. This portion of the compound is essentially irreversibly sorbed, is only extracted by highly vigorous means, and is neither available to microorganisms nor to cause injury to susceptible humans, animals, and plants. Not all of the compound will be sequestered and become nontoxic because soils into which 2,3,7,8-TCDD, polychlorinated biphenyls, or polybrominated biphenyls had been introduced years earlier still have considerable mammalian toxicity (*41, 42, 48, 50–52*). This toxicity is unlikely to have resulted from chemicals in solution because each of those compounds is extensively sorbed.

From the information presented, it is clear that regulatory decisions based on the currently used vigorous extraction procedures, which are designed to remove as much of the toxicant from soil as possible, may overestimate risk. This is not surprising, not only in view of the information cited above but also from an extensive literature that shows that the toxicity of the same concentration of an insecticide or herbicide may be vastly different in soils with dissimilar properties (*43, 44, 53, 54*).

Because of the sequestration of toxicants in soil, evaluations need to be made of the possibly reduced risk to humans, animal populations, plant populations, and

ecosystems. The very fact that the organic compounds in Superfund and most other hazardous waste sites have been in the contaminated soils for long periods of time emphasizes the need for assessing the significance of aging to toxicity. Tests of toxicity with pure chemicals in the absence of soil or chemicals freshly added to soil probably overestimate risk. Exhaustive extraction for determining toxicants in soil may be unrealiable for assessing the need for and effectiveness of remediation. An approach more meaningful than the ones used presently to establish priorities for remediation would include an assessment of the degree to which sequestering in soil alters the availability of environmental pollutants.

Notice

The Office of Research and Development (ORD) has produced this document to provide procedures for the derivation of equilibrium partitioning sediment benchmarks (ESBs) for mixtures of polycyclic aromatic hydrocarbons (PAHs). ESBs may be useful as a complement to existing sediment assessment tools. This document should be cited as:

U.S. EPA. 2003. Procedures for the Derivation of Equilibrium Partitioning Sediment Benchmarks (ESBs) for the Protection of Benthic Organisms: PAH Mixtures. EPA-600-R-02-013. Office of Research and Development. Washington, DC 20460

The information in this document has been funded wholly by the U.S. Environmental Protection Agency. It has been subject to the Agency's peer and administrative review, and it has been approved for publication as an EPA document.

Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

Abstract

This equilibrium partitioning sediment benchmark (ESB) document describes procedures to derive concentrations of PAH mixtures in sediment which are protective of the presence of benthic organisms. The equilibrium partitioning (EqP) approach was chosen because it accounts for the varying biological availability of chemicals in different sediments and allows for the incorporation of the appropriate biological effects concentration. This provides for the derivation of benchmarks that are causally linked to the specific chemical, applicable across sediments, and appropriately protective of benthic organisms.

EqP can be used to calculate ESBs for any toxicity endpoint for which there are water-only toxicity data; it is not limited to any specific effect endpoint. In this document, the Final Chronic Value (FCV) for PAHs derived using the National Water Quality Criteria (WQC) Guidelines was used as the toxicity endpoint for this ESB. This value is intended to be the concentration of a chemical in water that is protective of the presence of aquatic life. For this PAH mixtures ESB, narcosis theory was used to (1) demonstrate that the slope of the acute toxicity-octanol water partition coefficient (K_{OW}) relationship was similar across species; (2) normalize the acute toxicity of all PAHs in water to an aquatic species using a reference K_{OW} of 1.0 (where the concentration in water and lipid of the organism would be essentially the same); (3) establish an acute sensitivity ranking for individual species at the K_{OW} of 1.0 and to use the rankings to calculate a Final Acute Value (FAV) following the WQC Guidelines; (4) calculate the final acute-chronic ratio (ACR) from water-only acute and chronic toxicity tests; (5) calculate the Final Chronic Value (FCV) at the reference K_{OW} of 1.0 from the quotient of the FAV and ACR; and (6) to calculate the PAH-specific FCV in µg/L using the FCV at the reference K_{OW} of 1.0, the PAH-specific K_{OW}, the slope of the K_{OW}-K_{OC} relationship and the universal narcotic slope of the K_{OW}-acute toxicity relationship. The EqP approach and the slope of the K_{OW}-K_{OC} relationship was then used to calculate, from the product of the PAH-specific FCV and $K_{OC,}$ the FCV concentration for each specific PAH in sediment ($C_{OC,PAHi,FCVi}$, µg/g organic carbon). Based on this approach, the recommended ESB for total PAH should be the sum of the quotients of a minimum of each of the suggested 34 individual PAHs in a specific sediment divided by the $C_{OC,PAHi,FCVi}$ of that particular PAH. This sum is termed the Equilibrium Partitioning Sediment Benchmark Toxic Unit ($\Sigma ESBTU_{FCV}$). Freshwater or saltwater sediments containing ≤ 1.0 $\Sigma ESBTU_{FCV}$ of the mixture of the 34 PAHs or more PAHs are acceptable for the protection of benthic organisms, and if the $\Sigma ESBTU_{FCV}$ is greater than 1.0, sensitive benthic organisms may be unacceptably affected.

The ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with PAH mixtures or the potential for bioaccumulation and trophic transfer of PAH mixtures to aquatic life, wildlife or humans.

Foreword

Under the Clean Water Act (CWA), the U.S. Environmental Protection Agency (EPA) and the States develop programs for protecting the chemical, physical, and biological integrity of the nation's waters. To support the scientific and technical foundations of the programs, EPA's Office of Research and Development has conducted efforts to develop and publish equilibrium partitioning sediment benchmarks (ESBs) for some of the 65 toxic pollutants or toxic pollutant categories. Toxic contaminants in bottom sediments of the nation's lakes, rivers, wetlands, and coastal waters create the potential for continued environmental degradation even where water column contaminant levels meet applicable water quality standards. In addition, contaminated sediments can lead to water quality impacts, even when direct discharges to the receiving water have ceased.

The ESBs and associated methodology presented in this document provide a means to estimate the concentrations of a substance that may be present in sediment while still protecting benthic organisms from the effects of that substance. These benchmarks are applicable to a variety of freshwater and marine sediments because they are based on the biologically available concentration of the substance in the sediments. These ESBs are intended to provide protection to benthic organisms from direct toxicity due to this substance. In some cases, the additive toxicity for specific classes of toxicants (e.g., metal mixtures or polycyclic aromatic hydrocarbon mixtures) is addressed. The ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with PAH mixtues or the potential for bioaccumulation and trophic transfer of PAH mixtures to aquatic life, wildlife or humans.

ESBs may be useful as a complement to existing sediment assessment tools, to help assess the extent of sediment contamination, to help identify chemicals causing toxicity, and to serve as targets for pollutant loading control measures.

This document provides technical information to EPA Regions, States, the regulated community, and the public. It does not substitute for the CWA or EPA's regulations, nor is it a regulation itself. Thus, it cannot impose legally binding requirements on EPA, States, or the regulated community. EPA and State decisionmakers retain the discretion to adopt approaches on a case-by-case basis that differ from this technical information where appropriate. EPA may change this technical information in the future. This document has been reviewed by EPA's Office of Research and Development (Mid-Continent Ecology Division, Duluth, MN; Atlantic Ecology Division, Narragansett, RI), and approved for publication.

This is contribution AED-02-050 of the Office of Research and Development National Health and Environmental Effects Research Laboratory's Atlantic Ecology Division.

Executive Summary

This equilibrium partitioning sediment benchmark (ESB) document recommends an approach for summing the toxicological contributions of mixtures of 34 polynuclear aromatic hydrocarbons (PAHs) in sediments to determine if their concentrations in any specific sediment would be protective of benthic organisms from their direct toxicity. The combination of the equilibrium partitioning (EqP), narcosis theory, and additivity provide the technical foundation for this benchmark. These approaches were required because PAHs occur in sediments in a variety of proportions as mixtures and can be expected to act jointly under a common mode of action. Therefore, their combined toxicological contributions must be predicted on a sediment-specific basis. This overall approach provides for the derivation of this Tier 1 ESB that is causally linked to the specific mixtures of PAHs in a sediment, yet is applicable across sediments and appropriately protective of benthic organisms.

EqP theory holds that a nonionic chemical in sediment partitions between sediment organic carbon, interstitial (pore) water and benthic organisms. At equilibrium, if the concentration in any one phase is known, then the concentrations in the others can be predicted. The ratio of the concentration in water to the concentration in sediment organic carbon is termed the organic carbon partition coefficient (K_{OC}), which is a constant for each chemical. The ESB Technical Basis Document (U.S. EPA, 2003a) demonstrates that biological responses of benthic organisms to nonionic organic chemicals in sediments are different across sediments when the sediment concentrations are expressed on a dry weight basis, but similar when expressed on a μg chemical/g organic carbon basis ($\mu g/g_{OC}$). Similar responses were also observed across sediments when interstitial water concentrations were used to normalize biological availability. The Technical Basis Document (U.S. EPA, 2003a) further demonstrates that if the effect concentration in water is known, the effect concentration in sediments on a $\mu g/g_{OC}$ basis can be accurately predicted by multiplying the effect concentration in water by the chemical's K_{OC}.

EqP can be used to calculate ESBs for any toxicity endpoint for which there are water-only toxicity data; it is not limited to any specific effect endpoint. In this document, the Final Chronic Value (FCV) for PAHs derived using the National Water Quality Criteria (WQC) Guidelines (Stephan et al., 1985) was used as the toxicity endpoint for this ESB. This value is intended to be the concentration of a chemical in water that is protective of the presence of aquatic life. For this PAH mixtures ESB, narcosis theory was used to (1) demonstrate that the slope of the acute toxicity-octanol water partition coefficient (K_{OW}) relationship was similar across species; (2) normalize the acute toxicity of all PAHs in water to an aquatic species using a reference K_{OW} of 1.0 (where the concentration in water and lipid of the organism would be essentially the same); (3) establish an acute sensitivity ranking for individual species at the K_{OW} of 1.0 and to use the rankings to calculate a Final Acute Value (FAV) following the WQC Guidelines (Stephan et al., 1985); (4) calculate the final acute-chronic ratio (ACR) from water-only acute and chronic toxicity tests; (5) calculate the Final Chronic Value (FCV) at the reference K_{OW} of 1.0 from the quotient of the FAV and ACR; and (6) to calculate the PAH-specific FCV in μg/L using the FCV at the reference K_{OW} of 1.0, the PAH-specific K_{OW} and the universal narcotic slope of the acute-K_{OW} toxicity relationship. The EqP approach and the slope of the K_{OW}-K_{OC} relationship was then used to calculate, from the product of the PAH-specific FCV and $K_{OC,}$ the FCV concentration for each specific PAH in sediment ($C_{OC,PAHi,FCVi}$, μg/g organic carbon).

Importantly, because PAHs occur in sediments as mixtures and their toxicities in water, tissues, or sediments are additive or nearly additive, their combined toxicities must be considered so that the benchmark is appropriately protective. For this reason, the combined toxicological contributions of the PAH mixture must be used. In this document, the 34 PAHs monitored in the EMAP program are used to derive a concentration of "total PAH." Many monitoring and assessment efforts measure a smaller group of PAHs, such as 13 or 23 PAHs. While adjustment factors have been calculated to relate these smaller subsets to the expected concentration of the 34 PAHs, their imprecision precludes their use in critical sediment assessments. Therefore, this document recommends that the ESB for total PAH should be the sum of the quotients of the concentrations of each of the 34 individual PAHs in a specific sediment divided by the $C_{OC,PAHi,FCVi}$ of that particular PAH. This sum is termed the Equilibrium Partitioning Sediment Benchmark Toxic Unit ($\Sigma ESBTU_{FCV}$), which is based on the FCV. Freshwater or saltwater sediments containing ≤ 1.0 $\Sigma ESBTU_{FCV}$ of the mixture of the 34 PAHs or more PAHs are acceptable for the protection of benthic organisms, and if the $\Sigma ESBTU_{FCV}$ is greater than 1.0, sensitive benthic organisms may be unacceptably affected. This provides for the derivation of a benchmark that is causally linked to the specific mixtures of PAHs in a sediment, applicable across sediment types, and appropriately protective of benthic organisms. A sediment-specific site assessment would provide further information on PAH bioavailability and the expectation of toxicity relative to the $\Sigma ESBTU_{FCV}$ and associated uncertainty.

These ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with PAHs or the potential for bioaccumulation and trophic transfer of PAHs to aquatic life, wildlife or humans. Consistent with the recommendations of EPA's Science Advisory Board, publication of these documents does not imply the use of ESBs as stand-alone, pass-fail criteria for all applications; rather, ESB exceedances could be used to trigger the collection of additional assessment data. ESBs apply only to sediments having $\geq 0.2\%$ organic carbon by dry weight.

Tier 1 and Tier 2 ESB values were developed to reflect differing degrees of data availability and uncertainty. Tier 1 ESBs have been derived for polycyclic aromatic hydrocarbon (PAH) mixtures in this document, and for the nonionic organic insecticides endrin and dieldrin, and metal mixtures in U.S. EPA (2003c,d,e). Tier 2 ESBs are reported in U.S. EPA (2003f).

Glossary of Abbreviations

ACR	Acute-Chronic Ratio
AR	Approximate Randomization
ASTM	American Society for Testing and Materials
BaP	Benzo[a]pyrene
BCF	Bioconcentration factor
C_{d}	Freely-dissolved interstitial water concentration of contaminant
C_{L}	Chemical concentration in target lipid
C_{*L}	Critical body burden in the target lipid fraction of the organism
C_{OC}	Chemical concentration in sediments on an organic carbon basis
$C_{OC,PAHi}$	PAH-specific chemical concentration in sediment on an organic carbon basis
$C_{octanol}$	Chemical concentration in octanol
C_{Org}	Chemical concentration in the organism
C_{*Org}	Critical body burden in the organism
C_{IW}	Total interstitial water concentration of contaminant
$C_{OC,PAHi,FCVi}$	Effect concentration of a PAH in sediment on an organic carbon basis calculated from the product of its FCV and K_{OC}
$C_{OC,PAHi,Rhepox,LC50}$	Sediment LC50 concentration on an organic carbon basis for a specific PAH for *Rhepoxinus* calculated from the product of its LC50 value at a K_{OW} of 1.0 and K_{OC}
$C_{OC,PAHi,Maxi}$	Maximum solubility limited PAH concentration in sediment on an organic carbon basis
CV	Coefficient of Variation
CWA	Clean Water Act
DOC	Dissolved Organic Carbon
EC50	Concentration affecting 50% of the test organisms
EMAP	Environmental Monitoring and Assessment Program
EPA	United States Environmental Protection Agency
EqP	Equilibrium partitioning
ESB	Equilibrium Partitioning Sediment Benchmark(s)

$ESBTU_{FCVi}$	Equilibrium Partitioning Sediment Benchmark Toxic Unit for PAH_i based on the FCV
$ESBTU_{Rhepox}$	Equilibrium Partitioning Sediment Benchmark Toxic Unit for PAH_i based on the LC50 of *Rhepoxynius abronius*.
$\Sigma ESBTU_{FCV}$	Sum of Equilibrium Partitioning Sediment Benchmark Toxic Units, where the units are based on FCV values
f_{Lipid}	Fraction of lipid in the organism
f_{OC}	Fraction of organic carbon in sediment
f_{SC}	Fraction of soot carbon in sediment
FACR	Final Acute-Chronic Ratio
FAV	Final Acute Value
FCV	Final Chronic Value
GMAV	Genus Mean Acute Value
IWTU	Interstitial Water Toxic Unit
$IWTU_{FCV}$	Interstitial water toxic unit calculated by dividing the dissolved interstitial water concentration by the FCV
K_{DOC}	Dissolved organic carbon: water partition coefficient
K_{LW}	Lipid: water partition coefficient
K_{OC}	Organic carbon: water partition coefficient
K_{OW}	Octanol: water partition coefficient
K_P	Sediment: water partition coefficient
K_S	Setschenow constant
K_{SC}	Soot carbon: water partition coefficient
LC50	Concentration estimated to be lethal to 50 % of the test organisms within a specified time period
LFER	Linear free energy relationship
MV	Molar Volume
NA	Not Applicable, Not Available
NAPL	Non-aqueous Phase Liquid
ND	Not Determined, Not Detected
NOAA	National Oceanographic and Atmospheric Administration

NOEC	No Observed Effect Concentration
NTU	Narcotic Toxic Units
OEC	Observable Effect Concentration
PAH	Polycyclic aromatic hydrocarbon
PAH_{OC}	Organic carbon-normalized PAH concentration in sediment
PCB	Polychlorinated Biphenyl
POC	Particulate Organic Carbon
PSTU	Predicted Sediment Toxic Units
QSAR	Quantitative Structure Activity Relationship
REMAP	Regional Environmental Monitoring and Assessment Program
S	Aqueous Solubility
SAB	U.S. EPA Science Advisory Board
SCV	Secondary Chronic Value
SE	Standard Error
SMAV	Species Mean Acute Value
SPARC	SPARC Performs Automated Reasoning in Chemistry
TOC	Total Organic Carbon
TU	Toxic Unit
WQC	Water Quality Criteria
$WQCTU_{FCVi}$	Water Quality Criteria Toxic Unit based on the FCV

Section 1

Introduction

1.1 General Information

Toxic pollutants in bottom sediments of the Nation's lakes, rivers, wetlands, estuaries, and marine coastal waters create the potential for continued environmental degradation even where water column concentrations comply with established WQC. In addition, contaminated sediments can be a significant pollutant source that may cause water quality degradation to persist, even when other pollutant sources are stopped (Larsson, 1985; Salomons et al., 1987; Burgess and Scott, 1992). The absence of defensible equilibrium partitioning sediment benchmarks (ESBs) make it difficult to accurately assess the extent of the ecological risks of contaminated sediments and to identify, prioritize, and implement appropriate cleanup activities and source controls (U.S. EPA 1997a, b, c).

As a result of the need for a procedure to assist regulatory agencies in making decisions concerning contaminated sediment problems, the U.S. Environmental Protection Agency (EPA) Office of Science and Technology, Health and Ecological Criteria Division (OST/HECD) and Office of Research and Development National Health and Environmental Effects Research Laboratory (ORD/NHEERL) established a research team to review alternative approaches (Chapman, 1987). All of the approaches reviewed had both strengths and weaknesses, and no single approach was found to be applicable for the derivation of benchmarks in all situations (U.S. EPA, 1989, 1992). The equilibrium partitioning (EqP) approach was selected for nonionic organic chemicals because it presented the greatest promise for generating defensible, national, numeric chemical-specific benchmarks applicable across a broad range of sediment types. The three principal observations that underlie the EqP approach to establishing sediment benchmarks are as follows:

1. The concentrations of nonionic organic chemicals in sediments, expressed on an organic carbon basis, and in interstitial waters correlate to observed biological effects on sediment-dwelling organisms across a range of sediments.

2. Partitioning models can relate sediment concentrations for nonionic organic chemicals on an organic carbon basis to freely-dissolved concentrations in interstitial water.

3. The distribution of sensitivities of benthic organisms to chemicals is similar to that of water column organisms; thus, the currently established water quality criteria (WQC) final chronic values (FCV) or secondary chronic values (SCV) can be used to define the acceptable effects concentration of a chemical freely-dissolved in interstitial water.

The EqP approach, therefore, assumes that (1) the partitioning of the chemical between sediment organic carbon and interstitial water is at or near equilibrium; (2) the concentration in either phase can be predicted using appropriate partition coefficients and the measured concentration in the other phase (assuming the freely-dissolved interstitial water concentration can be accurately measured); (3) organisms receive equivalent exposure from water-only exposures or from any equilibrated phase: either from interstitial water via respiration, from sediment via ingestion or other sediment-integument exchange, or from a mixture of exposure routes; (4) for nonionic chemicals, effect concentrations in sediments on an organic carbon basis can be predicted using the organic carbon partition coefficient (K_{OC}) and effects concentrations in water; (5) the FCV or SCV concentration is an appropriate effects concentration for freely-dissolved chemical in interstitial water; and (6) ESBs derived as the product of the K_{OC} and FCV are protective of benthic organisms. ESB concentrations presented in this document are expressed as µg chemical/g sediment organic carbon ($\mu g/g_{OC}$) and not on an interstitial water basis because (1) interstitial water

is difficult to sample and (2) significant amounts of the dissolved chemical may be associated with dissolved organic carbon; thus, total concentrations in interstitial water may overestimate exposure.

Sediment benchmarks generated using the EqP approach are suitable for use in providing technical information to regulatory agencies because they are:

1. Numeric values
2. Chemical specific
3. Applicable to most sediments
4. Predictive of biological effects
5. Protective of benthic organisms

ESBs are derived using the available scientific data to assess the likelihood of significant environmental effects to benthic organisms from chemicals in sediments in the same way that the WQC are derived using the available scientific data to assess the likelihood of significant environmental effects to organisms in the water column. As such, ESBs are intended to protect benthic organisms from the effects of chemicals associated with sediments and, therefore, only apply to sediments permanently inundated with water, to intertidal sediment, and to sediments inundated periodically for durations sufficient to permit development of benthic assemblages. ESBs should not be applied to occasionally inundated soils containing terrestrial organisms, nor should they be used to address the question of possible contamination of upper trophic level organisms or the synergistic, additive, or antagonistic effects of multiple chemicals. The application of ESBs under these conditions may result in values lower or higher than those presented in this document.

ESB values presented herein are the concentrations of PAH mixtures in sediment that will not adversely affect most benthic organisms. It is recognized that these ESB values may need to be adjusted to account for future data. They may also need to be adjusted because of site-specific considerations. For example, in spill situations, where chemical equilibrium between water and sediments has not yet been reached, sediment chemical concentrations less than an ESB may pose risks to benthic organisms. This is because for spills, disequilibrium concentrations in interstitial and overlying water may be proportionally higher relative to sediment concentrations. In systems where biogenic organic carbon dominates, research has shown that the source or "quality" of total organic carbon (TOC) in natural sediments does not affect chemical binding when sediment toxicity was measured as a function of TOC concentration (DeWitt et al., 1992). K_{OC}s have also been demonstrated to not vary in gradients of chemicals across estuarine sediments (Burgess et al., 2000a). However, in systems where other forms of carbon are present at elevated levels, the source or 'quality' of TOC may affect chemical binding despite expressing toxicity as a function of TOC concentration. At some sites, concentrations in excess of an ESB may not pose risks to benthic organisms because the compounds are partitioned to or a component of a particulate phase such as soot carbon or coal or exceed solubility such as in the case of undissolved oil or chemical (e.g. conditions at a manufactured gas plant site). In these situations, an ESB would be overly protective of benthic organisms and should not be used unless modified using the procedures outlined in "Procedures for the Derivation of Site-Specific Equilibrium Partitioning Sediment Benchmarks (ESBs) for the Protection of Benthic Organisms" (U.S. EPA, 2003b). If the organic carbon has a low capacity (e.g., hair, sawdust, hide), an ESB would be underprotective. An ESB may also be underprotective where the toxicity of other chemicals are additive with an ESB chemical or where species of unusual sensitivity occur at the site.

This document presents the theoretical basis and the supporting data relevant to the derivation of ESBs for PAH mixtures. The data that support the EqP approach for deriving ESBs for nonionic organic chemicals are reviewed by Di Toro et al. (1991) and EPA (U.S. EPA, 2003a). Before proceeding through the following text, tables, and calculations, the reader should also consider reviewing Stephan et al. (1985).

1.2 General Information: PAH Mixtures

The EPA developed ESBs for metal mixtures (Cd, Cu, Pb, Ni, Ag, Zn) (U.S. EPA 2003c) and the insecticides endrin and dieldrin (U.S. EPA 2003d,e) and proposed ESBs for the individual polycyclic aromatic hydrocarbons (PAHs) acenaphthene, fluoranthene and phenanthrene (U.S. EPA 1993a,b,c). Because PAHs occur in the environment as mixtures, rather than single chemicals, ESBs for individual PAHs have the potential to be substantially under-protective because they do not account for other co-occurring PAHs. This ESB for PAH mixtures replaces the earlier draft individual PAH documents.

Numerous efforts have previously sought to address and estimate the toxicity of PAH mixtures in sediments (Barrick et al., 1988; Long and Morgan, 1991; PTI Environmental Services, 1991; Long et al., 1995; Swartz et al., 1995; Ingersoll et al., 1996; MacDonald et al., 1996, 2000; Cubbage et al., 1997; Di Toro and McGrath, 2000; Di Toro et al., 2000; Ozretich et al., 1997, 2000). The resultant sediment benchmarks have engendered considerable controversy over such issues as the correlative versus causal relations between dry weight sediment chemistry and biological effects, the bioavailability of sediment contaminants, the effects of covarying chemicals and mixtures, and ecological relevance. Overviews of the various approaches are useful (Mount et al., 2003; Swartz et al., 1999). The use of sediment benchmarks derived in a variety of ways must be linked to the derivation procedure and specific intent of the methodology. The U. S. EPA research team has concluded, based upon additional investigation, that recommendation of sediment benchmarks for PAHs based on EqP, narcosis theory and additivity was necessary to resolve outstanding issues related to causality. Sediment benchmarks for mixtures of PAHs that are derived using these approaches are adequately protective of benthic organisms, as well as ecologically relevant.

The ΣPAH model developed by Swartz et al. (1995) and based upon a combination of the EqP approach, quantitative structure activity relationships (QSAR), narcosis theory, and additivity models provided initial insight into a technical approach for resolving these complexities. This EqP-based ΣPAH model provides a method to address causality, account for bioavailability, consider mixtures, and predict toxicity and ecological effects. The most significant contribution to the development of the scientific basis for deriving ESBs for PAH mixtures is described by Di Toro et al. (2000) and Di Toro and McGrath (2000). This pioneering research in developing a methodology for deriving ESBs for mixtures of narcotic chemicals and PAHs forms major portions of this document.

1.2.1 PAH Chemistry

Portions of the following overview of PAH chemistry are directly, or in part from, Neff's1979 classic book "Polycyclic Aromatic Hydrocarbons in the Aquatic Environment" and to a lesser extent Schwarzenbach et al. (1993). PAHs are composed of two or more fused aromatic or benzene rings. Two aromatic rings are fused when a pair of carbon atoms is shared. The resulting structure is a molecule with all carbon and hydrogen atoms lying in a single plane. Naphthalene ($C_{10}H_8$), which consists of two fused aromatic rings, is the lowest molecular weight PAH. The ultimate fused-ring aromatic system is graphite, an allotropic form of elemental carbon. Of primary environmental concern are mobile compounds ranging in molecular weight from naphthalene ($C_{10}H_8$, molecular weight 128.17) to coronene ($C_{24}H_{12}$, molecular weight 300.36). Within this range is an extremely large number of PAHs differing in the number and positions of aromatic rings and in the number, chemistry, and position of substituents on the ring system. Figure 1-1 presents a selection of PAH structures.

Physical and chemical characteristics of PAHs vary in a more or less regular fashion with molecular weight. Resistance to oxidation and reduction tends to decrease with increasing molecular weight. Vapor pressure and aqueous solubility decrease almost logarithmically with increasing molecular weight. As a consequence of these differences, PAHs of different molecular weights vary substantially in their behavior and

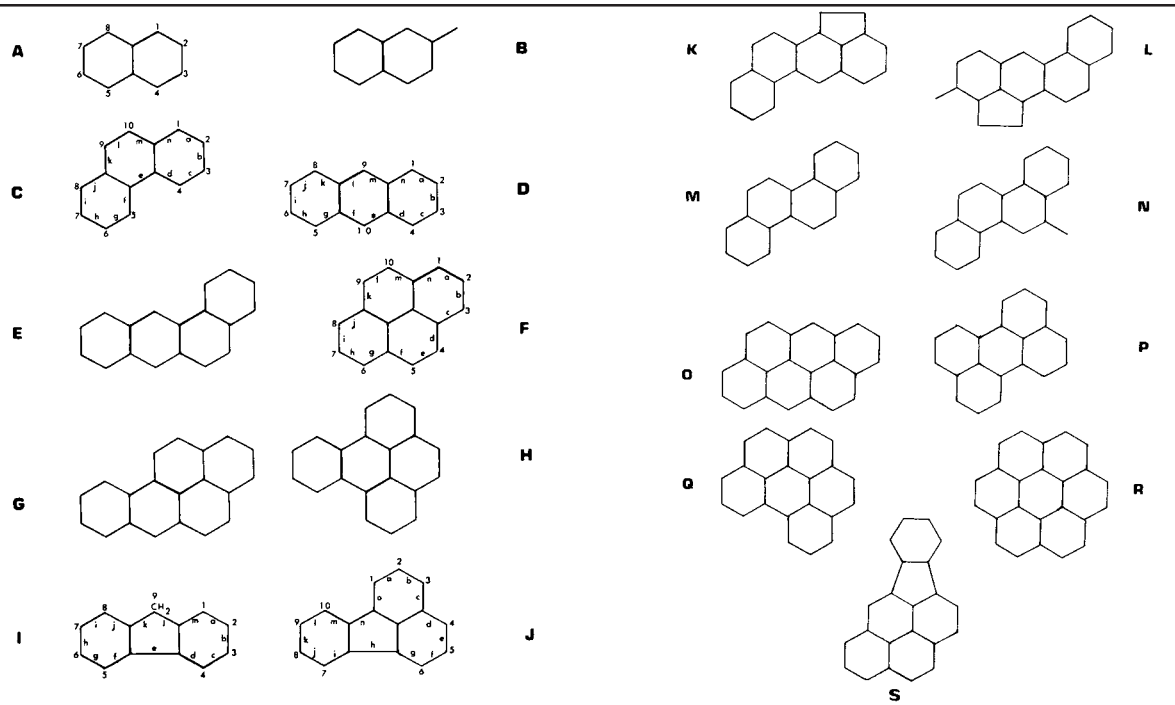

Figure 1-1. Ring structures of representative polycyclic aromatic hydrocarbons. The numbering and lettering system for several PAHs is also given. A, naphthalene; B, 2-methylnaphthalene; C, phenanthrene; D, anthracene; E, benz[*a*]anthracene; F, pyrene; G, benzo[*a*]pyrene; H, benzo[*e*]pyrene; I, fluorene; J, fluoranthene; K, benz[*j*]aceanthrylene = cholanthrene; L, 3-methylcholanthrene; M, chrysene; N, 5-methylchrysene; O, dibenzo[*cd,jk*]pyrene = anthranthrene; P, perylene; Q, benzo[*ghi*]perylene; R, coronene; S, indeno[1,2,3-*cd*]pyrene (from Neff 1979).

distribution in the environment and their toxic effects. PAHs undergo three types of chemical reactions characteristic of aromatic hydrocarbons - electrophilic substitution, oxidation, and reduction. Oxidation and reduction reactions destroy the aromatic character of the affected benzene ring but electrophilic substitution does not.

Several systems of nomenclature have been used to describe PAH ring structures. Nomenclature used in this document is that adopted by the International Union of Pure and applied Chemistry (IUPAC) and described in detail in *The Ring Index* (Patterson et al., 1960).

As noted above, there is an extremely large number of possible PAH structures (>10,000). Later in this document, 34 PAH structures (specific non-alkylated compounds and generic alkylated forms) are identified as representing a minimum for 'total PAHs'. It is recognized that this subset of all possible PAHs is not complete; however, the 34 PAHs identified are the ones that are generally most abundant and commonly measured as part of environmental monitoring programs. As analytical techniques improve, the number of PAHs composing 'total PAHs' will most certainly increase and users of this document are encouraged to include newly quantified PAHs in the derivation of benchmark values assuming good supporting data are available (e.g., K_{OW}s, solubilities).

PAHs found in aquatic environments originate from three possible sources: pyrogenic, petrogenic and diagenic. Pyrogenic PAHs result from the incomplete but high temperature, short-duration combustion of organic matter including fossil fuels and biomass (Neff 1979; Meyers and Ishiwatari 1993). These pyrogenic PAHs are believed to form from the breakdown or 'cracking' of organic matter to lower molecular weight radicals during pyrolysis, followed by rapid reassembly into non-alkylated PAH structures (Neff 1979). Petrogenic PAHs are created by diagenic processes at relatively low temperatures over geologic time scales, leading to the formation of petroleum and other fossil fuels containing PAHs (Meyers and

Ishiwatari 1993; Boehm et al., 2001). PAHs formed at relatively low temperatures (~150 °C) over long periods of time will be primarily alkylated molecules. The alkylated structure of petrogenic PAHs reflects the ancient plant material from which the compounds formed (Neff 1979). Diagenic PAHs refer to PAHs from biogenic precursors, like plant terpenes, leading to the formation of compounds such as retene and derivatives of phenanthrene and chrysene (Hites et al., 1980; Meyers and Ishiwatari 1993; Silliman et al., 1998). Perylene is another common diagenic PAH. Although its exact formation process remains unclear, an anaerobic process appears to be involved (Gschwend et al., 1983; Venkatesan 1988; Silliman et al., 1998). While diagenic PAHs are frequently found at background levels in recent sediments (i.e., deposited over the last 150 years), they often dominate the assemblage of PAHs present in older sediments deposited before human industrial activity (Gschwend et al., 1983). A potential fourth source of PAHs is biogenic; that is, purely from bacteria, fungi, plants or animals in sedimentary environments without any contributions from diagenic processes. However, attempts to produce biogenic PAHs have arguably failed, indicating this source is not significant (Hase and Hites 1976; Neff 1979).

The majority of PAHs found in aquatic environments originate from pyrogenic sources (Blumer 1976; Suess 1976; Hites et al., 1977; LaFlamme and Hites, 1978; NRC 1985; Wu et al., 2001). However, petrogenic PAHs do also occur alone or in combination with pyrogenic PAHs (Lake et al., 1979; Wakeham et al., 1980; NRC 1985; Gschwend and Hites 1981; Readman et al., 1992). In general, petrogenic PAHs appear to be associated with local or point sources, such as refineries and other petroleum industries, and adjacent to roads and navigational routes. This contrasts with the distribution of pyrogenic PAHs, which occur on a broader geographic scale. These distribution are also affected by the relative persistence of pyrogenic and petrogenic PAHs in the environment. As compared to petrogenic PAHs, pyrogenic PAHs are found more extensively in the sediment core record and appear to be less vulnerable to biotic and abiotic degradation (Burgess et al., 2003). Finally, diagenic PAHs occur at background levels although anthropogenic sources (e.g., perylene) can contribute to these types of PAHs.

1.2.2 PAH Mixtures

Unlike most other organic chemicals in the environment, PAHs are not released in a 'pure' or well-characterized form. Rather, because PAHs consist of thousands of structures originating from at least three sources, they always occur in the environment as complex mixtures (Burgess et al., 2003). As discussed above, pyrogenic PAHs, although not generally alkylated, are produced as mixtures of parent PAHs based on the conditions of their combustive formation (e.g., temperature, presence of oxygen, original organic matter). Similarly, the composition of petrogenic PAHs is a function of the diagenic conditions under which the original organic matter was exposed for thousands of years (e.g., pressure, temperature). Of course, human industrial practices convert some crude petrogenic PAH mixtures into more purified forms (e.g., fuel oils, creosote). These purified forms also contain complex mixtures of PAH molecules. As a consequence of these factors, when PAHs are released into the aquatic environment from the burning of fossil fuels and biomass, discharge of industrial chemicals, and transport of petroleum products they eventually accumulate in the sediments as complex mixtures (Neff 1979).

1.3 Application of Sediment Benchmarks

ESBs as presented in this document are meant to be used with direct toxicity testing of sediments as a method of sediment evaluation, assuming the toxicity testing species is sensitive to the chemical(s) of interest. They provide a chemical-by-chemical specification of sediment concentrations protective of benthic aquatic life. The EqP method should be applicable to nonionic organic chemicals with a K_{OW} above 3.0.

For the toxic chemicals addressed by the ESB documents Tier 1 (U.S. EPA, 2003c, d, e, and this document) and Tier 2 (U.S. EPA, 2003f) values

were developed to reflect the differing degrees of data availability and uncertainty. Tier 1 ESBs are more scientifically rigorous and data intensive than Tier 2 ESBs. The minimum requirements to derive a Tier 1 ESB include: (1) Each chemical's organic carbon-water partition coefficient (K_{OC}) is derived from the octanol-water partition coefficient (K_{OW}) obtained using the SPARC (SPARC Performs Automated Reasoning in Chemistry) model (Karickhoff et al., 1991) and the K_{OW}-K_{OC} relationship from Di Toro et al. (1991). This K_{OC} has been demonstrated to predict the toxic sediment concentration from the toxic water concentration with less uncertainty than K_{OC} values derived using other methods. (2) The FCV is updated using the most recent toxicological information and is based on the National WQC Guidelines (Stephan et al., 1985). (3) EqP-confirmation tests are conducted to demonstrate the accuracy of the EqP prediction that the K_{OC} multiplied by the effect concentration from a water-only toxicity test predicts the effect concentration from sediment tests (Swartz, 1991a; DeWitt et al., 1992). Using these specifications, Tier 1 ESBs have been derived for PAH mixtures in this document, metals mixtures (U.S. EPA, 2003c) and, the nonionic organic insecticides endrin and dieldrin (U.S. EPA, 2003d, e). In comparison, the minimum requirements for a Tier 2 ESB (U.S. EPA, 2003f) are less rigorous: (1) The K_{OW} for the chemical that is used to derive the K_{OC} can be from slow-stir, generator column, shake flask, SPARC or other sources (e.g., Site 2001). (2) FCVs can be from published or draft WQC documents, the Great Lakes Initiative or developed from AQUIRE. Secondary chronic values (SCV) from Suter and Mabrey (1994) or other effects concentrations from water-only toxicity tests can be used. (3) EqP cconfirmation tests are recommended, but are not required for the development of Tier 2 ESBs. Because of these lesser requirements, there is greater uncertainty in the EqP prediction of the sediment effect concentration from the water-only effect concentration, and in the level of protection afforded by Tier 2 ESBs. Examples of Tier 2 ESBs for nonionic organic chemicals are found in U.S. EPA (2003f).

1.4 Data Quality Assurance

All data used to derive the FCV used to calculate the ESB for PAHs from water-only toxicity tests were obtained from a comprehensive literature search completed in 1995. Discussions in other sections of this document utilized literature obtained up to 2003. Data were evaluated for acceptability using the procedures in the Stephan et al. (1985): *Guidelines for deriving numerical national water quality criteria for the protection of aquatic organisms and their uses*. Data not meeting the criteria for acceptability were rejected. All calculations were made using the procedures in Stephan et al. (1985). All data and intermediate values are presented in tables or appendices in the document. Four significant figures were used in intermediate calculations to limit the effect of rounding error, and are not intended to indicate the true level of precision. The document was reviewed as part of a formal peer review and all original data were made available as part of the review process. Any errors of omission or calculation discovered during the peer review process were corrected. The document was revised according to the comments of peer reviewers and additional scientific literature and significant data identified by reviewers were incorporated into the document. Hard copies of peer-review comments and responses to these comments are available from the ORD/NHEERL Atlantic Ecology Division - Narragansett, Rhode Island. Hard copies of all literature cited in this document reside at ORD/ NHEERL Atlantic Ecology Division - Narragansett, Rhode Island.

1.5 Overview

This document presents the theoretical basis and supporting data relevant to the derivation of ESBs for mixtures of PAHs.

Section 2 of this document "Narcosis Theory: Model Development and Application for PAH Mixtures" contains an analysis of the narcosis and EqP models to demonstrate the scientific basis for the derivation of WQC and ESBs for mixtures of narcotic chemicals, including PAHs. Data are

presented that demonstrate that the toxicity of narcotic chemicals when based on concentration in water increase with their K_{OW} and that the slope of the K_{OW}-toxicity relationship is not different across species. The universal slope of this relationship (-0.945) is applicable for all narcotic chemical classes, whereas the intercept is chemical class-specific. The intercept of this slope at a K_{OW} of 1.0 predicts the tissue effect concentration. The toxicities of mixtures of narcotic chemicals in water are shown to be approximately additive, thus the toxic unit concept is applicable to mixtures. The toxicities of narcotic chemicals are shown to be limited by their solubilities in water, hence their toxicities in sediments are limited.

Section 3 of this document "Toxicity of PAHs in Water Exposure and Derivation of PAH-specific FCVs" presents an analysis of acute and chronic water-only toxicity data for freshwater and saltwater aquatic organisms exposed to individual PAHs. It examines (1) the relative sensitivities of freshwater and saltwater organisms to determine if separate FCVs are required, and (2) the relative sensitivities of benthic organisms and organisms used to derive WQC to determine if the WQC FCV should be based only on benthic organisms. These data are used with the narcosis model presented in Section 2, the EqP approach (U.S. EPA, 2003a), and the U.S. EPA National WQC (Stephan et al., 1985) to derive the FCV for individual PAHs (PAH-specific FCV).

Section 4 "Derivation of PAH $\Sigma ESBTU_{FCV}$" contains the approach used for deriving the ΣESBs for mixtures of PAHs. The $C_{OC,PAHi,FCVi}$ is derived for each individual PAH as the product of the PAH-specific FCV and the respective K_{OC} value as recommended by the EqP approach. The use of the $C_{OC,PAHiFCVi}$ value for individual PAHs is inappropriate for use as the ESB because PAHs occur as mixtures. The toxicities of mixtures of narcotic chemicals has been shown to be approximately additive, therefore, combined toxic contributions of all PAHs in the mixture can be determined by summing the quotients of the concentration of each PAH in the sediment divided by its $C_{OC,PAHi,FCVi}$ to determine the sum of these Equilibrium Partitioning Sediment Benchmark Toxic Units ($\Sigma ESBTU_{FCV}$). If the $\Sigma ESBTU_{FCV}$ is ≤1.0, the sediment benchmark for the PAH mixture is not exceeded and the PAH concentration in the sediment is protective of benthic organisms. If the $\Sigma ESBTU_{FCV}$ exceeds 1.0, the sediment benchmark for the PAH mixture is exceeded and sensitive benthic organisms may be affected by the PAHs. The $\Sigma ESBTU_{FCV}$ is derived for PAH mixtures in sediments from national monitoring programs to reveal the incidence of sediment benchmark exceedences.

Section 5 "Actual and Predicted Toxicity of PAH Mixtures in Sediment Exposures" examines the applicability of the EqP methodology for $C_{OC,PAHi,FCVi}$ and ESB derivation. The $C_{OC,PAHi,FCVi}$ and ESB are compared to (1) databases of observed sediment toxicity, and (2) amphipod abundance in sediments from the field where PAHs are the probable contaminants of concern.

Section 6 "Implementation" defines the PAHs to which the ESB apply. An example calculation is provided to explain the conversion of concentrations of individual PAHs on a dry weight basis into the benchmark. The photo-activation of PAHs in UV sunlight and teratogenicity and carcinogenicity of certain PAHs in the mixture are examined. The importance of equilibrium and the partitioning of PAHs to other organic carbon phases (e.g., soot and coal) is described. An approach for calculating PAH solubilities for temperatures or salinities at specific sites is provided.

Section 7 "Sediment Benchmark Values: Application and Interpretation" presents the sediment benchmark values and lists several factors to consider when applying and interpreting these values.

Section 8 "References" lists references cited in all sections of this document.

Appendices provide supplementary tabulated information.

Section 2

Narcosis Theory: Model Development and Application for PAH Mixtures

2.1 Section Overview

This section of the ESB document presents a model of the toxicity of narcotic chemicals to aquatic organisms that is applicable to the derivation of WQC and ESBs for mixtures of narcotic chemicals, including PAHs. Both the model and this section of the document are largely excerpted from the publications of Di Toro et al. (2000) and Di Toro and McGrath (2000) which should be consulted for information on components of the overall model that are not included in this ESB document. The narcosis model includes a scientific analysis of the toxicities of narcotic chemicals fundamental to the derivation of WQC and ESBs for their mixtures. The ESB for PAH mixtures described in Section 4 of this document is derived using this model and toxicity data exclusively for PAHs (see Section 3).

The narcosis model is used to describe the toxicity of all type I narcotic chemicals. Since PAHs are expected to be type I narcotic chemicals (Hermens, 1989; Verhaar et al., 1992), the toxicological principles that apply to them should be more accurately characterized by an analysis of the principles that apply to narcotic chemicals overall. Model development utilizes a database of LC50 values comprising 156 chemicals and 33 aquatic species, including fish, amphibians, arthropods, molluscs, annelids, coelenterates and echinoderms. The analysis detailed in this section is used to demonstrate that (1) the toxicities of narcotic chemicals, and therefore PAHs, are dependant on the chemical's K_{OW}; (2) the slope of the K_{OW}-toxicity relationship is the same for all species of aquatic organisms and classes of narcotic chemicals with the intercepts being species and chemical class-specific; (3) the species-specific LC50 values normalized to a K_{OW} =1.0 permit ranking of species sensitivities and are equivalent to the body burden LC50 on a lipid basis; and (4) the toxicities of mixtures of narcotic chemicals are additive.

The analysis of narcotic chemical toxicity data presented in this section shows that the proposed model accounts for the variations in toxicity due to differing species sensitivities and chemical differences. The model is based on the idea that the target lipid is the site of action in the organism. Further, it is assumed that target lipid has the same lipid-octanol linear free energy relationship for all species. This implies that the $\log_{10}$LC50 vs $\log_{10}K_{OW}$ slope is the same for all species. However, individual species may have varying target lipid body burdens of narcotic chemicals that cause mortality. The target lipid LC50 body burdens estimated by extrapolations from the water-only acute toxicity data and K_{OW} values are compared to measured total lipid LC50 body burdens for five species. They are essentially equal, indicating that the extrapolation in the model is appropriate for estimation of LC50 body burdens, i.e., that the target lipid concentration is equal to the total extracted lipid concentration. The precise relationship between target lipid and octanol is established.

2.2 Narcosis Model Background

A comprehensive model of type I narcosis chemicals which considers multiple species has been presented by Van Leeuwen et al. (1992).

They developed QSARs for individual species and performed species sensitivity analysis. The analysis and model presented below and in Di Toro et al. (2000) and that of Van Leeuwen et al. (1992) are similar. The key differences in the Di Toro et al. (2000) model are the use of a single universal slope for the $\log_{10}$LC50 versus $\log_{10}K_{OW}$ QSAR for all the species, the inclusion of corrections for chemical classes, such as PAHs, that are slightly more potent than reference narcotics, and the interpretation of the y-intercepts as the species-specific critical body burdens for narcosis mortality.

2.3 Body Burden Model

The initial QSAR models for narcotic toxicity relied on correlations of $\log_{10}$LC50 and $\log_{10}K_{OW}$ (Konemann, 1981; Veith et al., 1983). An interesting and important interpretation of this inverse relationship which relates the toxicity to chemical body burden has been presented by McCarty et al. (1991), and proceeds as follows. The relationship between the LC50 (mmol/L) and K_{OW} for the narcosis LC50 for fish is approximately

$$\log_{10}\text{LC50} \simeq -\log_{10}K_{OW} + 1.7 \qquad (2\text{-}1)$$

For each LC50, a fish body burden, on a wet weight basis, corresponding to narcosis mortality can be computed using a bioconcentration factor BCF (L/kg) which is defined as the ratio of the chemical concentration in the organism C_{Org} (mmol/kg wet weight) to the chemical concentration dissolved in the water C_d (mmol/L)

$$\text{BCF} = \frac{C_{Org}}{C_d} \qquad (2\text{-}2)$$

Using the BCF, the organism concentration corresponding to the LC50, which is referred to as the critical body burden and denoted by C^*_{Org}, can be computed using

$$C^*_{Org} = \text{BCF} \times \text{LC50} \qquad (2\text{-}3)$$

The superscript * indicates that it is a critical body burden corresponding to the LC50. The BCF also varies with K_{OW}. For fish, the relationship is

$$\log_{10}\text{BCF} \simeq \log_{10}K_{OW} - 1.3 \qquad (2\text{-}4)$$

Therefore, the critical body burden corresponding to the LC50 for fish narcosis can be computed using the narcosis LC50 and the BCF

$$\log_{10} C^*_{Org} = \log_{10}\text{BCF} + \log_{10}\text{LC50}$$

$$\simeq \log_{10}K_{OW} - 1.3 - \log_{10}K_{OW} + 1.7$$

$$\simeq 0.4 \qquad (2\text{-}5)$$

or

$$C^*_{Org} \simeq 2.5\ \mu\text{mol/g wet wt} \qquad (2\text{-}6)$$

Thus, McCarty et al. (1991) rationalized the relationship between LC50 values and K_{OW} by suggesting that mortality is caused as a result of a constant body burden of the narcotic chemical.

The reason the critical body burden is a constant concentration for all the narcotic chemicals represented by the narcosis LC50 is a consequence of the unity slopes for $\log_{10}K_{OW}$ in Equations 2-1 and 2-4. For example, if the fraction of lipid in the fish is ass umed to be 5% ($f_{Lipid} = 0.05$), then the critical body burden in the lipid fraction of the fish is

$$C^*_L = \frac{C^*_{Org}}{f_{Lipid}} = \simeq 50\ \mu\text{mol / g lipid} \qquad (2\text{-}7)$$

which is the estimate of the chemical concentration in the lipid of these fish that causes 50 % mortality. The model presented below is an extension of this idea.

2.4 Target Lipid Model

The body burden model relates the narcosis concentration to a whole body concentration using a BCF. If different species are tested, then species-specific BCFs and lipid concentrations would be required to convert the LC50 concentration to a body burden for each species. A more direct approach is to relate narcotic

lethality to the concentration of the chemical in the target tissue of the organism, rather than to the concentration in the whole organism. If the partitioning into the target tissue is independent of species, then the need for species-specific BCFs is obviated. The identity of the target tissue is still being debated (Abernethy et al., 1988; Franks and Lieb, 1990), but we assume that the target is a lipid fraction of the organism. Hence the name, target lipid.

The target lipid model is based on the assumption that mortality occurs when the chemical concentration in the target lipid reaches a threshold concentration. This threshold is assumed to be species-specific rather than a universal constant that is applicable to all organisms (e.g., 50 µmol/g lipid, see Equation 2-7). The formulation follows the body burden model (McCarty et al., 1991). The target lipid-water partition coefficient K_{LW} (L/kg lipid) is defined as the ratio of chemical concentration in target lipid, C_L (µmol/g lipid = mmol/kg lipid), to the freely-dissolved aqueous concentration C_d, (mmol/L)

$$K_{LW} = \frac{C_L}{C_d} \qquad (2\text{-}8)$$

This equation can be used to compute the chemical concentration in the target lipid phase producing narcotic mortality, i.e., the critical body burden in the lipid fraction C_L^*, when the chemical concentration in the water phase is equal to the LC50

$$C_L^* = K_{LW} \times LC50 \qquad (2\text{-}9)$$

Assuming the narcosis hypothesis is true, i.e., that 50% mortality occurs if any narcotic chemical reaches the concentration C_L^*, then the LC50 for any chemical can be calculated using the same critical target lipid concentration C_L^* and the chemical-specific target lipid-water partition coefficient

$$LC50 = \frac{C_L^*}{K_{LW}} \qquad (2\text{-}10)$$

or

$$\log_{10}LC50 = \log_{10}C_L^* - \log_{10}K_{LW} \qquad (2\text{-}11)$$

The problem is determining the K_{LW} for narcotic chemicals. It is commonly observed for many classes of organic molecules that the logarithms of the partition coefficient between two liquids are related by a straight line (Leo, 1972). For target lipid and octanol, the relationship would be

$$\log_{10}K_{LW} = a_0 + a_1 \log_{10}K_{OW} \qquad (2\text{-}12)$$

Such a relationship is called a linear free energy relationship (LFER) (Leo et al., 1971; Brezonik, 1994). Combining Equations 2-11 and 2-12 yields the following linear relationship between $\log_{10}LC50$ and $\log_{10}K_{OW}$

$$\log_{10}LC50 = \log_{10}C_L^* - a_0 - a_1 \log_{10}K_{OW} \qquad (2\text{-}13)$$

where $\log_{10}C_L^* - a_0$ is the y intercept and $-a_1$ is the slope of the line.

This derivation produces the linear relationship between $\log_{10}LC50$ and $\log_{10}K_{OW}$ which is found experimentally (see, for example, Table 6 in Hermens et al., 1984)

$$\log_{10}LC50 = m \log_{10}K_{OW} + b \qquad (2\text{-}14)$$

where m and b are the slope and intercept of the regression, respectively. In addition, it identifies the meanings of the parameters of the regression line. The slope of the line m is the negative of the slope of the LFER between target lipid and octanol, a_1. The intercept of the regression $b = \log_{10}C_L^* - a_0$ is composed of two parameters: C_L^* is the target lipid concentration at narcosis mortality, and a_0 is the constant in Equation 2-12.

The difference between the target lipid model and the McCarty et al. (1991) body burden model is that for the latter, the coefficients a_0 and a_1 for fish are assumed to be known: $a_0 = -1.3$ and $a_1 = 1.0$. It is interesting to examine the consequences of a similar assumption applied to the target lipid model. If it is assumed that the partitioning of narcotic chemicals in lipid and octanol are equal, i.e., that lipid is octanol, a common first approximation, then $a_1 = 1$ and $a_0 = 0$ and the y-intercept becomes

$$b = \log_{10}C_L^* \qquad (2\text{-}15)$$

which is the target-lipid concentration producing 50% narcosis mortality.

This result can be understood by examining Figure 2-l. The y-intercept b is the LC50 value for a chemical with a $\log_{10}K_{OW} = 0$ or $K_{OW} = 1$. The K_{OW} is the ratio of the chemical's concentration in octanol to its concentration in water. Hence, for this hypothetical chemical (an example would be 2-chloroethanol for which $\log_{10}K_{OW} = -0.048$l 0 the chemical's concentration in water is equal to its concentration in octanol. However, if the K_{LW} equals the K_{OW}, i.e., lipid is octanol, then its concentration in water must be equal to its concentration in the target lipid of the organism. Therefore, the y-intercept is the target lipid phase concentration at which 50% mortality is observed. That is

$$LC50|_{K_{OW}=1} = b = C^*_{octanol} = C^*_L \qquad (2\text{-}16)$$

Note that this interpretation is true only if $a_0 = 0$ (see Equation 2-13).

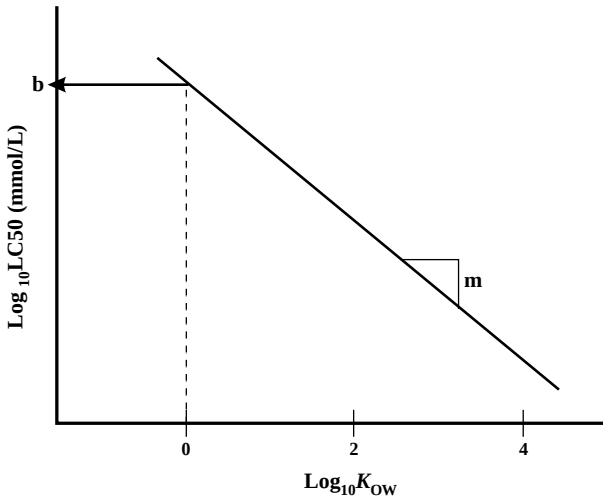

Figure 2-1. Schematic diagram of the $\log_{10}$LC50 versus $\log_{10}K_{OW}$ relationship. At $\log_{10}K_{OW} = 0$ ($K_{OW} = 1$), the concentration in water equals the concentration in octanol.

Thus, the target lipid narcosis model differentiates between the chemical and biological parameters of the $\log_{10}$LC50 - $\log_{10}K_{OW}$ regression coefficients in the following way

$$\begin{aligned} \text{slope} \quad &= \quad \text{chemical} \\ m \quad &= \quad -a_1 \\ \text{intercept} \quad &= \quad \text{chemical} \quad \text{biological} \\ b \quad &= \quad -a_0 \quad + \quad \log_{10}C^*_L \end{aligned} \qquad (2\text{-}17)$$

The chemical parameters a_0 and a_1 are associated with the LFER between octanol and target lipid (Equation 2-12). The biological parameter is the critical target lipid concentration C^*_L. This result is important because it suggests that the slope $m = -a_1$ of the $\log_{10}$LC50- $\log_{10}K_{OW}$ relationship should be the same regardless of the species tested since it is a chemical property of the target lipid - the slope of the LFER. Of course this assumes that the target lipid of all species have the same LFER relative to octanol. This seems to be a reasonable expectation since the mechanism of narcosis is presumed to involve the phospholipids in the cell membrane and it appears to be a ubiquitous mode of action. However, the biological component of the intercept C^*_L (Equations 2-13 and 2-17) should vary with species sensitivity to narcosis since it is commonly found that different species have varying sensitivity to the effects of exposure to the same chemical. The expectations that follow from the target lipid model - that the slope should be constant among species and that the intercepts should vary among species - is the basis for the data analysis presented below.

2.5 Acute Lethality Database Compilation

An acute lethality (LC50) database for type I narcotics from water-only toxicity tests was compiled from available literature sources. The principal criterion for acceptance was that a number of chemicals were tested using the same species so that the slope and intercept of the $\log_{10}$LC50 - $\log_{10}K_{OW}$ relationship could be estimated. The data were restricted to acute exposures and a mortality end point to limit the sources of variability. A total of 33 aquatic species including amphibians, fishes, arthropods (insects

and crustaceans), molluscs, annelids, coelenterates and protozoans were represented. Seventy-four individual datasets were selected for inclusion in the database which provided a total of 796 individual data points. Details are provided in Appendix A. The individual chemicals which comprise the database are listed in Appendix B. There are 156 different chemicals including halogenated and non-halogenated aliphatic and aromatic hydrocarbons, PAHs, alcohols, ethers, furans, and ketones.

The $\log_{10}K_{OW}$ values and aqueous solubilities of these chemicals were determined using SPARC (SPARC Performs Automated Reasoning in Chemistry) (Karickhoff et al., 1991), which utilizes the chemical's structure to estimate various properties. The reliability of SPARC was tested using $\log_{10}K_{OW}$ values measured using the slow stir flask technique (de Bruijn et al., 1989). Fifty three compounds such as phenols, anilines, chlorinated monobenzenes, PAHs, PCBs and pesticides were employed. A comparison of the $\log_{10}K_{OW}$ values measured using the slow stir flask technique to the SPARC estimates demonstrates that SPARC can be used to reliably estimate measured $\log_{10}K_{OW}$ values over nearly a seven order of magnitude range of $\log_{10}K_{OW}$ (Figure 2-2A). Note that this comparison tests both SPARC and the slow stir measurements, since SPARC is not parameterized using octanol-water partition coefficients (Hilal et al., 1994).

2.5.1 Aqueous Solubility

The toxicity data were screened by comparing the LC50 value to the aqueous solubility, S, of the chemical (Figure 2-2B). (Note: For this and other figures in this document where a large number of data points are available, the plotting procedure limits the actual number of data plotted.) Individual LC50 values were eliminated from the database if the LC50 > S, which indicated the presence of a separate chemical phase in the experiment. For these cases, mortality must have occurred for reasons other than narcosis - for example, the effect of the pure liquid on respiratory surfaces - since the target lipid concentration cannot increase above that achieved at the water solubility concentration. A total of 55 data points were eliminated, decreasing

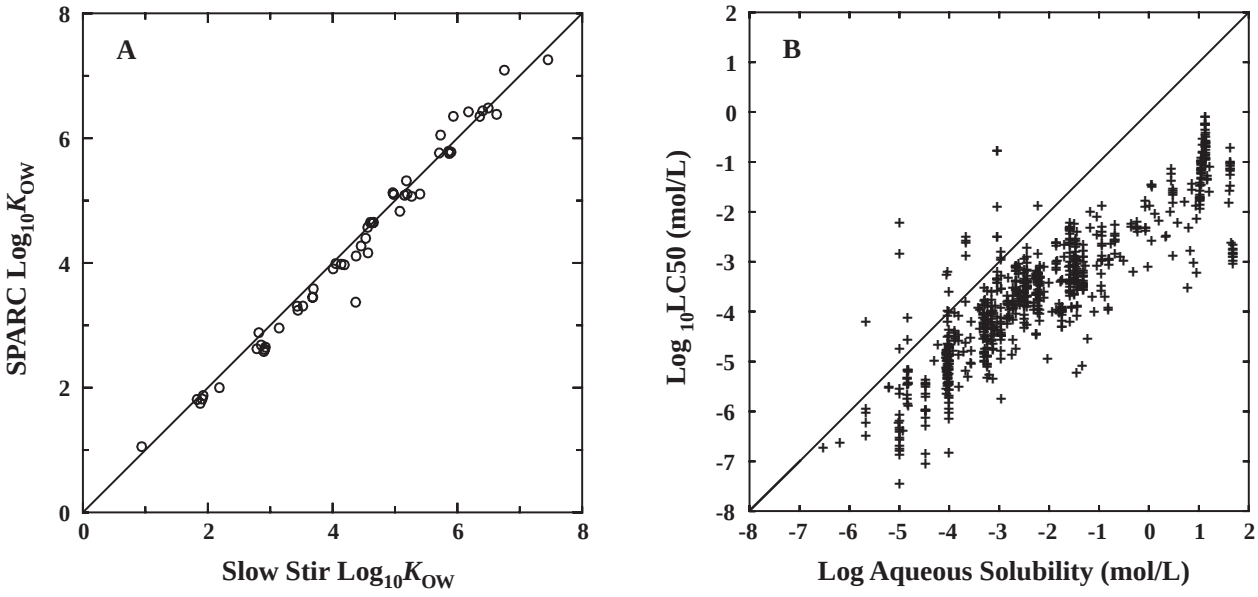

Figure 2-2. Comparisons of (A) $\log_{10}K_{OW}$ predicted by SPARC versus measured $\log_{10}K_{OW}$ using slow stir method and (B) reported $\log_{10}$LC50 values versus the aqueous solubility estimated by SPARC. The diagonal line represents equality.

the number to 736 and the number of individual chemicals to 145 (Appendix B).

2.5.2 Exposure Duration

The duration of exposure varied in the dataset from 24 to 96 hours (Appendix A). Before the data could be combined for ana ysis, the individual datasets should be adjusted to account for this difference. The required equilibration time may vary with both organism and chemical. An increase in either organism body size or chemical hyodrphobicity may increase the time to reach equilibrium.

To determine if acute lethality for narcotic chemicals varied with exposure time, cata were selected where toxicity was reported at multiple exposure times for the same organism and the same chemical. For seven fish species, data were available for 96 hours and either 24, 48 or both 24 and 48 hours of exposure. Arithmetic ratios of the LC50 values for 48 to 96 hours and for the 24 and 96 hours exposure are compared to log 10 K_{OW}. The 48 to 96 hour ratio is 1.0 for essentially all the data (Figure 2-3A). The 24 to 96 hour ratio is larger, approaching 1.4 for the higher Kow chemicals (Figure 2-3B). A linear regression is used to fit the relationship in Figure 2-3B.

$$LC50_{(24)}/LC50_{96} = 0.0988 \log_{10} K_{OW} + 0.9807 \qquad (2\text{-}18)$$

where $LC50_{24}$ and $LC50_{96}$ are the LC50 values for 24 and 96 hour exposures. Since approximately 46% of the data points in the overall database represent narcosis mortality after exposure of fish to a chemical for 24 hours, these data were converted to 96 hour LC50 values using Equation 2-18 for chemicals having $\log_{10}K_{OW}$ values of >1. No correction factor is applied to 24 hour toxicity data for invertebrates and fishes exposed to chemicals having $\log_{10}K_{OW}$ values of <1 (Di Toro et al., 2000).

2.6 Data Analysis

The analysis of the toxicity data is based on the target lipid model assumption that the slope of the $\log_{10}K_{OW}$ is the same for all species. This assumption was tested using a linear regression model to estimate the species-specific body burdens and the universal narcosis slope.

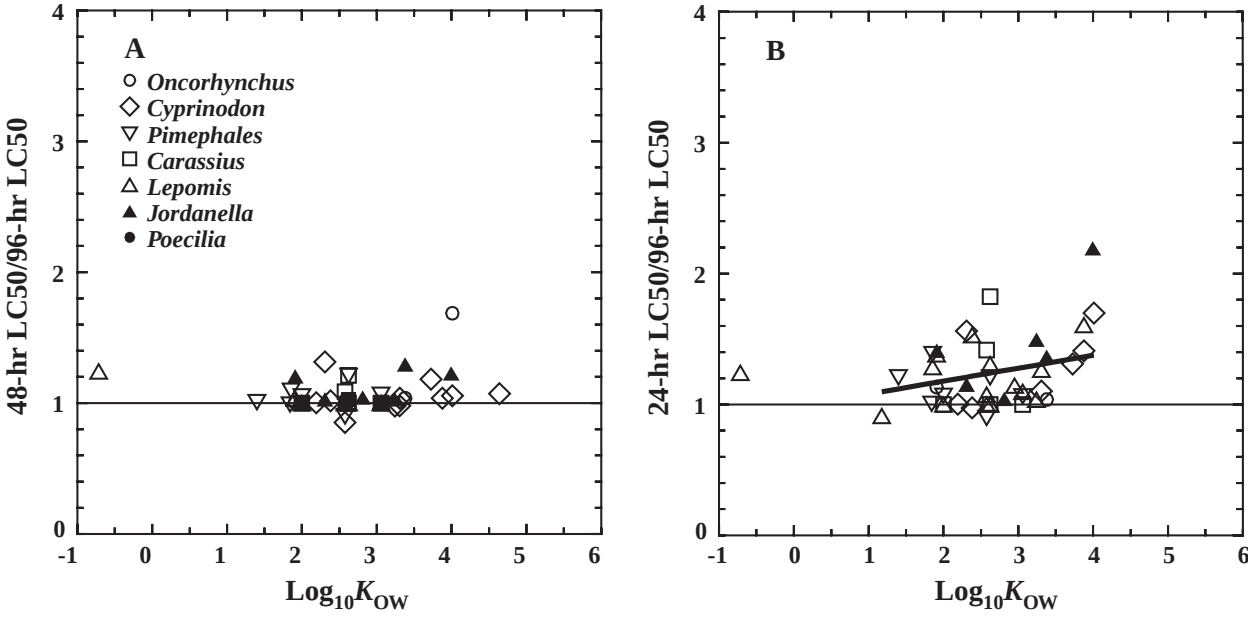

Figure 2-3. Ratios of (A) 48- to 96-hour LC50 values and (B) 24- to 96-hour LC50 values versus $\log_{10}K_{OW}$. The line in (B) is the regression used to correct the 24-hour LC50 to 96-hour LC50.

2.6.1 Regression Model

Consider a species k and a chemical j. The $LC50_{k,j}$ for that species-chemical pair is

$$\log_{10}LC50_{k,j} = \log_{10}C_L^*(k) - a_0 - a_1 \log_{10}K_{OW}(j) \quad (2\text{-}19)$$

$$= b_k - a_1 \log_{10}K_{OW}(j) \quad (2\text{-}20)$$

where

$$b_k = \log_{10}C_L^*(k) - a_0 \quad (2\text{-}21)$$

is the y-intercept. The problem to be solved is: how to include all the b_k, k = 1,...,N_S corresponding to the N_s = 33 species and a single slope a_1 in one multiple linear regression model equation.

The solution is to use a set of indicator variables $*_{ki}$ that are either zero or one depending on the species associated with the observation being considered. The definition is

$$\delta_{ki} = 1 \qquad k = i$$

$$\delta_{ki} = 0 \qquad k \neq i \quad (2\text{-}22)$$

which is the Kronecker delta (Kreyszig, 1972). The regression equation can be formulated using δ_{ki} as follows

$$\log_{10}LC50_{i,j} = a_1 \log_{10}K_{OW}(j) + \sum_{k=1}^{N_S} b_k \delta_{ki} \quad (2\text{-}23)$$

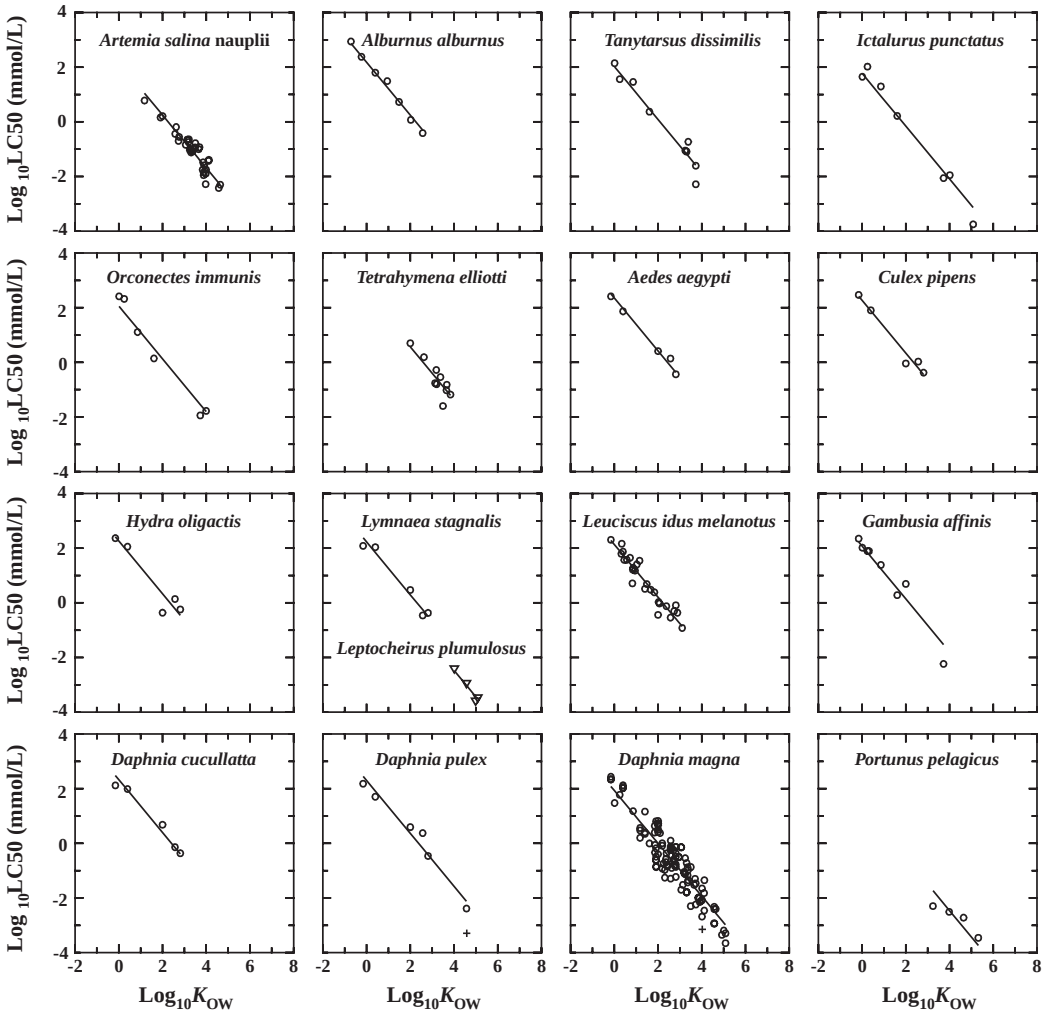

Figure 2-4. $Log_{10}LC50$ versus $log_{10}K_{OW}$ for the indicated species. The line has a constant slope of −0.945. The y-intercepts vary for each species. Outliers are denoted by a plus symbol (+).

Equation 2-23 is now a linear equation with N_s+1 independent variables: $\log_{10}K_{OW}(j)$ and δ_{ki}, k = 1,...,N_s. There are N_s+1 coefficients to be fit: a_1 and b_k, k = 1,...,N_S. For each $LC50_{ij}$ corresponding to species i and chemical j, one of the b_k corresponding to the appropriate species k = i has a unity coefficient $\delta_{ii} = 1$ while the others are zero. The way to visualize this situation is to realize that each row of data consists of the LC50 and these N_S+1 independent variables, for example for j = 1 and i = 3

$\log_{10}(LC50_{ij})$	$\log_{10}(K_{OW}(j))$	δ_{1i}	δ_{2i}	δ_{3i}	...	δ_{Nsi}
0.788	1.175	0	0	1	0	0

(2-24)

which is actually the first of the 736 records in the database. The result is that b_3 is entered into the regression equation as the intercept term associated with species i = 3 because that δ_{ki} is one for that record. By contrast, the slope term $a_1\log_{10}K_{OW}(j)$ is always included in the regression because there is always an entry in the $\log_{10}K_{OW}(j)$ column (Equation 2-24). Hence, the multiple linear regression estimates the common slope a_1 and the species-specific intercepts b_k, k = 1,...,N_s.

A graphical comparison of the results of fitting Equation 2-23 to the full dataset are shown in Figure 2-4 for each of the 33 species. The regression coefficients are tabulated and discussed subsequently after a further refinement is made to the model. The lines appear to be representative of the data as a whole. There appear to be no significant deviations from the common slope. A few outliers, which are plotted as +, were not included in the regression analysis. An outlier is identified if the difference between predicted and observed LC50 values are greater than one log unit when they are included in the regression. This decreases the total number of data points from 736 to 722.

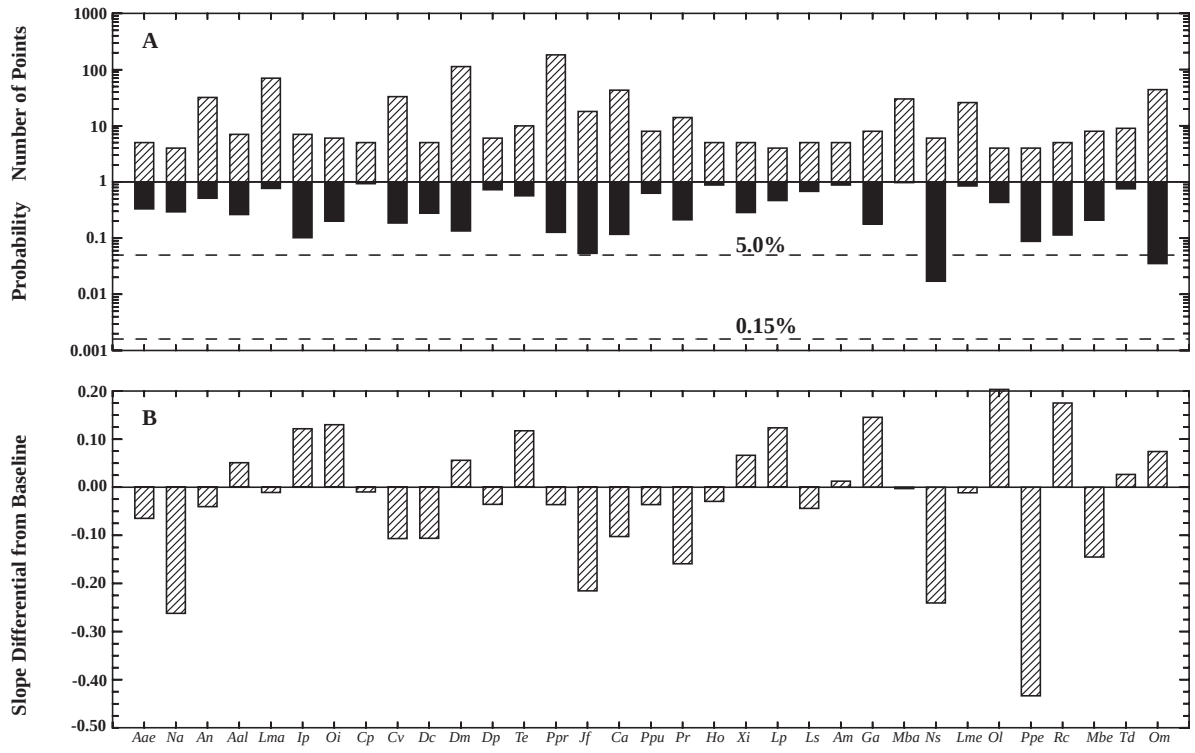

Figure 2-5 Statistical comparison of slopes fitted to individual species to the universal slope of −0.945 showing (A) the probability that the difference occurred by chance (filled bars) and number of data points in the comparison (hatched bars) for each species in the database, and (B) the deviations of the individual estimates from the universal slope.

2.6.2 Testing Model Assumptions

The adequacy of the regression model is tested by answering three questions:

1. Are the data consistent with the assumption that the slope is the same for each species tested?
2. Does the volume fraction hypothesis (Abernethy et al., 1988) provide a better fit?
3. Are there systematic variations for particular chemical classes?

The first assumption, that the slope estimated for a particular species is statistically indistinguishable from the universal slope a_1 = -0.97 without chemical class correction (see Section 2.5.4), can be tested using conventional statistical tests for linear regression analysis (Wilkinson, 1990). The method is to fit the data for each species individually to determine a species-specific slope. Then, that slope is tested against the universal slope a_1 = -0.97 without chemical class correction to determine the probability that this difference could have occurred by chance alone. The probability and the number of data points for each species are shown in Figure 2-5A. The slope deviations are shown in Figure 2-5B. Some of the slope deviations are quite large. However, only three species equal or exceed the conventional significance level of 5% for rejecting the equal slope hypothesis.

Testing at the 5% level of significance is misleading, however, because there is a one in twenty chance of rejecting one species falsely when 33 species are being tested simultaneously. The reason is that the expected number of rejections for a 5% level of significance would be 33 x 0.05 = 1.65, i.e., more than one species on average would be rejected due to statistical fluctuations even though all the slopes are actually equal. In fact, only 20 tests at 5% would, on average, yield one slope that would be incorrectly judged as different. The correct level of significance is (1/33)(1/20) = 0.152% so that the expected number of rejections is 33 x 0.00152 = 0.05 or 5% (Wilkinson, 1990). This level of significance is displayed together with the slope data presented in Figure 2-5A. As can be seen, there is no statistical evidence for rejecting the claim of equal slopes for the tested species. As would be expected, when 5% was used as the level of significance two species were identified as having unique slopes. When the current level of significance (0.00152) was used for the 33 samples none were significantly different.

2.6.3 Volume Fraction Hypothesis

The volume fraction hypothesis asserts that narcotic mortality occurs at a constant volume fraction of chemical at the target site of the organism (Abernethy et al., 1988). Basically, this involves expressing the LC50 as a volume fraction of chemical rather than a molar concentration. This is done using the molar volume of the chemicals (see column MV in Appendix B). The LC50 on a molar volume basis is

$$LC50(cm^3/L) = LC50\,(mmol/L) \times MV\,(cm^3/mmol) \quad (2\text{-}25)$$

The question is: does using molar volume as the concentration unit improve the regression analysis? The results are shown below

	Molar concentrations (mmol/L)	Molar volumes (cm^3/L)
Slope	-0.97 ±0.012	-0.90 ± 0.012
R^2	0.94	0.96

The coefficient of determination (R^2 value) for the volume fraction analysis (0.96) is slightly greater than that for the molar concentration (0.94). Because they are essentially the same, this document uses the molar concentration rather than those based on the volume fraction. Importantly, the slope for both volume and weight units of concentration is not unity.

2.6.4 Chemical Classes

The analysis presented above assumes that all of the 145 chemicals listed in Appendix B are narcotic chemicals. That is, the only distinguishing chemical property that affects their toxicity is K_{OW}.

A criteria has been suggested that can be used to determine whether a chemical is a narcotic (Bradbury et al., 1989), namely that it demonstrates additive toxicity with a reference narcotic. However, it is not practical to test each possible chemical. The more practical test is whether the toxicity can be predicted solely from the $\log_{10}LC50$ - $\log_{10}K_{OW}$ regression. In fact, this is used in methods that attempt to discriminate reference narcotics from other classes of organic chemicals (Verhaar et al., 1992).

Using this approach, differences in toxicity among chemical classes would be difficult to detect if differing species were aggregated or different slopes were allowed in the regression analysis. However, with the large dataset employed above, these differences can be seen by analyzing the residuals grouped by chemical class.

The criteria for choosing the relevant classes are not obvious without a detailed understanding of the mechanism of narcotic toxicity. Hence, the conventional organic chemical classes based on structural similarities, e.g. ethers, alcohols, ketones, etc., are used. The results are shown in Figure 2-6A. The means ±2 standard error (SE) of the means are shown for each class. Although not a rigorous test, the ±2 SE range does not encompass zero for certain classes. Thus, it is likely that there are statistically significant chemical class effects.

2.6.4.1 Statistical Analysis of K_{OW}-Toxicity Relationships

A rigorous test is conducted by including correction constants for each of the chemical classes in a manner that is analogous to Equation 2-23. The model equation is formulated using N_C - 1 corrections, Δc_ℓ, corresponding to the $\ell = 1,...,N_C$ - 1 chemical classes. These are interpreted as corrections relative to the reference class which is chosen to be aliphatic non-halogenated hydrocarbons. The regression equation is formulated as before with a variable $\xi_{\ell j}$ that is one if chemical j is in chemical class ℓ and zero otherwise

$\xi_{\ell j} = 1$ if chemical j is in class ℓ

$\xi_{\ell j} = 0$ otherwise (2-26)

The regression equation that results is

$$\log_{10}LC50_{i,j} = a_1\log_{10}K_{OW}(j) + \sum_{k=1}^{N_S} b_k\delta_{k_i} + \sum_{\ell=1}^{N_C-1}\Delta c_\ell\xi_{\ell j} \quad (2\text{-}27)$$

Each data record now contains t he dependent variable $\log_{10}LC50_{i,j}$, the independent variables $\log_{10}K_{OW}(j)$, and the δ_{ki}, $k = 1,...,N_s$ and $\xi_{\ell j}$, $\ell = 1,...,N_C$ - 1 indicator variables which are 0 or 1 depending on which species and which chemical class is represented by the $LC50_{i,j}$.

Only N_C - 1 chemical class corrections are required because including N_C class corrections under-determines the equation set with one too many unknowns. The reason is that every equation would have one b_i and one Δc_ℓ for species i and chemical j in chemical class ℓ. Since this condition would occur in every equation there is no unique solution for the b_k and the Δc_ℓ values. One of these constants could be adjusted by an arbitrary amount and the rest could then be adjusted to compensate while still achieving the same fit of the data. Thus, a reference chemical class is chosen: non-halogenated aliphatic hydrocarbons for which $\Delta c_\ell = 0$. The remaining regression constants Δc_ℓ, $\ell = 1,...,N_c$ - 1 are then the differential toxicity of chemical class ℓ relative to the reference chemical class. This is the reason for the Δc notation.

The requirement for a chemical class correction is decided using a statistical test that compares the Δc_ℓ values that result from the regression to the hypothesis $\Delta c_\ell = 0$. For the classes which are not statistically different, they are included in the reference class and the parameters are re-estimated. This is continued until all the remaining Δc_ℓ values are statistically different from zero. After a number of trials, it was found that treating halogen substitutions as a separate additive correction gave the least number of statistically significant class corrections. Thus, chemical class corrections are applied to the base structure, if necessary, and an additional correction is made if any substitute is a halogen. Therefore,

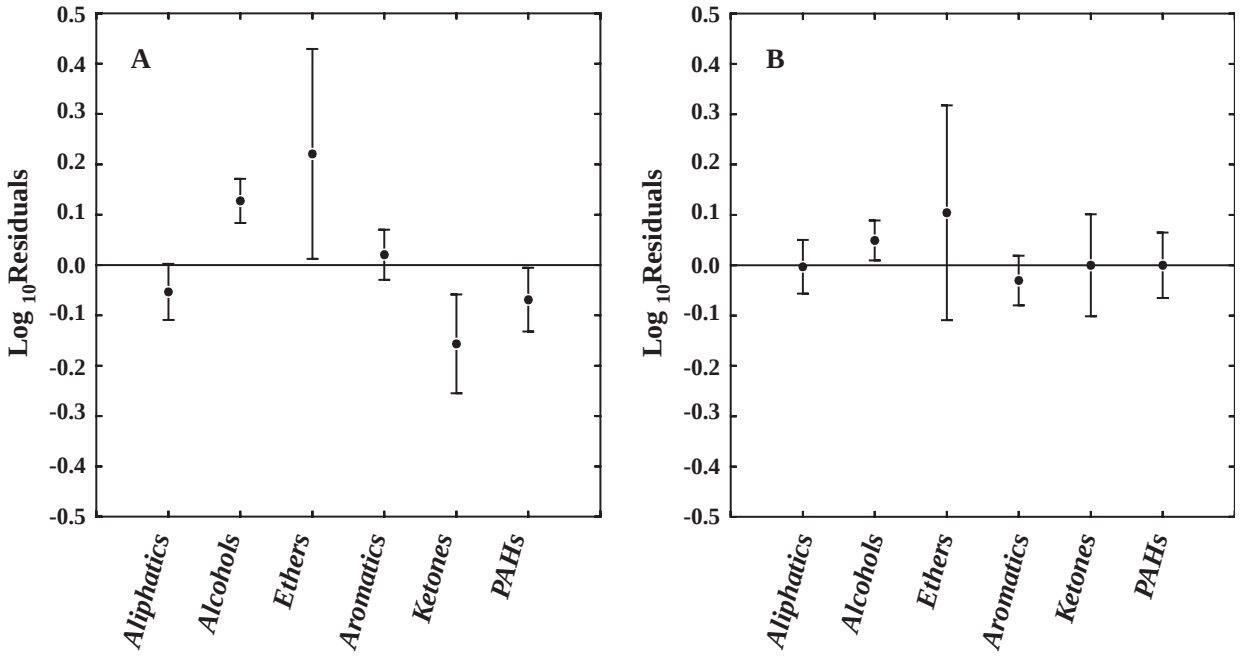

Figure 2-6. Chemical class comparisons of residuals from the regression grouped by class with (A) mean ± 2 standard errors and (B) chemical class corrections included in the regression.

for halogenated chemicals it is possible that two $\xi_{ij} = 1$ in Equation 2-27. The chemical classes are listed in Appendix B.

The results of the final regression analysis are listed in Table 2-1. Both the logarithmic b_i and arithmetic 10^{b_i} values of the intercepts are included together with their standard errors. Chemical classes which demonstrate higher potency than the reference class are ketones and PAHs. Halogenation increases the potency as well. After accounting for different potencies in the chemical classes, the mean residuals are statistically indistinguishable from zero (Figure 2-6B).

2.6.4.2 Standard Errors and Residuals

The standard errors of the body burdens $SE(b_i)$ found from the regression (Equation 2-27) are in an almost one-to-one correspondence with the number of data points for that species. Thus, the b_i for *Pimephales promelas* (fathead minnow) with 182 data points has a 10% coefficient of variation, $CV(b_i) = SE(b_i)/b_i$, while the b_i for *Neanthes arenaceodentata* (polychaete worm) with 4 data points has a 50% coefficient of variation (Table 2-1). The relationship of the sample size (N) to the coefficient of variation of the estimated critical body burden, $CV(b_i)$, is shown in Figure 2-7A.

The residuals are log normally distributed (Figure 2-7B) and exhibit no trend with respect to K_{OW} (Figure 2-7C) which confirms the assumption underlying the use of regression analysis. The reason they are restricted to ±1 order of magnitude is that 14 data points outside that range were originally excluded as outliers (for some values previously less than ± one order of magnitude, chemical class corrections produced values slightly greater than one order of magnitude as shown in Figure 2-7C).

2.6.4.3 Chemical Class Corrections

The corrections due to chemical classes reduce the critical body burden by a factor of approximately one-half for ketones and PAHs. Correction for halogenation reduces it further by

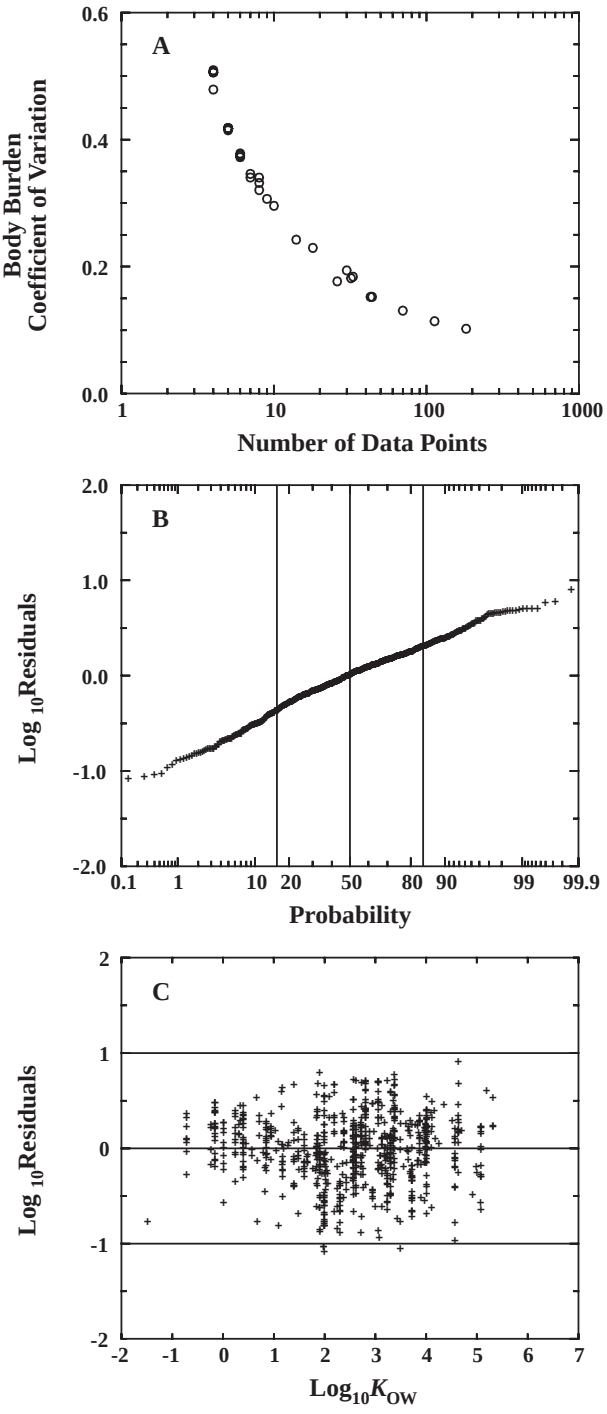

Figure 2-7. The coefficient of variation of the estimated species-specific body burdens versus (A) the number of data points for that species (B), the log probability plot of the residuals, and (C) the residuals versus $\log_{10}K_{OW}$.

0.570 (Table 2-1). Thus, a chlorinated PAH would exhibit a critical body burden of approximately one-third of a reference narcotic. The coefficients of variation for these corrections are approximately 10%.

The chemical class differences among the type I narcotics affect the LC50-K_{OW} relationship. The model no longer predicts a single straight line for the $\log_{10}$LC50-$\log_{10}K_{OW}$ relationship for all narcotic chemicals. What is happening is that the y-intercepts are changing due to the changing $)c_R$ values. The model (Equation 2-27) when applied to a single species k is

$$\log_{10}LC50_{k,j} = a_1 \log_{10}K_{OW}(j) + b_k + \sum_{\ell=1}^{N_C-1} \Delta c_\ell \xi_{\ell j} \qquad (2\text{-}28)$$

This is a straight line if only reference narcotics are considered Δc_ℓ, = 0 or if only one chemical class correction is involved, e.g., all halogenated reference narcotics. Otherwise, more than one Δc_ℓ, enters into Equation 2-28 and the line is jagged. Figure 2-8 presents three examples. The deviations from the reference narcosis straight line are caused by the different chemical class potencies.

2.7 Universal Narcosis Slope

The universal narcosis slope: m = -0.945±0.014 which results from the final analysis that includes chemical class corrections (Table 2-1) is smaller than that determined above without chemical class corrections (-0.97±0.012). It is close to unity, a value commonly found (Hansch and Leo, 1995), and larger than the average of individual slopes (-0.86±0.14) reported by Van Leeuwen et al. (1992), but comparable with a recent estimate for fathead minnows of -0.94 (Di Toro et al., 2000).

The fact that the slope is not exactly one suggests that octanol is not quite lipid. However, it is also possible that for the more hydrophobic chemicals in the database, the exposure time may not have been long enough for complete equilibration of water and lipid to have occurred. To test this hypothesis, the regression analysis is

restricted to successively smaller upper limits of $\log_{10}K_{OW}$. The results are listed below

Maximum $\log_{10}K_{OW}$	3.5	4.0	4.5	5.0	5.5
Slope	-0.959	-0.970	-0.958	-0.950	-0.945
Standard Error	0.018	0.015	0.015	0.014	0.015

The variation is within the standard errors of estimation, indicating that there is no statistically significant difference if the higher $\log_{10}K_{OW}$ data are removed from the regression. This suggests that the universal narcosis slope is not minus one but is actually -0.945 ± 0.014.

One consequence of the use of a universal narcosis slope is that the species sensitivity ranking derived from comparing either the water-only LC50 values or the critical body burdens of various species are the same. This occurs because the critical body burden is calculated from the LC50 value and the universal slope (Equations 2-14 and 2-15)

$$\log_{10}C_L^* = \log_{10}LC50 + 0.945\log_{10}K_{OW} \qquad (2\text{-}29)$$

If this were not the case, then the species sensitivity order could be reversed if LC50 values or C_L^* were considered.

Equation 2-29 is important because it can be used to compute the critical body burden of any type I narcotic chemical. Thus it predicts what the critical body burden should be for a particular species at its LC50 value. This would be the concentration that would be compared to a directly measured critical body burden. It can be thought of as a normalization procedure that corrects type I narcotics for the varying K_{OW} and places them on a common footing, namely, the critical body burden.

The motivation for the development of the target lipid model was to apply it to mixtures of PAHs and other persistent narcotic chemicals in sediments. The narcosis database used to determine the universal narcosis slope and the critical body burdens consists of 145 chemicals, of which 10 are un-substituted and substituted PAHs (Di Toro et al., 2000). A comparison of the LC50 data for just these chemicals and the target lipid

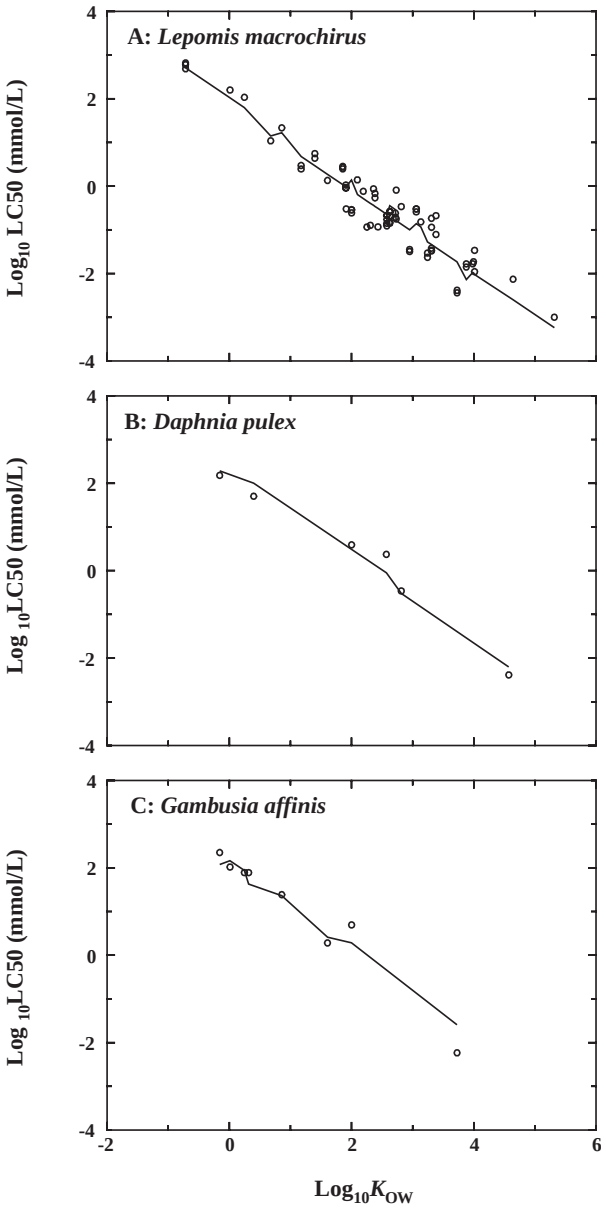

Figure 2-8. $\log_{10}$LC50 versus $\log_{10}K_{OW}$ for (A) *Lepomis macrochirus*, (B) *Daphnia pulex*, and (C) *Gambusia affinis*. The line connects the individual estimates of the $\log_{10}$LC50 values, including the chemical class correction.

model is shown in Figure 2-9. The solid $\log_{10}$LC50 - $\log_{10}K_{OW}$ lines are computed using the universal narcosis slope and the appropriate body burdens for PAHs for each organism listed. The dotted lines apply to the chloronaphthalenes which have a slightly lower critical body burden due to the halogen substitution. The lines are an adequate fit of the data, although the scatter in the *D. magna* data is larger than some of the other

b_i = y-intercept.
SE(b_i)=Standard error of b_i.
Δc_ℓ =chemical class correction to the y-intercept.
SE(Δc_ℓ)=standard error of Δc_ℓ.
†=Standard errors of 10^{b_i} and $10^{\Delta c_\ell}$ are based on the assumption that the estimation errors for b_i and Δc_ℓ are gaussian. The formulas follow from the standard error of a log normally distributed random variable (Aitchison and Brown, 1957). For $x = b_i$ or Δc_ℓ, $\mu_\ell = 2.303x$, $\sigma_\ell = 2.303\ SE(x)$, and $SE(10^x) = SE(e^{2.303x}) = e^{\mu_\ell}\sqrt{e^{2\sigma_\ell^2} - e^{2\sigma_\ell^2}}$.

species with multiple sources of data and there is a clear outlier for *Americamysis bahia*. It is for this reason that the slope representing all data for narcosis chemicals is used to derive the target lipid concentration from water-only toxicity data for PAHs in Section 3 of this document.

2.8 Comparison to Obsered Body Burdens

The target lipid model predicts the concentration in octanol (the y-intercept) that causes 50% mortality in 96 hours. The question is: how do these compare to measured critical body burdens? The species-specific y-intercepts, b_i, are related to the target lipid concentration by the relationship

$$\text{y-intercept} = b_i = \log_{10} C_L^*(i) - a_0 \qquad (2\text{-}30)$$

or, with chemical class corrections,

$$\text{y-intercept} = b_i + \Delta c_\ell = \log_{10} C_L^*(i) - a_0 \qquad (2\text{-}31)$$

for species i and chemical class ℓ, where a_0 is the parameter in the LFER between octanol and target lipid (Equation 2-12).

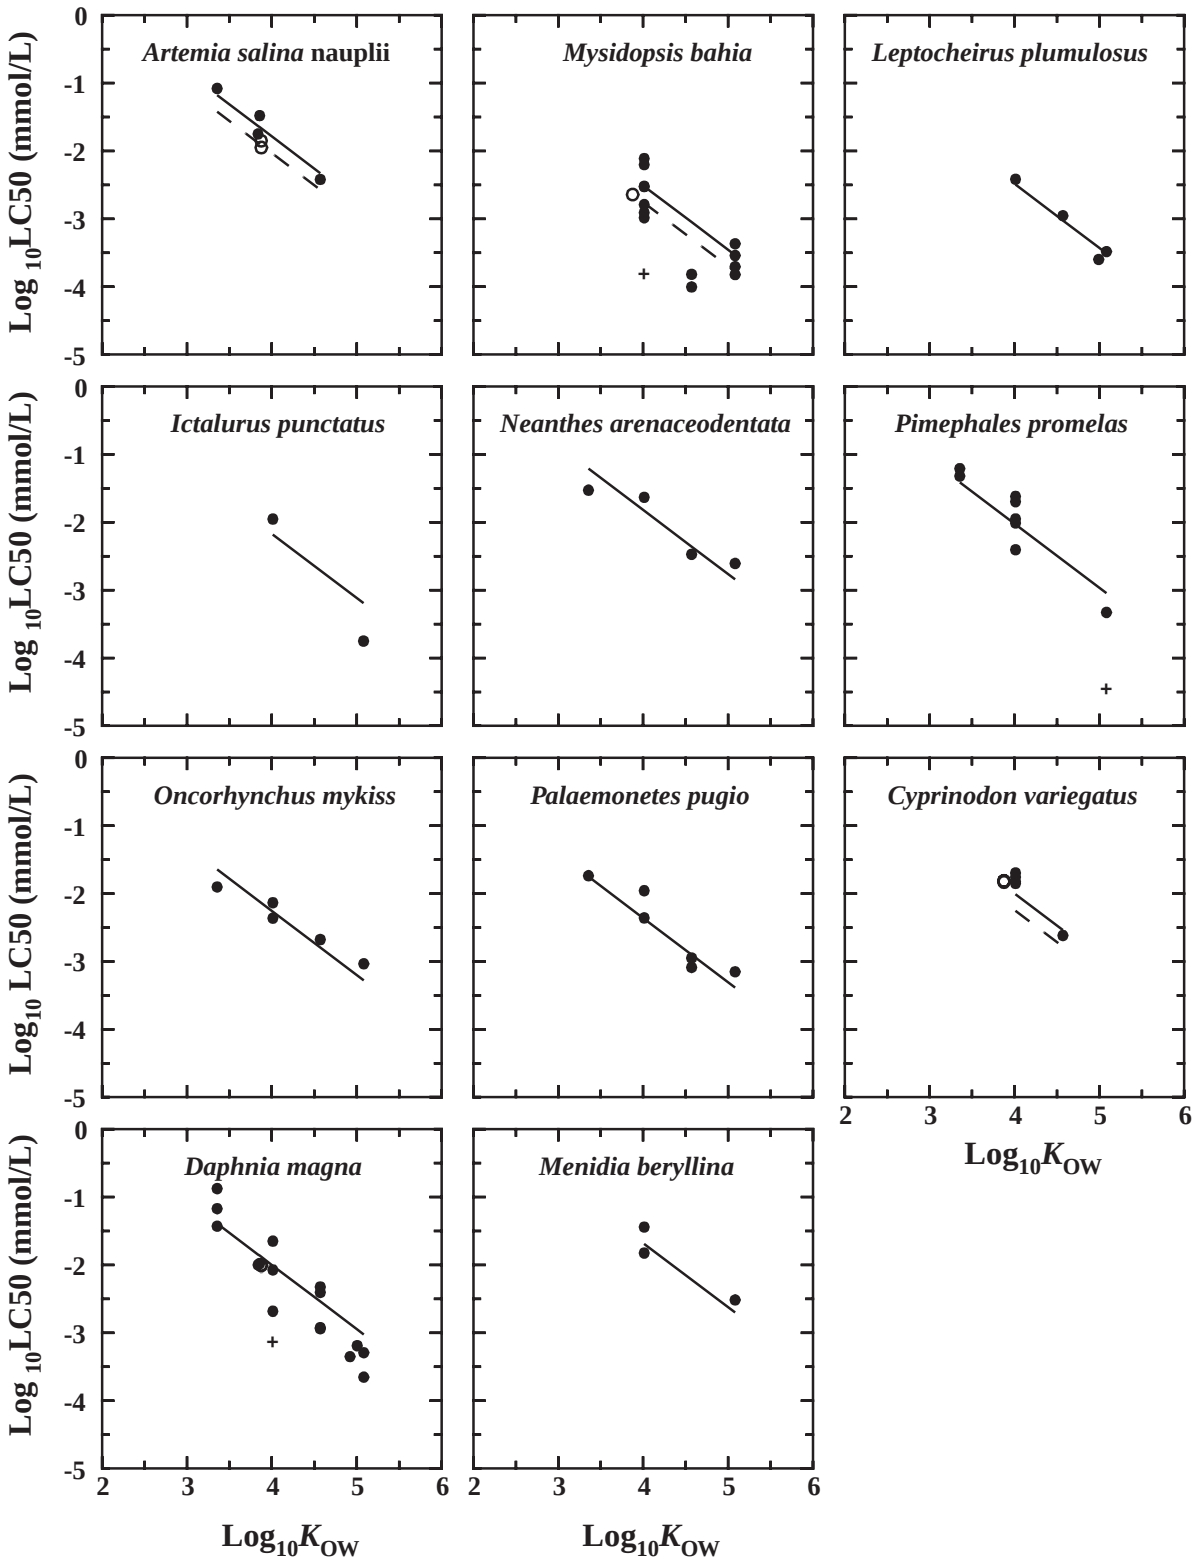

Figure 2-9. Comparison of target lipid model, line-of-fit and observed LC50 data for individual PAHs, by species.

The relationship between the predicted concentration in octanol, $b_i + \Delta c_\ell$, to the concentration measured in extracted lipid, $\log_{10}C_L^*$, is examined in Table 2-2 which lists observed LC50 body burdens (µmol/g lipid) and predicted critical body burdens (µmol/g octanol) for organisms in the database for which measured lipid-normalized critical body burdens were available. Three fish species: *Gambusia affinis* (mosquito fish), *Poecilia reitculata* (guppy) and *P. promelas*, and a crustacean: *Portunus pelagicus* (crab) are compared in Figure 2-10. The predicted and measured body burdens differ by less than a factor of 1.6. The fish were observed to have higher critical body burdens than the crustacean, which the model reproduces.

The apparent near equality between the estimated and measured critical body burdens, which come from two independent sets of data, strongly suggest that in fact

$$a_0 = 0 \qquad (2\text{-}32)$$

so that

$$\log_{10}C_L^*(i) = b_i + \Delta c_\ell = \text{y-intercept} \qquad (2\text{-}33)$$

This relationship implies that the target lipid is the lipid measured by the extraction technique used in the body burden datasets. This is an important practical result since it suggests that body burdens normalized to extracted lipid are expressed relative to the appropriate phase for narcotic toxicity. Since the intercepts appear to be the organism's lipid concentration, the y-intercepts ($b_i + \Delta c_\ell$) in the discussion presented below are referred to as body burden lipid concentrations although the units (µmol/g octanol) are retained since these are, in fact, the actual units of the intercepts.

2.9 Mixtures and Additivity

Narcotic chemicals, including PAHs, occur in the environment as mixtures, therefore, their mixture effects need to be appropriately resolved. If the toxicity of mixtures is additive, mixture effects can be assessed using the concept of toxic units. A toxic unit (TU) is defined as the ratio of the concentration in a medium to the effect concentration in that medium.

The additivity of the toxicity of narcotic chemicals in water has been demonstrated by a number of investigators. The results of mixture experiments which employed a large enough number of narcotic chemicals so that non-additive behavior would be detected is presented in Figure 2-11 as adopted from Hermens (1989). Three of the four experiments demonstrated essentially additive behavior and the fourth, a chronic exposure, was almost additive.

2.10 Aqueous Solubility Constraint

The existence of the need for a solubility cut-off for toxicity was suggested by Veith et al. (1983) based on data from fathead minnows (*P. promelas*) and guppies (*P. reticulata*). The highest dissolved concentration in water that can be achieved by a chemical is its aqueous solubility (S). Therefore, the maximum lipid concentration that can be achieved is limited as well. It is for this reason that the LC50 database is limited to chemicals with $\log_{10}K_{OW} \leq 5.3$. This is also the reason that the LC50 database that was used to generate the FCVs for specific PAHs in Section 3 of this document, was screened initially for LC50 values $\leq$ S, using the solubilities from Mackay et al. (1992), rather than $\log_{10}K_{OW} \leq 5.3$ used by Di Toro et al. (2000).

For sediments, a solubility constraint should be applied as well. This is readily calculated using the relationship between interstitial water and the organic carbon-normalized sediment concentration. Since the interstitial water concentration is limited by S, the sediment concentration should be limited by the concentration in sediment organic carbon that is in equilibrium with the interstitial water at the aqueous solubility. Therefore, observed sediment concentrations are limited by the condition

$$C_{OC} \leq C_{OC,max} = K_{OC}S \qquad (2\text{-}34)$$

Section 3

Toxicity of PAHs in Water Exposures and Derivation of PAH-Specific FCVs

3.1 Narcosis Theory, EqP Theory and WQC Guidelines: Derivation of PAH-Specific FCVs for Individual PAHs

Polycyclic aromatic hydrocarbons occur in the environment as mixtures. Therefore, in order to adequately protect aquatic life the approach used to derive a WQC FCV or sediment benchmark for PAHs must account for their interactions as a mixture. In this section, we present an approach for deriving FCVs for individual PAHs which can be used to derive the ESB for mixtures of PAHs.

Concepts developed by Di Toro et al. (2000) and presented in Section 2 of this document provide the technical framework for screening and analyzing aquatic toxicity data on PAHs (Tables 3-1, 3-2). In particular, Section 2 demonstrated that: (1) the universal slope of the K_{OW}-toxicity relationship for narcotic chemicals is the same for all aquatic species; and (2) the intercept of the slope at a K_{OW} of 1.0 for each species provides the LC50/EC50 in µmol/g octanol that indicates the critical body burden in and relative sensitivities of each species.

These concepts permit the use of the U.S. EPA National WQC Guidelines (Stephan et al., 1985) to derive WQC FCVs for individual PAHs and PAH mixtures. The universal slope is used with PAH-specific LC50/EC50 values to derive test-specific K_{OW} normalized reference acute values at a K_{OW} of 1.0. This normalization was performed to put the data on the toxicities of narcotic chemicals on an internally consistent scale. This was also performed using hardness when WQC were derived for metals. These K_{OW} normalized reference acute values are used to calculate species mean acute values (SMAVs) and genus mean acute values (GMAVs): (1) because only acute and chronic toxicity data from water-only tests with freshwater and saltwater species exposed to individual PAHs are used, a PAH chemical class correction is not needed; (2) the data are screened for acceptability following the requirements for use of species resident to North America, test durations, test quality, etc. of the U.S. EPA National WQC Guidelines (Stephan et al., 1985); (3) the PAH-specific species mean acute values (PAH-specific SMAVs) from Appendix C are adjusted using the universal slope of the K_{OW}-toxicity relationship from the narcotic chemical analysis that was shown to apply to all aquatic species in Section 2 (Equation 2-29) to derive the acute value for that species at a K_{OW} of 1.0 (K_{OW} normalized PAH-specific SMAV) (Appendix C); (4) the intercept of the slope at a K_{OW} of 1.0 provides the LC50/EC50 in µmol/g octanol that indicates the relative sensitivity of each tested species and PAH, which was used to calculate SMAVs and GMAVs in µmol/g octanol, which are indicative of critical tissue concentrations in organisms on a µmol/g lipid basis. The GMAVs are used to calculate the final acute value (FAV) applicable to PAHs at a K_{OW} of 1.0 (Stephan et al., 1985). This FAV at a K_{OW} of 1.0, when divided by the Final Acute-Chronic Ratio (FACR), becomes the FCV at a K_{OW} of 1.0. Importantly, the FCV for any specific PAH can then be derived by back calculating using FAV at a K_{OW} of 1.0, the K_{OW} of the specific PAH and the universal narcosis slope. When the PAH-specific FCV exceeds the known solubility of that PAH, the maximum contribution of that PAH to the toxicity of the mixture is set at the K_{OC} multiplied by the solubility of that PAH.

Final Acute Value = 9.31 µmol/g octanol
Final Acute-chronic Ratio = 4.16
Final Chronic Value = 2.24 µmol/g octanol

The FCV at a K_{OW} of 1.0 for PAHs derived in this section of the document differs slightly from that which would be derived for other narcotic chemicals according to Di Toro et al. (2000) in that it: (1) is derived using only acute and chronic toxicity data from water-only tests with freshwater and saltwater species exposed to individual PAHs, therefore, the data do not require the PAH chemical class correction; (2) the data are rigorously screened for acceptability following the requirements for the use of species resident to North America, test durations, test quality, etc. of the U.S. EPA National WQC Guidelines (Stephan et al., 1985). All other steps in the derivation of FCVs are the same as those used by Di Toro et al. (2000).

3.2 Acute Toxicity of Individual PAHS: Water Exposures

3.2.1 Acute Toxicity of PAHs

One hundred and four acute water-only toxicity tests with 12 different PAHs have been conducted on 24 freshwater species from 20 genera that meet the requirements of the U.S. EPA National WQC Guidelines (Stephan et al., 1985, see Appendix C). The tested life-stages of 15 of the genera were benthic (infaunal or epibenthic). The most commonly tested freshwater species were the cladocerans (*Daphnia magna* and *D. pulex*), rainbow trout (*O. mykiss*), fathead minnow (*P. promelas*) and bluegill (*Lepomis macrochirus*). The most commonly tested PAHs with freshwater organisms were acenaphthene, fluoranthene, fluorene, naphthalene, phenanthrene and pyrene.

Seventy-seven acute water-only toxicity tests with 8 different PAHs have been conducted on 30 saltwater species from 29 genera (Appendix C). The tested life-stages of 21 of the genera were benthic (infaunal or epibenthic). The most commonly tested saltwater species were the annelid worm (*N. arenaceodentata*), mysid (*Americamysis bahia*), grass shrimp (*Palaemonetes pugio*), pink salmon (*Oncorhynchus gorbuscha*), and sheepshead minnow (*Cyprinodon variegatus*). The most commonly tested PAHs with saltwater organisms were acenaphthene, fluoranthene, naphthalene, phenanthrene and pyrene.

3.2.2 Acute Values at a K_{ow} of 1.0

The rules for test acceptability of the National WQC Guidelines (Stephan et al., 1985) were used to identify the LC50 values or EC50 (µg/L) values from individual acute aquatic toxicity tests (Appendix C) and these values were used to derive the K_{OW} normalized GMAV (µmol/g octanol) in the following manner. The goal of this process was to convert individual LC50 or EC50 values that vary for a species across PAHs into a PAH-specific GMAV normalized to a K_{OW} of 1.0. The use of normalizing factors in FCV derivation is not unique to this ESB document. The use of K_{OW} to normalize the toxicity of PAHs to put the toxicity data on an internally consistent scale is analogous to the hardness normalization applied to the freshwater WQC for cadmium, copper, lead, nickel and zinc and the pH and temperature normalization applied to the freshwater WQC for ammonia. For multiple PAHs tested against one species, the K_{OW} normalization should result in similar PAH-specific SMAVs. The first step in the analysis of published LC50 or EC50 values was to compare them to the known solubility in water of the PAH tested. If the LC50 or EC50 concentration exceeded the solubility of the tested PAH, the published LC50/EC50 is in parentheses in Appendix C, the solubility is listed in bold in Appendix C as a "greater than" acute value to indicate that the actual toxicity of the dissolved PAH was unknown. For these tests, this greater than solubility value, and not the published LC50 or EC50 value, was used in further calculations only when there were no acute values for that species at concentrations less than the solubility. Next, the LC50, EC50 or greater than solubility value was converted to mmol of the tested PAH/L. When the same PAH was tested more than once against a species, the geometric mean of all LC50 or EC50 values was calculated to determine the PAH-specific SMAV using the rules in Stephan et

al. (1985). The -0.945 universal slope of the toxicity/K_{OW} relationship (Equation 2-29) was applied to the PAH-Specific SMAVs (µmol/L) to calculate the PAH-specific SMAV (µmol/g octanol) at a K_{OW}=1.0. The SMAV for all tested PAHs is the geometric mean of the PAH-Specific SMAVs at a K_{OW} of 1.0. The GMAV (µmol/g octanol) at a K_{OW} of 1.0 is the geometric mean of the SMAVs at a K_{OW} of 1.0.

The SMAVs at a K_{OW} of 1.0 were similar for multiple PAHs (Appendix C). For 18 freshwater and saltwater species, two to nine different PAHs were tested. The ratios of the highest to lowest acute values for multiple PAHs tested against an individual species before normalization was 1.37 to 1170; an average ratio of 105. In contrast, the range in the ratios of the highest to lowest PAH-specific SMAVs at a K_{OW} of 1.0 was 1.4 to 12.2; average ratio of 4.27. For 10 of the 18 (56%) species tested against multiple PAHs, the ratio of high to low SMAVs at a K_{OW} of 1.0 was 4.0 or less. This compares favorably with the factor of four or less difference in the acute values for 12 of 19 (63%) of the same species in multiple tests with the same PAH. Therefore, the variability of SMAVs at a K_{OW} of 1.0 across PAHs is similar to the variability inherent for these data in acute toxicity testing with only one PAH. This suggests that the GMAVs provide data across PAHs that indicate the relative sensitivity of that species that can be used to describe species at risk and to calculate the FAV.

The K_{OW}-normalized GMAVs (not including values greater than the solubility of the tested PAH) range from 7.63 µmol/g octanol for *Americamysis* to 187 µmol/g octanol for *Tanytarsus*, a factor of only 24. Saltwater genera constitute four of the five genera with GMAVs at a K_{OW} of 1.0 within a factor of two of the most sensitive genus (*Americamysis*). Of the 49 genera, the most sensitive one-third include a freshwater hydra, two amphipods, an insect, saltwater fish, a crab, two mysids, two shrimp, and three saltwater amphipods. All of these 16 genera have GMAVs at a K_{OW} of 1.0 that are within a factor of three, and 14 of the genera are benthic. Benthic and water column genera are distributed throughout the sensitivity distributions indicating that they have similar sensitivities. Genera that are benthic have been tested more frequently than water column genera.

3.3 Applicability of the WQC as the Effects Concentration for Benthic Organisms

The use of the FAV or FCV as the effects concentration for calculation of ESBs assumes that benthic (infaunal and epibenthic) species, taken as a group, have sensitivities similar to all aquatic (benthic and water column) species used to derive the WQC FCV. The data supporting the reasonableness of this assumption over all chemicals for which there were published or draft WQC documents were presented in Di Toro et al. (1991) and U.S. EPA (2003a). The conclusion of similarity of sensitivity was supported by comparisons between (1) acute values for the most sensitive benthic species and acute values for the most sensitive water column species for all chemicals; (2) acute values for all benthic species and acute values for all species in the WQC documents across all chemicals after normalizing the LC50 values; (3) FAVs calculated for benthic species alone and FAVs in the WQC documents; and (4) individual chemical comparisons of benthic species versus all species. The following analysis examines the data on the similarity of sensitivity of benthic and all aquatic species for PAHs.

For PAHs, benthic life-stages were tested for 15 of 20 freshwater genera and 21 out of 29 saltwater genera (Appendix C). An initial test of the difference between the freshwater and saltwater FAVs for all species (water column and benthic) exposed to PAHs was performed using the Approximate Randomization (AR) Method (Noreen, 1989). The AR Method tests the significance level of a test statistic when compared to a distribution of statistics generated from many random sub-samples. The test statistic in this case was the difference between the freshwater FAV (computed from the GMAVs at a K_{OW} of 1.0 for combined water column and benthic organisms) and the saltwater FAV (computed from the GMAVs at a K_{OW} of 1.0 for combined water

column and benthic organisms) (Appendix C). In the AR Method, the freshwater and the saltwater GMAVs at a K_{OW} of 1.0 were combined into one dataset. The dataset was shuffled, then separated back so that randomly generated "freshwater" and "saltwater" FAVs could be computed. The LC50 values were re-separated such that the number of GMAVs at a K_{OW} of 1.0 used to calculate the sample FAVs were the same as the number used to calculate the original FAVs. These two FAVs were subtracted and the difference used as the sample statistic. This was done iteratively so that the sample statistics formed a probability distribution representative of the population of FAV differences (Figure 3-1A). The test statistic was compared to this distribution to determine its level of significance. The null hypothesis was that the GMAVs at a K_{OW} of 1.0 that comprise the freshwater and saltwater data bases were not different. If this was true, the difference between the actual freshwater and saltwater FAVs should be common to the majority of randomly generated FAV differences. For PAHs, the test-statistic occurred at the 93.5 percentile of the generated FAV differences (Table 3-3). This percentile suggests that saltwater genera may be somewhat

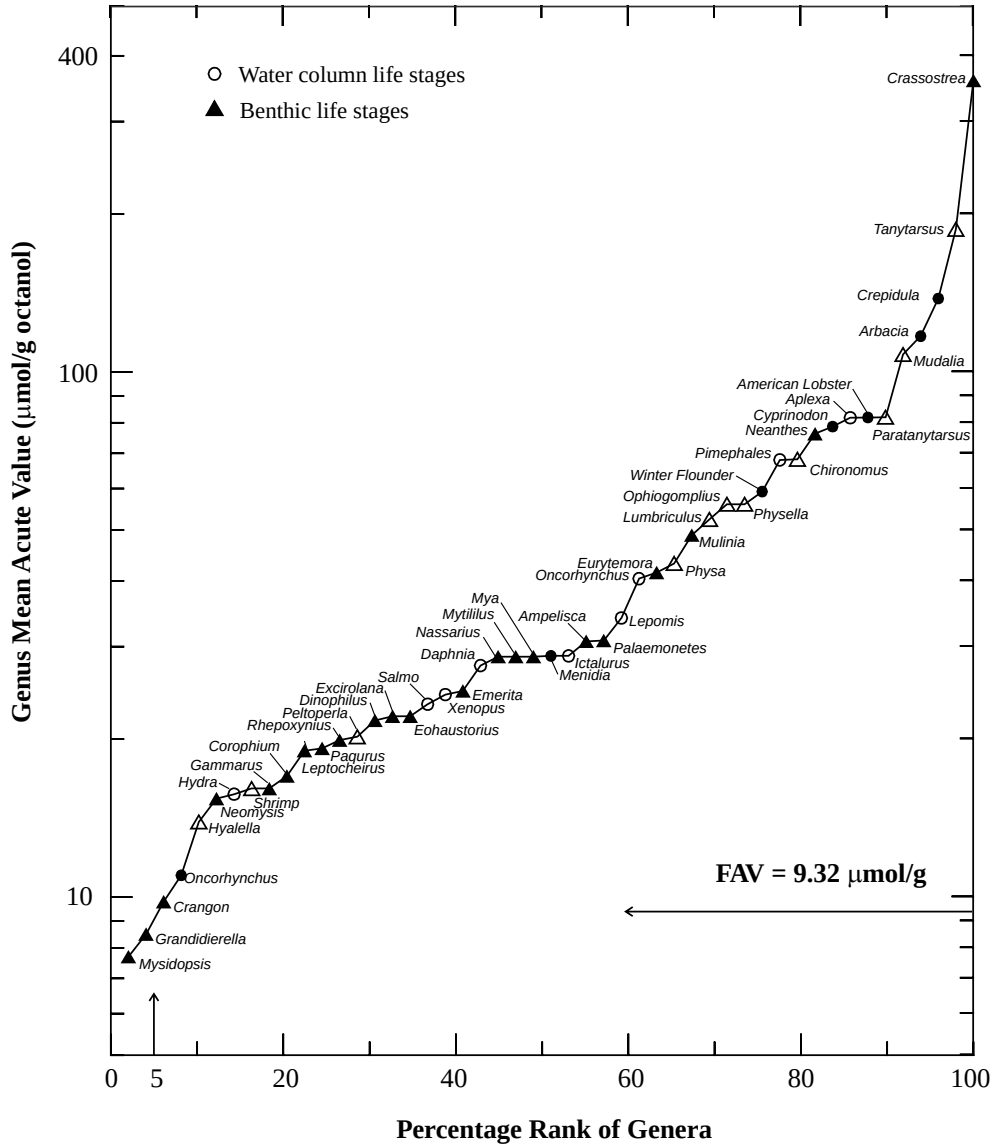

Figure 3-1 Probability distributions of FAV difference statistics to compare water-only toxicity data from (A) freshwater versus saltwater genera and (B) benthic versus WQC.

Table 3-3. Results of approximate randomization (AR) test for the equality of the freshwater and saltwater FAV distributions at a K_{OW} of 1.0 and AR test for the equality of benthic and combined benthic and water column FAVs for freshwater and saltwater distributions.

Comparison	Habitat or Water Type[A]		AR Statistic[B]	Probability[C]
Fresh vs Salt	Fresh (20)	Salt (29)	5.746	93.5
Freshwater: Benthic vs WQC[D]	WQC (49)	Benthic (33)	0.862	82.8

[A] Values in parantheses are the number of GMAVS at a K_{OW} of 1.0 used in the comparison.
[B] AR statistic = FAV difference between original compared groups.
[C] Probability that the theoretical AR statistic ≤ the observed AR statistic given that all samples came from the same population.
[D] Combined freshwater and saltwater.

more sensitive than freshwater genera as illustrated in Figure 3-2 and Appendix C. However, since the probability was less than 95% in the AR analysis, the null hypothesis of no significant difference in sensitivity for freshwater and saltwater species was accepted (Table 3-3).

Since freshwater and saltwater species showed no significant differences in sensitivity, the AR Method was applied jointly for the analysis of the difference in sensitivity for benthic and all aquatic organisms (benthic and water column species are always combined to derive WQC, therefore, the complete GMAV dataset is hereafter referred to as "WQC"). Using the criteria in U.S. EPA (2003a), each life stage of each test organism, hence each GMAV at a K_{OW} of 1.0, was assigned a habitat (Appendix C). The test statistic in this case was the difference between the WQC FAV, computed from the WQC GMAVs at a K_{OW} of 1.0, and the benthic FAV, computed from the benthic organism GMAVs at a K_{OW} of 1.0. The approach used to conduct this analysis was slightly different than that used in the previous test for freshwater and saltwater GMAVs. The difference was that freshwater and saltwater GMAVs in the first test represented two separate groups. In this test, the GMAVs at a K_{OW} of 1.0 for benthic organisms were a subset of the GMAVs at a K_{OW} of 1.0 in the entire WQC dataset. In the AR analysis for this test, the number of data points coinciding with the number of benthic organisms were selected from the WQC dataset to compute each "benthic" FAV. The original WQC FAV and the "benthic" FAV were then used to compute the difference statistic. This was done iteratively and the distribution that results was representative of the population of FAV difference statistics. The test statistic was compared to this distribution to determine its level of significance. The probability distributions of the computed FAV differences are shown in Figure 3-1B. The test statistic for this analysis occurred at the 82.8 percentile and the null hypothesis of no difference in the sensitivities between benthic species and species used to derive the WQC FCV was accepted (Table 3-3). This analysis supports the derivation of the FCV for PAHs based on all GMAVs at a K_{OW} of 1.0.

3.4 Derivation of the FAV at a K_{OW} of 1.0

The FAV is an estimate of the concentration corresponding to a cumulative probability of 0.05 in the GMAVs at a K_{OW} of 1.0. The analysis above demonstrates that the acute sensitivities of freshwater and saltwater genera and the sensitivities of benthic and benthic plus water column genera do not differ. Therefore, for calculation of the FAV, the GMAVs at a K_{OW} of 1.0 for all freshwater and saltwater genera can be grouped together to represent the relative sensitivities of all benthic organisms (Figure 3-2). The FAV at a K_{OW} of 1.0 is calculated using the procedure in Stephan et al. (1985), the GMAVs at

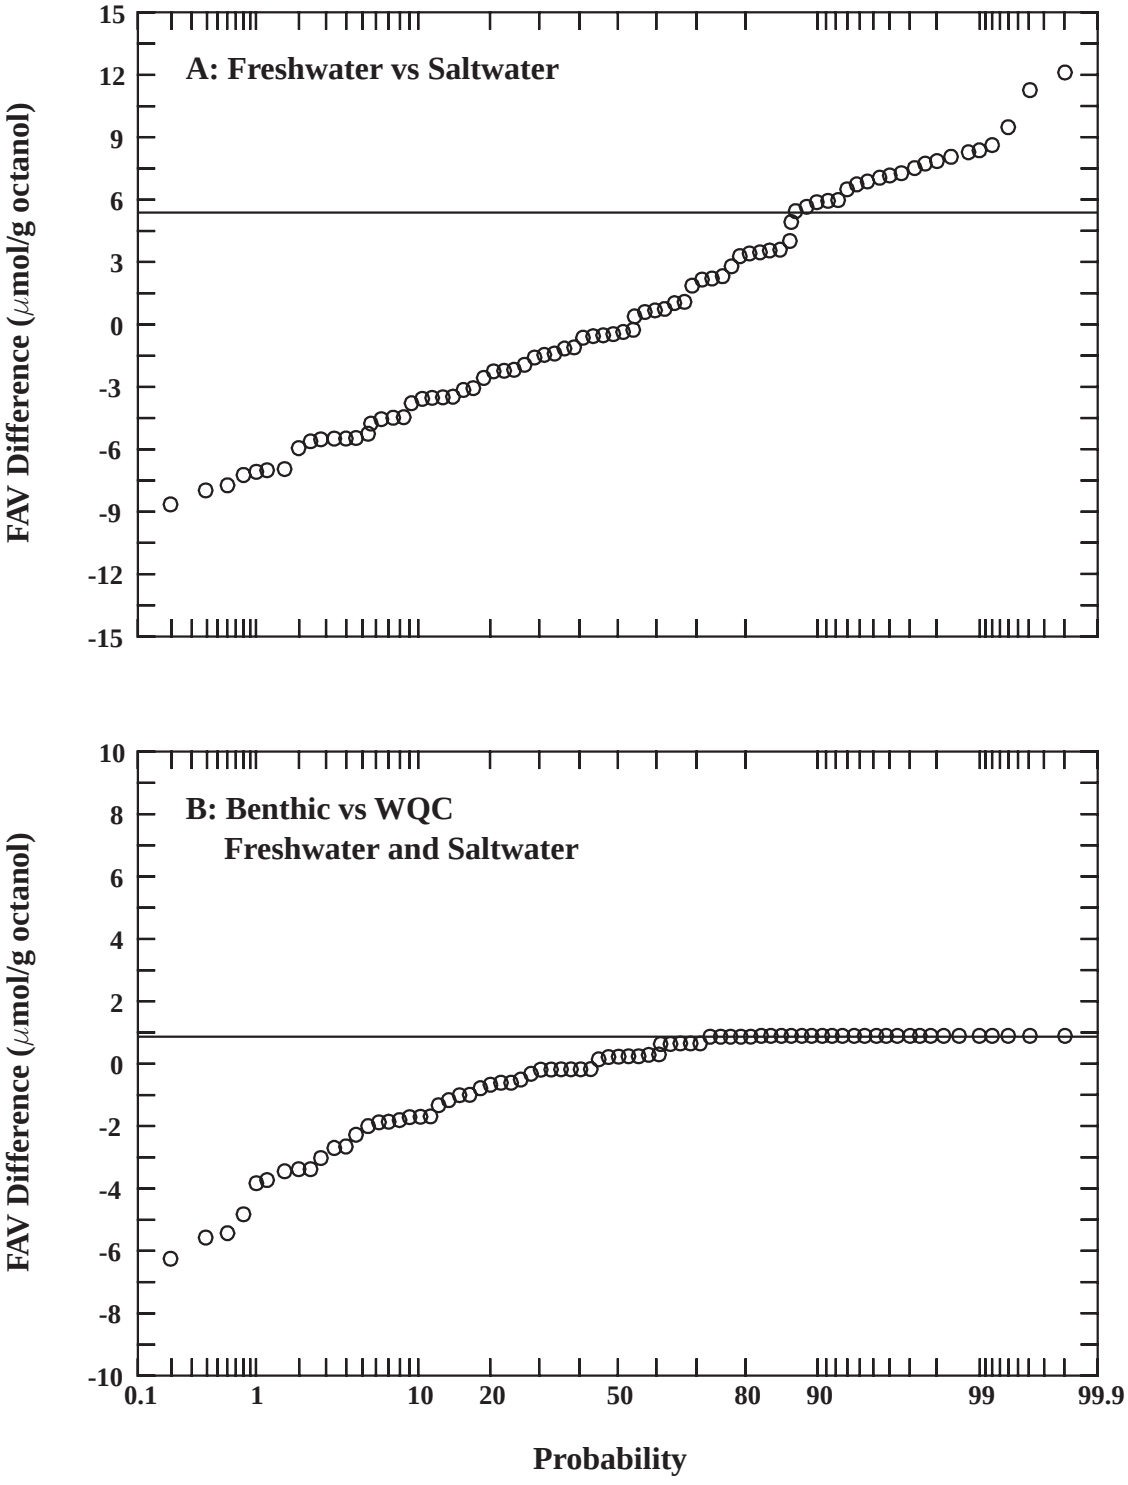

Figure 3-2. GMAVs at a $\log_{10}K_{OW}$ of 1.0 from water-only acute toxicity tests using freshwater and saltwater genera versus percentage rank of their sensitivity.

a K_{OW} of 1.0 of 7.63 µmol/g octanol for *Americamysis*, 8.51 µmol/g octanol for *Grandidierella*, 9.83 µmol/g octanol for *Crangon*, 11.0 µmol/g octanol for *Oncorhynchus* and the total number of genera tested (N = 49). The FAV at a K_{OW} of 1.0 is 9.31 µmol/g octanol. This FAV is greater than the GMAVs of the two most acutely sensitive genera as would be expected given the calculation procedure and the presence of 31 GMAVs.

3.5 Chronic Toxicity of Individual PAHs: Water Exposures

3.5.1 Acenaphthene

Chronic life-cycle toxicity tests have been conducted with acenaphthene with the freshwater midge (*Paratanytarsus* sp.) and the saltwater mysid (*A. bahia*), and early life-stage tests have been conducted with the fathead minnow (*P. promelas*) and sheepshead minnow (*C. variegatus*) (Table 3-1). For each of these species, one or more benthic life-stages were exposed. Other chronic toxicity tests have been conducted with the freshwater chironomid (*Paratanytarsus* sp.) and *P. promelas* (Lemke et al.,1983; Lemke, 1984; Lemke and Anderson, 1984) but insufficient documentation is available to permit use of these results (Thursby, 1991a).

Two acceptable life-cycle toxicity tests have been conducted with *Paratanytarsus* sp. (Northwestern Aquatic Sciences, 1982). In the first test, 575 µg/L reduced survival 90%, reduced growth 60%, and all eggs failed to hatch (Table 3-1). No adverse effects occurred at acenaphthene concentrations up to 295 µg/L acenaphthene. In the second test, survival was reduced 20% and growth 30% at 315µg/L. Egg hatchability was not affected in the highest concentration of 676 µg/L; although survival of hatched larvae was reduced ~60%. No significant effects were observed at acenaphthene concentrations up to 164 µg/L.

A total of six early life-stage toxicity tests have been conducted with *P. promelas* as part of a round-robin test series; two each from three laboratories (Table 3-1) (Academy of Natural Sciences, 1981; ERCO, 1981; Cairns and Nebeker, 1982). The lowest observed effect concentrations (LOEC) across laboratories and tests ranged from 98 to 509 µg/L, a factor of 5.2. Growth (dry weight), survival, or both growth and survival were reduced. Only one of these test pairs had a suitable measured acute value that allowed calculation of an ACR (Cairns and Nebeker, 1982). The concentration-response relationships were similar for the two tests of Cairns and Nebeker (1982). In the first test, the early life-stages of this fish were unaffected in acenaphthene concentrations ranging from 67 to 332 µg/L, but 495 µg/L reduced growth 54% relative to control fish. In the second test, growth was reduced 30% at 509 µg/L, but no effects were detected in fish exposed to 197 to 345 µg/L.

Data from saltwater chronic toxicity tests with acenaphthene are available for *A. bahia* and *C. variegatus*. Reproduction of *A. bahia* was affected by acenaphthene in two life-cycle tests from two different laboratories. In the first test (Horne et al., 1983), 340 µg/L reduced reproduction 93% relative to controls and all *A. bahia* died at 510 µg/L. No effects were observed on the parental generation at 100 to 240 µg/L and second generation juveniles were not affected at ≤ 340 µg/L. In the second test (Thursby et al., 1989b), no effects were observed at ≤ 44.6 µg/L, but a concentration of 91.8 µg/L reduced reproduction 91%. No reproduction occurred at higher concentrations, and growth was reduced 34% at 168 µg/L and survival 96% at 354 µg/L.

A test with early life-stages of *C. variegatus* showed that 240 to 520 µg/L had no effects, but that concentrations of 970, 2,000 and 2,800 µg/L reduced survival of embryos and larvae by ≥70% (Table 3-1; Ward et al., 1981).

In general, the above results show that the difference between acute and chronic toxicity of acenaphthene is small and differed minimally between species (Table 3-2). Species mean acute-chronic ratios for acenaphthene are 6.68 for *Paratanytarsus* sp., 1.48 for *P. promelas*, 3.42 for *A. bahia* and 4.36 for *C. variegatus*.

3.5.2 Anthracene

A single life-cycle toxicity test has been conducted with *D. magna* exposed to only three concentrations of anthracene (Holst and Geisy, 1989). Minimal decreases were observed on the number of broods produced in all three of the concentrations tested: 2.1 mg/L (5.3%), 4.0 µg/L (8.0%) and 8.2 µg/L (13.8%). No acute toxicity tests were conducted by the authors. Therefore, an ACR could not be derived for anthracene.

3.5.3 Fluoranthene

Fluoranthene has been tested in life-cycle toxicity tests with the freshwater cladoceran, *D. magna* (Spehar et al., 1999) and the saltwater mysid, *A. bahia* (U.S. EPA, 1978, Spehar et al., 1999), and early life-stage tests have been conducted with the fathead minnow (Spehar et al., 1999) (Table 3-1). No effects were observed with *D. magna* at ≤17 µg/L, but growth was reduced 17% at 35 µg/L and 25% at 73 µg/L. There were 37% fewer young per adult at 73 µg/L and no daphnids survived at 148 µg/L. An early life-stage toxicity test conducted with the fathead minnow showed no effects at ≤10.4 µg/L, but reduced survival (67%) and growth (50%) at 21.7 µg/L.

Saltwater mysids (*A. bahia*) were tested in two life-cycle toxicity tests. In the first test, the mysids were exposed to fluoranthene for 28 days (U.S. EPA, 1978). There was no effect on survival or reproduction (growth was not measured) in concentrations ranging from 5-12 µg/L. At a fluoranthene concentration of 21 µg/L, survival was reduced 26.7% and reproduction 91.7%, relative to the controls. At the highest concentration of fluoranthene, 43 µg/L, all *A. bahia* died. In the second test, *A. bahia* were exposed to fluoranthene for 31 days (Spehar et al., 1999). Effect concentrations were similar to those in the U.S. EPA (1978) test. *A. bahia* were not affected at fluoranthene concentrations from 0.41-11.1 µg/L. At the highest concentration tested, 18.8 µg/L, survival was reduced 23% relative to controls and there was no reproduction. Reproduction was reduced by 77% in 11.1 µg/L, but this was not significantly different from controls even at α=0.1.

The difference between acute and chronic sensitivity to fluoranthene varied minimally between species (Table 3-2). Three species mean ACRs are available for fluoranthene: 4.78 for *D. magna*, 4.60 for *P. promelas*, and 2.33 for *A. bahia*.

3.5.4 Phenanthrene

Phenanthrene has been tested in life-cycle toxicity tests with *D. magna* and *A. bahia* and an early life-stage test has been conducted with rainbow trout (*O. mykiss*) (Table 3-1). There were no effects of phenanthrene on *D. magna* at ≤57 µg/L, but survival was reduced 83% and reproduction 98% at 163 µg/L (Call et al., 1986). In a test with *O. mykiss*, no effects were observed at 5 µg/L. The percentage of abnormal and dead fry at hatch was significantly increased at the highest exposure concentration of 66 µg/L and survival of hatched fry was reduced with increase in exposure concentration (Call et al., 1986). Mortality was 41, 48, 52 and 100% at 8, 14, 32, and 66 µg/L, respectively. Wet weight was reduced 33, 44, and 75% at 8, 14 and 32 µg/L, respectively.

A life-cycle toxicity test with *A. bahia* exposed to phenanthrene showed that the effect concentrations were similar to those that affected *O. mykiss* (Kuhn and Lussier, 1987) (Table 3-1). Survival, growth and reproduction were not affected at ≤5.5 µg/L. However, at the highest test concentration of phenanthrene (11.9 µg/L), all mysids died.

The difference between acute and chronic sensitivity to phenanthrene varied minimally between *D. magna* (PAH-specific ACR= 1.21), *O. mykiss* (ACR=7.90) and *A. bahia* (ACR= 3.33). The ACR for *O. mykiss* (Call et al., 1986) was derived using the EC50 for immobilization (50 µg/L) and not the 96-hour LC50 of 375 µg/L as was required in Stephan et al. (1985).

3.5.5 Pyrene

A life-cycle toxicity test with *A. bahia* exposed to pyrene was conducted by Champlin and Poucher (1992b). There were no effects at 3.82 µg/L, but

20.9 µg/L reduced survival 37% and no mysids survived at the next higher concentration of 38.2 µg/L (Table 3-1). Reproduction was significantly reduced in ≥5.37 µg/L. The ACR from this test was pyrene is 6.24.

3.5.6 Naphthalene

Fathead minnows were exposed to naphthalene in an early life-stage toxicity test (DeGraeve et al., 1982). Hatching of fry was significantly reduced in 4.38 and 8.51 µg/L and none were alive in these concentrations at the end of the 30-day test. Weight and length of fish surviving the test were significantly reduced in 0.85 and 1.84 µg/L. No significant effects were detected in concentrations ≤0.45 µg/L. Control survival was only 42%, which does not meet requirements according to the American Society of Testing and Materials (ASTM, 1998). Also, the carrier methanol was absent from the control. These data are summarized in the text for completeness, but the ACR of 12.7, chronic value of 0.62 µg/L, and 96-hour LC50 of 7.9 µg/L for naphthanlene are not included in Tables 3-1 and 3-2.

The calanoid copepod (*Eurytemora affinis*) was exposed indvidually to 14.21 µg/L naphthalene, 15.03 µg/L 2-methylnaphthalene, 8.16 µg/L 2,6-dimethylnaphthalene and 9.27 µg/L 2,3,5-trimethylnaphthalene in life-cycle toxicity tests (Ott et al., 1978). Survival and reproduction were affected by each of the naphthalenes, but ACRs could not be derived because the duration of the acute test was too short (24 hours) according to WQC Guidelines (Stephan et al., 1985), and no other concentrations were tested chronically.

3.5.7 Derivation of the Final Acute Chronic Ratio

The FACR for the six PAHs is 4.16. This FACR is the geometric mean of all species mean ACRs for *Daphnia* (2.41), *Paratanytarsus* (6.68), *Pimephales* (2.61), *Oncorhynchus* (7.90), *Americamysis* (3.59), and *Cyprinodon* (4.36) (Table 3-2).

3.6 Derivation Of FCVs

3.6.1 Derivation of the FCV at a K_{OW} of 1.0

The FCV is the value that should protect 95% of the tested species. The FCV is the quotient of the FAV and the FACR for the substance. The FAV at a K_{OW} of 1.0 is 9.31 mmol/g octanol. It is an estimate of the acute LC50 or EC50 concentration corresponding to a cumulative probability of 0.05 for the GMAVs at a K_{OW} of 1.0. The FACR of 4.16 is the mean ratio of acute to chronic toxicity for six species exposed exposed both acutely and chronically to one or more of six individual PAHs in 15 experiments. (For more information on the calculation of ACRs, FAVs, and FCVs see the U.S. EPA National WQC Guidelines (Stephan et al., 1985.))

The FAV at a K_{OW} of 1.0 of 9.31 µmol/g octanol is divided by the FACR of 4.16 to obtain a FCV at a K_{OW} of 1.0 of 2.24 µmol/g octanol (Table 3-3). Because nonionic organic chemicals partition similarly into octanol and lipid of organisms, the FCV at a K_{OW} of 1.0 in µmol/g octanol approximately equals tissue-based "acceptable" concentration of about 2.24 µmol/g lipid.

3.6.2 Derivation of the PAH-Specific FCVs

The PAH-specific FCVs (mg/L) (Table 3-4, Appendix D) are calculated from the FCV at a K_{OW} of 1.0 (µmol/g octanol), the slope of the K_{OW}-K_{OC} relationship, the universal narcotic slope of the K_{OW}-acute toxicity relationship, and the PAH-specific K_{OW} values (Equation 3-1, 3-2, and 3-3).

$$\log_{10}\text{PAH-specific FCV} = (\text{slope})\log_{10}K_{OW} + \log_{10}\text{FCV at a } K_{OW} \text{ of 1.0} \quad (3\text{-}1)$$

$$\log_{10}\text{PAH-specific FCV} = -0.945\log_{10}K_{OW} + \log_{10}(2.24) \quad (3\text{-}2)$$

$$\text{PAH-specific FCV (mmol/L)} = 1000(\text{antilog}(-0.945\log_{10}K_{OW} + 0.3502)) \quad (3\text{-}3)$$

Table 3-4. $C_{OC,PAHi,FCVi}$ concentrations and properties required for their derivation[A].

[A] Four significant figures are used even when fewer are appropriate for the parameter to limit the effects of rounding error when calculating $\Sigma ESBTU_{FCV}$ which has two significant figures.

[B] See Appendix E for solubilities.

[C] For C#-PAHs, reported $log_{10}K_{OW}$ values are the average $log_{10}K_{OW}$ values of all structures.

[D] $C_{OC,PAHi,Maxi}$ is based on solubility; if $C_{OC,PAHi,FCVi}$ is > $C_{OC,PAHi,Maxi}$, then $C_{OC,PAHi,Maxi}$ may be used to calculate ESB toxic units (see Section 6).

Section 4

Derivation of PAH ESB_{FCVS}

4.1 Derivation of Potencies for Individual PAHs in Sediments ($C_{OC,PAHi,FCVi}$)

The critical concentration of a PAH in sediment ($C_{OC,PAHi,FCVi}$) that is related to the FCV is derived following the EqP method (U.S. EPA, 2003a; Di Toro et al., 1991) because the interstitial water-sediment partitioning of PAHs follows that of other nonionic organic chemicals. Therefore, a sediment effects concentration for any measure of effect can be derived from the product of the water-only effects concentration for that effect and the K_{OC} for that particular PAH. The use of K_{OC} to derive a sediment effects concentration for PAHs is applicable because partitioning for these chemicals is primarily determined by the organic carbon concentration of the sediment.

The partitioning equation between the organic carbon-normalized sediment concentration, C_{OC} ($\mu mol/g_{OC} = \mu mol/kg_{OC}$), and the free interstitial water concentration, C_d (mmol/L), is given by the equation

$$C_{OC} = K_{OC}\, C_d \qquad (4\text{-}1)$$

where K_{OC} (L/kg_{OC}), defined above, can be calculated from a K_{OW} obtained from SPARC (Hilal et al., 1994) using the following equation from Di Toro (1985)

$$\log_{10}K_{OC} = 0.00028 + 0.983 \log_{10}K_{OW} \qquad (4\text{-}2)$$

$C_{OC,PAHi,FCVi}$ for individual PAHs are then calculated using Equation 4-1 with the FCV as the water concentration

$$C_{OC,PAHi,FCVi} = K_{OC}\, FCV_i \qquad (4\text{-}3)$$

Since K_{OC} is presumed to be independent of sediment type for nonionic organic chemicals, so also is $C_{OC,PAHi,FCVi}$.

Table 3-4 contains the $C_{OC,PAHi,FCVi}$ ($\mu g/g_{OC}$) for 74 PAHs found in sediments, including the 34 PAHs (in bold) analyzed by the U.S. EPA in their EMAP program (U.S. EPA, 1996a,b; 1998). $C_{OC,PAHi,FCVi}$ values for PAHs not in Table 3-4 can be calculated in a similar manner (see Section 7.2 for discussion on the PAHs to which the ESB applies). The range in the $C_{OC,PAHi,FCVi}$ values for the 74 PAHs listed in Table 3-4, which were derived using only data for PAHs, is from 349 to 1435 $\mu g/g_{OC}$. In contrast, the range of the same value, termed the $C_{S,OC}$ by Di Toro and McGrath (2000), was about the same (655 to 1940 $\mu g/g_{OC}$) for the 23 PAHs commonly measured when derived using the database for narcotic chemicals with a PAH correction.

4.2 Derivation of the ESB_{FCV} for PAH Mixtures

The correct derivation of the ESB for a mixture of PAHs is based on the approximate additivity of narcotic chemicals in water and tissue (Di Toro et al., 2000; Section 2.8 of this document) and in sediment (Section 5.2). Because WQC and ESBs are based on FCVs they are not intended to cause toxicity in water or sediments to most species, the term toxic unit could be misleading. Therefore, we refer to the quotient of the concentration of a specific chemical in water and its WQC FCV as water quality criteria toxic units ($WQCTU_{FCVi}$). Similarly, the quotient of the sediment concentration for a specific PAH ($C_{OC,PAHi}$) and the $C_{OC,PAHi,FCVi}$ in sediments should be termed equilibrium partitioning sediment benchmark toxic unit ($ESBTU_{FCVi}$). Thus, the ESB for the mixture of PAHs is the sum of the $ESBTU_{FCVi}$ for all of the PAHs in the particular sediment termed the $\Sigma ESBTU_{FCV}$

$$\Sigma ESBTU_{FCV} = \sum_{i} \frac{C_{OC,PAHi,}}{C_{OC,PAHi,FCVi}} \qquad (4\text{-}4)$$

For a particular sediment, if the $\Sigma ESBTU_{FCV}$ for "total PAHs" is less than or equal to 1.0, the concentration of the mixture of PAHs in the sediment is acceptable for the protection of benthic organisms (see Section 7.2 for the technical basis for defining total PAH as the $\Sigma ESBTU_{FCV}$ for the 34 PAHs monitored in the U.S. EPA EMAP). The equilibrium partitioning sediment benchmark is given by the equation

$$ESB = \Sigma ESBTU_{FCV} \leq 1.0 \quad (4\text{-}5)$$

For a particular sediment, if the $EESBTU_{FCV}$ is > 1.0, the concentration of the mixture of PAHs in the sediment may not acceptable for the protection of benthic organisms

$$ESB = \Sigma ESBTU_{FCV} > 1.0 \quad (4\text{-}6)$$

4.3 Aqueous Solubility Constraint

A solubility constraint is applied to sediment concentrations when computing their individual contributions to the effect of the PAH mixture because the $C_{OC,PAHi,FCVi}$ derived for each PAH is solubility limited, i.e., the interstitial water concentration of the PAH is limited by the solubility S. Therefore, $C_{OC,PAHi,FCVi}$ is limited by the concentration in sediment organic carbon that is in equilibrium with the interstitial water at the aqueous solubility (Equation 4-7). This is termed the maximum $C_{OC,PAHi,Max}$ (Table 3-4)

$$C_{OC,PAHi,FCVi} \leq C_{OC,PAHi,Maxi} = K_{OC}S \quad (4\text{-}7)$$

Thus, only the contribution up to the maximum $C_{OC,PAHi,Maxi}$ is counted in the $\Sigma ESBTU_{FCV}$ for the PAH mixture.

Narcosis theory suggests that highly insoluble PAHs should contribute fractional toxic units and $ESBTU_{FCVi}$, limited by the solubility constraint, to the sum of the effects of the mixture when these PAHs are present in mixtures. If so, then this points out the importance of knowing the aqueous solubility of these PAHS so that Equations 4-4 and 4-5 can be applied correctly.

The question of whether highly insoluble chemicals that are not by themselves acutely or chronically toxic, e.g., high molecular weight PAHs, contribute fractional toxic units to the total toxicity when present as mixtures is discussed in Section 5.2.8 of this document and in Spehar et al. (*In preparation*). Spehar et al. (*In preparation*) demonstrate that high K_{OW} PAHs do contribute to the total toxicity of the PAH mixture.

4.4 Comparison of the $\Sigma ESBTU_{FCV}$ for Mixtures of PAHS in Estuarine Sediments

Coastal and estuarine monitoring data were compiled from eight sources to obtain a preliminary assessment of the $\Sigma ESBTU_{FCV}$ values for PAHs in the sediments of the Nation's water bodies (NOAA, 1991; Adams et al., 1996; Anderson et al., 1996; Fairey et al., 1996; U.S. EPA, 1996a,b, 1998; Hunt et al., 1998). Data sources which were identified had measured concentrations for the 23 PAHs (18 parent and 5 alkylated groups) (see Table 6-2) as well as the corresponding sediment organic carbon measurements. Sediments analyzed were from randomly selected and specifically targeted locations, samples of surficial grabs and vertical profiles, and studies where the relative frequency and intensities of sampling varied. This analysis is presented as an aid in assessing the range of reported PAH concentrations, and the extent to which they may exceed 1.0 $\Sigma ESBTU_{FCV}$. The sediments analyzed were not randomly selected from the entire United States. Therefore, this analysis is not intended to reflect expected occurrence nationwide or at any specific site of concern. Sediments where 23 PAHs were analyzed will underestimate the $\Sigma ESBTU_{FCV}$ if 34 PAHs had been analyzed. $\Sigma ESBTU_{FCV}$ values were computed by summing the $ESBTU_{FCVi}$ for each PAH measured in the sediment sample. For insoluble PAHs, the $C_{OC,PAHi,Maxi}$ (Table 3-4) was used to calculate $\Sigma ESBTU_{FCV}$.

The probability distribution for the $\Sigma ESBTU_{FCV}$ data are shown on Figure 4-1. The number of data points used to generate each distribution is provided in the lower right hand corner of each graph. For visual effect, only non-

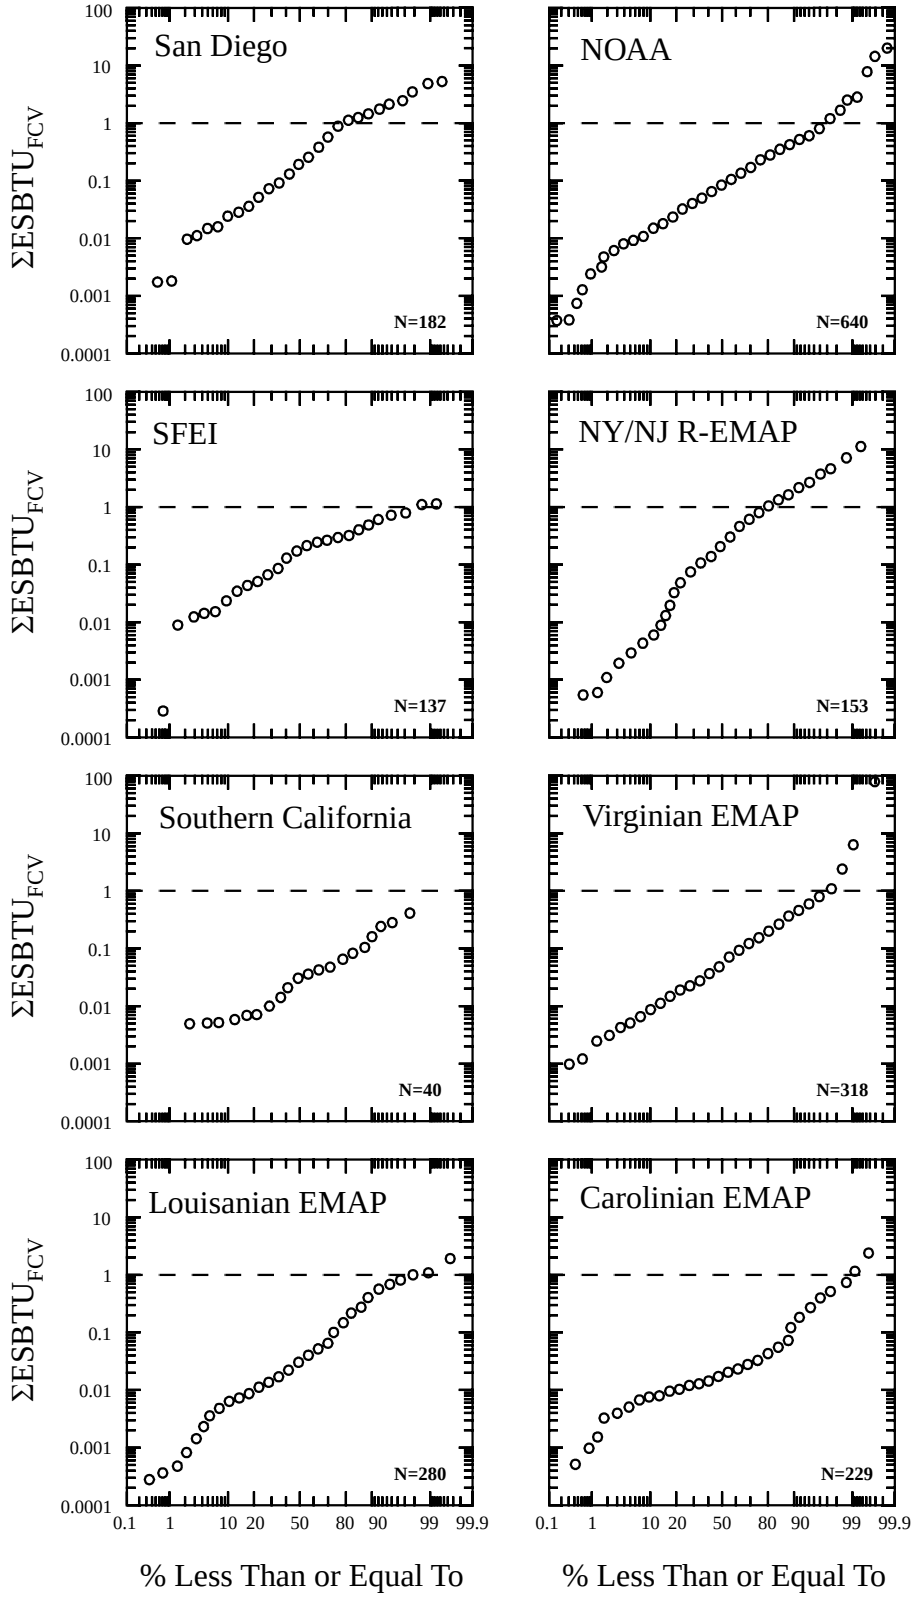

Figure 4-1. Probability distribution of the $\Sigma ESBTU_{FCV}$ for PAH mixtures in sediments from individual coastal and estuarine locations in the United States.

overlapping data are shown. For comparison purposes, a line indicating 1.0 $\Sigma ESBTU_{FCV}$ is also shown. Data presented are from sediments with 0.201 to 15.2% organic carbon. With the exception of the Louisianian and Carolinian Province EMAP datasets, all of the datasets had only 23 PAHs measured. The Louisianian and Carolinian Province EMAP datasets had a total of 34 measured PAHs (18 parent and 16 alkylated groups). The PAHs in addition to the 23 were the C1 through C4 alklyated forms of some of the parent PAHs. To assess the total number of PAHs, a C1-PAH series was considered as one PAH. Computed $\Sigma ESBTU_{FCV}$ values are based on the total number of PAHs measured. The distributions across the different locations are relatively similar. With the exception of the Southern Californian data, all of the datasets had $\Sigma ESBTU_{FCV}$ values greater than 1.0 at the 95th percentile. Although the $\Sigma ESBTU_{FCV}$ from the Lousianian and Carolinian Province EMAP data are computed from 34 PAHs, these sediments do not contain greater $\Sigma ESBTU_{FCV}$ values than sediments from the other studies which measured only 23 PAHs.

A single probability distribution using all of the data is shown in Figure 4-2. The total number of sediments is 1979. $\Sigma ESBTU_{FCV}$ values computed from 23 PAHs are denoted by open circles, and for the 34 PAHs, by open squares. The median $\Sigma ESBTU_{FCV}$ was about 0.06. Approximately 6% of the samples (109 sediments) had $\Sigma ESBTU_{FCV}$ values greater than 1.0.

Although the EqP-based ESBs for nonionic organic chemicals are not intended for use with largely sandy sediments having <0.2% TOC, the EMAP Lousianian and Carolinian Provinces (34 PAHs) and the Elliot Bay (31 PAHs) monitoring databases were examined to determine the frequency of ESB exceedences. A total of 115 of the 654 sediments in these databases had <0.2% TOC. Only two of these sediments (1.7 percent) exceeded the ESB of >1.0 $\Sigma ESBTU_{FCV}$.

Section 5

Actual and Predicted Toxicity of PAH Mixtures in Sediment Exposures

5.1 Introduction

The $C_{OC,PAHi,FCVi}$ for individual PAHs and ESBs for their mixtures were derived using water-only toxicity data (Appendix C) and both equilibrium partitioning (U.S. EPA, 2003a; Di Toro et al., 1991) and narcosis theory (Di Toro et al., 2000; Di Toro and McGrath, 2000). This section examines data from toxicity tests with spiked and field sediments contaminated with individual PAHs and their mixtures to demonstrate the strength of the technical approach used to derive ESBs and the applicability of ESBs to sediments from the field.

5.2 Spiked Sediment Toxicity Tests

5.2.1 Interstitial Water Concentrations and Sediment Toxicity: Relevance to Water-Only Toxicity Tests and WQC FCVs

The key hypothesis in the derivation of ESBs from EqP and narcosis theory is that effects concentrations from water-only aquatic toxicity tests data using benthic species are similar to effects concentrations in sediment toxicity tests based on interstitial water concentrations or sediment concentrations predicted to be toxic using EqP. This hypothesis has been tested in two ways: 1) by comparing LC50 values determined in water-only experiments to interstitial water LC50 values determined in spiked-sediment exposures, and 2) by comparing organic carbon-normalized sediment LC50 values observed in spiked-sediment exposures with those predicted from water-only LC50 values multiplied by the K_{OC} using the equilibrium partitioning model (Di Toro et al, 1991).

The interstitial water and water-only LC50 values for 28 experiments with a variety of PAHs and several freshwater and marine species are listed in Appendix F (Swartz et al., 1990; Swartz, 1991a; DeWitt et al., 1992; Suedel et al., 1993; Driscoll et al., 1997a,b, 1998). The mean ratio of the water-only LC50 to interstitial water LC50 from 20 experiments with definitive LC50 values was 1.60, indicating agreement generally within less than a factor of two. Interstitial water LC50 values almost always slightly exceeded water-only LC50 values. Three factors may contribute to that result: 1) some test species, especially epibenthic or tube-dwelling organisms, frequently encounter unspiked, overlying water and, thus, are not exclusively exposed to interstitial water; 2) interstitial water near the sediment surface may be slowly diluted by overlying water because of bioturbation and other transport processes; and 3) chemical analyses of interstitial water may include a portion of the non-bioavailable PAH fraction that is bound to dissolved organic matter. Despite these limitations, the interstitial water and water-only LC50 values are remarkably close, especially for sensitive, free-burrowing, infaunal species like *R. abronius*. These data support the evaluation of the risks of sediment-associated chemicals by comparisons between dissolved concentrations in interstitial water and water concentrations of concern from water-only toxicity tests.

A more comprehensive evaluation of the degree to which the response of benthic organisms can be predicted from contaminant concentrations in interstitial water can be made utilizing organism responses in each treatment from toxicity tests with sediments spiked with various

chemicals, including acenaphthene (Swartz, 1991a), phenanthrene (Swartz, 1991a), fluoranthene (Swartz et al., 1990; DeWitt et al., 1992), endrin (Nebeker et al., 1989; Schuytema et al., 1989), dieldrin (Hoke, 1992), DDT (Nebeker et al., 1989; Schuytema et al., 1989) or kepone (Adams et al., 1985) (Figure 5-1). Interstitial Water Toxic Units (IWTU) are calculated by dividing the concentration of a chemical in the interstitial water (µg/L) of a treatment by the water-only LC50 (µg/L). Theoretically, 50% mortality should occur at 1.0 IWTU. Mortality should be <50% at interstitial water concentrations < 1.0 IWTU, and > 50% at concentrations > 1.0 IWTU. Figure 5-1 presents the percent mortality in individual treatments for each chemical versus the IWTUs. Mortality was generally low at concentrations <1.0 IWTU, and increased sharply at ≥1.0 IWTU as would be expected if interstitial water concentrations account for the bioavailability of nonionic organic chemicals across sediments and water-only LC50 values are surrogates for interstitial water LC50 values.

5.2.2 Sediment Toxicity: Prediction Using Water-Only Toxicity and K_{OC}

The equilibrium partitioning model predicts the organic carbon-normalized sediment PAH concen-tration (PAH_{OC}) as the product of the PAH-specific partition coefficient between organic carbon and water (K_{OC}) and the water-only effect concentration for the PAH in water (example, 10-day LC50 or FCV)(Di Toro et al., 1991).

$$\text{Predicted LC50 } (\mu g/g_{OC}) = \text{water-only LC50 } (\mu g/L) \times K_{OC}\ (L/kg_{OC}) \quad (5\text{-}1)$$

Equation 5-1 was used with the water-only LC50 values in table 5-1 and the K_{OC}s in table 3-4 to predict the sediment LC50s ($\mu g/g_{OC}$) for 22 combinations of a variety of PAHs and test species (Table 5-1). Corresponding LC50 values were also determined for each combination in standard sediment toxicity tests. The mean ratio of observed/predicted LC50 values was 2.07, indicating that Equation 5-1 predicts PAH LC50 values $\mu g/g_{OC}$ in sediment with an accuracy within a factor of two (Table 5-1). This result is essentially equal to the ratio of the interstitial water and water-only LC50 values and may be the result of the same factors listed previously.

As in the case of IWTU, predicted sediment toxic units (PSTU) can be estimated by dividing the measured PAH concentration in sediments from individual treatments of spiked-sediment toxicity tests ($\mu g/g_{OC}$) by the predicted LC50 ($\mu g/g_{OC}$). This standardization allows a compre-hensive analysis of the efficacy of the EqP prediction of a sediment effect concentration from the product of the K_{OC} and water-only effects data for that chemical and duration of exposure. Figure 5-2 combines PSTU-response data for diverse chemicals including acenaphthene (Swartz, 1991a), phenanthrene (Swartz, 1991a), fluoranthene (Swartz et al., 1990; DeWitt et al., 1992), endrin (Nebeker et al., 1989; Schuytema et al., 1989), dieldrin (Hoke, 1992) or kepone (Adams et al., 1985) (Figure 5-2). As with the IWTU plot, 50% mortality should occur at about 1.0 PSTU. Figure 5-2 shows that mortality was generally low at PSTU < 1, increased rapidly at PSTU ≈ l, and was high for most samples with PSTU > 1.

These analyses support the concept that water-only LC50 values and K_{OC}s can be used to predict the sediment concentrations on an organic carbon basis that are toxic to benthic organisms. It seems probable that this EqP prediction of sediment effect concentrations from water-only effect data is applicable to other measures of aquatic toxicity, including WQC final chronic values. Therefore, an FCV for a specific PAH multiplied by its K_{OC} value should be applicable to the derivation of a value analogous to the FCV, but based on a sediment concentration. This concentration is the ESB.

5.2.3 Toxicity of Individual PAHs

Spiked-sediment toxicity tests have provided an important tool for investigating the effects of sediment-associated PAHs and the applicability of the EqP approach for the derivation of sediment benchmark concentrations. The toxicity test

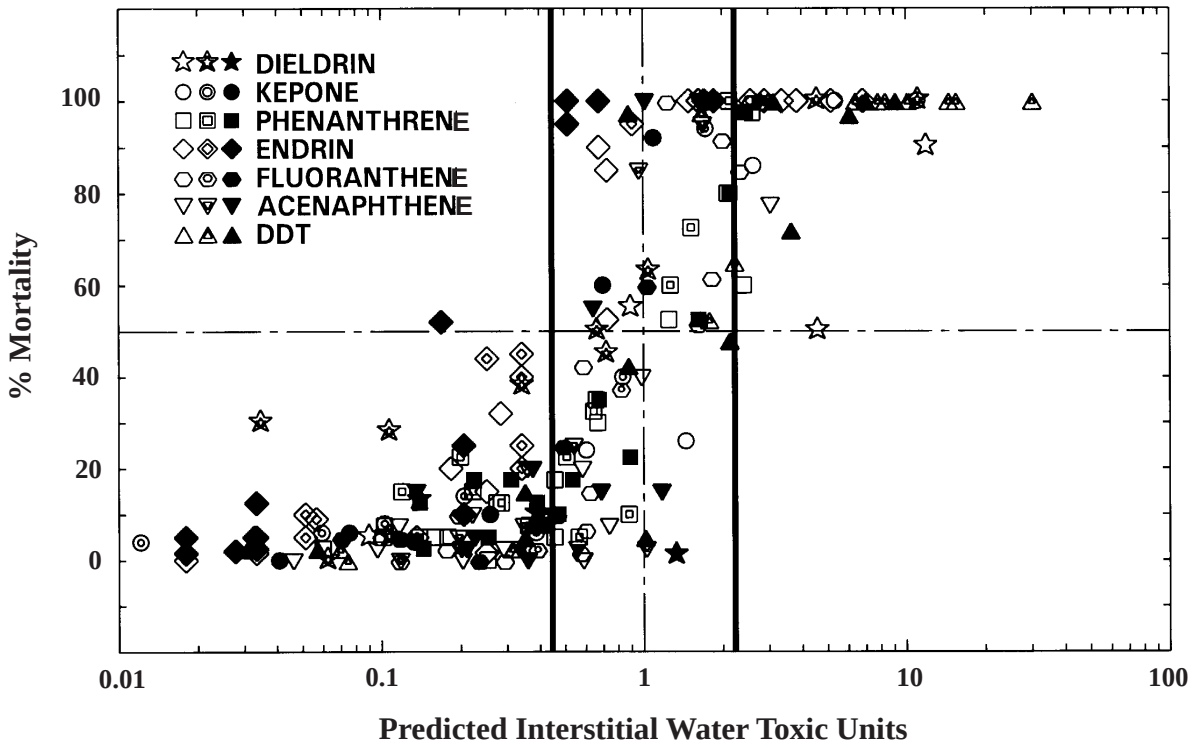

Figure 5-1. Percent mortality versus predicted interstitial water toxic units for seven chemicals and three sediments per chemical (each sediment represented by unique symbol).

method involves: 1) addition and thorough mixing of the PAH into a reference sediment that contains little or no background contamination and is not toxic, by itself, to the test species; 2) storage of the spiked sediment for up to 28d to allow the PAH to reach an equilibrium of the partitioning of the PAH between interstitial water and dissolved and particulate sedimentary materials; 3) conduct of a sediment toxicity test following standard U.S. EPA (1994) or ASTM (1993) procedures; and 4) analytical measurements, typically of the sediment/interstitial water concentration of the PAH, organic carbon, and other sediment variables. The method yields a dataset on the relation between the measured PAH concentration and the toxicity response, from which a LC50, IWTU, PSTU, and other statistical parameters can be calculated.

Sediment contaminant concentrations of nonionic organic chemicals are typically normalized to either the dry weight or organic carbon content of the sediment. To facilitate comparisons among the four PAHs from spiked sediment toxicity tests with *R. abronius*, PAH concentrations in sediments from each treatment in each spiked sediment toxicity test are normalized in this section to the PAH-specific $C_{OC,PAHi,FCVi}$ (see Table 3-4). This ratio is termed the $ESBTU_{FCVi}$, which is the ratio of the measured PAH concentration in sediments from the toxicity tests ($\mu g/g_{OC}$) to the $C_{OC,PAHi,FCVi}$ concentration ($\mu g/g_{OC}$) for that PAH, i.e., the fraction of $ESBTU_{FCV}$ represented by the observed PAH concentration in sediment. The $C_{OC,PAHi,FCVi}$ normalization does not alter the original variability in concentration-response but allows comparison of PAH effects among species, compounds, and response criteria. For example, the $C_{OC,PAHi,FCVi}$-normalized raw data for effects of individual PAHs on the amphipod, *R. abronius*, indicates similar patterns of concentration-response for acenaphthene, phenanthrene, fluoranthene, and pyrene (Figure 5-3). The individual LC50 values for the four PAHs ranged from 3.3 to 4.5 $ESBTU_{FCVi}$ (mean = 3.8)

Table 5-1. Water-only and spiked-sediment LC50 values used to test the applicability of narcosis and equilibrium partitioning theories to the derivation of ESBs for PAHs. See Appendix F for water-only and interstitial water LC50s (µg/L).

indicating that sediment concentrations would have to exceed the $C_{OC,PAHi,FCVi}$ by about a factor of four to cause 50% mortality in this amphipod during a 10-day exposure. The presence of mortality only at PAH concentrations in excess of the $C_{OC,PAHi,FCVi}$ would be expected.

5.2.4 Comparison of Sediment Toxicity to C_{OC,PAH_i,FCV_i}

The degree to which ESBs derived from narcosis and EqP theory and FCVs derived from water-only toxicity databases are appropriately protective of benthic organisms can be independently tested using data from spiked-sediment toxicity tests. The individual PAH concentrations in sediment (C_{OC}) affecting benthic organisms in toxicity tests were divided by the $C_{OC,PAHi,FCVi}$ to determine the $ESBTU_{FCVi}$. If most benthic organisms are sensitive at the $ESBTU_{FCVi}$ greater than 1.0 then the ESB for the PAH mixture may be appropriately protective of benthic organisms (see Section 4.2).

A review of the literature on spiked-sediment toxicity tests yielded 54 estimates of LC50, EC50 or EC25 (concentration affecting 25% of the test organisms) values for four individual PAHs (acenaphthene, phenanthrene, fluoranthene, pyrene; Appendix F). The duration of most of the tests was 10 days, but a few were longer-term tests that measured sublethal effects on reproduction or emergence (sediment avoidance). Over all the data, there was a substantial range (500 to 147,000 $\mu g/g_{OC}$) in the estimates of the median response concentrations. For example, the relative sensitivity of marine amphipods in this dataset was *Rhepoxynius abronius* > *Eohaustorius estuarius* > *Leptocheirus plumulosus*. This range in median response concentrations reflects differences in species sensitivity, PAH bioavailability and probably, most importantly, specific experimental conditions.

The data from some of the toxicity tests with individual PAHs spiked into sediments needed to be modified or not included in further analyses. Some tests with *Diporeia* sp., *Lumbriculus variegatus*, *Limnodrilus hoffmeisteri* and *Hyalella azteca* were conducted at concentra-tions in the sediment that could not have been at equilibrium with the concentration of the PAH at solubility in interstitial water (Kukkonen and Landrum, 1994; Landrum et al., 1994; Lotufo and Fleeger, 1996; Driscoll et al., 1997a,b). The reported median effect concentration is in parenthesis and maximum sediment concentration at water solubility (given in Table 3-4) for each PAH is indicated in bold in Appendix D. To facilitate comparisons of species sensitivity and to account for bioavailability, median response concentrations were divided by the $C_{OC,PAHi,FCVi}$ values to obtain the test-specific $ESBTU_{FCVi}$ values. Then PAH-specific SMAVs and GMAVS across PAHs were calculated only for 10-day lethality tests. The maximum solubility-limited sediment concentration was used to calculate the test-specific $ESBTU_{FCVi}$ and PAH-specific SMAVs and GMAVs only if there insufficient no data from tests that lacked this solubility constraint. Some tests were conducted with newly spiked sediments where time was likely insufficient to permit equilibrium to be achieved between the interstitial water and organic carbon and other sediment partitioning phases (Suedel et al., 1993). Data from these tests were not used because the median effect concentration in sediments would be lower than that expected if sediments and interstitial water were at equilibrium.

For the seven species tested acceptably against one or more PAH, the 43 test-specific $ESBTU_{FCVi}$ ranged from 1.47 to 57.8, a factor of 39.3, with no values below 1.0 $ESBTU_{FCVi}$ (Figure 5-4; Appendix D). Within each individual species, the range of test-specific $ESBTU_{FCVi}$ across multiple tests with one or more PAH, based on 10-day LC50 values, was within only a factor of 1.5 to 4.1 (mean 3.0). For the three saltwater amphipods tested against multiple PAHs the range of PAH-specific SMAVs was within a factor of 1.4 to 2.0 (mean 1.7). These observations indicate that the species tested differed in their sensitivities to PAHs, but that within a species there was a similarity of response across tests with the same or multiple PAHs. The range and frequency

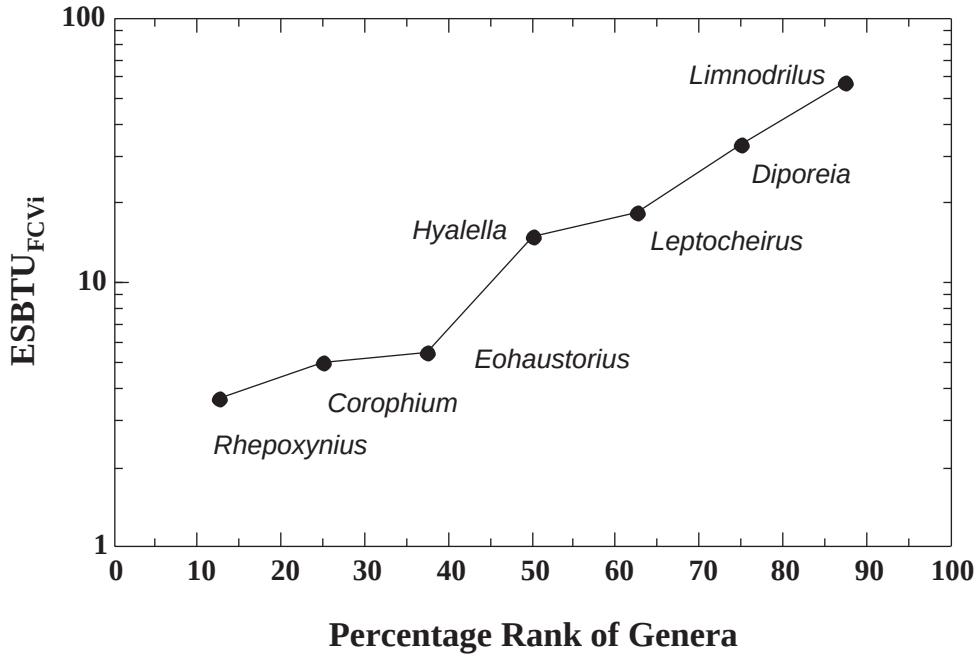

Figure 5-4. Percentage rank, based on ESBTU$_{FCVi}$, of the sensitivities of genera of benthic organisms from spiked sediment toxicity tests.

distribution of contaminant sensitivity among aquatic species is comparable to that of benthic species in water-only tests (see Section 3.4).

This analysis of data from spiked-sediment toxicity tests with individual PAHs supports the conclusion that the $C_{OC,PAHi,FCVi}$ derived from water-only toxicity tests, narcosis theory and national WQC are appropriately protective of benthic organisms. These comparisons between sediments spiked with individual PAHs and their respective $C_{OC,PAHi,FCVi}$ have value in suggesting the validity of the EqP and narcosis approaches. However, PAHs occur in nature not as individual compounds, but as mixtures.

5.2.5 PAH Mixtures

Sediments spiked with PAH mixtures have been used to resolve two issues that are relevant to the validation of the ESB for PAHs (Swartz et al., 1997; Landrum et al., 1991; Boese et al., 1999; Burgess et al., 2000b; Spehar et al., In preparation). The first concerns the toxicological additivity of the effects of the individual components of the mixture. If effects are additive, relatively simple models can be used to predict the effects of mixtures. The second issue concerns the low solubility of PAHs with high octanol-water partitioning coefficients (i.e., PAHs with $K_{OW} > 5.5$). The predicted LC50 of many high K_{OW} compounds exceeds their solubility limit. Accordingly, experimental attempts to establish the LC50 for individual high K_{OW} PAHs spiked into sediment have observed little or no acute or chronic toxicity. High K_{OW} PAH mixtures have been recently tested to see if individual high K_{OW} PAHs contribute fractional toxic units that are additive with effects of other PAHs (Spehar et al., *In preparation*).

5.2.6 Additivity of PAH Mixtures

There is a wealth of aquatic toxicological data that supports the additivity of PAHs and other narcotic chemicals in water (Konemann, 1980;

Hermens et al., 1984; Broderius and Kahl, 1985; Fig. 2-11). The additivity of sediment-associated contaminants is less well documented, although several publications indicate that PAHs in sediment are either additive or slightly less than additive (Swartz et al., 1995, 1997; Landrum et al., 1991, 1994). Landrum et al. (1991) found that the effects of a mixture of 11 sediment-associated PAHs on the freshwater amphipod, *Diporeia* sp. were "approximately additive with no overt evidence of synergism or antagonism." Landrum et al. (1991) also noted that additivity is further supported by the fact that LD50 values, expressed as PAH molar concentration in amphipod tissue, were the same for a single compound (pyrene) and the mixture of 11 compounds.

The results from some of the above 10-day studies were analyzed by dividing the concentrations of each of the PAHs in the sediments by the $C_{OC,PAHi,FCVi}$ and summing the quotients to derive the $\Sigma ESBTU_{FCV}$ for the mixture (Table 5-2). No acute toxicity was observed with *Diporeia* exposed to a $\Sigma ESBTU_{FCV}$ for all PAHs up to 3.08 (Landrum et al., 1991), but none would be expected given the 10-day LC50 value of >34.0 $\Sigma ESBTU_{FCV}$ for this species (Table 5-2). Toxicity to *R. abronius* was absent in several tests with mixtures of PAHs in treatments from 1.42 to 27.8 $\Sigma ESBTU_{FCV}$ and occurred in treatments with 5.80 and 10.3 $\Sigma ESBTU_{FCV}$ (Swartz et al., 1997; Boese et al., 1999). For *R. abronius*, the GMAV from 10-day spiked sediment tests with individual PAHs was 3.67 $\Sigma ESBTU_{FCV}$ (Table 5-2). This suggests a less than additive toxicity of the PAH mixtures tested. The amphipod *A. abdita* was exposed to a total of 2.58 and 6.05 $\Sigma ESBTU_{FCV}$ by Burgess et al. (2000b). Toxicity was absent from both treatments, and none probably should have been expected given the 4-day LC50 at 13.8 $\Sigma ESBTU_{FCV}$ (Table 5-2).

Additivity of mixtures of 13 PAHs was assumed in the development of the ΣPAH model that was used to accurately classify PAH-contaminated, field-collected sediment as toxic or not toxic (Swartz et al., 1995). Swartz et al. (1997) concluded that sediment spiked with a mixture of acenaphthene, phenanthrene, fluoranthene and pyrene caused effects on *R. abronius* that were slightly less than additive. Di Toro and McGrath (2000) reanalyzed these data and concluded that the mixture was additive (also see Section 5.2.7). Even if PAH interactions are slightly less than additive, the potential error introduced by the assumption of additivity in the derivation of an ESB for PAH mixtures would be relatively small and would be environmentally protective (i.e., the toxicity of mixtures would be slightly over-estimated).

5.2.7 PAH Additivity Demonstrated Using the Universal Narcosis Slope

The additivity of mixtures of PAHs spiked into sediments was tested using narcosis theory to calculate PAH-specific 10-day LC50 values in sediments for *R. abronius*. The experimental data from Swartz et al., (1997) was reexamined using predicted PAH-specific 10-day sediment LC50 values for *R. abronius*. The narcosis methodology was used to test additivity, rather than the actual sediment LC50 values as was presented above and by Swartz et al., (1997). This is because the predicted sediment LC50 values were derived using data from many tests with a variety of PAHs. Also, because sediment LC50 values could be predicted for the 31 or 34 PAHs analyzed from field sediments used in 10-day toxicity tests with data from toxicity tests with *R. abronius* to test narcosis and EqP predictions (See Section 5.3.1).

Interstitial water concentrations were used in place of water-only LC50 values in this process because water-only toxicity data were not available. This is justified because interstitial water and water-only LC50 values have been shown to be nearly the same (see Section 5.2.1). The 10-day interstitial water LC50 values were for eight PAHs (fluoranthene, naphthalene, pyrene, 1-methylfluorene, 2-methylphenanthrene, 9-methylanthracene, 2,6-dimethylnaphthlene, and 2,3,5-trimethylnaphthlene) tested in separate experiments. The interstitial water LC50 values for fluoranthene were from seven separate experiments (mean LC50 = 19.5 µg/L) (Swartz et al., 1990; DeWitt et al., 1992), whereas the LC50

$$\log_{10}\text{PAH-specific LC50}_{R.\ abronius} = -0.945 \log_{10}K_{OW} + \log_{10}(15.8\ \mu\text{mol/g octanol}) \quad (5\text{-}2)$$

The PAH-specific $LC50_{R.\ abronius}$ is used to calculate the PAH-specific sediment LC50 ($\mu g/_{OC}$) for *R. abronius* (equation 5-3).

$$\text{PAH-specific sediment LC50}_{R.\ abronius} = K_{OC} \times \text{PAH-specific LC50}_{R.\ abronius} \quad (5\text{-}3)$$

values for the remaining seven PAHs are from single experiments (Ozretich et al., 1997) (Table 5-1). The individual LC50 values, and mean value for fluoranthene, were normalized to a K_{OW} of 1.0 using the universal narcosis slope (Equation 2-29). The geometric mean of these LC50 values at a K_{OW} of 1.0 is the critical body burden of 15.8 µmol/g octanol (octanol serves as a surrogate for lipid). The critical body burden is used to calculate the PAH-specific 10-day LC50 values (µg/L) for *R. abronius* (Equation 5-2). This equation is analogous to Equation 3.2 which is used to calculate the PAH-specific WQC.

The mortality of *R. abronius* in the standard 10-day sediment tests where the sediments were spiked individually (acenaphthene, fluoranthene, phenanthrene or pyrene (open symbols)), or a mixture of these four PAHs (solid circles), is compared to the predicted sediment toxic units (PSTU) to test the utility of this approach to normalize the toxicity of individual PAHs and, most importantly, to test the additivity of the PAH mixture experiment of Swartz et al. (1997) (Figure 5-5A). PSTUs are the quotients of the concentration of each PAHs measured in the individual spiked sediment treatments divided by the predicted PAH-specific 10-day sediment LC50 values for *R. abronius*. For the mixture, PSTUs were summed to obtain the total toxic unit contribution (in Section 5.3.1, sediments from the field are similarly analyzed; Figure 5-5B). The percent mortality-PSTU relationship is similar for the individual PAHs and the mixture. Apparent LC50 values are approximately within a factor of two of 1.0 PSTU. This analysis based on the universal narcosis slope and a similar analysis for narcotic chemicals in water-only experiments (Section 2.10), suggests that the assumption of near additivity of mixtures of PAHs is a reasonable approximation.

5.2.8 Additivity of Mixtures of High K_{OW} PAHs

The solubility of PAHs in water generally decreases with increasing K_{OW}, while the water column toxicity of PAH increases with increasing K_{OW}. Although the solubility of individual PAHs are a function of their structure and polarity rather than just K_{OW}, the general relationship between solubility and K_{OW} is such that solubility decreases with increasing K_{OW} slightly faster than toxicity increases. The net result of this relationship is that PAHs with high K_{OW} (roughly $\log_{10}K_{OW}$ of 5.5 and higher) have solubilities below their predicted LC50. This has led to the conventional wisdom that high K_{OW} PAHs are not toxic (at least on an acute basis) because they are insufficiently soluble to cause toxicity. For example, high K_{OW} PAHs are generally not toxic in water-only toxicity tests (Appendix C).

This argument is founded, however, on the basis of single chemicals. PAHs do not occur as single chemicals in the environment, and available experimental evidence indicates that their toxicities are additive, or slightly less than additive, when present in mixtures. This has special significance for the higher K_{OW} PAHs; although they may be too insoluble to cause toxicity individually, they could still contribute fractional toxic units to the overall toxicity of PAH mixtures.

Historically, toxicity experiments with mixtures have been conducted by testing the toxicity of individual chemicals to determine their potency, then testing mixtures of these chemicals to determine the potency of the mixture. Comparing the toxicity of the mixture to the toxic units contributed by each chemical allows evaluation of the interactive toxicity of the mixture. In the case of high K_{OW} PAHs, this experimental approach cannot be used, because the toxicity of the individual chemicals cannot be measured. Use of the narcosis model, however, allows prediction of toxicity for the mixture components and can be used to evaluate the overall toxicity of the mixture.

Spehar et al. (*In preparation*) conducted a

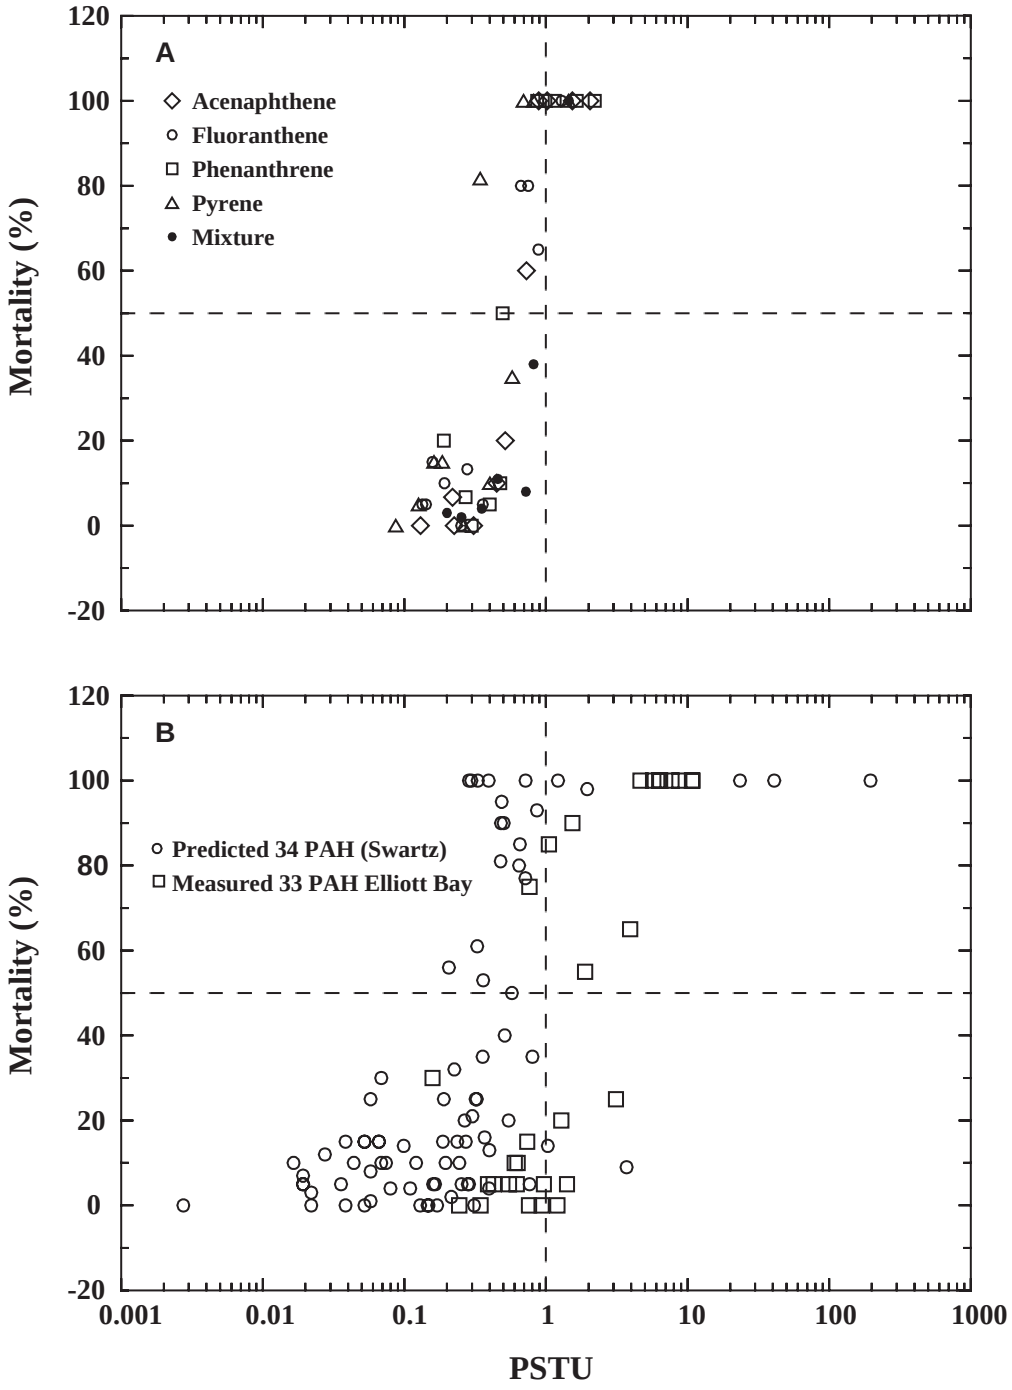

Figure 5-5. Mortality of the amphipod, *Rhepoxynius abronius*, from 10-day spiked sediment toxicity tests with four parent PAHs separately (open symbols) and in combination (closed circles) (A) and in tests with sediments from the field (B) versus predicted sediment toxic units (PSTUs). PSTUs are the quotients of the concentration of each PAH measured in sediments from the individual spiked sediment treatments, or individual sediments from the field, divided by the predicted PAH-specific 10-day sediment LC50 values for *R. abronius.* The predicted PAH-specific 10-day sediment LC50 values for *R. abronius*is were calculated using the critical body burden of 15.8 Fmol/g octanol and Equation 5-2. PSTUs were summed to obtain the total toxic unit contribution of the mixture of PAHs in spiked or field sediments.

series of sediment toxicity tests using a mixture of 13 PAHs with $\log_{10}K_{OW}$ ranging from 5.36 to 6.76 (Table 5-3). Potency of each chemical was predicted using an earlier version of the narcosis model, and the concentration for each chemical in the highest concentration of the mixture was established at an estimated 0.5 TU for *Hyalella azteca* (re-analysis using current models and the *H. azteca* GMAV from Appendix C predicts more than 0.5 TU for most PAHs). For some of these chemicals, solubility would be expected to limit their TU contribution (Table 5-3). The PAH mixture was spiked into a clean freshwater sediment at several concentrations, and into a clean marine sediment at the highest concentration only.

Several toxicity tests were conducted. A 42-day survival, growth, and reproduction study with *H. azteca* (Spehar et al., *In preparation*) was conducted in a flow-through system (2x daily renewal of overlying water) using four concentrations of the PAH mixture. In this study, chemical analysis of the bulk sediment showed that about 80% of the nominal PAH spike was measured in the sediment at the start of the exposure, and concentrations of PAH in the interstitial water were generally within a factor of 2 of the concentrations predicted from K_{OC} and solubility. After 10 days of exposure, significant effects on the dry weight of the amphipods were observed in the three highest concentrations of the PAH mixture (Figure 5-6), but there were no effects on survival. After 28 days of exposure, survival was significantly reduced in the two highest treatments, although the growth effects observed at day 10 were no longer present (Figure 5-7). As per the test protocol, organisms were removed from the sediment at day 28 and held for 14 more days in clean water to assess reproduction. No further effects on survival, growth, or reproduction were observed between days 28 and 42.

Toxicity of the PAH mixture was lower than would have been predicted based on narcosis

theory. However, concentrations of PAH measured in the tissue of exposed *Hyalella* were considerably lower than would be in equilibrium with interstitial water, suggesting that the *Hyalella* may have avoided the test sediment, thereby reducing their exposure. Avoidance of toxic sediments by *Hyalella* has been reported previously (e.g., Whiteman et al., 1996). When 10-day growth and 28-day survival responses are compared on the basis of measured tissue burden, the thresholds for response fall in the same range as is predicted by narcosis theory (Figure 5-8). Thus, although *Hyalella* had lower uptake of these PAHs, they did show a response to the high K_{OW} PAHs suggesting that these chemicals can cause toxicity to benthic organisms. Moreover, the relationship of measured tissue concentrations to biological responses was consistent with that expected from a narcotic mode of action and additivity among PAHs in the mixture. It should be noted that because the toxicity of the individual mixture components was predicted rather than measured (which would not be possible if they are not individually toxic at solubility), we can only conclude that these results are consistent with the additivity, or approximate additivity, hypothesis, but they are not, by themselves, proof of additivity.

Because of concerns that *Hyalella* may have avoided exposure to PAH in the flow-through test by spending more time in the overlying water which was being replaced 2x daily, an additional test was conducted using the same PAH-spiked sediments, but conducting the test with renewal of overlying water-only three times during the entire 10-day test. This reduced frequency of renewal should have increased the concentrations of PAH in the overlying water (not measured), thereby increasing exposure of *Hyalella* to the PAH mixture. While the flow-through test showed effects only on growth after 10 days of exposure, results of the second test showed a concentration-dependent response of both survival and growth (Figure 5-9). When expressed on the basis of total PAH molar concentration in the sediment

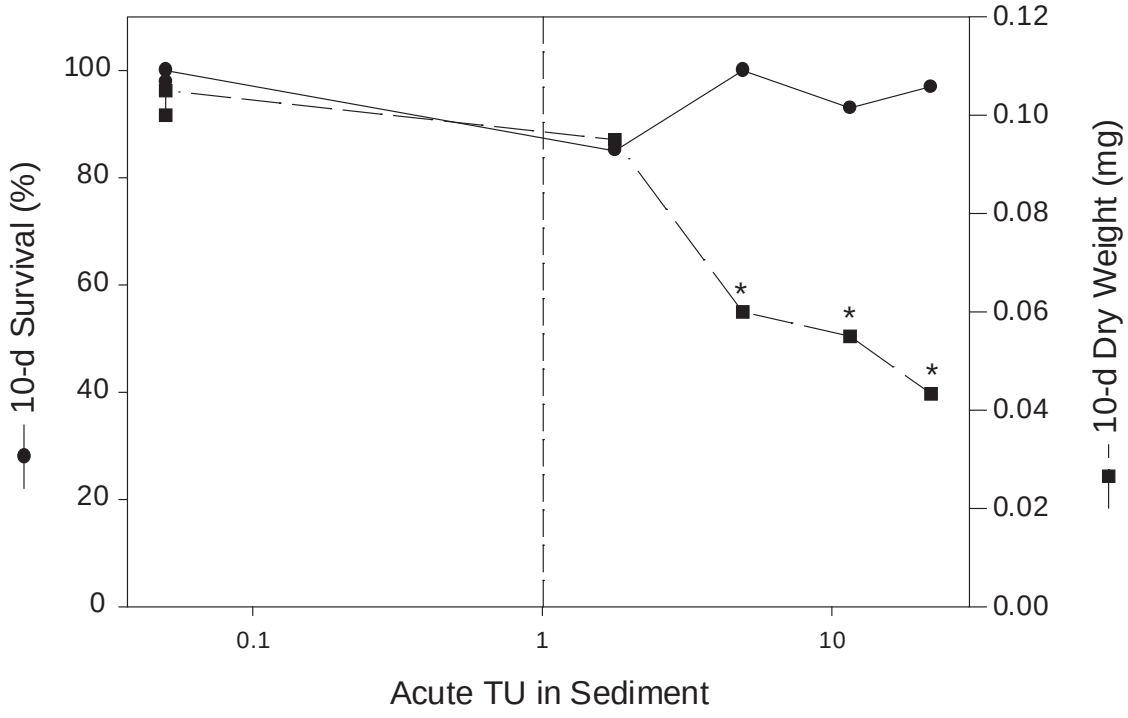

Figure 5-6. Response of *Hyalella azteca* exposed for 10 days under flow-through conditions to sediment spiked with a mixture of high K_{ow} PAH.

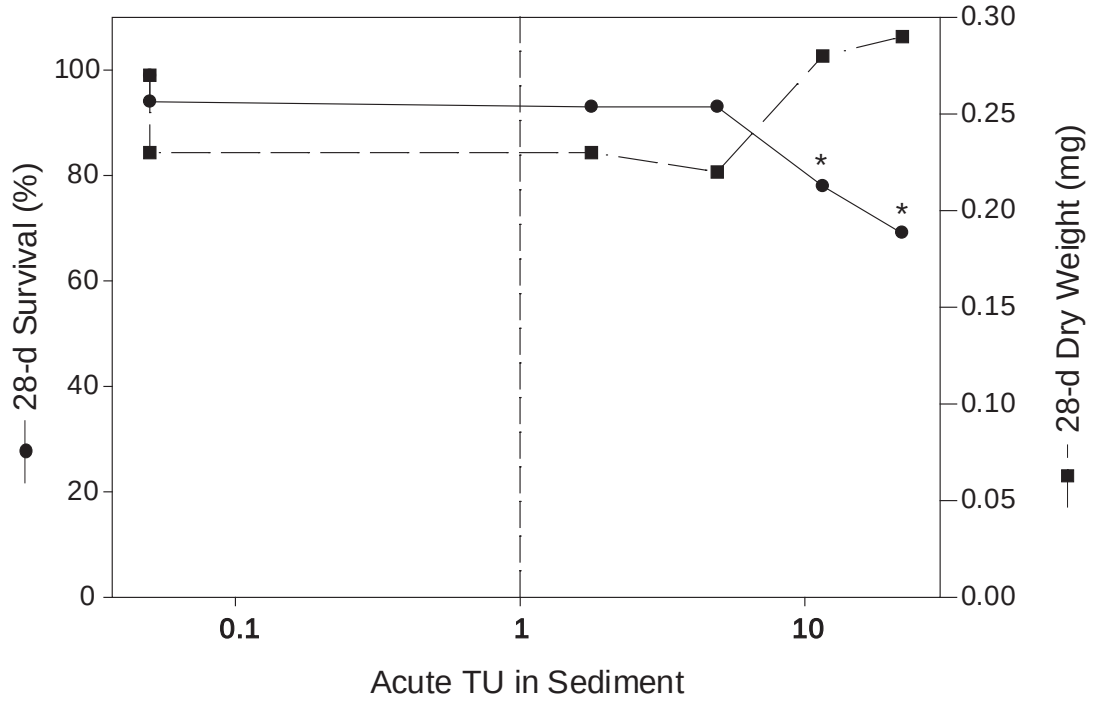

Figure 5-7. Response of *Hyalella azteca* exposed for 28 days under flow-through conditions to sediment spiked with a mixture of high K_{ow} PAH.

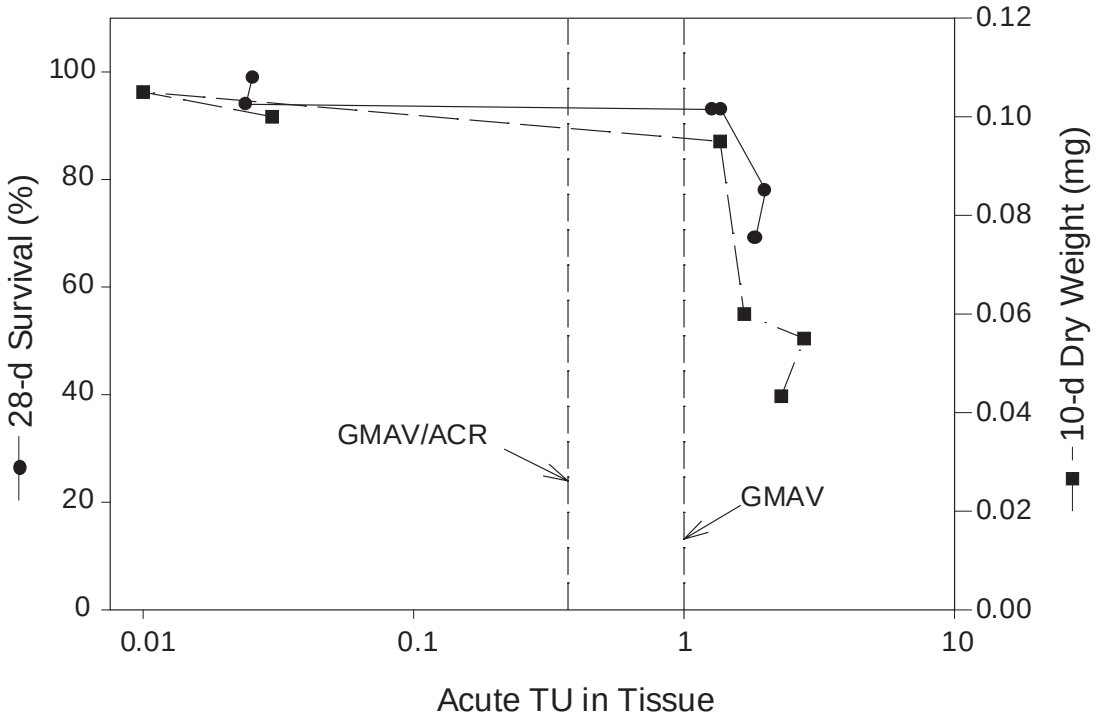

Figure 5-8. Survival (after 28 days) and growth (after 10 days) of *Hyalella azteca* expressed on the basis of measured PAH concentrations in tissues (lipid normalized).

(normalized to organic carbon), the threshold for survival and growth effects were close to the sediment concentration predicted to cause acute effects based on the narcosis model. Similarly, the tissue concentration of the mixture in the amphipods compared favorably with the critical body burden predicted to cause effects based on the narcosis model.

In addition to the freshwater experiments described above, additional experiments were conducted using marine organisms (Spehar et al., *In preparation*). Two marine organisms, a mysid (*Americamysis bahia*) and a marine amphipod (*Ampelisca abdita*), were exposed to a marine sediment spiked with the highest concentration of the PAH mixture. After 10 days of exposure to the sediment in a static system, both species showed marked mortality, with 85% mortality of mysids and 95% mortality of the amphipods. Because this sediment would be predicted to contain a large number of acute TU based on the GMAVs for these species (41 acute TU for mysids; 10 acute TU for *A. abdita*), these results cannot be used to evaluate accuracy of the narcosis model rigorously; however, they provide further support to emphasize that mixtures of high K_{OW} PAHs can cause toxicity.

In a separate test, another species of marine amphipod (*Leptocheirus plumulosus*) was exposed for 10 days to a series of concentrations of the PAH mixture spiked into the freshwater sediment used in the freshwater studies (*L. plumulosus* is tolerant of the lower salinity in the freshwater sediment, while *A. bahia* and *A. abdita* are not) (Spehar et al., In preparation). After 10 days under static conditions, *L. plumulosus* showed reduced survival in the four highest PAH concentrations (Figure 5-10). The observed toxic unit threshold for mortality was within a factor of 2 of that predicted using narcosis theory and the GMAVs in sediment from Appendix C for *L. plumulosus*.

Taken together, the results of these experiments with high K_{OW} PAHs clearly demonstrate that they can cause toxicity to benthic organisms when present in mixtures. Thresholds for toxicity in several experiments were slightly

higher than would be predicted directly from the narcosis model, though this may reflect uncertainties in the GMAV values as well as exposure-related factors (e.g., avoidance). Measured tissue concentrations in freshwater amphipods from treatments where toxicity was observed were consistent with those shown to be toxic for lower K_{OW} PAHs. Therefore, $\Sigma ESBTU_{FCV}$ for mixtures must include the partial contributions of high K_{OW} PAH in the mixture to insure that the ESB is not under protective.

5.3 Field Sediments Versus ESB_{FCV} for PAH Mixtures

The ultimate test of validity of sediment benchmarks is their predictive ability. That is, can they be used to predict effects seen in field collected samples. Unfortunately, the problem of validation using field collected samples has no straightforward solution. It is extremely difficult to separate actual cause and effect from simple correlation. The primary reason is the presence of covariation of many chemical contaminants in field collected sediments, some of which may be unmeasured. Therefore, it cannot be presumed that the response observed is due to only the chemical(s) being investigated.

However, if the PAH benchmark predicts an effect at a certain $\Sigma ESBTU_{FCV}$ for a mixture of PAHs (e.g., 50% mortality of a test organism), and the organism survives exposures significantly above the $\Sigma ESBTU_{FCV}$ value, then the benchmark may not be valid. No other comparison is more definitive. Of course, mortality at $\Sigma ESBTU_{FCV}$ values below those predicted to cause effects may be due to other causes, and provide no evidence for the validity or invalidity of the prediction.

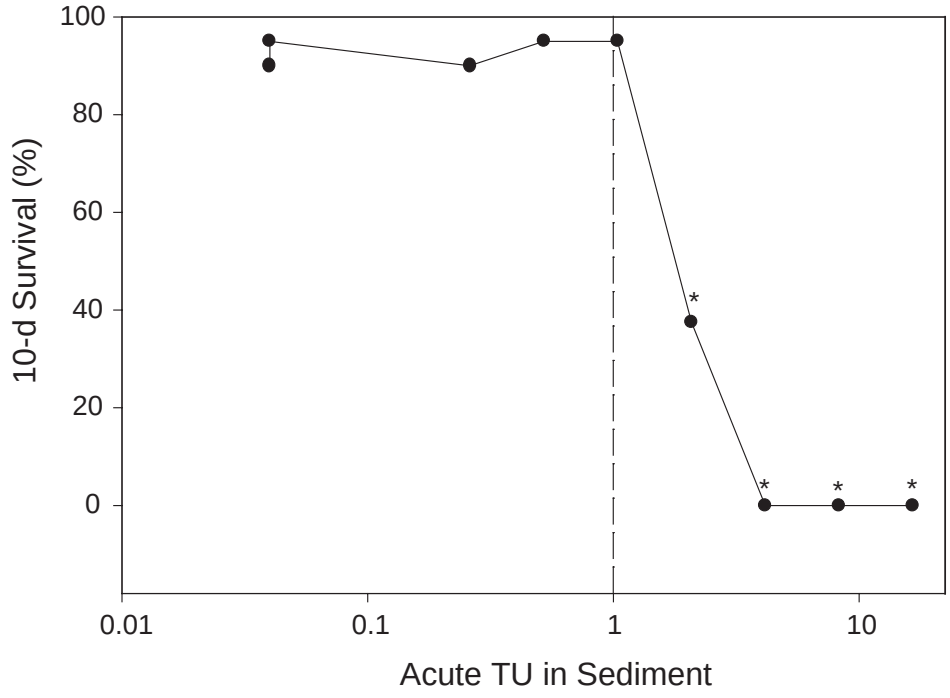

Figure 5-10. Response of *Leptocheirus plumulosus* exposed for 10 days under static conditions to sediment spiked with a mixture of high K_{ow} PAH.

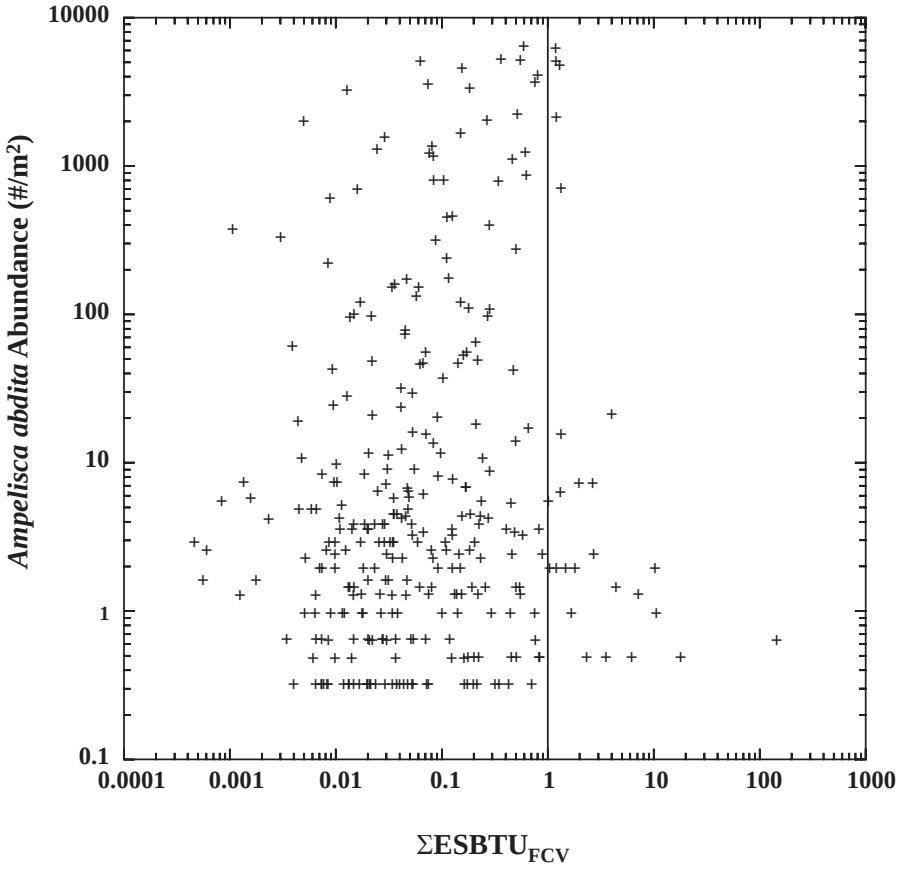

Figure 5-11. Amphipod (*Ampelisca abdita*) abundance versus $\Sigma ESBTU_{FCV}$.

5.3.1 Toxicity to R. abronius of Field Sediments Containing PAH Mixtures vs. ΣPSTUs Derived from Narcosis Theory

A set of 10-day toxicity data using *R. abronius* exposed to sediments from locations where 13 PAHs were measured and PAHs are suspected to be the primary cause of toxicity has been assembled by Swartz et al. (1995). A similar set of data from Elliott Bay where 32 PAHs (18 parent and 14 alkylated groups) were measured (Ozretich et al., 2000) is also available (See Table 3-4 for the list of PAHs). As explained in Section 5.2.7, predicted PAH-specific 10-day sediment LC50 values for *R. abronius* were derived using narcosis theory and 10-day LC50 values based on interstitial water concentrations of eight PAHs for *R. abronius*. The mortality of *R. abronius* in the standard 10-day sediment tests in each of these sediments from the field is compared to the sum of the PSTUs for that sediment (Figure 5-5B). PSTUs are the quotients of the concentration of each PAHs measured in the individual field sediments divided by the predicted PAH-specific 10-day sediment LC50 values for *R. abronius*. The sum of the PSTUs for the sediments where only 13 PAHs were analyzed were multiplied by the uncertainty factor of 2.75 (the mean ratio of the toxic contribution of the 34 PAHs analyzed by the U.S. EPA EMAP program to the 13 PAHs (see Table 6-1)). The uncertainty factor of 2.75, rather than the 95th percent uncertainty factor, was used to adjust for fewer than 34 PAHs because the goal was to use the best estimate of the sum of the toxic units to compare to the observed amphipod mortality in a specific sediment.

Consider, first, the data for which the sum of the PSTUs of the 13 PAHs (termed "predicted 34 PAH" in the figure as represented by the open circles in Figure 5-5B). There is only one

sediment where the sum of the PSTUs exceeds two where mortality was less than 50%. The important point here is that all, except one, of the sediments exceeding this concentration exhibited >50% mortality consistent with the prediction. There could be several explanations why the exception might occur in that one sediment. For example, the 13 PAHs multiplied by the mean uncertainty factor may have under-represented the true total PAH concentration.

For the remaining data, the total PAH concentrations are from field sediments where 31 of the 34 PAHs were measured (open squares). For all of these data there appears to be a concentration-response relationship with an apparent LC50 approximately at the predicted LC50 ± a factor of two, and only one sediment with less than 50% mortality had >2.0 PSTUs. This suggests that the assumption of near additivity of mixtures of PAHs is a reasonable approximation for predicting the toxicity of sediments from the field and for deriving ESBs for PAH mixtures.

5.3.2 Organism Abundance vs. ESB_{FCV} for PAH Mixtures

Another test of this sediment benchmark is the observations of the abundance of sensitive amphipods versus the total PAH concentrations in field collected sediments. Figure 5-11 presents the observed *A. abdita* abundance versus $\Sigma ESBTU_{FCV}$ when 34 PAHs were measured or estimated using the 50% uncertainty factor of 1.64 (see Table 6-1) when 23 PAHs were measured. The data are from sediments collected as part of the Virginian and Louisianian province EMAP (U.S. EPA, 1996a,b) and the New York/New Jersey Harbor REMAP (Adams et al., 1996) sediment sampling programs. The vertical line is at the ESB of 1.0 $\Sigma ESBTU_{FCV}$. The results are very encouraging. The absence of sediments having high abundances of *A. abdita* at slightly above 1.0 $\Sigma ESBTU_{FCV}$ and the decrease in amphipod abundance as the $\Sigma ESBTU_{FCV}$ increases above 1.0 is consistent with that predicted by this ESB for PAH mixtures.

It is tempting to conclude from the coincidence of $\Sigma ESBTU_{FCV}$ values >1.0 and the drop in amphipod abundance, that in fact, these data support the validity of the ESB. However, it should be pointed out again that these data can only be used to demonstrate that the ESB is not in conflict with observations. They cannot be used to validate the ESB. However, these data, and those in Figure 5-5A and B, might have cast doubt on the ESB if effects were predicted and none were observed.

The validation procedure requires sediments for which the nature of all the bioavailable chemicals are known and quantified. This is usually only satisfied with laboratory spiked sediments. This is why the experimental validity of the narcosis mixture theory as is demonstrated in Section 5.2 and illustrated in Figure 5-5A is so important.

Section 6

Implementation

6.1 Introduction

This section on implementation defines "total PAHs" for use with this ESB for PAH mixtures, presents an example ESB calculation, provides guidance on the interpretation of the ESB relative to sediment toxicity tests, describes the role of photo-activation of PAH toxicity by ultraviolet light and the relative importance of teratogenicity and carcinogenicity as a mode of toxic action for PAHs, and critically examines equilibrium of PAHs in sediments, including the presence of soot carbon, coal and similar materials as sediment binding phases other than natural organic carbon. The section ends with an approach for calculating PAH solubilities for temperatures or salinities at a specific site. This information is needed to apply this ESB and assess the risks of mixtures of sediment-associated PAHs based on the EqP methodology.

6.2 Defining Total PAH Concentration in Field Collected Sediments

"Total PAHs" required for deriving the ESB for PAH mixtures is defined in this subsection as the sum of the $ESBTU_{FCV}$ values for a minimum of the 34 PAHs (18 parents and 16 alkylated groups) measured in the U.S. EPA EMAP (U.S. EPA, 1996b, 1998) (Table 6-1). This pragmatic definition is required because databases from sediment monitoring programs that have measured a greater number of PAHs are rare, methodologies for quantification of greater than the 34 PAHs are not standard, and the use of fewer than 34 PAHs may greatly underestimate the total toxicological contribution of the PAH mixtures. We recommend that the uncertainty factors developed in this section for the 13 or 23 commonly quantified PAHs NOT be used to estimate the ESB for the 34 PAHs when important decisions are to be made based on the ESB. However, uncertainty values may be useful in specific non-ESB related decisions. The recommendation to not use the uncertainty factors for derivation of ESBs is intended to prevent the under- or over-estimation of an ESB acceptable for the protection of benthic organisms and to encourage the analysis of a minimum of the 34 PAHs using readily available analytical methodologies for new monitoring programs (NOAA, 1998)

It is expected that many sediment assessors may be in the position where available data are limited to only certain PAHs (e.g., 13 un-substituted compounds) and it is impractical to re-analyze all samples for the full suite of PAHs, but

Table 6-1. Relative distribution of $\Sigma ESBTU_{FCV,TOT}$ to $\Sigma ESBTU_{FCV,13}$ and $\Sigma ESBTU_{FCV,23}$ for the combined EMAP dataset (N=488).

Percentile	$\Sigma ESBTU_{FCV,TOT}/\Sigma ESBTU_{FCV,13}$	$\Sigma ESBTU_{FCV,TOT}/\Sigma ESBTU_{FCV,23}$
50	2.75	1.64
80	6.78	2.8
90	8.45	3.37
95	11.5	4.14
99	16.9	6.57

also undesirable to accept uncertainties stemming from the incomplete PAH characterization. In this instance, an intermediate approach may be to analyze a subset of sediment samples for the full suite of PAHs and use these data to develop a site-specific correction factor. This approach requires the assumption that this correction factor is consistent across the site, but it seems likely that the uncertainty with this assumption will be less than the uncertainty involved in using the generic correction factors from Table 6-1.

The following subsection presents the analysis that led to the adoption of the 34 PAHs as total PAH. Hereafter, mention of "total PAHs" in this document refers to use of a minimum of the 34 PAHs to derive the $\Sigma ESBTU_{FCV}$.

6.2.1 Introduction

PAHs are present in sediments as mixtures rather than as single compounds. It has been shown that the toxicity of sediment associated PAHs is approximately additive, and that PAHs with both low and high K_{OW} values contribute to the total toxicity (Section 5). Therefore, assessment of the toxicological contribution from the total PAH concentration present in sediments would theoretically require the measurement in every sediment of all PAHs. If the compounds formed by the alkylation of parent PAHs are included, there are more than several hundred possible structures, and quantifying all of them is impractical and costly.

As an alternative to measuring all PAHs, it may be possible to estimate the total PAH concentration in sediments using a subset of the commonly measured PAHs. This is desirable because the number of individual PAHs measured in field sediment monitoring programs varies and if too few PAHs are measured, the toxicity of sediment-associated PAHs will be underestimated. For some historical sediment monitoring data, only 13 PAHs identified by the U.S. EPA as parameters of concern were measured (Table 6-2). The National Oceanic and Atmospheric Administration (NOAA, 1991) began to quantify 10 additional PAHs in sediments, bringing the total number of PAHs measured to 23. Since then, the majority of sediment monitoring programs have measured these 23 PAHs (Table 6-2). More recently, the U.S. EPA EMAP has increased the number of PAHs measured from 23 to 34 by quantifying the C1 through C4 alkylated series for some patent PAHs where the C# indicates an alkyl group substitution (Table 6-2). The C1 represents one methyl substitution at any location on the PAH. The C2 represents either two methyl substitutions at any two locations or one ethyl substitution at any one location. The C3 represents either three methyl groups, one methyl and one ethyl group or one propyl group substitution. Similarly, the C4 represents any combination of methyl, ethyl, propyl and butyl groups so that the total number of carbons added to the parent PAH is four (Table 6-2). Although a C# PAH series by itself represents several different structures, for simplicity a C# PAH series was considered as one PAH. In total, this C# PAH alkylated series represents 16 groups of compounds as listed in Table 6-2.

In this section, the uncertainty limits are derived for estimating the total PAH toxicological contribution of the 34 PAHs from the 13 or 23 commonly measured PAHs. Data are presented using $ESBTU_{FCVi}$ to sum the contributions of the individual PAHs and determine the total PAH toxicity of the mixture as represented by the $\Sigma ESBTU_{FCV}$.

6.2.2 Data Collection

Coastal and estuarine sediment data from the Nation's water bodies were compiled from nine sources (NOAA, 1991; Adams et al., 1996; Anderson et al., 1996; Fairey et al., 1996; U.S. EPA, 1996a,b,1998; Ozretich et al., 2000; Hunt et al., 1998). With the exception of the Elliott Bay data (Ozretich et al., 2000), all of the data sources were from state and/or government funded sediment monitoring programs. In Elliott Bay, the PAHs were suspected to be causing the toxicity due to their elevated levels. Data sources that were identified had measured concentrations for at least the 23 PAHs identified by NOAA and

Table 6-2. PAH measured in various sediment monitoring programs. See Di Toro and McGrath (2000) for data sources.

[A] Benzo(b)fluoranthene and benzo(k)flouranthene were measured together.
[B] A specific C1-PAH was not included in the total if the C1 alkylated PAH series was measured. For example, 1-methylnaphthalene was not included in the total if the C1-naphthalenes were measured.

corresponding sediment organic carbon measurements. Three sources, Elliott Bay, EMAP Louisianian Province and EMAP Carolinian Province, had measurements for some of the alkylated PAH series. The two EMAP sources analyzed for the same alkylated PAH series. The Elliott Bay dataset had some alkylated PAHs that were similar to the EMAP sources and some alkylated PAHs that were not included in the EMAP sources. A listing of the PAHs measured in each dataset is provided in Table 6-2. The first 13 PAHs in the list are the initial 13 PAHs identified by the U.S. EPA as PAHs of concern. The first 23 PAHs in the list include the additional PAHs monitored by NOAA. The total number of PAHs measured in each dataset is also provided. To prevent duplicate counting, a specific C1, C2, C3 or C4 PAH was not included in the total number of PAHs if the alkylated PAH series was measured. As an example, for Carolinian EMAP, 1-methylnaphthalene was not included in the total, because the C1-naphthalenes were measured.

To screen for insoluble PAHs, interstitial water concentrations were computed from measured solid phase concentrations using EqP theory (Di Toro et al., 1991). If the resulting interstitial water concentrations were greater than the corresponding solubilities, insoluble PAHs were assumed to be present in the sediment. For these cases, the measured solid phase concentrations were replaced by solid phase concentrations based on the aqueous solubility of each compound ($C_{OC,PAHi,Maxi}$).

The data were converted to $ESBTU_{FCVi}$ for individual PAHs by dividing the concentration of the specific PAH in the sediment (C_{OC},µg/g_{OC}) by the $C_{OC,PAHi,FCVi}$. $\Sigma ESBTU_{FCV}$ for each sediment sample were computed by summing the $ESBTU_{FCVi}$ for each PAH measured. For purposes of this section, $\Sigma ESBTU_{FCV}$ for the 34 PAHs is denoted by $\Sigma ESBTU_{FCV,TOT}$. Equation 6-1 was used to compute $\Sigma ESBTU_{FCV,TOT}$

$$ESBTU_{FCV,TOT} = \Sigma ESBTU = \sum_{i} \frac{C_{OCi}}{C_{OC,PAHi,FCVi}} \leq 1.0 \qquad (6\text{-}1)$$

6.2.3 Methodology

The objective was to determine the uncertainty of using the 13 PAHs or the 23 PAHs to predict the $\Sigma ESBTU_{FCV,TOT}$. Only the monitoring databases containing 34 PAHs were used in this analysis. The 13 PAHs were selected since the majority of the existing sediment monitoring data include these PAHs. The uncertainty values for estimating total PAHs from datasets where 13 or 23 PAHs were measured were developed from a database of ratios of $\Sigma ESBTU_{FCV,TOT}$ to $\Sigma ESBTU_{FCV,13}$ or $\Sigma ESBTU_{FCV,23}$. In addition, regression analyses of $\Sigma ESBTU_{FCV,TOT}$ to $\Sigma ESBTU_{FCV,13}$ or to $\Sigma ESBTU_{FCV,TOT}$ to $\Sigma ESBTU_{FCV,23}$ on a log-log linear basis were conducted to demonstrate the utility of the ratio approach across the range of $\Sigma ESBTU_{FCV}$ values.

6.2.4 Uncertainty in Predicting $\Sigma ESBTU_{FCV,TOT}$

For use in determining the uncertainty in predicting $\Sigma ESBTU_{FCV,TOT}$ from datasets consisting of the 13 or 23 PAHs, the two EMAP data sources that measured the 34 PAHs were combined and treated as a single data source. In doing this, a larger dataset that represents both alkylated and parent PAHs, and therefore, inherently has the correlative relationships of both types of PAHs, was generated (N=488). The relative distributions of the $\Sigma ESBTU_{FCV,TOT}$ to the $\Sigma ESBTU_{FCV}$ for the 13 and 23 PAHs for this dataset are provided in Table 6-1. Based on the observed ratios, the measured $\Sigma ESBTU_{FCV,13}$ for the 13 PAHs must be multiplied by 11.5 to obtain an accurate estimation of the $\Sigma ESBTU_{FCV,TOT}$ with 95 % confidence. Similarly, the measured $\Sigma ESBTU_{FCV,23}$ for the 23 PAHs must be multiplied by 4.14 to obtain an estimate of the $\Sigma ESBTU_{FCV,TOT}$ with 95% confidence. High adjustment factors needed to estimate $\Sigma ESBTU_{FCV,TOT}$, particularly from 13 PAHs, indicate the importance of having real measurements of the 34 PAHs from sediments where the PAH concentrations are of likely toxicological significance. In contrast, for

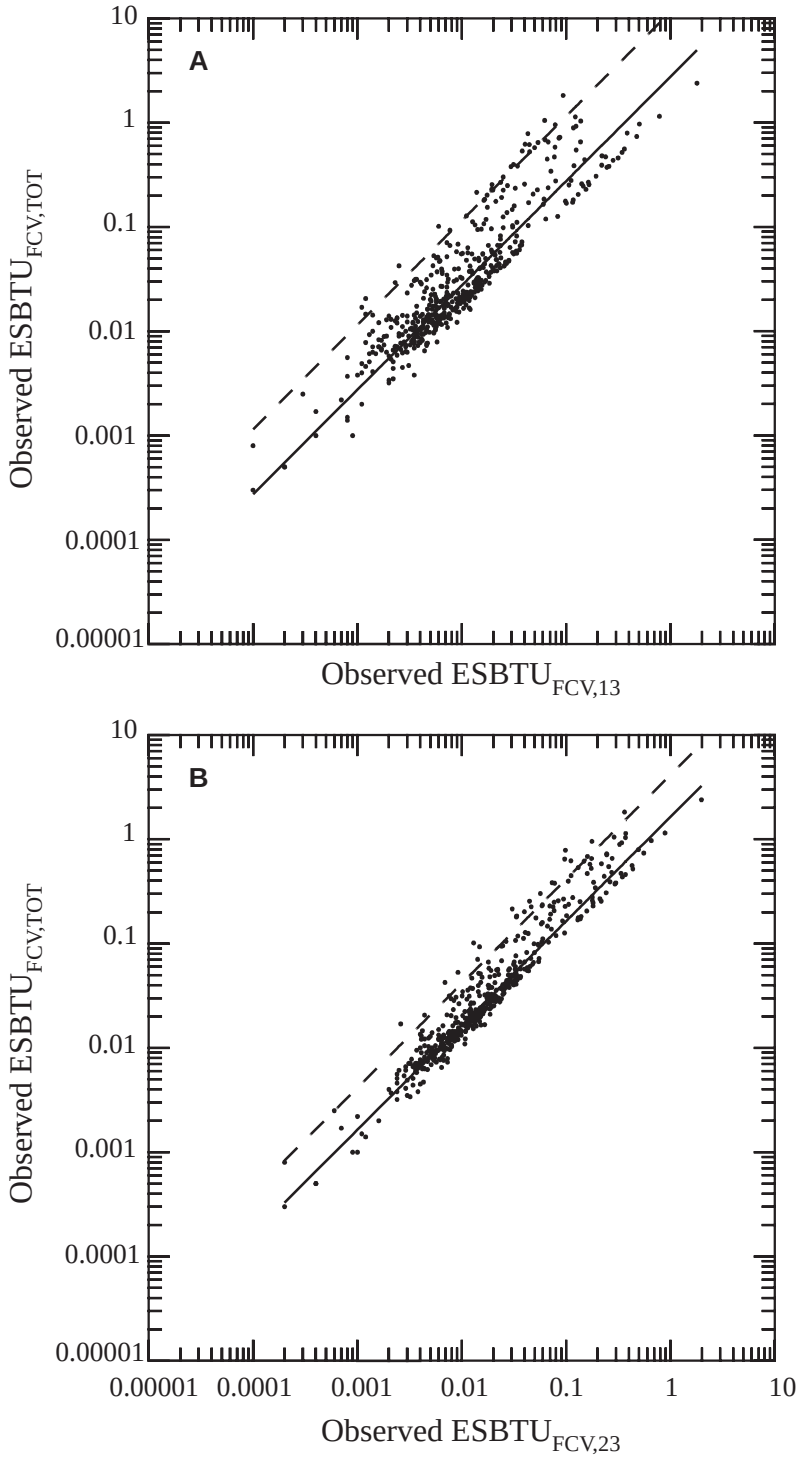

Figure 6-1. Comparison of observed ΣESBTU$_{FCV,TOT}$ to observed (A) ΣESBTU$_{FCV,13}$ from13 PAHs and (B) ΣESBTU$_{FCV,23}$ from 23 PAHs for the combined dataset including U.S. EPA EMAP Louisianian and Carolinian Provinces.

sediments where the $\Sigma ESBTU_{FCV,13}$ or $\Sigma ESBTU_{FCV,23}$ times the uncertainty factors does exceed the ESB, additional measurements including the 34 PAHs would not be warranted.

The $\Sigma ESBTU_{FCV,TOT}$ can be plotted against the $\Sigma ESBTU_{FCV,13}$ for the 13 PAHs and regression analysis conducted to show that the ratios can be used fairly well to estimate the $\Sigma ESBTU_{FCV}$ for the 34 PAHs from the sum of the 13 PAHs across a wide range of $\Sigma ESBTU_{FCV,TOT}$ because the slope is nearly 1.0 (0.9595) (Figure 6-1A). The solid line is the mean (50%) ratio of 2.75 from Table 6-1 and the dashed line is the line representing 95% of the data with a ratio of 11.5. The resulting linear regression equation from a log-log relationship is

$$\log_{10} \Sigma ESBTU_{FCV,TOT} = 0.9595 \log_{10} \Sigma ESBTU_{FCV,13} + 0.4251 \quad (R^2 = 0.8236) \qquad (6\text{-}2)$$

A similar analysis using the $\Sigma ESBTU_{FCV,TOT}$ plotted against the sum $\Sigma ESBTU_{FCV,23}$ of 23 PAHs with a regression analysis conducted to show that the slope of the regression is also nearly 1.0 (1.038) (Figure 6-1B). The solid line is the mean (50%) ratio of 1.64 from Table 6-1 and the dashed line represents 95% of the data with a ratio of 4.14. The resulting linear regression equation from a log-log relationship is

$$\log_{10} \Sigma ESBTU_{FCV,TOT} = 1.038 \log_{10} \Sigma ESBTU_{FCV,23} + 0.3576 \quad (R^2 = 0.9272) \qquad (6\text{-}3)$$

The regression approach has been used to derive uncertainty factors for estimating the $\Sigma ESBTU_{FCV,TOT}$ for the 34 PAHs using combinations of as few as three to as many as 13 or 23 PAHs (McGrath and Di Toro, 2000)

The probability distributions of the $\Sigma ESBTU_{FCV,13}$ and $\Sigma ESBTU_{FCV,23}$ values for each sediment from the databases in Table 6-2 were plotted in Figure 6-2 (A and B, respectively). The actual $\Sigma ESBTU_{FCV,13}$ values (triangles) exceeded 1.0 for 5.22% of the 1992 sediment samples (Figure 6-2A) and the $\Sigma ESBTU_{FCV,23}$ values (triangles) exceeded 1.0 for 6.55% of the 2001

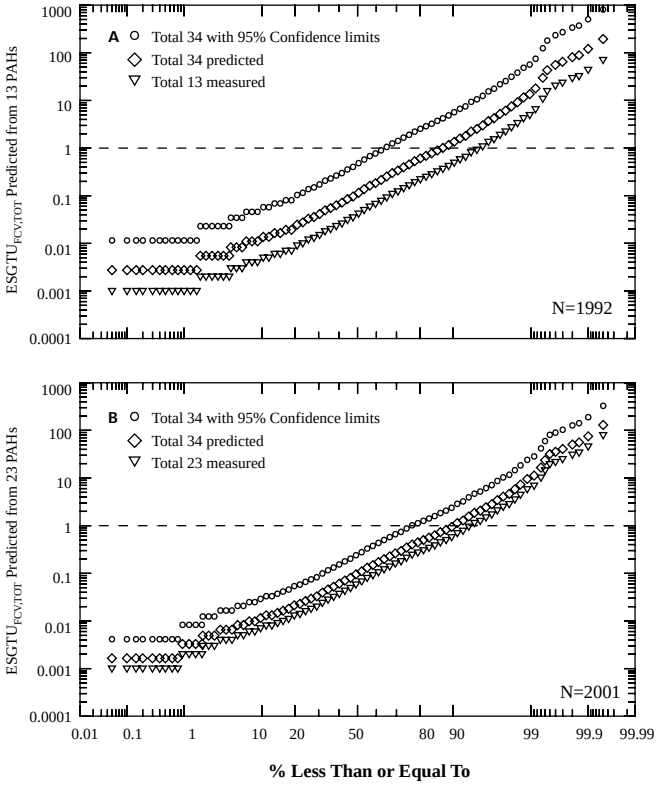

Figure 6-2. Probability distribution of the (A) $\Sigma ESBTU_{FCV,13}$ and (B) $\Sigma ESBTU_{FCV,23}$ values for each sediment from the entire database.

sediment samples (Figure 6-2B). To estimate the 50% uncertainty of $\Sigma ESBTU_{FCV,TOT}$ (plotted as diamonds in Figure 6-2), the mean ratio of the $\Sigma ESBTU_{FCV,TOT}$ to $\Sigma ESBTU_{FCV,13}$ (2.75; see Table 6-1) was applied to the sediment-specific $\Sigma ESBTU_{FCV,13}$ values and the mean ratio of $\Sigma ESBTU_{FCV,TOT}$ to $\Sigma ESBTU_{FCV,23}$ (1.64) was applied to the sediment-specific $\Sigma ESBTU_{FCV,23}$ values. The $\Sigma ESBTU_{FCV,TOT}$ estimated from the $\Sigma ESBTU_{FCV,13}$ exceeded 1.0 for 12.9% of the 1992 sediment samples and the $\Sigma ESBTU_{FCV,TOT}$ estimated from the $\Sigma ESBTU_{FCV,23}$ exceeded 1.0 for 9.85% of the 2001 sediment samples. The 95% uncertainty estimates of the $\Sigma ESBTU_{FCV,TOT}$ for each sediment (plotted as circles in Figure 6-2) was determined by multiplying the sediment-specific $\Sigma ESBTU_{FCV,13}$ values by 11.5 and by multiplying the sediment-specific $\Sigma ESBTU_{FCV,23}$ by 4.14 (Table 6-1). The 95% limits on the $\Sigma ESBTU_{FCV,TOT}$ estimated from the $\Sigma ESBTU_{FCV,13}$ exceeded 1.0 for 35.5% of the 1992 sediment samples and the 95% limits on the $\Sigma ESBTU_{FCV,TOT}$

estimated from the $\Sigma ESBTU_{FCV,23}$ exceeded 1.0 for 23.7% of the 2001 sediment samples. Therefore, if the 95% uncertainty ratios are applied to the $\Sigma ESBTU_{FCV,13}$ or the $\Sigma ESBTU_{FCV,23,}$ the predicted $\Sigma ESBTU_{FCV,TOT}$ for about one-third of the sediments are in excess of the ESB for PAH mixtures of 1.0 $\Sigma ESBTU_{FCV}$. This strongly suggests that new monitoring programs should quantify a minimum of the 34 PAHs monitored by the U.S. EPA EMAP program. In addition, field sediments containing PAHs of principally petrogenic origin will contain a greater proportion of alkalyated PAHs and PAHs not quantified in the 34 "total PAHs"(Bence et al., 1996; Means, 1998; Ho et al., 1999; Page et al., 2002). Therefore, the uncertainty factors derived above from sediments containing mostly pyrogenic PAHs, will underestimate the total PAH toxic unit contribution of the PAH mixture in sediments contaminated with mostly petrogenic PAHs. It is important to repeat that at present, the uncertainty of using the 34 PAHs to estimate the total toxicological contributions of the unmeasured PAHs is unknown and needs additional research.

For existing databases, individuals may wish to utilize uncertainty factors for sediment assessment applications other than the derivation of an ESB for PAH mixtures. An example, the use of the 50% uncertainty factors from Table 6-1 to provide the "best estimate" of the $\Sigma ESBTU_{FCV,TOT}$ for the 34 "total PAHs" in field sediments to compare with amphipod abundance (Section 5.3.1, Figure 5-11). If the number and kinds of PAHs are of similar proportions from a database from a specific site, uncertainty factors for adjusting the concentrations of the PAHs at that site may be derived using the approach detailed above. Research to determine the toxicological contributions of PAHs in sediments that are not included in the 34 PAHs is encouraged so that the uncertainty of this definition of "total PAHs" can be estimated.

6.3 Example Calculation of ESB_{FCV} for PAHs and EqP-based Interpretation

To assist the users of this ESB for mixtures of PAHs, example calculations for deriving the ESB are provided in Table 6-3. For each of three sediments, the calculations began with measured concentrations (in bold) of individual PAHs (µg/g dry wt.) and TOC (%) in each sediment. All other values were calculated. The specific concentrations in each sediment were selected to provide examples of how the chemical measurements are used with the ESB to determine the acceptability of the mixture of PAHs in a specific sediment and how the risks of sediment-associated PAHs can be evaluated within the technical framework of the EqP and narcosis approaches. The 34 PAHs constituting what is defined as "total PAH" in Section 6 are listed. Also listed are the critical concentrations in sediment of each of the 34 individual PAHs ($C_{OC,PAHi,FCVi}$) from Table 3-4.

Sediment A is provided as an example to demonstrate how to calculate the ΣESBTU when less than the required 34 PAHs have been chemically analyzed. It is important to remember that because of the uncertainty in such calculations the resultant ΣESBTU must not be considered as an ESB nor used in important sediment management decisions. Uncertainty factors applied to the ΣESBTU have value, for example, in determining if additional chemical analyses are required and prioritizing which sediments require the additional analyses.

Sediment A is from a historical monitoring database, it contains concentrations of 13 PAHs measured as µg PAH/g dry sediment and has 0.81% TOC. First, the dry weight concentrations for each PAH were converted to µg PAH/g organic carbon (C_{OC}, $\mu g/g_{OC}$) by dividing by the fraction organic carbon (f_{OC} = 0.0081), where f_{OC} = %TOC/100. Second, the organic carbon-normalized PAH concentrations in the sediment were divided by the PAH-specific sediment concentration of concern ($C_{OC,PAHi,FCVi}$) to derive the toxic unit-like $ESBTU_{FCVi}$ for each individual PAH. In this sediment, none of the measured C_{OCi} exceed the corresponding $C_{OC,PAHi,Maxi}$ so solubility constraints do not affect the calculation of $ESBTU_{FCVi}$ for this sediment. The $ESBTU_{FCVi}$ for the 13 PAHs were added to derive the ΣESBTU for the 13 PAHs ($\Sigma ESBTU_{FCV,13}$) which is 0.348

Sum total of $ESBTU_{FCVi}$					$\Sigma ESBTU_{FCV,TOT}$ = 3.831

[A] PAHs and corresponding $C_{OC,PAHi,FCVi}$ and $C_{OC,PAHi,Maxi}$ values are from Table 3-4 (bold).

[B] Because C_{OC} exceeds $C_{OC,PAHi,Maxi}$, $C_{OC,PAHi,Maxi}$ is substituted for C_{OC} to calculate $ESBTU_{FCVi}$ (see text).

(Table 6-3). Importantly, only 13 of the 34 individual PAHs defined as total PAH were measured. Because the toxicological contributions of all 34 PAHs must be considered if the ESB is to be protective of benthic organisms, some assumption must be made regarding the contribution of the unmeasured PAHs. For a confidence level of 95%, the uncertainty factor from Table 6-1 is 11.5, which is then multiplied by the calculated $\Sigma ESBTU_{FCV,13}$ of 0.348 for an estimated value of $\Sigma ESBTU_{FCV,34}$ of 4.00. Since this value is greater than one, it suggests the potential for adverse effects from PAHs. However, one must realize that this finding is, in part, a function of the correction factor selected to relate the data for 13 PAHs to an estimated ΣESBTU for 34 PAHs. If the value for 50% confidence was selected from Table 6-1 (2.75), the estimated $\Sigma ESBTU_{FCV,34}$ drops to 0.957, which is much lower than the value predicted for the 95% confidence interval. This difference illustrates the importance of measuring all 34 PAH compounds in order to eliminate unnecessary uncertainty in applying the PAH ESB.

Sediment B is a PAH-contaminated sediment from one of the U.S. EPA EMAP monitoring programs where all 34 of the PAHs in the sediment and TOC (0.886%) were measured. The concentrations of each PAH on a μg PAH/g organic carbon (C_{OC}, $\mu g/g_{OC}$) basis were derived by dividing the dry weight concentrations by the fraction organic carbon (f_{OC} = 0.00886), where f_{OC} = %TOC/100. The organic carbon-normalized PAH concentrations in sediment were divided by the PAH-specific sediment concentration of concern ($C_{OC,PAHi,FCVi}$) to derive the $ESBTU_{FCVi}$ for each individual PAH. As was the case for Sediment A, none of the measured C_{OC} exceeded $C_{OC,PAHi,Maxi.}$, so solubility constraints did not factor into the calculation of $ESBTU_{FCVi}$. The $ESBTU_{FCVi}$ values for the 34 PAHs were summed to determine the $\Sigma ESBTU_{FCV}$ which was 4.41, which exceeds the ESB ($\Sigma ESBTU_{FCV}$ >1.0) for PAH mixtures. Further examination of this sediment suggested that it is contaminated with primarily petrogenic PAHs; i.e., the ratio of $\Sigma ESBTU_{FCV,13}$ (which contains no alkylated PAHs) to $\Sigma ESBTU_{FCV}$ for the 34 PAHs is low (approximately 0.1). Chemical analysis of the PAHs in interstitial water indicated that this sediment may be unacceptably contaminated by the mixture of PAHs because it contained 5.6 interstitial water toxic units ($IWTU_{FCV}$). Ten day toxicity tests, which were part of the monitoring project, showed 64% mortality of *R. abronius* which is consistent with the $IWTU_{FCV}$ and the 10-day spiked sediment LC50 for *R. abronius* at 3.68 $\Sigma ESBTU_{FCV}$ values (Appendix D). This suggests the EqP- and narcosis-based ESB is appropriate to the sediment. The sediment is unacceptable for the protection of benthic organisms due to the PAH mixture present and additional studies to quantify the spatial extent of contamination are desirable.

Sediment C is also a PAH-contaminated sediment from an U.S. EPA EMAP monitoring program where the 34 PAHs and TOC of 6.38% were measured. The concentrations of each PAH on a µg PAH/g organic carbon (C_{OC}, $\mu g/g_{OC}$) basis were derived by dividing the dry weight concentrations by the fraction organic carbon (f_{OC} = 0.0638), where f_{OC} = %TOC/100. Except for perylene, the organic carbon-normalized PAH concentrations in sediment were divided by the PAH-specific sediment concentration of concern ($C_{OC,PAHi,FCVi}$) to derive the $ESBTU_{FCVi}$ for each individual PAH. The concentration of perylene 442.2 $\mu g/g_{OC}$ exceeded the solubility-constrained solid phase concentration ($C_{OC,PAHi,Maxi}$). Thus, the $ESBTU_{FCVi}$ for perylene was calculated as the quotient of the solubility-constrained solid phase concentration over the perylene-specific solid phase concentration equivalent to the FCV ($ESBTU_{FCV,Perylene} = C_{OC,Perylene,Maxi} / C_{OC,Perylene,FCV}$). The $ESBTU_{FCVi}$ values for the 34 PAHs were summed to determine the $\Sigma ESBTU_{FCV}$ which was 3.83, a similar value as in sediment B. The PAH mixture in sediment C exceeds the ESB ($\Sigma ESBTU_{FCV}$ >1.0) for PAH mixtures. In contrast to sediment B, sediment C was not toxic to *R. abronius* in 10-day sediment toxicity tests. This sediment is contaminated with primarily pyrogenic PAHs; i.e., the ratio of $\Sigma ESBTU_{FCV,13}$ (which contains no alkylated PAHs) to $\Sigma ESBTU_{FCV}$ for the 34 PAHs is high (approximately 0.5).

Because this PAH mixture appears to be combustion related, it suggests the potential for the presence of soot carbon, coal, or other carbon forms that show unusual partitioning behavior relative to normal diagenetic carbon (see Section 6.8). Indeed, chemical analysis of interstitial water from this sediment showed <0.12 $IWTU_{FCV}$ of PAHs. If normal partitioning behavior was occuring, one would expect the $IWTU_{FCV}$ to be very close to the calculated $\Sigma ESBTU_{FCV}$ (in this case, 3.89) is indicative of this unusual partitioning behavior. Physical examination of the sediment showed the presents of soot-like particles. The presence of soot and associated differences in chemical partitioning make the directly calculated $\Sigma ESBTU_{FCV}$ overly protective for this sediment. However, one could apply the general PAH ESB approach to the interstitial water using $IWTU_{FCV}$, or develop site-specific partition coefficients and recalculate $\Sigma ESBTU_{FCV}$ using site-specific $C_{OC,PAHi,FCVi}$ values calculated from the site-specific partition coefficients, as described in U.S. EPA (2003b).

6.4 Interpreting ESBs in Combination with Toxicity Tests

Sediment toxicity tests provide an important complement to ESBs in interpreting overall risk from contaminated sediments. Toxicity tests have different strengths and weaknesses compared to chemical-specific benchmarks, and the most powerful inferences can be drawn when both are used together.

Unlike chemical-specific benchmarks, toxicity tests are capable of detecting any toxic chemical, if it is present in toxic amounts; one does not need to know what the chemicals of concern are to monitor the sediment. Toxicity tests are also useful for detecting the combined effect of chemical mixtures, if those effects are not considered in the formulation of the applicable chemical-specific benchmark. However, if the sediment requirements of the test species are not met, observed mortality may not be due to chemical contaminants in the sediment.

On the other hand, toxicity tests have weaknesses also; they provide information only for the species tested, and also only for the endpoints measured. This is particularly critical given that most sediment toxicity tests conducted at the time of this writing measure primarily short-term lethality; chronic test procedures have been developed and published for some species, but these procedures are more resource-intensive and have not yet seen widespread use. In contrast, chemical-specific benchmarks are intended to protect most species against both acute and chronic effects.

Many assessments may involve comparison of sediment chemistry (e.g., using ESB values) and toxicity test results. In cases where results using these two methods agree (either both positive or both negative), the interpretation is clear. In cases where the two disagree, the interpretation is more complex; some investigators may go so far as to conclude that one or the other is "wrong," which is not necessarily the case.

Individual ESBs consider only the effects of the chemical or group of chemicals for which they are derived. For this reason, if a sediment shows toxicity but does not exceed the ESB for a chemical of interest, it is likely that the cause of toxicity is a different chemical or group of chemicals.

In other instances, it may be that an ESB is exceeded but the sediment is not toxic. As explained above, these findings are not mutually exclusive, because the inherent sensitivity of the two measures is different. ESBs are intended to protect relatively sensitive species against both acute and chronic effects, whereas toxicity tests are performed with specific species that may or may not be sensitive to chemicals of concern, and often do not encompass the most sensitive endpoints (e.g., chronic survival, growth or reproduction). It is also possible for a sediment above the ESB to be non-toxic if there are site-specific partitioning conditions that run counter to the equilibrium partitioning model and its assumptions (see Section 7.2).

The first step in interpreting this situation is to consider the magnitude of the ESB exceedance

and the sensitivity of the test organism and endpoint to the suspect chemical. For example, the acute-chronic ratio used for the PAH mixtures ESB is 4.16 (Section 3.3.7); as such, if $\Sigma ESBTU_{FCV} = 4$, one would anticipate lethal effects only for highly sensitive species. Between $\Sigma ESBTU_{FCV}$ of 1 and 4, one would expect only chronic effects, unless the test species was unusually sensitive. If $\Sigma ESBTU_{FCV}$ for PAHs was 2, for example, one would not generally expect to see lethality from PAHs in short term sediment lethality tests.

A more precise method for evaluating the results of toxicity tests is to calculate effect concentrations in sediment that are species specific. For species contained in the toxicity data for the PAH mixtures ESB (Section 3.2.1), effect concentrations in sediment can be calculated that are specific for that organism (using procedures in Section 4). These values could then be used to directly judge whether the absence of toxicity in the toxicity test would be expected from the corresponding level of sediment contamination.

If the exceedance of the PAH ESB is sufficient that one would expect effects in a toxicity test but they were not observed, it is prudent to initially evaluate the partitioning behavior of the chemical in the sediment based on sediment organic carbon content. Later evaluations may require evaluating partitioning based on other partitioning phases as described in Section 6.8. This is performed by isolation of interstitial water from the sediment and analyzing it for the same PAHs measured in the solid phase. Predicted concentrations of chemicals in the interstitial water can be calculated from the measured concentrations in the solid phase (normalized to organic carbon)

$$C_d = C_{OC} / K_{OC} \qquad (6\text{-}4)$$

For chemicals with $\log_{10}K_{OW}$ greater than 5.5, corrections for DOC binding in the interstitial water will be necessary

$$C_d = C_{OC}/K_{DOC} \qquad (6\text{-}5)$$

If the measured chemical in the interstitial water is substantially less (e.g., 2-3 fold lower or more), it suggests that the organic carbon in that sediment may not partition similarly to more typical organic carbon, and derivation of site-specific ESBs based on interstitial water may be warranted (U.S.EPA, 2003b).

6.5 Photo-Activation

6.5.1 Overview

Research over the last decade has shown that the presence of ultraviolet (UV) light can greatly enhance the toxicity of many PAHs. This "photo-activated" toxicity has been shown to cause rapid, acute toxicity to several freshwater and marine species including fish, amphibians, invertebrates, plants and phytoplankton (Bowling et al., 1983; Cody et al., 1984; Kagan et al., 1984; Landrum et al., 1984a,b; Oris et al., 1984; Allred and Giesy, 1985; Kagan et al., 1985; Oris and Giesy, 1985, 1986, 1987; Gala and Giesy, 1992; Huang et al., 1993; Gala and Giesy, 1994; Ren et al., 1994; Arfsten et al., 1996; Boese et al., 1997; Huang et al., 1997; McConkey et al., 1997; Pelletier et al., 1997; Diamond and Mount, 1998; Hatch and Burton, 1998; Boese et al.,1999; Monson et al., 1999; Spehar et al., 1999; Pelletier et al., 2000; Barron et al., 2003). Depending on the organism and exposure regime, photo-activation can increase toxicity of certain PAHs by one to four orders of magnitude over that caused by narcosis.

The mechanism for phototoxicity has been related to the absorption of ultraviolet radiation (UV) by the conjugated bonds of selected PAH molecules

$$PAH + UV \rightarrow PAH^* + O_2 \rightarrow PAH + O_2^* \qquad (6\text{-}6)$$

This excites the PAH molecules to a triplet state (PAH*) which rapidly transfers the absorbed energy to ground state molecular oxygen (O_2) forming excited singlet oxygen intermediaries (O_2*) (Newsted and Giesy, 1987). Although extremely short-lived (2 to 700 μs), oxygen intermediaries are highly oxidizing and can cause severe tissue damage upon contact. Despite the many different parent PAHs and related alkylated

forms, not all PAHs induce photo-activated toxicity. Those PAHs that are photo-activated can be predicted using various molecular physical-chemical variables (Newsted and Giesy, 1987; Oris and Giesy, 1987); however, the Highest Occupied Molecular Orbital - Lowest Unoccupied Molecular Orbital gap model (HOMO-LUMO) has been the most successful (Mekenyan et al., 1994a,b; Veith et al., 1995a,b; Ankley et al., 1996; Ankley et al., 1997). As research on the nature of photo-activated toxicity has evolved, certain key elements of this phenomena have been better defined including interactions of UV and PAH dose, effects of temperature, humic substances, organism behavior, turbidity, dissolved oxygen, mixtures, photoperiod and additivity (Oris et al., 1990; McCloskey and Oris, 1991; Ankley et al., 1995, 1997; Ireland et al., 1996; Hatch and Burton,1998, 1999; Erickson et al., 1999; Nikkilä et al., 1999; Weinstein and Oris 1999, Weinstein 2002).

Several studies have been performed with sediments contaminated with PAHs to assess the importance of photo-activated toxicity in the benthos (Davenport and Spacie, 1991; Ankley et al., 1994; Monson et al., 1995; Sibley et al., 1997; Swartz et al., 1997; Boese et al., 1998; Kosian et al., 1998; Boese et al., 1999; Spehar et al., 1999; Wernersson et al., 1999; Pelletier et al., 2000). These studies conclude that photo-activated toxicity may occur in shallow water environments; however, the magnitude of these effects are not as well characterized as in water-only exposures and are probably not as dramatic as those observed in the water column. Comparisons by Swartz et al. (1995) suggest that responses of benthic communities in PAH-contaminated sites correlate well with the toxicity that is predicted based on narcosis, suggesting that photo-activation was not a major confounding factor for those environments. However, Boese et al., (1997) and Pelletier et al. (In prepartion) show that life history of benthic organisms is critical to assessing whether or not photo-activated toxicity will occur. For example, several marine species which frequently encounter ultraviolet radiation during low tide are not vulnerable to photo-activated toxicity due to light protective adaptation (e.g., shells, pigments, borrowing). Additionally, there is evidence that maternal transfer of PAHs from benthic adult bivalves to pelagic embryos does occur (Pelletier et al., 2000).

6.5.2 Implications to Derivation of ESB

Because the PAH mixture ESB derived here is based on narcosis, if there is additional toxicity caused by photo-activation it may cause the ESB to be underprotective. At present, the magnitude of potential errors can not be specifically quantified, and are the subject of scientific debate (Swartz et al., 1997; Boese et al., 1999; Diamond and Mount, 1998; McDonald and Chapman, 2002). If photoactivation of PAHs is ecologically relevant, it is probably most significant primarily for organisms that inhabit very shallow or very clear water. This is because of the rapid attenuation of ultraviolet radiation in the water column (Pickard and Emery 1982; Wetzel, 1983). For example, <25% of incident UV penetrates below the first meter of water in productive aquatic systems. In areas where PAH-contaminated sediments are present in shallow environments the risk of photo-activated toxicity is greater and a site-specific ESB may need to be generated that considers this potential risk (U.S. EPA, 2003b).

6.6 Teratogenicity and Carcinogenicity

This subsection presents an analysis intended to determine if the ESB for PAH mixtures of <1.0 $\Sigma ESBTU_{FCV}$ is protective for non-narcosis modes of toxic action of individual PAHs. Published articles were screened for applicable data on teratogenic (Appendix G) and carcinogenic (Appendix H) effects of individual PAHs and their mixtures. Five laboratory studies with benzo(a)pyrene (BaP), predominantly water exposures, and one with anthracene were selected for analysis of teratogenic effects; two laboratory studies with BaP were selected for analysis of carcinogenic effects (Table 6-4). In the teratogen studies, typically radio-labeled BaP was used to quantify the accumulation of the PAH and its metabolites in fish ranging in lifestage from

Table 6-4. Teratogenic and carcinogenic effects of benzo(a)pyrene (BaP) and anthracene on freshwater and saltwater fishes. Measured concentrations of exposure are converted to sediment concentrations (C_{OC}) likely to result in the equivalent effect using EqP and SAR methodology.

[A] If the concentration of BaP exceeded its solubility of 3.81 μg/L, the published concentration in water is listed in parenthesis with the solubility of 3.81 μg/L listed above as the concentration of exposure. Therefore the maximum C_{OC} value for these exposures is 3840μg BaP/g_{OC}.

[B] Concentrations in eggs on a wet weight basis are converted to concentrations on a lipid basis using lipid concentrations (f_{Lipid}) from Table 1 in Kamler (1992).

[C] Water concentrations of BaP were not stable throughout the duration of the experiment.

[D] The solubility of BaP in water theoretically limits the maximum concentration in eggs to ~3,840 μg/g lipid and in sediments to ~3,840 $\mu g/g_{OC}$, but metabolites of BaP will likely be included in radio-labeled quantification of total BaP equivalents.

embryo to adults. The water PAH concentrations associated with teratogenic and carcinogenic effects were generally high and steady-state was not always achieved. The solubility limit in water for BaP of 3.81 µg/L was exceeded in 6 of 8 experiments (Table 6-4). In contrast, for seven of the experiments, the BaP concentration in eggs or fish tissue was also listed as an observed effect concentration. The theoretical solubility-limited maximum of 3840 µg BaP/g lipid was exceeded only in one of the experiments. For these reasons, when the concentration of BaP plus metabolites was measured in the eggs or tissue of the organism, this concentration was considered the most valid representation of the true observed exposure concentration and the water concentration was not used in further analysis. Elutriates from crude oil contained non-PAH compounds and the relationship of total PAH concentrations in the study vs total PAH as defined in this document were difficult to determine in the Carls et al. (1999) study; therefore, these data were also excluded from this analysis. Although metabolism of PAHs is known to occur in invertebrates such as polychaetes, mollusks and crustaceans (McElroy et al., 2000), data on the potential carcinogenic effects of the metabolites is unknown.

As indicated in Table 6-4 and Appendix H, the database for carcinogenic effects of PAHs on aquatic (fish) species from laboratory studies is limited. Most of the available data are from studies of epizootic outbreaks of neoplasia (tumors) from highly contaminated field sites such as the Black River, Ohio (see Baumann and Harshbarger 1998 for a review) or Puget Sound, WA (Malins et al., 1987, Myers et al., 1990), to mention only a notable few. The applicability of these field studies to a causal relationship between carcinogenic effects observed and PAH concentrations is limited by the possible interactive effects of the PAHs with PCBs and other simultaneously occurring chemicals. The bulk of laboratory experimental evidence for carcinogenic effects of PAHs is based on the distribution of neoplasms in fish species exposed to PAH-enriched sediment extracts (Black, 1983; Metcalfe et al., 1988; Fabacher et al., 1991), dietary exposures or inter-peritoneal injection (Hendricks et al., 1985), or intermittent water exposures of 7,12-dimethylbenzanthracene (Schultz and Schultz, 1982). These studies are listed in Appendix H for completeness, but were not included in Table 6-4 for further analysis. This is because the exposure regime or concentrations of individual or mixtures of PAHs were not provided in sufficient detail to permit critical measured sediment concentrations, or sediment concentrations derived from concentrations in water or tissue, to be compared to the observed carcinogenic effects. The study with 7,12-dimethylbenzanthracene (Schultz and Schultz, 1982) was not considered for analysis because this PAH is not commonly measured as part of environmental monitoring programs (see Table 6-2).

A far more extensive database exists on the influence of PAHs on various aspects of tumor biology, such as PAH-DNA adduct formation and phase I (oxidation, reduction, and hydrolysis reactions) and phase II (glucuronidation and glutathione conjugation) metabolism of individual compounds. However, as indicative of cytotoxicity as these biomarkers may or may not be, they have been excluded from the analysis for the explicit purposes of this subsection. The methods of PAH exposure that were useful for this analysis were aqueous (Hannah et al., 1982; Hose et al., 1982, 1984; Winkler et al., 1983; Goddard et al., 1987; Hawkins et al., 1988, 1990), maternal (Hall and Oris, 1991), or inter-peritoneal injection of adult English sole (Parophrys vetulus) followed by measurement of concentrations in embryos (Hose et al., 1981).

6.6.1 Calculations

When the measured concentration of the PAH dissolved in water (C_d; µg/L) associated with a teratogenic or carcinogenic effect was available it was multiplied by its K_{OC} (L/kg_{OC}) x 10^{-3} to derive an equivalent effect concentration in sediment (C_d-derived C_{OC}; $\mu g/g_{OC}$), as per the EqP methodology (Table 6-4; Appendix G and H). When the measured concentration of the PAH in eggs or tissue (C_L; μg PAH/g lipid) associated with an

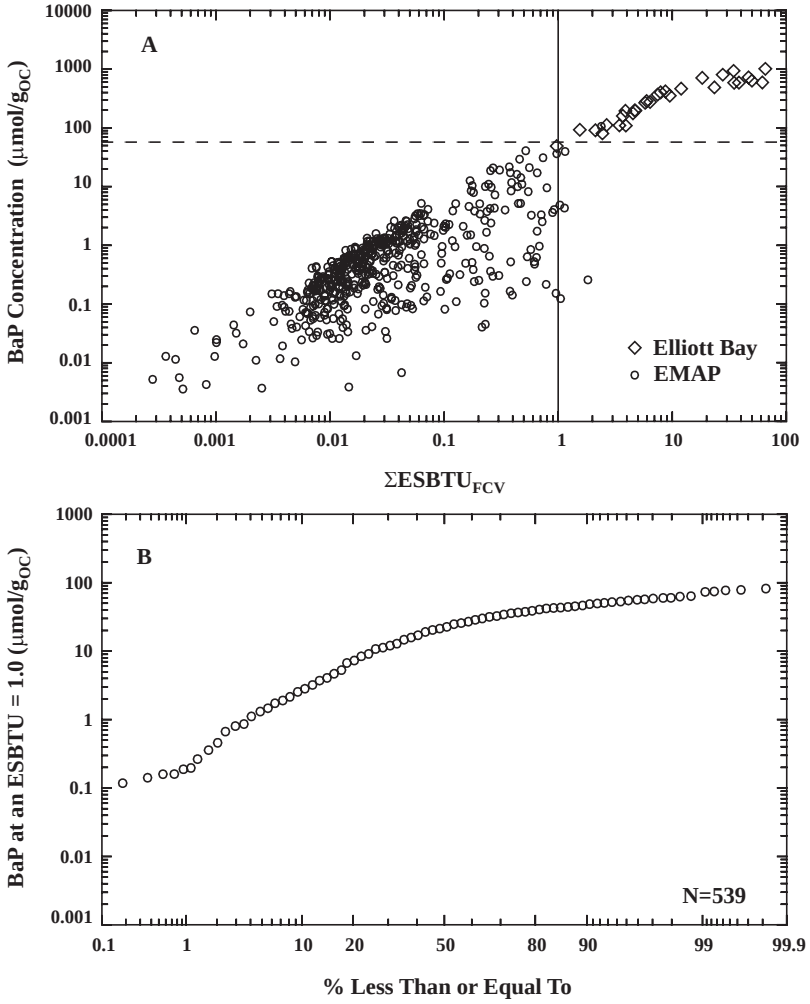

Figure 6-3. BaP concentration of 539 sediment samples from the EMAP and Elliott Bay datasets versus (A) the ΣESBTU$_{FCV}$ values of 34 PAHs and (B) a probability plot of these BaP concentrations at an ΣESBTU$_{FCV}$ = 1.0.

effect was available, its equivalent effect concentration in sediment (C_L-derived C_{OC}; μg/g_{OC}) was calculated using the equation.

$$\log_{10}C_{OC} = 0.00028 + \log_{10}C_L + 0.038\log_{10}K_{OW} \qquad (6\text{-}7)$$

6.6.2 Critical Sediment Concentrations for Teratogenic and Carcinogenic Effects versus ESBs for PAH Mixtures

The critical sediment concentrations (i.e., C_d- or C_L-derived C_{OC}) that would be expected to cause teratogenic or carcinogenic effects on the five freshwater and three saltwater fishes exposed to BaP ranged from 57 to 8,937 µg/g_{OC}; the only C_{OC} for anthracene was 219 µg/g_{OC} (Table 6-4). The majority of C_{OC} values were derived using concentrations measured in fish eggs. Six of the nine C_{OC} concentrations for BaP were less than the solubility-limited maximum concentration of 3,840 µg/g_{OC}. The C_{OC} value of 8,937 µg /g_{OC} is retained because the concentrations in the eggs probably included metabolites of BaP that are quantified as total BaP equivalents in the radio-label analysis. The C_{OC} values for individual PAHs in sediments were then compared to PAH concentrations in monitored field sediments to determine if teratogenic or carcinogenic effects might occur in sediments having <1.0 ΣESBTU$_{FCV}$. This analysis was used to determine if the ESB derived from the narcosis mode of action was protective of teratogenic or carcinogenic effects.

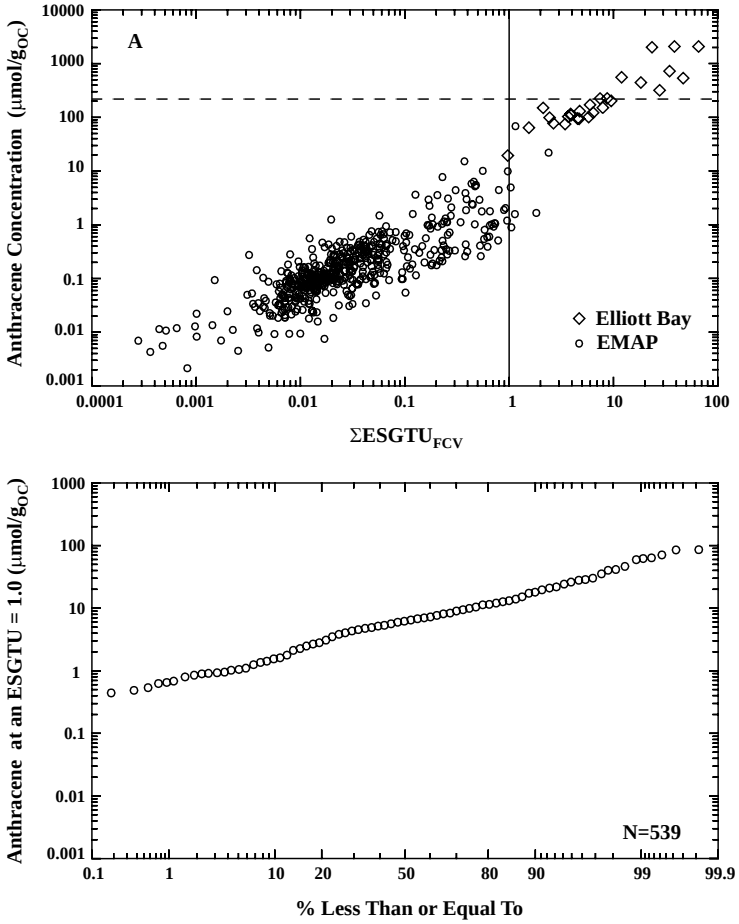

Figure 6-4. Anthracene concentration of 539 sediment samples from the EMAP and Elliott Bay datasets versus (A) the ΣESBTU$_{FCV}$ values of 34 PAHs and (B) a probability plot of these anthracene concentrations at an ΣESBTU$_{FCV}$ 1.0.

The database from the U.S. EPA EMAP (U.S. EPA 1996b, 1998) and Elliot Bay (Ozretich et al., 2000) sediment monitoring programs were used to compare the BaP (Figure 6-3A) or anthracene (Figure 6-4A) concentration of 539 sediment samples where 34 PAHs, or 33 of 34 PAHs for Elliott Bay, were measured versus the ΣESBTU$_{FCV}$ for all PAHs measured in those sediments. The lowest critical sediment concentration for teratogentic or carcinogenic effects is indicated with a solid line at 57 µg/g$_{OC}$ for BaP and at 219 μg/g$_{OC}$ for anthracene. None of the sediments having <1.0 ΣESBTU$_{FCV}$ contained BaP or anthracene at concentrations likely to cause the teratogenetic or carcinogenic effects reported in Table 6-4. The same database of PAH concentrations in field sediments was used to calculate the sediment-specific BaP:ΣESBTU$_{FCV}$ ratio and the sediment-specific anthracene: ΣESBTU$_{FCV}$ ratio. The total PAH concentration in each of the 539 sediments was multiplied by its sediment-specific ratio to determine the BaP or anthracene concentration for the sediment if the ΣESBTU$_{FCV}$ was equal to 1.0. Probability plots of the calculated concentrations for BaP and anthracene at 1.0 ΣESBTU$_{FCV}$ are in Figures 6-3B and 6-4B, respectively. The dashed lines represent the critical sediment concentration of 57 µg/g$_{OC}$ for BaP and 219 µg/g$_{OC}$ for anthracene. Based on this analysis, none of the sediments for anthracene and only 3.53% of the sediments for BaP would be expected to produce teratogenic or carcinogenic effects if the proportions of BaP or anthracene in these sediments were maintained and the concentrations of each of the other PAHs were increased so that all sediments contained 1.0

$\Sigma ESBTU_{FCV}$. The approach of examining these relationships individually with BaP or anthracene may be flawed because it may under-represent the teratogenic of carcinogenic contributions of other PAHs with the same mode of action in the PAH mixture. However, at present insufficient data are available to appropriately sum the contributions of multiple teratogenic or carcinogenic PAHs.

6.7 Equilibrium and ESBs

Care must be used in application of ESBs in disequilibrium conditions. In some instances site-specific ESBs may be required to address this condition (U.S. EPA, 2003b). Benchmarks based on EqP theory assume that nonionic organic chemicals are in equilibrium with the sediment and interstitial water, and that they are associated with the sediment primarily through absorption into sediment organic carbon. In order for these assumptions to be valid, the chemical must be dissolved in interstitial water and partitioned into sediment organic carbon. The chemical must, therefore, be associated with the sediment for a sufficient length of time for equilibrium to be reached. With PAHs, the absence of toxicity when the ESB is exceeded may be because of the presence of less available PAHs associated with soot, coal or similar materials in sediments (see discussion in Section 6.8). Alternatively, disequilibrium exists, and ESB may be over-protective, when PAHs occur in sediments as undissolved liquids or solids; although the use of solubility limited acceptable sediment concentrations should adequately account for this.

In very dynamic locations, with highly erosional or depositional sediments, the partitioning of nonionic organic chemicals between sediment organic carbon and interstitial water may only attain a state of near equilibrium. Likewise, nonionic organic chemicals with high $\log_{10}K_{OW}$ values may come to equilibrium in clean sediment only after a period of weeks or months. Equilibrium times are shorter for chemicals with low $\log_{10}K_{OW}$ values and for mixtures of two sediments with similar organic carbon-normalized concentrations, each previously at equilibrium. This is particularly relevant in tidal situations where large volumes of sediments are continually eroded and deposited, yet near equilibrium conditions between sediment and interstitial water may predominate over large spatial areas. For locations where times are sufficient for equilibrium to occur, near equilibrium is likely the rule and disequilibrium uncommon. In many environments, disequilibrium may occur intermittently, but in those cases ESBs would be expected to apply when the disturbance abates. In instances where long-term disequilibrium is suspected, application of site-specific methodologies may be desirable (U.S. EPA, 2003b).

6.8 Other Partioning Phases

6.8.1 Overview

In general, laboratory studies with PAHs have shown the same partitioning behavior demonstrated by many classes of nonpolar organic contaminants (Chiou et al., 1979,1983; Karickhoff et al., 1979; Means et al., 1980; Di Toro et al., 1991). However, there are some data indicating that PAHs do not always follow equilibrium partitioning behavior in the environment. Specifically, some studies have reported larger partitioning coefficients for PAHs in field-collected sediments than is predicted based on laboratory or theoretically-generated $\log_{10}K_{OW}/K_{OC}$ values (Prahl and Carpenter, 1983; Socha and Carpenter, 1987; Broman et al., 1990; McGroddy and Farrington, 1995; Maruya et al., 1996; McGroddy et al., 1996). The observed differences in partitioning of PAHs may relate to differences in PAH sources with the speculation that PAHs from pyrogenic sources (e.g., soot carbon, coal or similar materials) may be more strongly associated with the particulate phase than PAHs from some petrogenic sources (Readman et al., 1984; Socha and Carpenter, 1987; McGroddy and Farrington, 1995; Meador et al., 1995; Naes et al., 1995; Chapman et al., 1996; Maruya et al., 1996; McGroddy et al., 1996; Gustafsson and Gschwend, 1997; Gustafsson et al., 1997; Naes and Oug, 1997; de Maagd et al. 1998; Naes and Oug 1998;

Naes et al., 1998; Bucheli and Gschwend 2000; Jonker and Smedes 2000; Ozretich et al., 2000; Jonker and Koelmans 2001, 2002a,b; Accardi-Dey and Gschwend 2002, 2003). The result is that PAH concentrations in interstitial water are significantly lower compared to the organic carbon-based sediment concentration from laboratory or theoretically-predicted K_{OC} values and, presumably, exhibit correspondingly lower bioavailability. Several studies have proposed that the lack of observable biological effects from sediments (and other samples) containing high concentrations of presumably bioavailable PAHs is related to this phenomena (Farrington et al., 1983; Varanasi et al., 1985; Bender et al., 1987; Hickey et al., 1995; Knutzen, 1995; Chapman et al., 1996; Paine et al., 1996; Maruya et al., 1997; Oug et al., 1998; Lamoureux and Brownawell 1999; Naes et al., 1999; West et al., 2001; Talley et al., 2002).

The mechanisms causing these field observations of unusual PAH partitioning are not well understood. One explanation proposes that PAHs condense into the soot matrix during particle formation, and are thereby sterically inhibited from partitioning to interstitial water as would be expected under equilibrium conditions. A second perspective assumes that the soot fraction represents a second partitioning phase in addition to normal organic carbon. The partitioning of PAHs from this phase approximates the equilibrium behavior assumed for normal organic carbon, but have a much higher partition coefficient than biologically-derived organic carbon (represented by K_{OC}) (Gustafsson and Gschwend, 1997, 1999). Methods for measuring the soot carbon fraction in sediments (f_{sc}) continue to be developed and evaluated (Verardo 1997; Gustafsson et al., 1997; Karapanagioti et al., 2000; Gelinas et al., 2001; Currie et al., 2002; Gustafsson et al., 2001; Song et al., 2002) but no one method is recognized as most accurate, although those based on Gustaffson et al. (1997) are probably used most frequently.

Once partition coeffifients are available and f_{SC} can be measured, the soot phase can then be incorporated into an expanded partitioning equation with two partitioning terms

$$K_p = f_{OC} K_{OC} + f_{SC} K_{SC} \qquad (6\text{-}8)$$

where, K_p is the partition coefficient for the expanded partitioning equation, f_{OC} and f_{SC} are the fraction organic carbon and fraction soot carbon, respectively, and K_{OC} and K_{SC} are the organic carbon and soot carbon partition coefficients. Recently, Bucheli and Gustaffson (2000) and Accardi-Dey and Gschwend (2002; 2003) proposed a new version of Equation 6-8 which includes a non-linear term for the soot carbon contribution to partitioning

$$K_p = f_{OC} K_{OC} + f_{SC} K_{SC} C_d^{n-1} \qquad (6\text{-}9)$$

where, the exponential 'n' is the Freundlich term used to fit the non-linear relationship between particulate and dissolved PAH. This description of the interaction of PAHs and soot carbon is more accurate but is currently limited in practicality by the lack of values for K_{SC} and n for many PAHs.

Another phase for which there is less data available as compared to soot carbon but which may also alter the partitioning and bioavailability of PAHs is non-aqueous phase liquids (NAPLs) like coal tar found at manufactured gas plant sites (Lane and Loehr 1992; Luthy et al., 1994; Mahjoub et al., 2000). The significance of these liquids relative to the benthic toxicity of PAHs is not yet understood fully.

6.8.2 Implications to Derivation of ESB

Irrespective of the mechanisms, these issues have the potential to affect the predictive power and accuracy of the PAH mixtures ESB. For soot, coal and similar materials, their presence are associated with reduced concentrations of PAH in interstitial water, one would presume that this results in decreased bioavailability of PAHs, a phenomenon demonstrated by West et al. (2001). This, in turn, would make the PAH mixtures ESB derived here overprotective, because the K_{OC}-based partitioning model would overpredict chemical activity and, therefore, concentrations of PAH in interstitial water and in organisms.

Importantly, most sediments are expected to

contain insufficient concentrations of PAHs to exceed the ESB. Therefore, even if partitioning to soot, coal and similar materials reduces the interstitial water concentration and biological availability of the PAHs, the partitioning effect is not important because PAH concentrations in the sediment are judged by the ESB as acceptable without invoking complex measurements of partitioning to soot, coal and similar materials. Further, most sediments where empirical data on partitioning that demonstrates soot, coal and similar materials are important are sediments that relative to the ESB are uncontaminated. Also, for sediments that have concentrations of PAHs in excess of the ESB, data suggest minimal error in ignoring partitioning to soot, coal and similar materials and ascribing partitioning to only organic carbon. Most applications of the PAH mixture narcosis model to toxicity data for field-collected sediments show good predictive ability for the ESB (see Section 5.3). This may be because most sediments that are sufficiently contaminated to cause narcosis are contaminated by PAH sources that exhibit normal partitioning behavior, such as creosote and other petrogenic sources. In their study of PAH-contaminated sediments, Ozretich et al. (2000) found that discrepancies between measured and predicted partitioning behavior predominated in sediments with lower PAH concentrations, while those with higher PAH concentrations showed partitioning behavior closer to that predicted from published K_{OW}/K_{OC} relationships. This differential behavior was attributed to the presence of two PAH sources, with creosote being the source causing the highest levels of contamination and toxicity.

In cases where it is suspected that soot, coal, or other materials including coal tars and other NAPLs may be causing unusual partitioning, direct measurement of PAH concentrations in interstitial water may be used to evaluate this possibility and, where necessary, derive site-specific sediment benchmarks which account for local differences in partitioning behavior (see U.S. EPA 2003b).

6.9 Aqueous Solubility Under Non-Standard Conditions

It has been long established that organic compounds are generally less soluble in aqueous solutions at colder temperatures than at warmer, and in salt solutions such as seawater, than in freshwater, a phenomenon termed the salting-out effect (May, 1980; Schwarzenbach et al., 1993; Xie et al., 1997). Setschenow (1889) derived an empirical relationship for the magnitude of the salting-out effect

$$\log_{10}({}^{t}S_0 / {}^{t}S_{‰}) = K_S\, C_{salt} \qquad (6\text{-}9)$$

where ${}^{t}S_0$ and ${}^{t}S_{‰}$ are the aqueous solubilities of the solute in fresh and saltwater (mol/L) at a given temperature (t in the units °C), respectively, K_S is

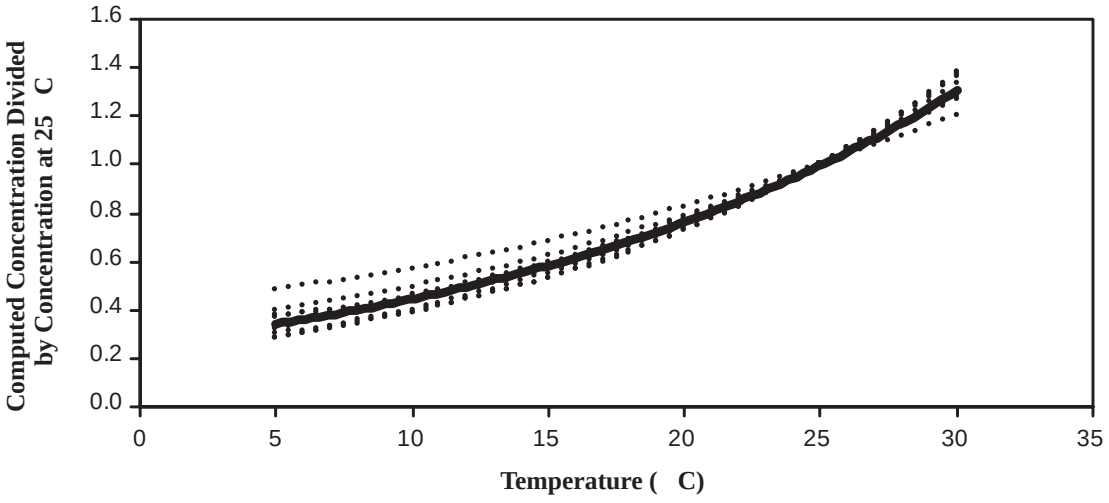

Figure 6-5. Computed solubilities of nine PAHs relative to their 25°C solubilities as a function of temperature.

the Setschenow constant (L/mol) for the salt solution and the solute of interest, and C_{salt} is the molar salt concentration. A one molar salt solution (NaCl) is approximately equivalent to 48‰ sea water (Owen and Brinkley, 1941), and K_S was found to be essentially invariant with temperatures from 1 to 30°C, averaging 0.28 ± 0.02 (mean ± SE) (May, 1980) for 9 PAHs. Temperature has been shown to have a non-linear effect on PAHs solubilities (May, 1980). Concentrations of nine PAHS (naphthalene, fluorene, phenanthrene, 1-methylphenanthrene, anthracene, fluoranthene, pyrene, benz(a)anthracene, and chrysene) were computed for distilled water at temperatures between 5 and 30°C using the relationships of May (1980) and are compared with the compound's concentrations at 25°C (Figure 6-5). The least-squares exponential representation of the data is as follows

$$({}^{t}S_0 = {}^{25}S_0) = 0.261\, e^{0.0536t},\ r^2 = 0.959 \qquad (6\text{-}10)$$

where ${}^{25}S_0$ is the commonly reported solubility of a compound at 25°C in freshwater. Although naphthalene's solubility has the least response to temperature of PAHs, estimates from Equation 6-10 are only +8% and -30% inaccurate for naphthalene at the temperature extremes (Figure 6-5).

The solubility of PAHs under environmental conditions can be estimated from the following relationship that is a combination of Equations 6-9 and 6-10 using the average Setschenow constant

$${}^{t}S_{‰} = {}^{t}S_0\ 10^{-0.000583‰} \qquad (6\text{-}11)$$

where ‰ is the salinity of the sea water. This correction for solubility can be used as part of the procedures to modify this ESB for site-specific conditions.

Section 7

Sediment Benchmark Values: Application and Interpretation

7.1 Benchmark Value

The procedures described in this document and in the "Technical Basis for the Derivation of Equilibrium Partitioning Sediment Benchmarks (ESBs) for the Protection of Benthic Organisms: Nonionic Organics" (U.S. EPA, 2003a) indicate that, except possibly where a locally important species is very sensitive or benthic organisms are exposed to both significant amounts of PAHs and UV light, benthic organisms should be acceptably protected from the effects of PAH mixtures in freshwater and saltwater sediments if the $EESBTU_{FCV}$ is less than or equal to 1.0:

$$ESB = \Sigma ESBTU_{FCV} = \sum_{i} \frac{C_{OCi}}{C_{OC,PAHi,FCVi}} \leq 1.0 \qquad (7\text{-}1)$$

Freshwater or saltwater sediments containing ≤ 1.0 $\Sigma ESBTU_{FCV}$ of the mixture of the 34 PAHs or more PAHs are acceptable for the protection of benthic organisms, and if the $\Sigma ESBTU_{FCV}$ is greater than 1.0, sensitive benthic organisms may be unacceptably affected. PAHs.

As indicated, this sediment-specific benchmark is the sum of the quotients of the concentrations of individual PAHs in a sediment, on an organic carbon basis, each divided by its respective $C_{OC,PAHi,FCVi}$. At a minimum, the definition of total PAHs for this ESB requires quantification of the 34 PAHs analyzed by the U.S. EPA as part of the EMAP and REMAP programs (PAHs are identified in bold in Table 3-4).

The ESB is intended to protect benthic organisms from direct toxicity associated with exposure to PAH-contaminated sediments. The ESB does not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with PAHs or the potential for bioaccumulation and trophic transfer of PAHs to aquatic life, wildlife or humans.

7.2 Special Considerations

To establish a national benchmark that is widely applicable, certain issues must be considered. It is possible that site-specific conditions may affect the broad applicability of such a benchmark. These include:

1. Fewer than 34 PAHs have been measured. Particularly in cases where historical data are being examined, chemistry data may be available for fewer than the 34 PAHs recommended for this benchmark. Calculating $\Sigma ESBTU_{FCV}$ directly using fewer PAHs will cause the benchmark to be underprotective because PAH mixtures found in the environment typically contain substantial concentrations of PAHs outside the suites of 13 or 23 PAHs commonly measured in monitoring programs. The analysis of PAH distributions across many geographic regions has been used to develop uncertainty factors that can be used to adjust $\Sigma ESBTU_{FCV}$ based on subsets of 13 or 23 PAHs with varying degrees of certainty (see Section 6.2). In some applications using these uncertainty factors, it may be important to minimize the frequency of false negatives (sediments judged to be acceptable when they are not). For these cases, the $\Sigma ESBTU_{FCV}$ calculated from a subset of 13 PAHs (see Table 6-1 for listing) can be multiplied by 11.5, or the $\Sigma ESBTU_{FCV}$ calculated from a subset of 23 PAHs

(see Table 6-1 for listing) can be multiplied by 4.14 to achieve 95% confidence that the actual $\Sigma ESBTU_{FCV}$ for all 34 PAHs would not be higher than the calculated value. In this case, the uncertainty for the 95% confidence level is applied. This means that most of the sediments may actually contain fewer $\Sigma ESBTU_{FCV}$ than indicated by the calculation. In cases where less conservative assumptions are appropriate, factors with lower confidence can be applied, as detailed in Section 6.2.

Use of the uncertainty factors from Section 6.2 assumes that the relative frequency distributions of PAHs in sediments used to calculate the factors are similar to those of the sediments to which the uncertainty factors are applied. This assumption is likely significantly violated for sediments containing predominately petrogenic PAHs. While the uncertainty factors can be used to derive the $\Sigma ESBTU_{FCV}$, this value should not be considered as an ESB. In principal, ESBs based on the $\Sigma ESBTU_{FCV}$ calculated using a minimum of the 34 specified PAHs and can be used to make important sediment decisions. In contrast, important sediment decisions should not be made using $\Sigma ESBTU_{FCV}$ values when fewer PAHs, such as the 13 or 23 PAHs commonly quantified, and uncertainty factors. To avoid errors introduced by the use of uncertainty factors, wherever possible, a more complete PAH chemical analysis should be undertaken with concentrations for a minimum of the 34 specified PAHs analyzed.

2. Interaction of PAHs with UV light. Benchmarks calculated in this document are based on narcotic toxicity only and do not consider enhanced toxicity that can occur if PAH-exposed organisms are simultaneously exposed to UV light. In environments where significant sunlight penetrates to the sediment and benthic organisms are exposed to UV light, the ESB may be underprotective. Consult Section 6.5 for additional details.

3. Influence of soot carbon and coal on PAH partitioning. PAHs may partition less to interstitial water in sediments that contain soot and/or coal particles or similar materials that expected with typical organic carbon partitioning. This could cause the benchmark to be overprotective. The influence of these phases can be assessed by measuring concentrations of PAHs directly in interstitial water and comparing these measures with concentrations predicted by EqP or through quantification of partitioning to these other sediment phases. See Section 6.8 and the site-specific ESBs (U.S. EPA, 2003b) for further discussion. NAPLs are not directly addressed by this document, but may be expected to result in reduced interstitial water concentrations of PAHs.

4. Unusual composition of organic carbon. Partition coefficients used for calculating the national PAH mixture ESB are based on measured partitioning from natural organic carbon in typical field sediments. Some sediments influenced heavily by industrial activities may contain sources of organic carbon whose partitioning properties are not similar, such as rubber, animal processing wastes (e.g., hair or hide fragments), or wood processing wastes (bark, wood fiber or chips). Relatively undegraded woody debris or plant matter (e.g., roots, leaves) may also contribute organic carbon that results in partitioning different from that of typical organic carbon. Sediments with large amounts of these materials may show higher concentrations of chemicals in interstitial water than would be predicted using generic K_{OC} values, making the ESB underprotective. Direct analysis of interstitial water can be used to evaluate this possibility (see U.S. EPA, 2003a,b).

5. Presence of additional narcotic compounds. The PAH mixture ESB is based on the additivity of the narcotic toxicity of PAHs. However, some sediments may contain additional nonionic narcotic chemicals that would contribute to narcotic toxicity, such as chlorobenzenes or PCBs (note: PCBs may also cause adverse effects through bioaccumulation and transfer to higher trophic levels; these bioaccumulative effects are not addressed by this narcosis-based ESB and should be evaluated separately). The presence of additional nonionic narcotic chemicals may make the PAH mixture ESB underprotective, because the ESB itself only addresses that part of the narcotic potency caused by PAHs. Di Toro et al.

(2000) and Di Toro and McGrath (2000) describe methods by which the contributions of other narcotic chemicals can be incorporated into an ESB-type assessment.

6. Site-specific temperature and salinity corrections. Temperature and salinity both affect solubility of PAHs and can therefore affect the solubility-constrained maximum contribution of individual PAHs to the overall ESB. Solubilities used in this document are calculated for 25°C and salinities less than 1‰. Solubilities can be recalculated to meet site specific conditions using procedures described in Section 6.9. Within a temperature range of 0 to 35°C and salinities from 0 to 35‰, solubility can be expected to decrease by a factor of about 30 to 40% with decrease in temperature or increase in salinity. Site-specific recalculation of solubilities will only affect $\Sigma ESBTU_{FCV}$ in cases where the contribution of one or more PAHs are solubility constrained (see Section 6.9).

7.3 Summary

Benthic organisms should be acceptably protected from the narcotic effects of PAH mixtures in freshwater and saltwater sediments if the $\Sigma ESBTU_{FCV}$ is less than or equal to 1.0, and if the $\Sigma ESBTU_{FCV}$ is greater than 1.0, sensitive benthic organisms may be adversely affected**.** This ESB is intended to protect benthic organisms from direct toxicity associated with exposure to PAH-contaminated sediments. This ESB does not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with PAH mixtures or the potential for bioaccumulation and trophic transfer of PAH mixtures to aquatic life, wildlife or humans.

[A]Life-stage: A = adult, J = juvenile, L = larvae, E = embryo, U = life-stage and habitat unknown, X = life-stage unknown but habitat known.
[B]Habitat: I = infauna, E = epibenthic, W = water column.
[C]log K_{OW}: Predicted using SPARC (Karickoff et al, 1991).
[D]Method: S= static, R = renewal, FT= flow-through.
[E] Concentration: U = unmeasured (nominal), M = chemical measured.
[F] Acute Values: 96 hour LC50 or EC50, except for *Daphnia* and *Tanytarsus* which are 48 hours duration.
[G] Bolded acute values are the water solubilities of the PAH (Mackay et al., 1992). For these tests the acute values exceeded solubility. Therefore, solubilities are used instead of the acute value for further calculations.
[H] PAH-specific SMAV: Geometric mean of the acute values by PAH and species.
[I] PAH-specific SMAVs at a log K_{OW}=1.0; calculated as antilog ($\log_{10}$LC50 + 0.945$\log_{10}K_{OW}$)/1000 (see Equation 2-33).
[J] Species SMAV: Geometric mean of K_{OW}-normalized SMAVs for a species across PAHs.
[K] GMAV: Geometric mean of SMAVs for all species within a genus.
[L] Not used in calculations.

[A] Bolded median response concentration (acute) values are the $C_{OC,PAHi,Maxi}$ based on the water solubilities of the PAH (Mackay et al., 1992). For these tests the interstitial water concentration at the median response concentration exceeded solubility. Therefore, solubilities are used instead of the acute value for further calculations.

[B] Test-specific ESBTUs: Quotient of the median response concentration (µg/goc) and $C_{OC,PAHi,FCVi}$ (from Table 3-4).

[C] PAH-specific SMAV: Geometric mean of the test-specific $ESBTU_{FCVi}$ values from 10-d LC50 tests by species and PAH. Test-specific $ESBTU_{FCVi}$ values greater that solubility included only if they are the sole 10-d LC50 for the species.

[D] GMAV: Geometric mean of the PAH-specific SMAVs for all species within a genus.

[E] Spiked sediments from Suedel et al. (1993) were unlikely at equilibrium; i.e., organisms were tested after only 18 to 24 hours after spiking.

Notice

The Office of Research and Development (ORD) has produced this compendium document to provide procedures for the derivation of equilibrium partitioning sediment benchmarks (ESBs) for several nonionic organic chemicals. ESBs may be useful as a complement to existing sediment assessment tools. This document should be cited as:

> U.S. EPA. 2008. Procedures for the Derivation of Equilibrium Partitioning Sediment Benchmarks (ESBs) for the Protection of Benthic Organisms: Compendium of Tier 2 Values for Nonionic Organics. EPA-600-R-02-016. Office of Research and Development. Washington, DC 20460

This document, and the other ESB documents, can also be found in electronic format at the following web address:

Abstract

This equilibrium partitioning sediment benchmark (ESB) document describes procedures to derive concentrations for 32 nonionic organic chemicals in sediment which are protective of the presence of freshwater and marine benthic organisms. The equilibrium partitioning (EqP) approach was chosen because it accounts for the varying biological availability of chemicals in different sediments and allows for the incorporation of the appropriate biological effects concentration. This provides for the derivation of benchmarks that are causally linked to the specific chemical, applicable across sediments, and appropriately protective of benthic organisms.

EqP can be used to calculate ESBs for any toxicity endpoint for which there are water-only toxicity data; it is not limited to any single effect endpoint. For the purposes of this document, ESBs for 32 nonionic organic chemicals, including several low molecular weight aliphatic and aromatic compounds, pesticides, and phthalates, were derived using Final Chronic Values (FCV) from Water Quality Criteria (WQC) or Secondary Chronic Values (SCV) derived from existing toxicological data using the Great Lakes Water Quality Initiative (GLI) or narcosis theory approaches. These values are intended to be the concentration of each chemical in water that is protective of the presence of aquatic life. For nonionic organic chemicals demonstrating a narcotic mode of action, ESBs derived using the GLI approach specifically for freshwater organisms were assumed to also be protective of marine organisms. This assumption is based on the similar sensitivity of freshwater and marine organisms to narcotic chemicals like some of the nonionic organics in this document. For this reason, SCVs derived using narcosis theory are protective of both freshwater and marine organisms. For chemicals with more specific modes of action, freshwater and marine organisms were not assumed to be similar in sensitivity, and separate freshwater and marine ESBs were derived as the available data allowed. Because of the lack of a comprehensive toxicity data set and other reasons discussed in this document in detail, values derived here are considered Tier 2 ESBs (ESB_{Tier2}). The presentation of these ESBs is such that updated values could be calculated as new toxicity data become available.

The ESB_{Tier2} is derived by multiplying the FCV or SCV by a chemical's K_{OC}, yielding the concentration in sediment that should provide the same level of protection that the FCV or SCV provides in water. The ESB_{Tier2} should be interpreted as a chemical concentration below which adverse effects are not expected. At concentrations above the ESB_{Tier2}, and assuming equilibrium between phases, effects may occur with increasing severity as the degree of exceedance increases. The document also includes examples demonstrating the calculation of conventionally-derived and narcosis-based ESBs that discuss an approach for addressing mixtures of narcotic chemicals.

ESB documents have also been developed for two pesticides (endrin, dieldrin), polycyclic aromatic hydrocarbon (PAH) mixtures, and metal mixtures.

The ESBs do not intrinsically consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with the individual nonionic organic chemicals discussed in this document or the potential for bioaccumulation and trophic transfer of these chemicals to aquatic life, wildlife or humans. However, for narcotic chemicals, an approach for considering the toxicity of mixtures is presented. Important assumptions and considerations for applying and interpreting the ESBs are also discussed.

Foreword

Under the Clean Water Act (CWA), the U.S. Environmental Protection Agency (EPA) and the States develop programs for protecting the chemical, physical, and biological integrity of the Nation's waters. To support the scientific and technical foundations of the programs, EPA's Office of Research and Development has conducted efforts to develop and publish equilibrium partitioning sediment benchmarks (ESBs) for some of the 65 toxic pollutants or toxic pollutant categories. Toxic contaminants in bottom sediments of the Nation's lakes, rivers, wetlands, and coastal waters create the potential for continued environmental degradation even where water column contaminant levels meet applicable water quality standards. In addition, contaminated sediments can lead to water quality impacts, even when direct discharges to the receiving water have ceased.

The ESBs and associated methodology presented in this document provide a means to estimate the concentrations of a substance that may be present in sediment while still protecting benthic organisms from the effects of that substance. These benchmarks are applicable to a variety of freshwater and marine sediments because they are based on the biologically available concentration of the substance in the sediments. These ESBs are intended to provide protection to benthic organisms from direct toxicity due to this substance. In some cases, the additive toxicity for specific classes of toxicants (e.g., metal mixtures or polycyclic aromatic hydrocarbon mixtures) is addressed. The ESBs do not intrinsically consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with the individual nonionic organic chemicals discussed in this document or the potential for bioaccumulation and trophic transfer of these chemicals to aquatic life, wildlife or humans. However, for narcotic chemicals, the ESBs can be used in a framework to evaluate the toxicity of mixtures.

ESBs may be useful as a complement to existing sediment assessment tools, to help evaluate the extent of sediment contamination, to identify chemicals causing toxicity, and to serve as targets for pollutant loading control measures. Both types of ESBs, Tier 1 and Tier 2, are intended for similar applications with the user's understanding that, because of limited data availability, Tier 2 ESBs are likely to have greater uncertainty associated with them as compared to Tier 1 ESBs. As new, high quality toxicological and geochemical data becomes available, it is encouraged that the ESB values are revised and updated.

This document provides technical information to EPA Program Offices, including Superfund, Regions, States, the regulated community, and the public. Decisions about risk management are the purview of individual regulatory programs, and may vary across programs depending upon the regulatory authority and goals of the program. For this reason, each program will have to decide whether the ESB approach is appropriate to that program and, if so, how best to incorporate this technical information into that program's assessment process. While it was necessary to choose specific parameters for the purposes of this document, it is important to realize that the basic science underlying this document can be adapted to a range of risk management goals by adjusting the input parameters. At the same time, the ESBs do not substitute for the CWA or other EPA regulations, nor are they regulation. Thus, they cannot impose legally binding requirements on EPA, States, or the regulated community. EPA and State decision makers retain the discretion to adopt approaches on a case-by-case basis that differ from this technical information where appropriate. It is recommended that the ESBs not be used alone but with other sediment assessment methods to make informed management decisions. EPA may change this technical information in the future. This document has been reviewed by EPA's Office of Research and Development (Atlantic Ecology Division, Narragansett, RI), undergone an external peer review, and approved for publication.

This is contribution AED-02-052 of the Office of Research and Development National Health and Environmental Effects Research Laboratory's Atlantic Ecology Division.

Executive Summary

This equilibrium partitioning sediment benchmark (ESB) document describes procedures to derive concentrations of 32 nonionic organic chemicals in sediment which are protective of the presence of freshwater and marine benthic organisms. The equilibrium partitioning (EqP) approach was chosen because it accounts for the varying biological availability of chemicals in different sediments and allows for the incorporation of the appropriate biological effects concentration (U.S. EPA 2003a). This provides for the derivation of benchmarks that are causally linked to the specific chemical, applicable across sediments, and appropriately protective of benthic organisms.

EqP theory holds that a nonionic chemical in sediment partitions between sediment organic carbon, interstitial (pore) water and benthic organisms. At equilibrium, if the concentration in any one phase is known, then the concentrations in the others can be predicted. The ratio of the concentration in water to the concentration in organic carbon is termed the organic carbon-water partition coefficient (K_{OC}), which is a constant for each chemical. The ESB Technical Basis Document (U.S. EPA 2003a) demonstrates that biological responses of benthic organisms to nonionic organic chemicals in sediments are different across sediments when the sediment concentrations are expressed on a dry weight basis, but similar when expressed on a µg chemical/g organic carbon basis ($\mu g/g_{OC}$). Similar responses were also observed across sediments when interstitial water concentrations were used to normalize biological availability. The Technical Basis Document (U.S. EPA 2003a) further demonstrates that if the effect concentration in water is known, the effect concentration in sediments on a $\mu g/g_{OC}$ basis can be accurately predicted by multiplying the effect concentration in water by the chemical's K_{OC}.

EqP can be used to calculate ESBs for any toxicity endpoint for which there are water-only toxicity data; it is not limited to any single effect endpoint. For the purposes of this document, ESBs for 32 nonionic organic chemicals, including several low molecular weight aliphatic and aromatic compounds, pesticides, and phthalates, were derived using Final Chronic Values (FCV) from Water Quality Criteria (WQC) or Secondary Chronic Values (SCV) derived from existing toxicological data using the Great Lakes Water Quality Initiative (GLI) or narcosis theory approaches. These values are intended to be the concentration of each chemical in water that is protective of the presence of aquatic life. For nonionic organic chemicals demonstrating a narcotic mode of action, ESBs derived using the GLI approach specifically for freshwater organisms were assumed to also be protective of marine organisms. This assumption is based on the similar sensitivity of freshwater and marine organisms to narcotic chemicals like some of the nonionic organics in this document. For this reason, SCVs derived using narcosis theory are presumed to be protective of both freshwater and marine organisms. For chemicals with other specific modes of action, freshwater and marine organisms were not assumed to have similar sensitivity and separate freshwater and marine ESBs were derived as the available data allowed. For pesticides, only freshwater- and marine-specific FCVs or SCVs were used to derive ESBs because of likely differences between freshwater and marine organism sensitivities. Similarly, for the phthalates, which are not thought to be narcotic, SCVs were derived using the GLI approach and considered protective of freshwater species only. Because of the lack of a comprehensive toxicity data set and other reasons discussed in this document in detail, values derived here are considered Tier 2 ESBs (ESB_{Tier2}). Ancillary analyses conducted as part of this derivation suggest that the sensitivity of benthic/epibenthic organisms is not significantly different from pelagic organisms; for this reason, the FCV or SCV and the resulting ESB_{Tier2} should be fully applicable to benthic organisms. The ESB_{Tier2} is derived by multiplying the FCV or SCV by a chemical's K_{OC}, yielding the concentration in sediment that should provide the same level of protection that the FCV or SCV provides in water. The ESB_{Tier2} should be interpreted as a chemical concentration below which adverse effects are not expected. At concentrations above the ESB_{Tier2}, assuming equilibrium between phases, effects may occur with increasing severity as the degree of

exceedance increases. A sediment-specific site assessment (e.g., toxicity testing) would provide further information on chemical bioavailability and the expectation of toxicity relative to the ESB_{Tier2} along with associated uncertainties. The document also includes examples demonstrating the calculation of conventionally-derived and narcosis-based ESBs that discuss an approach for addressing mixtures of narcotic chemicals.

As discussed, while this document uses the FCV or SCV, the EqP methodology can be used by environmental managers to derive a benchmark with any desired level of protection, so long as the water-only concentration affording that level of protection is known. Therefore, the resulting benchmark can be species or site-specific if the corresponding water-only information is available. For example, if a water-only effects concentration is known for an economically important benthic species, that value could be used to derive a sediment benchmark commensurate with the protection of that species and endpoint. Another way to increase the site-specificity of an ESB would be to incorporate information on sediment-specific partitioning of chemicals, particularly for sites where the composition and partitioning behavior of the sediment organic carbon may be substantially different than for typical diagenic organic matter (see U.S. EPA 2003b). However, it should also be noted that the ability to predict partitioning based on additional partitioning factors like black carbon is still evolving and may serve to decrease partitioning-related uncertainties in future applications.

The ESBs do not intrinsically consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with the individual nonionic organic chemicals discussed in this document or the potential for bioaccumulation and trophic transfer of these chemicals to aquatic life, wildlife or humans. However, for narcotic chemicals, ESB values may be used in a framework to evaluate the potential effects of chemical mixtures. Consistent with the recommendations of EPA's Science Advisory Board, publication of these documents does not imply the use of ESBs as stand-alone, pass-fail criteria for all applications; rather, ESB exceedances could be used to trigger the collection of additional assessment data. Similarly, ESBs are supportive of recent recommendations by Wenning et al. (2005), to apply a weight of evidence approach when evaluating contaminated sediments. These ESBs apply only to sediments having $\geq 0.2\%$ total organic carbon by dry weight and nonionic organic chemicals with log K_{OW}s ≥ 2.

Tier 1 and Tier 2 ESB values were developed to reflect differing degrees of data availability and uncertainty. Tier 1 ESBs have been derived for the nonionic organic pesticides endrin and dieldrin (U.S. EPA 2003c,d), polycyclic aromatic hydrocarbon (PAH) mixtures (U.S. EPA 2003e), and metal mixtures (U.S. EPA 2005a). Tier 2 ESBs for several nonionic organic chemicals for freshwater and marine sediments are reported in this document. Both types of ESBs are intended for similar applications with the user's understanding that Tier 2 ESBs are likely to have greater uncertainty associated with them as compared to Tier 1 ESBs. As new, high quality toxicological and geochemical data becomes available, recalculation of the Tier 2 ESB values is encouraged.

Uncertainties associated with ESB_{Tier2} values are discussed in detail through-out this document. They include unknown effects of antagonism, synergism and additivity, occurrence of chemical disequilibria, and presence of unusual types of sedimentary carbon, like black carbon, and large particles. Uncertainties for the ESB_{Tier2} values can be reduced by conducting additional acute and chronic water-only and spiked sediment toxicity tests to refine water-only effect concentrations and confirm predictions of sediment toxicity, respectively.

Glossary of Abbreviations

ACR	Acute–chronic ratio
AQUIRE	Aquatic Toxicity Information Retrieval
ASTER	ASsessment Tools for the Evaluation of Risk
ASTM	American Society for Testing and Materials
C_L*	Critical lipid concentration
CAS	Chemical Abstracts Service
CWA	Clean Water Act
DOC	Dissolved organic carbon
EC_{50}	Chemical concentration estimated to cause adverse effects to 50% of the test organisms within a specified time period
ECOTOX	ECOTOXicology databases
EMAP	Environmental Monitoring and Assessment Program
EPA	United States Environmental Protection Agency
EqP	Equilibrium partitioning
ESB	Equilibrium partitioning Sediment Benchmark; for nonionic organics, this term usually refers to a value that is organic carbon–normalized (more formally ESB_{OC}) unless otherwise specified
$ESB_{DRY\ WT}$	Equilibrium partitioning Sediment Benchmark; for nonionic organics, expressed on a sediment dry weight basis
ESB_{OC}	Equilibrium partitioning Sediment Benchmark; for nonionic organics, expressed on an organic carbon basis
ESB_{Tier2}	Equilibrium partitioning Sediment Benchmark; for nonionic organics, derived using Tier 2 data; specifically, the values in this document
$ESB_{Tier2DRY\ WT}$	Equilibrium partitioning Sediment Benchmark; for nonionic organics, derived using Tier 2 data, expressed on a sediment dry weight basis
$ESB_{Tier2OC}$	Equilibrium partitioning Sediment Benchmark; for nonionic organics, derived using Tier 2 data; expressed on organic carbon basis

ESBTU	Equilibrium Partitioning Sediment Benchmark Toxic Units
FACR	Final acute–chronic ratio
FAV	Final acute value
FCV	Final chronic value
f_{OC}	Fraction of organic carbon in sediment
f_{Solids}	Fraction of solids in sediment
GLI	Great Lakes Water Quality Initiative
GMAV	Genus mean acute value
GMCV	Genus mean chronic value
g_{OC}	Gram organic carbon
HECD	U.S. EPA, Health and Ecological Criteria Division
IC_{50}	Chemical concentration estimated to cause some form of inhibition to 50% of the test organisms within a specified time period
K_{BC}	Black carbon-water partition coefficient
K_{OC}	Organic carbon–water partition coefficient
K_{OW}	Octanol–water partition coefficient
K_P	Sediment–water partition coefficient
LC_{50}	Chemical concentration estimated to be lethal to 50% of test organisms within a specified time period
MC	Moisture content
MDR	Minimum data requirement
NHEERL	U.S. EPA, National Health and Environmental Effects Research Laboratory
OECD	Organization for Economic Cooperation and Development
ORD	U.S. EPA, Office of Research and Development
OST	U.S. EPA, Office of Science and Technology
OSWER	U.S. EPA, Office of Solid Waste and Emergency Response

PAH	Polycyclic aromatic hydrocarbon
PM	Particulate matter
QSAR	Quantitative structure-activity relationship
SACR	Secondary acute-chronic ratio
SAF	Secondary acute factor
SAV	Secondary acute value
SCV	Secondary chronic value
SCV_N	Secondary chronic value based on narcosis theory
SMACR	Species mean acute–chronic ratio
SMAV	Species mean acute value
SPARC	SPARC Performs Automated Reasoning in Chemistry
STORET	EPA's computerized database for STOrage and RETrieval of water-related data
TIE	Toxicity Identification Evaluation
TOC	Total organic carbon
WQC	Water Quality Criteria

Section 1

Introduction

1.1 General Information

Toxic pollutants in bottom sediments of the Nation's lakes, rivers, wetlands, estuaries, and marine coastal waters create the potential for continued environmental degradation even where water column concentrations comply with established WQC. In addition, contaminated sediments can be a significant pollutant source that may cause water quality degradation to persist, even when other pollutant sources are stopped (Larsson 1985, Salomons et al. 1987, Burgess and Scott 1992). The absence of defensible equilibrium partitioning sediment benchmarks (ESBs) make it difficult to accurately assess the extent of the ecological risks of contaminated sediments and to identify, prioritize, and implement appropriate cleanup activities and source controls (U.S. EPA 1997a, b, c, 2004).

As a result of the need for a procedure to assist regulatory agencies in making decisions concerning contaminated sediment problems, the U.S. Environmental Protection Agency (EPA) Office of Water Office of Science and Technology, Health and Ecological Criteria Division (OST/HECD) and Office of Research and Development National Health and Environmental Effects Research Laboratory (ORD/NHEERL) established a research team to review alternative approaches (Chapman 1987). All of the approaches reviewed had both strengths and weaknesses, and no single approach was found to be applicable for the derivation of guidelines in all situations (U.S. EPA 1989, 1993). The equilibrium partitioning (EqP) approach was selected for nonionic organic chemicals because it presented the greatest promise for generating defensible, national, numeric chemical-specific benchmarks applicable across a broad range of sediment types. The three principal observations that underlie the EqP approach to establishing sediment benchmarks are as follows:

1. The concentrations of nonionic organic chemicals in sediments, expressed on an organic carbon basis, and in interstitial waters correlate to observed biological effects on sediment-dwelling organisms across a range of sediments.

2. Partitioning models can relate sediment concentrations for nonionic organic chemicals on an organic carbon basis to freely-dissolved concentrations in interstitial water.

3. The distribution of sensitivities of benthic organisms to chemicals is similar to that of water column organisms; thus, the currently established water quality criteria (WQC) final chronic values (FCV) or secondary chronic values (SCV) can be used to define the acceptable effects concentration of a chemical freely-dissolved in interstitial water.

The EqP approach, therefore, assumes that (1) the partitioning of the chemical between sediment organic carbon and interstitial water is at or near equilibrium; (2) the concentration in either phase can be predicted using appropriate partition coefficients and the measured concentration in the other phase (assuming the freely-dissolved interstitial water concentration can be accurately measured); (3) organisms receive equivalent exposure from water-only exposures or from any equilibrated phase: either from interstitial water via respiration, from sediment via ingestion or other sediment-integument exchange, or from a mixture of exposure routes; (4) for nonionic chemicals, effect concentrations in sediments on an organic carbon basis can be predicted using the organic

carbon partition coefficient (K_{OC}) and effects concentrations in water; (5) the FCV or SCV concentration is an appropriate effects concentration for freely-dissolved chemical in interstitial water; and (6) ESBs derived as the product of the K_{OC} and FCV or SCV are protective of benthic organisms. ESB concentrations presented in this document are expressed as µg chemical/g sediment organic carbon (µg/g_{OC}) and not on an interstitial water basis because (1) interstitial water is difficult to sample and (2) significant amounts of the dissolved chemical may be associated with dissolved organic carbon; thus, total concentrations in interstitial water may overestimate exposure.

1.2 Development of Tier 2 Sediment Benchmarks

Aquatic toxicity values used in this compendium (Table 3-1) were developed in two possible ways: (1) conventionally using Water Quality Criteria (WQC) (when available) and Great Lakes Water Quality Initiative (GLI) generated values, and (2) narcosis theory. This compendium consists of Tier 2 ESBs for 32 chemicals including several low molecular weight aliphatic and aromatic compounds, pesticides and phthalates. Both types of ESBs, Tier 1 and Tier 2, are intended for similar applications with the user's understanding that Tier 2 ESBs are likely to have greater uncertainty associated with them as compared to Tier 1 ESBs. See Section 1.3 for further discussion of Tier 1 and Tier 2 ESBs.

The ESB values are reported in Tables 3-2 and 3-4. In the *References* section, along with the cited sources, the reference U.S. EPA (2001a) contains the sources and tables of data used to derive some of the Tier 2 ESBs.

For many of the chemicals in this document, the Tier 2 ESBs were developed using the GLI (1995) methodology for obtaining secondary chronic values (SCVs). As described in Section 2 and Appendix A, this methodology uses adjustment factors to allow derivation of chronic values when fewer toxicity data are available than are required under the National Ambient Water Quality Criteria methodology (Stephan et al. 1985). Because of these adjustment factors, SCVs are generally expected to be lower than would be likely if a complete data set were available. Consequently, Tier 2 ESBs would tend to be lower (i.e., be more conservative) compared to the Tier 1 ESBs developed exclusively from FCVs. The degree of conservatism will be a function of the database used to derive the SCVs. Further, the presence of these chemicals in mixtures will also affect the conservatism (see Section 4.2.5). The SCVs used in calculating most Tier 2 ESBs were derived using toxicity data primarily for freshwater species. In the toxicity data evaluation for the PAH mixtures ESB (U.S. EPA 2003e), there was no significant difference in sensitivity between freshwater and saltwater species when distributions of data for all species were compared using the approximate randomization (AR) method (Noreen 1989, U.S. EPA 2003e). Like PAHs, many of the Tier 2 ESB chemicals are also narcotics; from this, it is reasonable to presume that these ESBs would be applicable to both freshwater and saltwater sediments.

For pesticides, there are likely to be differences between FCVs or SCVs developed for freshwater and saltwater organisms (e.g., Thursby 1990, U.S. EPA 1980a,b, 1986, 1996, 2005b). Therefore, applying Tier 2 ESB values for pesticides derived using the GLI methodology to saltwater sediments is not recommended and would result in increased uncertainties. To address these uncertainties, Tier 2 ESBs are presented for pesticides for both freshwater and marine organisms based on FCVs from WQC (when available) or SCVs. Similarly, SCVs developed for phthalates in this document using the GLI approach were assumed to be protective only of freshwater species. Unlike the pesticides, WQC FCVs were not available for either freshwater or marine species for the phthalates.

As noted, many of the chemicals for which EPA has developed Tier 2 ESBs are known or suspected to affect aquatic organisms by a

narcotic mode of action (Russom et al. 1997). For these compounds, Tier 2 ESBs were also derived using the narcosis theory approach applied to develop ESBs for PAH mixtures (U.S. EPA 2003e). In contrast to the conventional GLI approach, the narcosis approach does not apply adjustment factors. As a consequence, narcosis-based values are often larger in magnitude compared to the GLI-derived values (discussed further in Section 2). In Table 3-1, narcosis-based SCVs are also reported for chemicals with other modes of actions in addition to narcosis (i.e., pesticides and phthalates). For these chemicals, potency via narcosis is generally small compared to the more specific mode(s) of action which would result in narcosis-based ESB values being considerably higher than the conventionally-derived values. Accepting these approaches for developing chronic toxicity values and the associated uncertainties, Tier 2 ESB values for narcotic chemicals, pesticides and phthalates should be meaningful interpretive tools for marine sediments as well as freshwater sediments (Tables 3-2 and 3-4).

With regard to using narcosis to derive ESB values, the approach applied in this document and U.S. EPA (2003e) uses narcosis theory to predict acute toxicity and then empirically based acute-chronic ratios (ACRs) to calculate chronic toxicity values. These chronic values (i.e., SCVs) are then used to calculate the ESBs. Strengthening our mechanistic understanding of the link between acute toxicity based on narcosis and chronic effects potentially caused by other forms of toxicity is an active area of research (e.g., Incardona et al. 2006). Users of this document should recognize deficiencies in our understanding of this link may introduce uncertainties into the narcosis based estimates of ESB values.

Regardless of the approach used to derive the Tier 2 toxicity values, these concentrations have been generated on a single chemical basis; that is, the benchmark addresses effects for that chemical only and does not consider additive effects from other chemicals that may be present in sediment. For that reason, as the number and concentration of other chemicals present increases, single chemical benchmarks would be expected to provide a lesser degree of protection than a mixtures-based approach. EPA has not yet recommended an approach for summing the particular chemicals in this document, but approaches for assessing the toxicity of narcotic mixtures in sediments have been published (Di Toro and McGrath 2000, DiToro et al. 2000), and the Agency has developed methodologies for deriving ESBs for mixtures of PAHs (U.S. EPA 2003e) and metals (U.S. EPA 2005a). The approach discussed in U.S. EPA (2003e) for addressing the toxicity of mixtures of PAHs may be useful for those interested in combining the toxic effects of narcotic chemicals in this compendium (see Section 4.3 for an example).

Values similar to some of those reported in this document were used to evaluate data for EPA's 1997 and 2004 National Sediment Quality Survey reports to Congress (USEPA 1997a,b,c, 2004). In those documents, the values were called sediment quality advisory levels (SQALs). These SQALs for nonionic organic chemicals were also included as "Ecotox Thresholds" in a 1996 ECO Update bulletin published by EPA's Office of Solid Waste and Emergency Response (OSWER) (U.S. EPA 1996). In some cases, the Tier 2 ESBs in this document may differ from the SQALs and Ecotox Thresholds because of different data sources. Further, the SQALs and Ecotox Thresholds did not include narcosis-based chronic toxicity values.

Sediment benchmarks generated using the EqP approach are suitable for use in providing technical information to regulatory agencies because they are:

1. Numeric values
2. Chemical specific
3. Applicable to most sediments
4. Predictive of biological effects
5. Protective of benthic organisms

ESBs are derived using the available scientific data to assess the likelihood of significant environmental effects to benthic organisms from chemicals in sediments in the same way that the WQC are derived using the available scientific data to assess the likelihood of significant environmental effects to organisms in the water column. As such, ESBs are intended to protect benthic organisms from the effects of chemicals associated with sediments and, therefore, only apply to sediments permanently inundated with water, to intertidal sediment, and to sediments inundated periodically for durations sufficient to permit development of benthic assemblages. ESBs should not be applied to occasionally inundated soils containing terrestrial organisms, nor should they be used to address the question of possible contamination of upper trophic level organisms or the generic synergistic, additive, or antagonistic effects of multiple chemicals. The application of ESBs under these conditions may result in values lower or higher than those presented in this document. It should be noted that under certain conditions with narcotic chemicals, additivity may be considered.

ESB values presented herein are the concentrations of 32 nonionic organic chemicals in sediment that are not expected to adversely affect most benthic organisms. Just as values in this document can be seen as an update of the SQALs and Ecotox Thresholds, it is recognized (and encouraged) that these ESB values may need to be adjusted to account for new data as they become available. They may also need to be adjusted because of site-specific considerations. For example, in spill situations, where chemical equilibrium between water and sediment has not yet been reached, sediment chemical concentrations less than an ESB may pose risks to benthic organisms. This is because for spills, disequilibrium concentrations in interstitial and overlying water may be proportionally higher relative to sediment concentrations. In systems where biogenic organic carbon dominates, research has shown that the source or 'quality' of total organic carbon (TOC) in natural sediments does not affect chemical partitioning when sediment toxicity was measured as a function of TOC concentration (DeWitt et al. 1992). K_{OC}s for several nonionic chemicals have also been shown to not vary significantly across estuarine sediments with differing organic carbon concentrations and quality (Burgess et al. 2000). However, in systems where other forms of carbon are present at elevated levels, the source or 'quality' of TOC may affect chemical binding despite expressing toxicity as a function of TOC concentration. At some sites, concentrations in excess of an ESB may not pose risks to benthic organisms because the compounds are partitioned to a component of a particulate phase such as black carbon or coal or exceed solubility such as in the case of undissolved oil or chemical (e.g., manufactured gas plant sites) (U.S. EPA 2003e, Cornelissen et al. 2005). In these situations, an ESB would be overly protective of benthic organisms and should not be used unless modified using the procedures outlined in "Procedures for the Derivation of Site-Specific Equilibrium Partitioning Sediment Benchmarks (ESBs) for the Protection of Benthic Organisms: Nonionic Organics" (U.S. EPA 2003b). It should also be noted that the ability to predict partitioning based on additional factors like black carbon is still evolving and may serve to decrease partitioning-related uncertainties in future applications. If the organic carbon has a low sorptive affinity (e.g., hair, wood chips, hide fragments), an ESB would be under protective. An ESB may also be under protective when the toxicity of other chemicals are additive with an ESB chemical or when species of unusual sensitivity occur at the site.

This document presents the derivation and calculation of Tier 2 ESBs for 32 nonionic organic chemicals. The data that support the EqP approach for deriving ESBs for nonionic organic chemicals are reviewed by Di Toro et al. (1991) and EPA (2003a). Before proceeding through the following text, tables, and calculations, the reader should also consider reviewing Stephan et al. (1985).

1.3 Application of Sediment Benchmarks

ESBs as presented in this document are meant to be used with direct toxicity testing of sediments as a method of sediment evaluation, assuming the toxicity testing species is sensitive to the chemical(s) of interest (e.g., ASTM 1998a,b,c, U.S. EPA 1994, 2000, 2001b). In this way, ESBs are supportive of recent recommendations by Wenning et al. (2005), to apply a weight of evidence approach when evaluating contaminated sediments. Specifically, the ESBs provide a chemical-by-chemical specification of sediment concentrations protective of benthic aquatic life (see Section 4.2.6 for more discussion). The EqP method should be most applicable to nonionic organic chemicals with a log $K_{OW} \geq 2$. However, for chemicals with log K_{OW} between 2 and 3, EqP will function but sedimentary conditions (i.e., f_{OC} and f_{Solids}) should be considered and adjustments to the derivation of the ESB maybe advisable (see Section 3.3). Examples of other chemicals to which the methodology applies include the pesticides endrin and dieldrin (U.S. EPA 2003c,d), metal mixtures (U.S. EPA 2005a), and PAH mixtures (U.S. EPA 2003e).

For the toxic chemicals addressed by the ESB documents, Tier 1 (U.S. EPA, 2003c, d, e, and 2005a) and Tier 2 (this document) values were developed to reflect the differing degrees of data availability and uncertainty. Tier 1 ESBs are more scientifically rigorous and data intensive than Tier 2 ESBs. The minimum requirements to derive a Tier 1 ESB include: (1) each chemical‘s organic carbon-water partition coefficient (K_{OC}) is derived from the octanol-water partition coefficient (K_{OW}) obtained using the SPARC model (Karickhoff et al. 1991) and the K_{OW}-K_{OC} relationship from Di Toro et al. (1991). This K_{OC} has been demonstrated to predict the toxic sediment concentration from the toxic water concentration with less uncertainty than K_{OC} values derived using other methods, (2) the FCV is updated using the most recent toxicological information and is based on the National WQC guidelines (Stephan et al. 1985), and (3) EqP-confirmation tests are conducted to demonstrate the accuracy of the EqP prediction that the K_{OC} multiplied by the effect concentration from a water-only toxicity test predicts the effect concentration from sediment tests (Swartz 1991, DeWitt et al. 1992, Hoke et al. 1994). Using these specifications, Tier 1 ESBs have been derived for the nonionic organic pesticides endrin and dieldrin (U.S. EPA 2003c,d), PAH mixtures (U.S. EPA 2003e), and metals mixtures (U.S. EPA 2005a). In comparison, the minimum requirements for a Tier 2 ESB (this document) are less rigorous: (1) the K_{OW} for the chemical that is used to derive the K_{OC} can be from slow-stir, generator column, shake flask, SPARC or other sources (e.g., Site 2001), (2) FCVs can be from published or draft WQC documents, the Great Lakes Water Quality Initiative (GLI 1995), or developed from AQUIRE (now ECOTOX). Secondary chronic values (SCV) from narcosis theory (Di Toro and McGrath 2000, Di Toro et al. 2000, U.S. EPA 2003e), Suter and Tsao (1996), or other effects concentrations from water-only toxicity tests can also be used. The U.S. EPA methodology for deriving water quality criteria SCVs required for the computation of Tier 2 ESBs is described in *Water Quality Guidance for the Great Lakes System: Supplementary Information Document (SID)* (U.S. EPA 1995a), and (3) EqP confirmation tests are recommended, but are not required for the development of Tier 2 ESBs. Because of these lesser requirements, there is greater uncertainty in the EqP prediction of the sediment effect concentration from the water-only effect concentration, and in the level of protection afforded by Tier 2 ESBs. This uncertainty can be decreased by conducting additional acute and chronic water-only and spiked sediment toxicity tests to evaluate effect concentrations and confirm predicted sediment concentrations, respectively.

1.4 Data Quality Assurance

Data sources, selections and manipulations used to generate K_{OW}s or K_{OC}s and SCV or FCVs are discussed in detail in Section 2. Toxicological data were selected from final and draft Water Quality Criteria, Suter and Tsao

(1996), U.S. EPA (1996), GLI (1995) and U.S. EPA (2001a) or derived using the approach described by Di Toro and McGrath (2000), Di Toro et al. (2000) and U.S. EPA (2003e). K_{OW} values were taken from Karickhoff and Long (1995) as well as other sources. Toxicity data were evaluated for acceptability using the procedures in Stephan et al. (1985), the Great Lakes Water Quality Initiative (GLI 1995), and the approach for deriving narcotic chronic toxicity values (Di Toro and McGrath 2000, Di Toro et al. 2000, U.S. EPA 2003e). Data not meeting criteria for acceptability were rejected. In general, three or four significant figures were used in intermediate calculations to limit the effect of rounding errors, and are not intended to indicate the true level of precision. The time periods covered in the literature searches associated with data in this document can be found in the cited source literature.

Literature searches supporting Suter and Tsao (1996), U.S. EPA (1996), GLI (1995) and U.S. EPA (2001a) were conducted in the mid-1990s. In order to capture more recent data, EPA's ECOTOX database (www.epa.gov/ecotox) was searched for any data pertaining to the chemicals evaluated in this document published after 1995. These data were then sorted to identify sources of acute toxicity data for North American species tested for a period appropriate to the species (Stephan et al. 1985) and for which test concentrations of chemical were measured. In addition, literature sources suggested by peer reviewers of this document were also consulted for data meeting minimum requirements. Fewer than 30 additional data points were identified, and only one of these affected the calculation of an SCV (see footnote in Table 3-1). As new, high quality toxicological and geochemical data becomes available, it is encouraged that the ESB values are revised and updated. See Section 2.5 for further discussion.

The document was reviewed as part of a formal external peer review coordinated at the U.S. EPA National Health and Environmental Effects Research Laboratory, Research Triangle Park, North Carolina and Atlantic Ecology Division, Narragansett, Rhode Island. Any errors of omission or calculation discovered during the peer review process were corrected.

1.5 Overview

This document presents the derivation and calculation of ESBs for 32 nonionic organic chemicals.

Section 2 reviews the toxicological and chemical data used to derive the ESB_{Tier2}s. Section 3 discusses the calculation of the ESB_{Tier2}s. Section 4 "Sediment Benchmark Values: Application and Interpretation" discusses the sediment benchmark values and lists several factors to consider when applying and interpreting these values. Section 5 lists references cited in all sections of this document. Appendix A discusses, in detail, the GLI approach for calculating chronic toxicity values.

Section 2

Derivation of Equilibrium Partitioning Sediment Benchmark Effects Concentrations

2.1 General Introduction

This section outlines the compilation of data used in the derivation of the Tier 2 ESBs presented in this compendium. The section follows the format for calculating the ESB values by first describing the derivation of the K_{OW} values, and then the derivation of the appropriate aquatic toxicity values. The derivation of the K_{OW} values follows procedures outlined in Karickhoff and Long (1996) and in many cases uses values summarized in Karickhoff and Long (1995). Because of the diversity of chemicals discussed in this compendium (i.e., narcotics, pesticides, phthalates), aquatic toxicity values were derived in two possible ways. Conventional aquatic toxicity values were derived either using the procedures detailed in the Great Lakes Water Quality Initiative (GLI, 1995) or taken from existing or draft WQC. For example, marine ESBs for pesticides were based only on FCVs from existing or draft WQC while freshwater ESBs for pesticides were derived using both WQC and GLI toxicity values. Similarly, ESBs for phthalates were derived only for freshwater species using the GLI approach as WQC values were not available. For chemicals designated as being narcotic, toxicity values were also derived using the narcosis theory used to develop ESBs for PAH mixtures (Di Toro et al. 2000, U.S. EPA 2003e). As discussed in Section 1, ESBs derived using either conventional or narcotic approaches, for narcotic chemicals in this document are applicable to both freshwater and marine species based on the concept that these organisms show similar sensitivity to narcotic chemicals. This concept was not exercised for pesticides and phthalates.

2.2 Determination of K_{OW} Values

The determination of K_{ow} values was based on experimental measurements taken primarily by the slow-stir, generator-column, and shake-flask methodologies. The SPARC properties calculator model (Karickhoff and Long 1995) was also used to generate K_{ow} values, when appropriate, for comparison with the measured values. Values that appeared to be considerably different from the rest were classified as outliers and were not used in the calculation. For each chemical, the available log K_{ow} value, based on one of the above mentioned methods, was given preference. If more than one such value was available, the log K_{ow} value was calculated as the arithmetic mean of those values (U.S. EPA 1995b). Most of the log K_{ow} values used in this document are summarized in an internal EPA report (Karickhoff and Long 1995). Subsequent to that evaluation, EPA has published a recommended procedure for selecting K_{ow} values, which can be seen in Karickhoff and Long (1996).

Log K_{ow} values were initially identified in summary texts on physical-chemical properties, such as Howard (1990) and Mackay et al. (1992a,b), and accompanying volumes. Additional compendia of log K_{ow} values were also evaluated including de Bruijn et al. (1989), De Kock and Lord (1987), Doucette and Andren (1988), Isnard and Lambert (1989), Klein et al. (1988), Leo (1993), Noble (1993), and Stephan (1993). To supplement these sources, on-line database searches were conducted in ChemFate,

TOXLINE, and Hazardous Substances Data Bank (HSDB) (National Library of Medicine); Internet databases such as EPA's ASsessment Tools for the Evaluation of Risk (ASTER) were also reviewed. Original references were located for the values, and additional values identified. In cases where log K_{ow} values varied over several orders of magnitude or measured values could not be identified, detailed on-line searches were conducted using TOXLIT, Chemical Abstracts, and DIALOG.

2.3 Selection and Determination of Aquatic Toxicity Values

For this discussion, all sources of toxicological information are considered 'conventionally-derived' approaches except for the narcosis source which will be referred to separately as the 'narcosis-based' approach.

A variety of sources were used for selecting conventional chronic toxicity values to be used in the derivation of the ESBs. The following were identified as possible sources to be used for determining chronic toxicity values:

1. Final Chronic Values from the Great Lakes Water Quality Initiative (GLI 1995, U.S. EPA 2001a)
2. Final Chronic Values from National Ambient Water Quality Criteria documents
3. Final Chronic Values from draft freshwater and marine National Ambient Water Quality Criteria documents
4. Final Chronic Values developed from data in AQUIRE (now ECOTOX) and other sources
5. Secondary Chronic Values from Suter and Tsao (1996)
6. Secondary Chronic Values developed from data in AQUIRE (now ECOTOX) and other sources (U.S. EPA 1996, 2001a)

2.3.1 Derivation of Conventional Chronic Toxicity Values

For the nine pesticides discussed in this document, values for freshwater ESBs for the following chemicals:

gamma-BHC/Lindane
diazinon
endosulfan (mixed isomers and alpha and beta forms)
toxaphene

were based on the FCVs from existing or draft National Ambient Water Quality Criteria documents (U.S. EPA 1980a,b, 1986, 2005b). Exceptions were the ESBs for BHCs other than Lindane, malathion and methoxychlor which were derived using SCVs with the GLI approach (GLI 1995, Suter and Tsao 1996, U.S. EPA 1996, 2001a). Marine ESBs for pesticides, in this document, were based only on WQC-derived FCVs. Consequently, marine ESBs for the following chemicals:

diazinon
endosulfan (mixed isomers and alpha and beta forms)
malathion
toxaphene

were derived from FCVs in existing or draft National Ambient Water Quality Criteria documents (Thursby 1990, U.S. EPA 1980b, 1986, 2005b). Similar FCVs for the pesticides BHCs other than Lindane, gamma-BHC/Lindane, and methoxychlor were unavailable and marine ESBs were not derived.

Twelve aquatic toxicity values, including three phthalates, used to develop freshwater SCVs were based on work conducted by Oak Ridge National Laboratories (Suter and Tsao 1996) using the GLI (1995) methodology. This methodology was developed to obtain whole-effluent toxicity screening values based on all available data, but the methodology can also be used to calculate SCVs with fewer toxicity data than are required for the WQC methodology. The SCVs are generally lower than values that are produced by the FCV methodology,

reflecting greater uncertainty and use of protective adjustment factors in the absence of additional toxicity data (see Section 2.4). According to GLI (1995), the minimum requirement for deriving an SCV is toxicity data from a single taxonomic family (Daphnidae), provided the data are acceptable. In general, those values from Suter and Tsao (1996), which included at least one daphnid test result in the calculation of the SCV, were included for the derivation of Tier 2 ESBs with the exception of ethylbenzene, toluene, 1,1,1-trichloroethane and trichloroethene. For these four chemicals, daphnids were not used for calculating the SCVs. SCVs from Suter and Tsao (1996) were used to develop Tier 2 ESBs for the following chemicals:

benzene
BHC (other than Lindane)
chlorobenzene
dibenzofuran
diethyl phthalate
di-n-butyl phthalate
ethylbenzene
tetrachloroethane, 1,1,2,2-
tetrachloroethene
toluene
trichloroethane, 1,1,1-
trichloroethene

A preliminary search of data records in the AQUIRE (now ECOTOX) database indicated that the following chemicals, which includes one phthalate, might have sufficient toxicity data for the development of SCVs using the GLI (1995) methodology:

biphenyl
4-bromophenyl phenyl ether
butyl benzyl phthalate
dichlorobenzene, 1,2-
dichlorobenzene, 1,3-
dichlorobenzene, 1,4-
hexachlorethane
malathion
methoxychlor
pentachlorobenzene
tetrachloromethane
tribromomethane
trichlorobenzene, 1,2,4-
m-xylene

The procedure used for deriving SCVs for other chemicals of concern using the GLI (1995) methodology and data from ACQUIRE (now ECOTOX) and other sources is described in detail in Appendix A and U.S. EPA (1996, 2001a).

2.3.2 Derivation of Narcotic Chronic Toxicity Values

Along with the derivation of aquatic toxicity values using conventional techniques (see discussion above), narcosis theory was used to derive SCVs for chemicals determined to be primarily narcotic in their mode of action by ASsessment Tools for the Evaluation of Risk (ASTER) (Russom et al. 1997). These chemicals include:

benzene
biphenyl
4-bromophenyl phenyl ether
chlorobenzene
dibenzofuran
1,2-dichlorobenzene
1,3-dichlorobenzene
1,4-dichlorobenzene
ethylbenzene
hexachloroethane
pentachlorobenzene
1,1,2,2-tetrachloroethane
tetrachloroethene
tetrachloromethane
toluene
tribromomethane
1,2,4-trichlorobenzene
1,1,1-trichloroethane
trichloroethene
m-xylene

It should be noted that for a given chemical multiple modes of action can affect an organism. Therefore, despite the categorization of these chemicals as primarily narcotics, other modes of action may be active. Section 4.3 discusses some of the implications of this issue.

Narcosis-based SCVs were derived using the approach discussed in the *Procedures for the Derivation of Equilibrium Partitioning Sediment Benchmarks (ESBs) for the Protection of Benthic Organisms: PAH Mixtures* (U.S. EPA 2003e) and Di Toro et al. (2000). In this approach, the SCV for these narcotic chemicals is derived using Equation 2-1:

$$\log (SCV_N) = \log[C_L^* \Delta c_l \div ACR] - 0.945 \cdot \log (K_{OW}) \quad (2\text{-}1)$$

where, SCV_N is the narcosis-based SCV for a given chemical (mmol/L), C_L^* is the critical lipid concentration predicted to cause 50% mortality equaling 35.3 µmol/g octanol, Δc_l is the chemical class specific correction, ACR is the acute-chronic ratio equaling 5.09, -0.945 the universal narcosis slope, and K_{OW} is specific to the chemical being investigated (Di Toro et al. 2000). This equation can be simplified to:

$$\log (SCV_N) = \log (6.94) + \Delta c_l - 0.945 \cdot \log (K_{OW}) \quad (2\text{-}2)$$

For the narcotic chemicals in this document, the chemical class specific correction value (Δc_l) for halogenated compounds was -0.244. For all other compounds, a correction was not necessary (Di Toro et al. 2000).

Narcosis values were also calculated for chemicals with other toxicological modes of action; specifically, the pesticides and phthalates. In every instance, the narcosis SCV_N was larger in magnitude than the conventional FCV or SCV. For example, the range of the ratio of narcosis to conventional values was 2.4 for di-n-butyl phthalate to nearly 50,000 for alpha-endosulfan. In general, the ratio of narcosis to conventional values was greater than 1000 and thus the pesticides and phthalates contribute only a small amount of narcotic potency. Despite the utility of knowing the contribution of narcosis to the overall toxicity of the pesticides and phthalates, the narcosis values should be used with caution. The narcosis equation above (Equation 2-2) provides chemical class specific corrections (i.e., Δc_l) for halogenated functional groups. However, several of the pesticides and phthalates contain other functional groups not directly addressed in Equation 2-2 including ester and sulfur groups. At this time, the effects of these types of groups on predictions by Equation 2-2 are unknown.

2.4 Comparison of Narcosis and Conventional Chronic Toxicity Values

For every narcotic chemical in this document, the narcosis-based SCV is greater than the conventionally-derived SCV, although the magnitude of the difference varies among chemicals (also see Table 3-1). Figure 2-1 shows the ratio of the two values, which ranges from 1.1 (1,2,4-trichlorobenzene) to 220 (1,1,1-trichloroethane). Of the 20 chemicals evaluated, four chemicals had ratios below 10, 13 chemicals had ratios between 10 and 50, and three chemicals had ratios greater than 100. To interpret these differences, one must consider the differences in how the two values are derived. There are two features of the conventional SCV derivation that create discrepancies. The first is the use of secondary acute factors (SAFs) to estimate a SAV from existing data (see Section A.5 of Appendix A for more discussion of SAFs). The SAFs applied to the chemicals in question here range from 4 up to 242, depending on the number of minimum data requirements met by the available toxicity data, and is applied to the lowest reported mean acute value available (see Suter and Tsao (1996) and U.S. EPA (2001) for a description of how the conventional SCVs were calculated).

The SAFs were derived based on an analysis of a wide range of chemicals. However, narcotics tend to show a much narrower range in species sensitivity than do many other chemicals; in fact, the total range in species sensitivity reported by Di Toro et al. (2000) is only a factor of 8.3 across a total of 33 species. More importantly, the conventional GLI SCV methodology requires that data for *Daphnia magna* be included in the data set. As shown by Di Toro et al. (2000), the ratio of the estimated SMAV for *Daphnia magna* and the FAV for all species is only a factor 3.1. In the case of

rainbow trout, a species for which data were frequently available for the present analysis, that ratio is only 1.7. What this means in terms of SCV derivation for narcotic chemicals is that the generic SAFs are larger than is appropriate for narcotic chemicals in particular; while values of 4 to 242 were used, one would expect the true value to have never been higher than 3.1, and commonly 1.7 or less. This difference in extrapolation therefore accounts for as much as a factor of >10 difference between the conventionally-derived and narcosis-based SAVs, which is directly translated into differences in the SCVs (Figure 2-1).

The second major factor lies in the acute-chronic ratios (ACRs) used to translate the SAV into a SCV. In the conventional approach, calculation of the ACR was based on the geometric mean of at least three ACRs. However, wherever there were less than three species-specific ACRs available, a value of 18 was used to replace the missing data (see Section A.5 of Appendix A for more discussion of ACRs); this value was derived through an analysis of ACRs for a variety of chemicals. For the narcotic chemicals shown in Figure 2-1, availability of chronic toxicity data varied from no measured ACRs to three measured ACRs. Where there were no measured ACRs, the conventionally-derived secondary ACR (SACR) was 18.

In their analysis, Di Toro et al. (2000) calculated a much lower mean ACR of 5.09 for narcotic chemicals specifically. Because narcosis appears to result in a lower ACR than the default value of 18 used in the conventional Tier 2 SCV derivation, one can expect additional conservatism in the conventionally-derived Tier 2 SCVs for those chemicals where little or no chronic data were available. Examples include chemicals like 1,2 dichlorobenzene and pentachlorobenzene, both of which were derived using SACRs of 18 and have correspondingly high ratios of the narcosis-based and conventionally-derived SCV values (Figure 2-1). In contrast, 1,2,4 – trichlorobenzene had enough acute toxicity data to meet all 8 minimum data requirements (MDRs) (so no SAF was applied) and the SACR (with two measured ACRs) was only 6.7, very close to the 5.09 estimated for narcotic chemicals (Di Toro et al. 2000). As a result, the conventionally-derived SCV and the narcosis-based SCVs are very close (Figure 2-1).

The applicability of narcosis theory to the compounds designated here as narcotics can be evaluated by comparing the individual species mean acute values (SMAVs) for each of the compounds to the SMAV one would predict based on narcosis theory. To do this, the individual SMAV values were extracted from the SCV derivation for the 20 narcotic chemicals listed in Section 2.3.2. For those species which also appeared in the dataset compiled by Di Toro et al. (2000), the mean species sensitivity was used along with the K_{OW} of each chemical to predict an LC50 for that species and chemical. These predicted LC50s for all 20 chemicals were compared to the observed SMAVs as shown in Figure 2-2. To allow better discrimination of data for individual chemicals, this same data set was segregated into three groups of chemicals, and replotted as Figures 2-3 through 2-5.

The strong agreement between observed and predicted values, shown by alignment along the one to one line, clearly indicates that the observed toxicity of these chemicals is consistent with a narcosis mode of action. Most of the measured values fall within a factor of two of the predicted value (shown by the dashed lines in Figures 2-2 through 2-5) with no consistent bias from a 1:1 relationship. This in turn suggests that deriving SCVs for these chemicals using narcosis theory is appropriate, and that the differences in the conventionally-derived and narcosis-based SCVs is primarily due to conservatism in the SAFs and default SACRs as discussed above.

Finally, for the three phthalates discussed in this document, 'FCVs' derived using the quantitative structure-activity relationship (QSAR) described by Parkerton and Konkel (2000) were compared to conventional SCVs in Table 3-1. ASTER does not classify phthalates

as narcotics but there is some evidence they may demonstrate narcotic-like behavior. The QSAR values derived by Parkerton and Konkel (2000) were 60, 62 and 1173 µg/L for butyl benzyl phthalate, di-n-butyl phthalate and diethyl phthalate, respectively. These values compare relatively well to the conventional SCVs of 19, 35 and 270 µg/L for butyl benzyl phthalate, di-n-butyl phthalate and diethyl phthalate, respectively. From this comparison, the conventional values for phthalates in this document appear to be slightly more conservative than the QSAR based numbers but not tremendously different with ratios ranging from 2 to 4. See Adams et al. (1995), Rhodes et al. (1995), Staples et al. (1997), Parkerton and Konkel (2000), and Call et al. (2001) for further discussion of phthalate aquatic toxicity.

2.5 Selection of New and Alternate Aquatic Toxicity Values

As discussed in the *Foreword*, the ESBs are intended primarily as technical information, not as formal guidelines. As such, the aquatic toxicity values used to derive the Tier 2 ESBs reported in this document are principally recommendations. The conventional (based on WQC and GLI) and narcosis approaches were selected to generate aquatic toxicity values for the 32 chemicals in this document because of their wide usage and acceptance by the scientific, regulatory and regulated communities. As new high quality aquatic toxicity data becomes available, it is encouraged that these Tier 2 ESBs be updated and revised. The GLI approach, as discussed in Appendix A, is one method for performing these updates and revisions. Periodic review of aquatic toxicity databases like ECOTOX may provide new high quality aquatic toxicity values for some of the chemicals discussed in this ESB, especially those for which a limited data base was initially available (see Section 2.3.1).

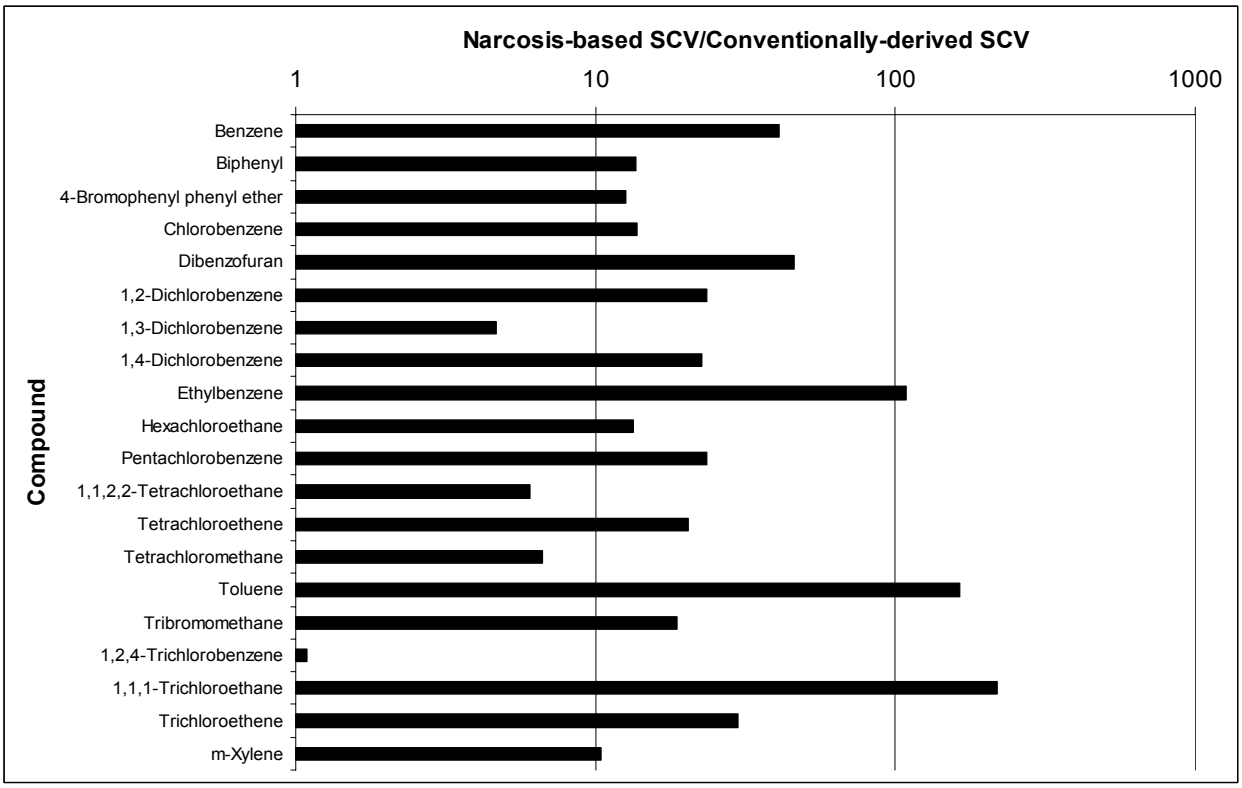

Figure 2-1 Comparison of narcosis-based and conventionally-derived chronic toxicity values. Chemicals with modes of action in addition to narcosis (i.e., pesticides and phthalates) are not shown.

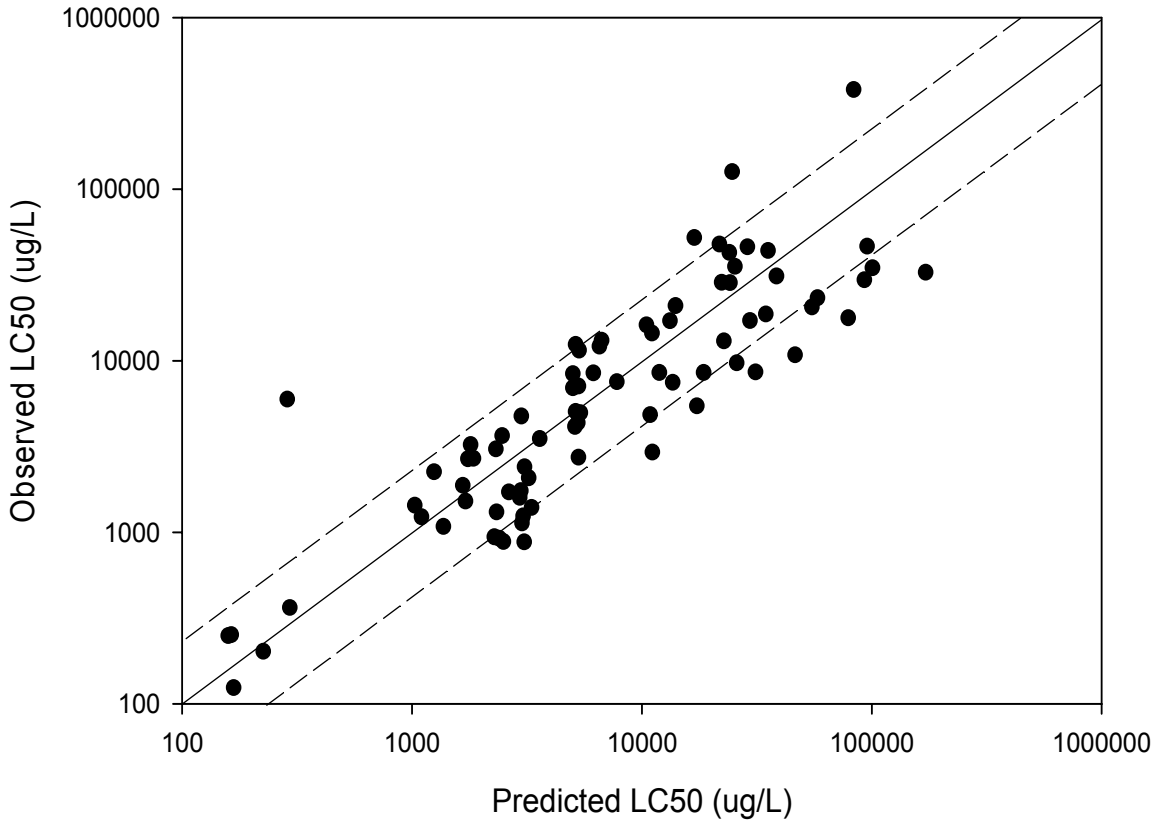

Figure 2-2 Comparison of observed LC_{50} values used in the calculation of secondary chronic values and LC_{50} values predicted using narcosis theory as described by Di Toro et al. (2000) for all 20 narcotic chemicals discussed in this document (including data from Chaisuksant et al. (1998)). Plot shows data for all species that had both measured LC50 values in the SCV derivation and have species-specific sensitivity data as calculated by Di Toro et al. (2000). See discussion in text for more details. The solid line is the one to one line and the dashed lines show ± a factor of two. Chemicals potentially having more specific modes of action (e.g., pesticides and phthalates) are not shown.

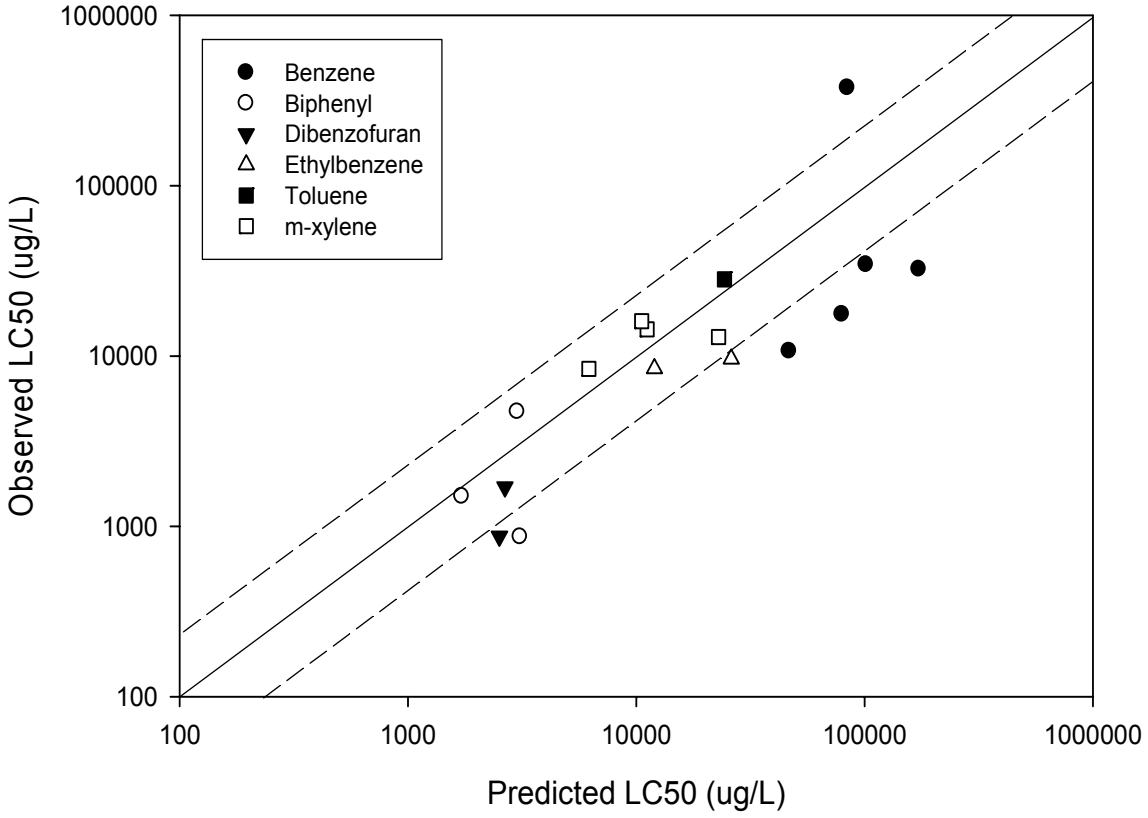

Figure 2-3 Comparison of observed LC_{50} values used in the calculation of secondary chronic values and LC_{50} values predicted using narcosis theory as described by Di Toro et al. (2000) for non-halogenated aromatic narcotic chemicals discussed in this document. Plot shows data for all species that had both measured LC50 data in the SCV derivation and have species-specific sensitivity data as calculated by Di Toro et al. (2000). See discussion in text for more details. The solid line is the one to one line and the dashed lines show ± a factor of two.

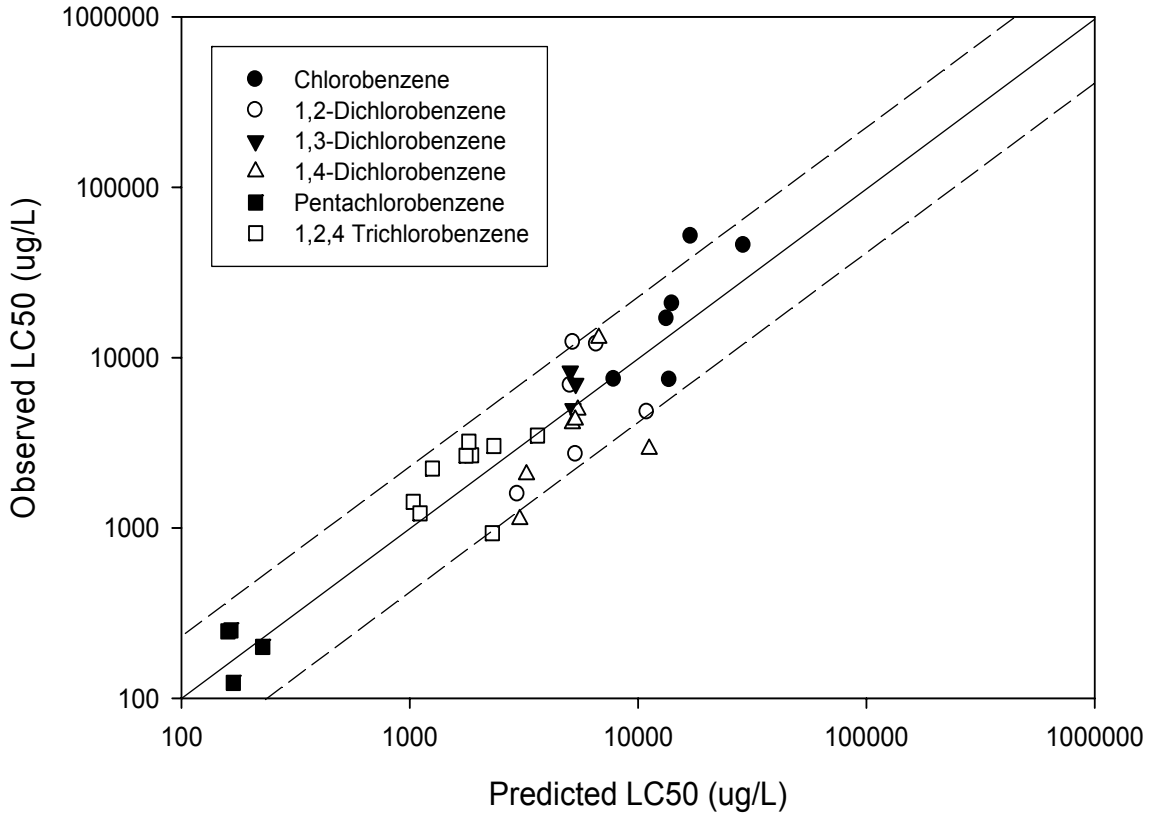

Figure 2-4 Comparison of observed LC_{50} values used in the calculation of secondary chronic values and LC_{50} values predicted using narcosis theory as described by Di Toro et al. (2000) for chlorobenzenes (including Chaisuksant et al. (1998)). Plot shows data for all species that had both measured LC50 data in the SCV derivation and have species-specific sensitivity data as calculated by Di Toro et al. (2000). See discussion in text for more details. The solid line is the one to one line and the dashed lines show ± a factor of two.

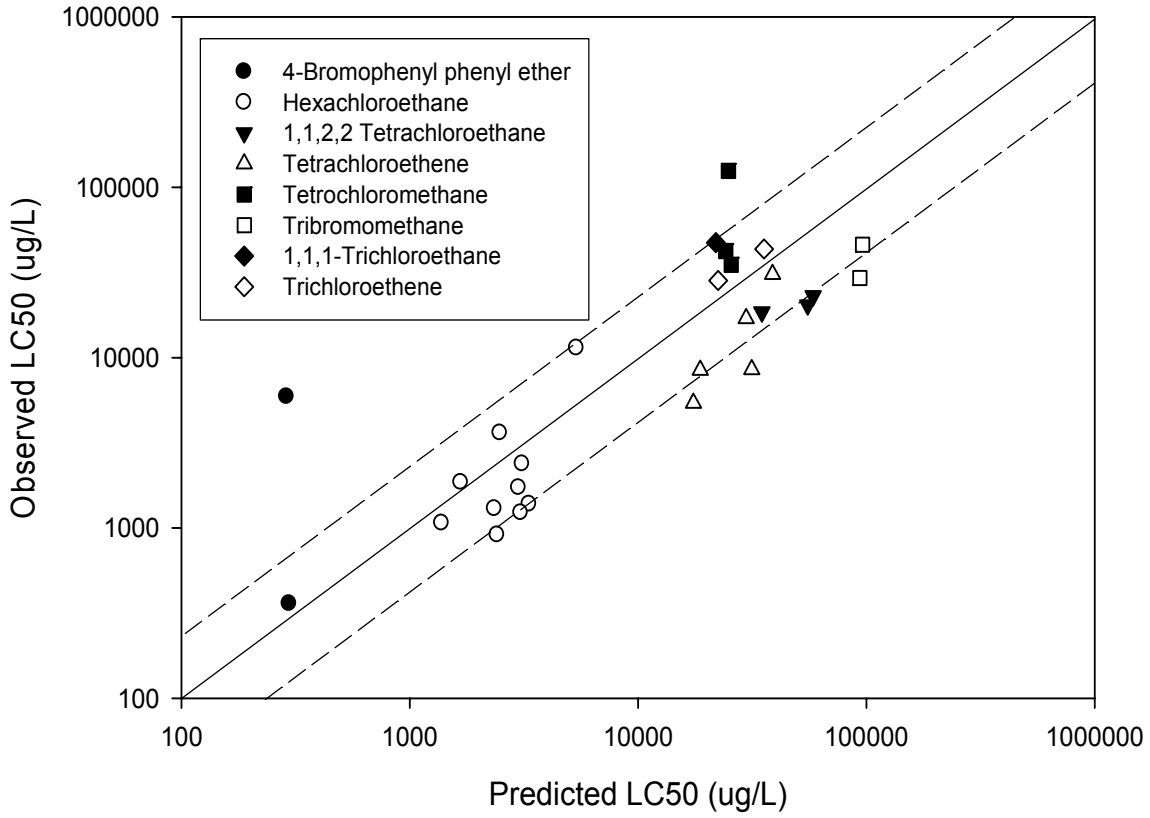

Figure 2-5 Comparison of observed LC_{50} values used in the calculation of secondary chronic values and LC_{50} values predicted using narcosis theory as described by Di Toro et al. (2000) for narcotic chemicals not shown in Figures 2-3 or 2-4, primarily halogenated hydrocarbons. Plot shows data for all species that had both measured LC50 data in the SCV derivation and have species-specific sensitivity data as calculated by Di Toro et al. (2000). See discussion in text for more details. The solid line is the one to one line and the dashed lines show ± a factor of two.

Section 3

Calculation of Equilibrium Partitioning Sediment Benchmarks

3.1 Overview of EqP Methodology

ESBs are the numeric concentrations of individual chemicals that are intended, based on the assumptions discussed in Section 1, to be predictive of biological effects, protective of the presence of benthic organisms, and applicable to the range of natural sediments from lakes, streams, estuaries, and near-coastal marine waters. For nonionic organic chemicals, ESBs are expressed as µg chemical/g_{OC} and apply to sediments having ≥ 0.2% organic carbon by dry weight. A brief overview follows of the concepts that underlie the EqP methodology for deriving ESBs. The methodology is discussed in detail in "Technical Basis for the Derivation of Equilibrium Partitioning Sediment Benchmarks (ESBs) for the Protection of Benthic Organisms: Nonionic Organics" (U.S. EPA 2003a), hereafter referred to as the ESB Technical Basis Document.

Bioavailability of a chemical at a particular sediment concentration often differs from one sediment type to another. Therefore, a method is necessary to determine ESBs based on the bioavailable chemical fraction in a sediment. For nonionic organic chemicals, the concentration–response relationship for the biological effect of concern can most often be correlated with the interstitial water (i.e., pore water) concentration (µg chemical/L interstitial water) and not with the sediment chemical concentration (µg chemical/g sediment) (Di Toro et al. 1991). This does not mean that all of the exposure is from the interstitial waters but from a purely practical point of view, this correlation suggests that if it were possible to measure the interstitial water chemical concentration, or predict it from the total sediment concentration and the relevant sediment properties, then that concentration could be used to quantify the exposure concentration for an organism. Thus, knowledge of the partitioning of chemicals between the solid and liquid phases in a sediment is a necessary component for establishing ESBs. For this reason, the methodology described below is called the EqP method. As stated above, an ESB can be derived using any given level of protection, in the following discussion the SCVs or FCVs for several nonionic organic chemicals are applied. The EqP approach used here to derive ESBs functions most effectively for nonionic organic chemicals with log K_{OW}s ≥ 2. However, for chemicals with log K_{OW} between 2 and 3, EqP will function but sedimentary conditions (i.e., f_{OC} and f_{Solids}) should be considered and adjustments to the derivation of the ESB maybe advisable (see Section 3.3).

3.2 Derivation of Tier 2 Equilibrium Partitioning Sediment Benchmarks

The ESB Technical Basis Document (U.S. EPA 2003a) demonstrates that benthic species, as a group, have sensitivities similar to all benthic and water column species tested (taken as a group) to derive the WQC concentration for a wide range of chemicals. Thus, an ESB can be established using the FCV, calculated based on the WQC guidelines (Stephan et al. 1985), or a SCV calculated based on other sources like the water quality guidance originally derived for the Great Lakes Water Quality Initiative (GLI 1995), as the acceptable effect concentration in interstitial or overlying water. The appropriate partition coefficient can then be used to relate the interstitial water concentration (i.e., the calculated FCV or SCV) to the sediment concentration via the partitioning equation.

For chemicals discussed in this document, this acceptable concentration in sediment is termed an ESB_{Tier2}.

The methodology for deriving FCVs and SCVs used in the development of these ESBs were taken from existing or draft WQC, the approach developed for the Great Lakes Water Quality Initiative (Tier 1 and 2) and, when necessary, available data were obtained from EPA's AQUIRE database (now ECOTOX accessible at www.epa.gov/ecotox) and other literature (see Section 2).

In addition to deriving FCVs or SCVs based on chemical-specific toxicity data, the likelihood that each chemical would act as a narcotic toxicant (as opposed to a more specific mode of action) was evaluated using the ASTER model (Russom et al. 1997) which predicts mode of toxic action based on chemical structure. For chemicals in this document that were flagged by the ASTER model as acting through a narcotic mode of action, SCVs were also derived using the narcosis model described in U.S. EPA (2003e), Di Toro and McGrath (2000) and Di Toro et al. (2000).

For chemicals evaluated using conventionally-derived SCVs, separate ESB values were calculated for freshwater and marine organisms according to data availability. For chemicals flagged as narcotic toxicants, only single values were calculated, as it is believed that there is little difference in sensitivity between freshwater and marine organisms under this mode of action (U.S. EPA 2003e). A listing of SCVs and FCVs using conventional and narcosis approaches are shown in Table 3-1.

An ESB is calculated as follows. Establishing the SCV or FCV (µg/L) as the acceptable concentration in water for the chemical of interest, the ESB is computed using the partition coefficient, K_P (L/Kg), between sediment and water:

$$ESB_{Tier2} = K_P \cdot SCV \qquad (3\text{-}1)$$

This is the fundamental equation used to generate an ESB_{Tier2}. Its' utility depends on the existence of a methodology for quantifying K_P.

Organic carbon appears to be the dominant sorption phase for most nonionic organic chemicals in naturally occurring sediments and, thus, controls the bioavailability of these compounds in sediments. Evidence for this can be found in numerous toxicity tests, bioaccumulation studies, and chemical analyses of interstitial water and sediments (Di Toro et al. 1991, U.S. EPA 2003a). The organic carbon binding of a chemical in sediment is a function of that chemical's K_{OC} and the weight fraction of organic carbon (f_{OC}) in the sediment. The relationship is as follows:

$$K_P = f_{OC} \cdot K_{OC} \qquad (3\text{-}2)$$

It follows that:

$$ESB_{Tier2OC} = K_{OC} \cdot SCV \qquad (3\text{-}3)$$

where $ESB_{Tier2OC}$ is an ESB_{Tier2} expressed on a sediment organic carbon normalized basis. For nonionic organics, normalization of the "ESB_{Tier2}" to organic carbon is assumed (more formally $ESB_{Tier2OC}$) unless otherwise specified.

Although K_{OC} is not usually measured, it is closely related to the octanol-water partition coefficient (K_{OW}), which has been measured for many compounds, and can be measured very precisely. A chemical's K_{OC} is related to the K_{OW} by the following equation (Di Toro et al. 1991):

$$\text{Log } K_{OC} = 0.00028 + 0.983 \cdot (\log K_{OW}) \qquad (3\text{-}4)$$

Karickhoff and Long (1996) established a protocol for recommending K_{OW} values for nonionic organic chemicals based on the best available measured, calculated, and estimated data. The recommended $\log_{10}K_{OW}$ values from Karickhoff and Long (1995) were used to derive many of the K_{OC} values for ESB calculation in this document (Table 3-2).

Based on this derivation, ESB_{Tier2} values for 32 nonionic organic chemicals using conventional and narcosis approaches are listed in Table 3-2.

Table 3-1. Chronic toxicity values (µg/L), SCVs and FCVs, used to derive Tier 2 ESBs based on conventional and narcosis approaches. Narcosis values for chemicals with a toxicological mode of action in addition to narcosis are italicized and bolded (e.g., pesticides and phthalates) and are provided for comparison not for use. Values presented with two significant figures except FCVs.

3.3 Effects of Low K_{OW} on Derivation of ESB_{Tier2}

As noted above, the EqP approach used here to derive ESBs functions most effectively for nonionic organic chemicals with log K_{OW}s ≥ 2. However, Fuchsman (2003) demonstrated recently that equilibrium partitioning may inaccurately predict the bioavailable concentration of organic compounds with low log K_{OW}s (i.e., approximately 3). This is because the basic equilibrium partitioning equation (Equation 3-3) assumes that the measured contaminant is associated overwhelmingly with sediment organic carbon and that the amount in the dissolved phase is negligible. However, for chemicals with comparatively low K_{OW} a more substantial fraction of total chemical may be present in the dissolved phase. As a result, the ESB calculation as shown in Equation 3-3, may result in overly protective ESBs.

A modification of the equilibrium partitioning equation (Equation 3-3) can be determined (Fuchsman 2003):

$$ESB_{Tier2DRY\ WT} = SCV\ [(f_{OC}\ K_{OC}) + ((1 - f_{Solids}) \div f_{Solids})] \quad (3\text{-}5)$$

In which, $ESB_{Tier2DRY\ WT}$ is in units of µg chemical/g dry weight sediment and f_{Solids} is the fraction of sediment present as solids. In the U.S. EPA Environmental Monitoring and Assessment Program (EMAP) data set discussed below, f_{Solids} values for 1024 sediment samples ranged from 0.085 to 0.938 with an average value of 0.553 (U.S. EPA 2007a). In Equation 3-5, the proportion $((1 - f_{Solids}) \div f_{Solids})$, is used to adjust the magnitude of the $ESB_{Tier2DRY\ WT}$ as a function of the amount of solids in the sediment. As K_{OC} increases; that is, the chemical becomes more hydrophobic, the proportion becomes less important and has little effect on the $ESB_{Tier2DRY\ WT}$. Conversely, for low K_{OC} chemicals, the proportion may have a substantial effect on the magnitude of $ESB_{Tier2DRY\ WT}$. The $ESB_{Tier2DRY\ WT}$ is converted to $ESB_{Tier2OC}$ by the following:

$$ESB_{Tier2OC} = ESB_{Tier2DRY\ WT} \div f_{OC} \quad (3\text{-}6)$$

It should be noted that in aquatic environments, f_{Solids} and f_{OC} are often inversely correlated. For example, in depositional areas, where contaminants discussed in this document frequently accumulate, f_{Solids} is often low and f_{OC} elevated because of the abundance of carbon-rich small particles with large surface area to volume ratios. Conversely, sediments in dynamic areas tend to have low f_{OC} and elevated f_{Solids} because of the dominance of large mineral particles with low surface area to volume ratios and comparatively low carbon content.

An analysis of the effects of low K_{OW} on the ESB calculation is shown in Figure 3-1. The departure of the standard ESB (Equation 3-3) from the modified ESB (Equations 3-5 and 3-6) occurs most substantially at low f_{OC} and low f_{Solids} conditions, starting at a log K_{OW} of approximately 4. Conversely, at high f_{Solids} and high f_{OC} conditions, there is little difference between the calculated values (Figure 3-1a). When high f_{OC} is combined with low f_{Solids} as well as low f_{OC} combined high f_{Solids}, departure between the two approaches for calculating ESBs are observed but at log K_{OW}s of about 2.50 (Figure 3-1b).

Table 3-3 provides examples of the specific effects of f_{Solid} on the derivation of ESBs for four chemicals with a range of K_{OW}s. For this exercise, f_{Solids} was calculated using paired sand and moisture content data from sediment samples collected in several U.S. EPA EMAP estuarine provinces (i.e., Acadian, Carolinian, Virginian) (U.S. EPA 2007a). From the moisture content (MC) data (as %), f_{Solids} was calculated as:

$$f_{Solids} = (100 - MC) \div 100 \quad (3\text{-}7)$$

and regressed against the sand content (%) to derive the relationship:

$$f_{Solids} = 0.264 + 0.00487 \cdot \text{Sand Content} \quad (3\text{-}8)$$

For this example, f_{OC} values were set to the environmentally relevant range of 0.002 to 0.05. Examining the extremes, in a sandy sediment

(80% sand), the ESB for low K_{OW} benzene is shown to increase by a factor of three between the standard equation (Equation 3-3) and the modified equation (Equation 3-5) calculations. Conversely, for high K_{OW} toxaphene, there is no difference between the ways of calculating ESBs in the same sandy sediment. For a low sand content sediment (20% sand), benzene ESBs are different by only 20% and again no difference was observed between toxaphene ESBs. The other two chemicals, malathion and 1,2,4-trichlorobenzene with K_{OW}s between benzene and toxaphene, follow similar trends.

Of the 32 chemicals discussed in this document, only four have log K_{OW}s less than 2.5 while 22 have log K_{OW}s that are equal to or less than log 4. In situations where low f_{OC} and low f_{Solids} are known to occur, it is recommended that Equation 3-5 be used to modify the predicted ESB. However, it is most likely chemicals in this document will occur in environments at concentrations of concern when f_{Solids} are low and f_{OC} is high, conditions where departure between the standard and modified ESBs takes place at log K_{OW} of about 2.5, not affecting these chemicals too substantially. It maybe possible under conditions where a contaminated groundwater discharge is occurring into a sedimentary environment for f_{Solids} to be elevated, f_{OC} to be low, and for low K_{OW} chemicals to be present. Under such conditions, the use of Equation 3-5 maybe warranted.

Finally, the value f_{Solids} is not often reported in sediment investigations. In sediments suspected of contamination by low K_{OW} chemicals, it may be important to record this sediment characteris-tic (see Equation 3-8 for predicting f_{Solids} based on sediment sand content). The f_{Solids} values should be available from laboratories conducting chemical analyses on any contaminated sediment samples as part of the determination of moisture content (i.e., Percent Solids = 100% - moisture content (expressed as %)).

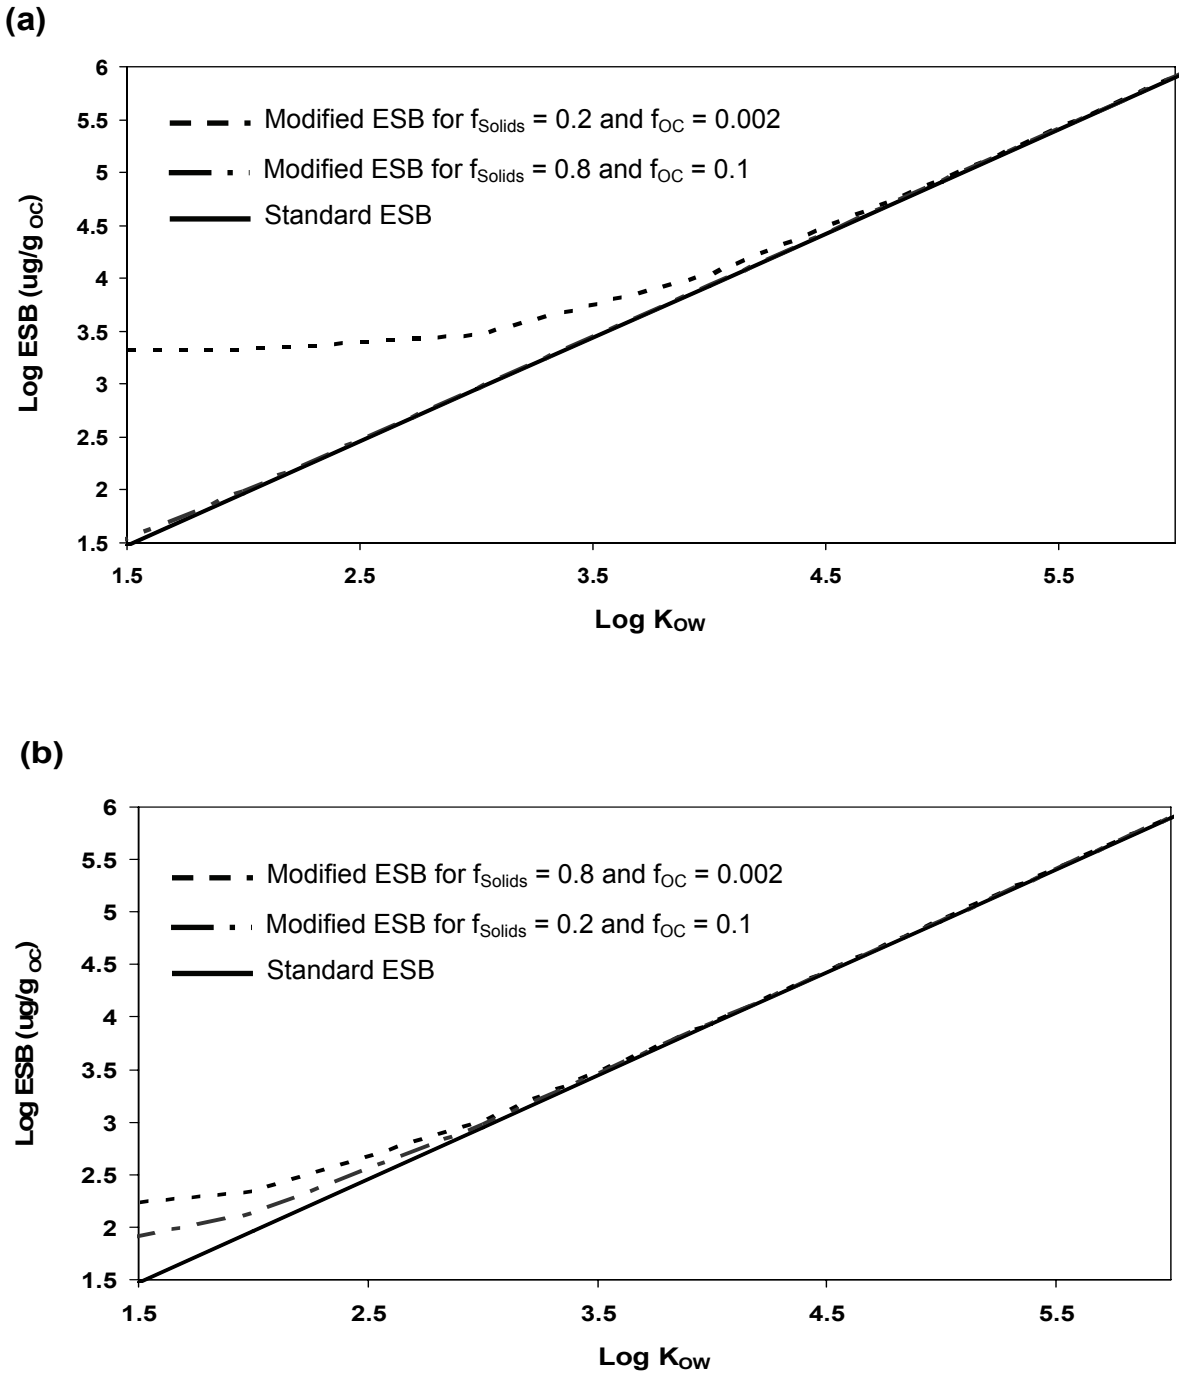

Figure 3-1 **Comparison of ESBs calculated using the standard equation (Equation 3-3) and modified equations which include the effects of low K_{OW} (Equations 3-5 and 3-6): (a) effects of low f_{Solids} and f_{OC} and high f_{Solids} and f_{OC} and (b) effects of high f_{Solids} and low f_{OC} and low f_{Solids} and high f_{OC}. In all cases, the FCV is 1000 ug/L.**

Table 3-3 Example calculations of conventional freshwater standard and modified $ESB_{Tier2DRY\ WT}$ values (µg/g dry weight) for four chemicals under different f_{OC} and f_{Solids} conditions. See text for discussion of the calculation of f_{Solids}. ESB values presented with two significant figures.

Chemical	FCV or SCV (µg/L)	Log K_{OW}:K_{OC}	Standard $ESB_{Tier2DRY\ WT}$: Modified $ESB_{Tier2DRY\ WT}$* (µg/g dry weight)		
			Sediment Characteristics		
			Sand = 80% Silt-Clay = 20% f_{OC} = 0.002 f_{Solids} = 0.65	Sand = 50% Silt-Clay = 50% f_{OC} = 0.025 f_{Solids} = 0.51	Sand = 20% Silt-Clay = 80% f_{OC} = 0.05 f_{Solids} = 0.36
Benzene	130	2.13:2.09	0.032:0.10	0.40:0.52	0.80:1.0

* = See Equation 3-5.

3.4 Conversion to Dry Weight Concentration

Since organic carbon is the major factor controlling the bioavailability of nonionic organic compounds in sediments, ESBs have been developed on an organic carbon normalized basis (e.g., $ESB_{Tier2OC}$) not on a dry weight basis. When the chemical concentrations in sediments are reported as dry weight concentration and organic carbon data are available, it is best to convert the sediment concentration to µg chemical/g organic carbon. These concentrations can then be directly compared to the ESB value. This facilitates comparisons between the ESB and field concentrations relative to identification of hot spots and the degree to which sediment concentrations do or do not exceed ESB values. Conversion from the dry weight to organic carbon-normalized concentration can be performed using the following equations:

$$\mu g\ Chemical/g_{OC} = \mu g\ Chemical/g_{DRY\ WT} \div (\%\ TOC \div 100) \quad (3\text{-}9)$$

or

$$\mu g\ Chemical/g_{OC} = \mu g\ Chemical/g_{DRY\ WT} \cdot 100 \div \%\ TOC \quad (3\text{-}10)$$

For example, sediment with a chemical concentration of 0.1 $\mu g/g_{DRY\ WT}$ and 0.5% TOC has an organic carbon-normalized concentration of 20 $\mu g/g_{OC}$ (0.1 $\mu g/g_{DRY\ WT} \cdot 100 \div 0.5 = 20\ \mu g/g_{OC}$). Another sediment with the same dry weight concentration (0.1 $\mu g/g_{DRY\ WT}$) but a TOC concentration of 5.0% would have an organic carbon-normalized concentration of 2.0 $\mu g/g_{OC}$ (0.1 $\mu g/g_{DRY\ WT} \cdot 100 \div 5.0 = 2.0\ \mu g/g_{OC}$).

In situations where TOC values for particular sediments are not available, a range of TOC values may be used in a 'worst case' or 'best case' analysis. In this situation, the organic carbon-normalized ESB values ($ESB_{Tier2OC}$) may be 'converted' to dry weight-normalized ESB values ($ESB_{Tier2DRY\ WT}$). This 'conversion' must be performed for each level of TOC of interest:

$$ESB_{Tier2DRY\ WT} = ESB_{Tier2OC}\ (\mu g/g_{OC}) \cdot (\%\ TOC \div 100) \quad (3\text{-}11)$$

where $ESB_{Tier2DRY\ WT}$ is the dry weight normalized ESB value. Examples of the Tier 2 ESB values ($ESB_{Tier2DRY\ WT}$) using conventional and narcosis approaches normalized to various organic carbon concentrations can be seen in Table 3-4.

Table 3-4. Example Tier 2 ESBs (µg/g dry weight) using freshwater conventional (C) and narcosis (N) approaches normalized to various total organic carbon (TOC) concentrations. Narcosis values for chemicals with a toxicological mode of action in addition to narcosis (e.g., pesticides and phthalates) are not presented. Values presented with two significant figures.

Section 4

Sediment Benchmark Values: Application and Interpretation

4.1 Benchmarks

Based on the level of protection provided by FCVs or SCVs, the procedures described in this document indicate that benthic organisms should be comparably protected from the adverse effects of the 32 nonionic organic chemicals listed in Table 3-2, when their concentrations in sediment are below the ESB_{Tier2} values. These values are appropriate for the protection of both freshwater and marine sediments based on the assumptions discussed in Section 1, except possibly where a locally important species is very sensitive or sediment organic carbon is <0.2% or the nonionic organic chemical's log K_{OW} is <2 (see Section 3.3 to modify ESB_{Tier2} values).

The benchmarks presented in this document are the concentrations of a substance that may be present in sediment while still protecting benthic organisms from the effects of that substance. These benchmarks are applicable to a variety of freshwater and marine sediments because they are based on the biologically available concentration of the substance in those sediments.

The ESBs do not intrinsically consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with the individual nonionic organic chemicals discussed in this document or the potential for bioaccumulation and trophic transfer of these chemicals to aquatic life, wildlife or humans. However, for narcotic chemicals, the toxicity of mixtures can be considered (see discussion below). Consistent with the recommendations of EPA's Science Advisory Board, publication of this document does not imply the use of ESBs as stand-alone, pass-fail criteria for all applications; rather, when used in a weight of evidence approach (Wenning et al. 2005), exceedances of ESBs could trigger collection of additional assessment data (e.g., benthic community composition, whole sediment toxicity testing, and other sediment quality guideline evaluations (e.g., Long et al. 1995, MacDonald et al. 1996, Long and MacDonald 1998, Swartz 1999, MacDonald et al. 2000a,b, Leung et al. 2005).

4.2 Considerations in the Application and Interpretation of ESBs

4.2.1 Relationship of ESB_{Tier2} to Expected Effects

The ESB_{Tier2} should be interpreted as a chemical concentration below which adverse effects are not expected. In contrast, at concentrations above the ESB_{Tier2}, assuming equilibrium between phases, effects may occur if the chemical is bioavailable as predicted by EqP theory. In general terms, the degree of effect expected increases with increasing exceedance of the ESB_{Tier2}. Because the FCV or SCV is derived as an estimate of the concentration causing chronic toxicity to sensitive organisms, effects of this type may be expected when sediment concentrations are near the ESB_{Tier2}. As sediment concentrations increase beyond the ESB_{Tier2}, one can expect chronic effects on less sensitive species and/or acute effects on sensitive species. See Section 4.2.6 for further discussion.

4.2.2 Use of EqP to Develop Alternative Benchmarks

The FCV or SCV is used to define a threshold for unacceptable effects based on its precedence in establishing unacceptable effects in the development of WQC. However, the use of EqP to assess sediment contamination is not limited to the ESB_{Tier2} and the associated level of protection discussed in this document. As discussed in earlier sections of this document, by substituting water-only effect values other than the FCV or SCV into the ESB equations, other benchmarks may be developed that are useful in evaluating specific types of biological effects, or that better represent the ecological protection goals for specific assessments.

4.2.3 Influence of Unusual Forms of Sediment Organic Carbon

Partition coefficients used for calculating these ESBs are based on estimated and measured partitioning from natural organic carbon in typical field sediments. Some sediments influenced heavily by anthropogenic activity may contain sources of organic carbon whose partitioning properties are not similar to natural organic carbon. The presence of rubber, animal or wood processing wastes, relatively undegraded woody debris or plant matter (e.g., roots, leaves) as well as black carbon (soot) and coal may alter contaminant partitioning and concentrations of chemicals in interstitial waters in unexpected ways (Iglesias-Jimenez et al. 1997, Grathwohl 1990, Xing et al. 1994). Sediments with substantial amounts of these materials may exhibit higher concentrations of chemicals in interstitial water than would be predicted using generic K_{OC} values, thereby making the ESBs under protective. If such a situation is encountered, the applicability of literature K_{OC} values can be evaluated by analyzing for the chemical of interest in both sediment and interstitial water. If the measured concentration in interstitial water is markedly greater (e.g., more than twofold) than that predicted using the K_{OC} values recommended herein (after accounting for dissolved organic carbon (DOC) partitioning in the interstitial water (U.S. EPA 2003b)), then the ESBs would be under protective and calculation of a site-specific ESB should be considered (see U.S. EPA 2001c, 2003b). Conversely, the presence of black carbon or coal in a sediment may result in reduced chemical activity in sediment and correspondingly reduced concentrations of chemical in interstitial water. Under these conditions, the ESB is likely to be over protective and a site-specific ESB may be warranted (U.S. EPA 2001c, 2003b). However, it should also be noted that the ability to predict partitioning based on additional partitioning factors like black carbon is still evolving and may serve to decrease partitioning-related uncertainties in future applications.

The presence of organic carbon in large particles may also influence the apparent partitioning. Large particles may artificially inflate the effect of the organic carbon because of their large mass, but comparatively small surface area; they may also increase variability in TOC measurements by causing sample heterogeneity. The effect of these particles on partitioning can be evaluated by analysis of interstitial water as described above (U.S. EPA 2001c), and site-specific ESBs may be used if required (U.S. EPA 2003b). It may be possible to screen large particles from sediment prior to analysis to reduce their influence on the interpretation of sediment chemistry relative to ESBs.

4.2.4 Relationship to Risks Mediated through Bioaccumulation and Trophic Transfer

As indicated above, ESBs are designed to address direct toxicity to benthic organisms exposed directly to contaminated sediment. They are not designed to address risks that may occur through bioaccumulation and subsequent exposure of pelagic aquatic organisms (e.g., predatory fish), terrestrial or avian wildlife, or humans. No inference can be drawn between attainment of the ESB_{Tier2} and the potential for risk via bioaccumulation and trophic transfer; the potential for those risks must be addressed by separate means.

4.2.5 Exposures to Chemical Mixtures

It is very important that users of this guidance are aware that the ESB_{Tier2} values provided here reflect the expected toxicity of that specific chemical individually; they do not consider the potential interactive toxicity of that chemical with other chemicals in the mixture, whether antagonistic, additive or synergistic. Thus, a sediment may have concentrations of several chemicals at concentrations below the individual ESB_{Tier2} values, but still cause toxicity because of the aggregate effects of the chemicals acting as a mixture. This potential is not explicitly incorporated into the derivation of the ESB_{Tier2} values because the types and concentrations of co-occurring chemicals is infinitely variable, and the expected interaction of those chemicals is therefore not predictable in a general case.

While the potential for mixture effects must be considered for all chemical mixtures, it is of special concern for the chemicals with a primarily narcotic mode of action discussed in this document. Published literature provides a convincing argument that narcotic chemicals do show additive toxicity with other narcotic chemicals (U.S. EPA 2003e). This is especially relevant for interpreting ESB_{Tier2} values because many, if not most, narcotic chemicals tend to co-occur with other narcotic chemicals because they have common sources. For example, benzene, xylene, toluene, and ethylbenzene commonly co-occur in refined petroleum products. Sources of chlorobenzenes often include multiple chlorobenzene compounds with differing levels of chlorination. Also common in sediments is contamination with narcotic chemicals outside those with ESB_{Tier2} values derived here, such as PAHs (see U.S. EPA 2003e).

For these reasons, it is *expected* that narcosis-based ESB_{Tier2} values will be *under protective* if applied as individual values in most sediments, because other narcotic chemicals are likely to co-occur. This issue can be addressed by using ESB_{Tier2} values in the context of a mixture assessment similar to that used for the ESB for PAH mixtures (U.S. EPA 2003e). In this approach, as shown in the examples in Section 4.3, the contribution of each individual narcotic chemical to the toxicity of the overall mixture is assessed by taking the ratio of the measured concentration of that individual chemical in the mixture by the corresponding single chemical ESB_{Tier2} value. This proportion is calculated individually for all narcotic chemicals in the mixture, then the proportions are summed. If the sum of these values is greater than one, then the expected toxicity of the mixture is greater than that associated with an ESB. If the sum of proportions is less than one, then the sediment would not be expected to be toxic to benthos as a result of that mixture of narcotic chemicals. If PAHs are present in the mixture, then the proportions calculated for PAHs according to the PAH mixture ESB (U.S. EPA 2003e) should be added to the proportions calculated for the narcotic ESB_{Tier2} chemicals. In addition, if there are other narcotic chemicals present in the sediment beyond PAHs and the narcotic chemicals with ESB_{Tier2} values given in this document, they can be incorporated into the analysis using parallel procedures as described by Di Toro and McGrath (2000) and Di Toro et al. (2000). Also, U.S. EPA (2003e), and the references within, provides information about narcotic chemicals. Finally, as discussed in Section 4.3, the narcotic contribution of chemicals with modes of action in addition to narcosis (i.e., the pesticides and phthalates) can be included.

While narcosis is generally discussed for chemicals without a more specific mode of action, theory would suggest that all nonionic organic chemicals would contribute to the overall narcotic potency of a mixture. While this is technically true, the impact of these other chemicals (e.g., pesticides) on the overall narcotic potency of a mixture would be dependent on the toxicity of the chemical acting through a specific mode of action compared to its narcotic potency. If a chemical has a very high conventional potency (low FCV/SCV) compared to its narcosis SCV, then it would exceed the conventional chemical-specific ESB before it was present in sufficient concentration to contribute significantly to the narcotic

potency of a mixture. One can make this comparison by examining the ratios between conventionally-derived FCV/SCV values and the narcosis SCV as given in Table 3-1. Most of these comparisons show that the conventional FCV/SCV is generally 100-fold or more lower than the narcosis SCV; accordingly, these chemicals could not contribute more than 1% to an exceedance of a narcosis mixture ESB without simultaneously violating the conventionally-derived ESB_{Tier2}. For this reason, the contribution of most non-narcotic chemicals discussed in this document can be ignored in the calculation of the narcotic potency of mixtures without substantial error. The exceptions are some of the phthalates, for which the conventionally-derived ESB_{Tier2} values are much higher relative to the narcosis SCV. Where these chemicals occur near their conventionally-derived ESB_{Tier2} concentrations, it may be worth considering the potential for them to contribute to the narcotic potency of that mixture.

4.2.6 Interpreting ESB_{Tier2}s in Combination with Toxicity Tests

Sediment toxicity tests provide an important complement to ESBs in interpreting overall risk from contaminated sediments. Toxicity tests have different strengths and weaknesses compared to chemical-specific guidelines, and the most powerful inferences can be drawn when both are used together.

Unlike chemical-specific guidelines, toxicity tests are capable of detecting any toxic chemical, if it is bioavailable in toxic amounts; one does not need to know what chemicals of concern are present to monitor the toxicity of sediment. Toxicity tests are also useful for detecting the combined effects of chemical mixtures, if those effects are not considered in the formulation of the applicable chemical-specific guideline or benchmark.

On the other hand, toxicity tests also have weaknesses; they provide information only for the species tested, and only for the endpoints measured. This is particularly critical given that a majority of the sediment toxicity tests conducted at the time of this writing primarily measure short-term lethality (in some cases growth), although the use of chronic sediment toxicity tests is becoming more common. Chronic sediment toxicity test procedures have been developed and published for some species (e.g., U.S. EPA 2001b), but these procedures are more resource-intensive as compared to acute tests. In contrast, the ESB_{Tier2} is intended to protect most species against both acute and chronic effects.

Many assessments may involve comparison of sediment chemistry (relative to ESBs or other sediment quality guidelines) and toxicity test results. In cases where results using these two methods agree (either both positive or both negative), the interpretation is clear. In cases where the two disagree, the interpretation is more complex and requires further evaluation.

Individual ESBs address only the effects of the chemical or group of chemicals for which they are derived. For this reason, if a sediment shows toxicity but does not exceed the ESB_{Tier2} value for a chemical of interest, it is likely that the cause of toxicity is a different chemical or chemicals (although the chemical of interest maybe contributing to observed toxicity as a component of a mixture). This result might also occur if the partitioning of the chemical in a sediment is different from that assumed by the K_{OC} value used (see Section 4.2.3 *Influence of Unusual Forms of Sediment Organic Carbon* above).

In other instances, it may be that an ESB_{Tier2} is exceeded but the sediment is not toxic. As explained above, these findings are not mutually exclusive, because the inherent sensitivity of the two measures is different. Four possible circumstances may account for this result. First, the ESB_{Tier2} is intended to protect relatively sensitive species against both acute and chronic effects, whereas toxicity tests are performed with species that may or may not be sensitive to chemicals of concern, and often do not encompass the most sensitive endpoints (e.g., growth or reproduction). As such, one may not expect a nonionic organic chemical concentration near the ESB_{Tier2} to cause lethality

in a short-term toxicity test. Second, a GLI-based SCV, because of the use of SAFs, may overestimate a contaminant's toxicity compared to the intended level of protection, as described in Section 2.4. Third, site-specific conditions may result in lower bioavailability than assumed based on equilibrium partitioning (see Section 4.2.3). Finally, the organism may avoid the sediment or have other mechanisms to reduce exposure relative to that assumed by the EqP approach. To distinguish these potential explanations, species- and endpoint-specific toxicity information could be used to better interpret toxicity test results, and SCV derivation could be reviewed. Spiked sediment tests could also be used to verify the exposure-response relationship for that particular organism and contaminant. If these lines of evidence do not account for the discrepancy between predicted and observed toxicity, then site-specific chemical partitioning could be investigated (U.S. EPA 2003b).

As discussed above, a good method for evaluating the results of toxicity tests is to calculate effect concentrations in sediment that are species and endpoint specific. For some species contained in the water-only toxicity data for the 32 nonionic organic chemicals discussed here, effect concentrations in sediment can be calculated that are specific for that organism (U.S. EPA 2003e). These values could then be used to directly judge whether the absence of toxicity in the test would be expected from the concentration of nonionic organics chemicals present. As noted above, the magnitude of error between toxicity test results and predicted effects is made larger because of the use of SCVs, and SAFs, to derive some ESB_{Tier2} values (see discussion in Section 2.4).

If the exceedance of an ESB is sufficient that one would expect effects in a toxicity test but they are not observed, it is prudent to evaluate the partitioning behavior of the chemical in the sediment. This is performed by isolating interstitial water from the sediment and analyzing it for the chemicals of interest. Predicted chemical concentrations in the interstitial water can be calculated from the measured concentrations in the solid phase (normalized to organic carbon) as follows:

$$\mu g\ chemical/L = (\mu g\ chemical/g_{OC}) \cdot (10^3 g_{OC}/Kg_{OC} \div K_{OC}) \quad (4\text{-}1)$$

For chemicals with log K_{OW} greater than 5.5, corrections for DOC partitioning in the interstitial water will be necessary (see Gschwend and Wu 1985, Burkhard 2000, U.S. EPA 2003b). See U.S. EPA (2003b) for a discussion of the effects of DOC on ESB derivation. If the measured chemical in the interstitial water is substantially less (e.g., 2-3 fold lower or more), it suggests organic carbon in that sediment may not partition similarly to more typical natural organic carbon, and derivation of site-specific ESBs based on interstitial water may be warranted (U.S. EPA 2003b).

Finally, in addition to the use of sediment toxicity tests for interpreting ESB_{Tier2} values, the generation of acute and chronic water-only data with benthic organisms for the nonionic organic chemicals discussed in this document would be very beneficial. Further, acute and chronic whole sediment toxicity data sets with these chemicals would also complement the interpretation of the ESBs.

4.2.7 Effects of Disequilibrium Conditions

As discussed throughout this document, the EqP is based on an assumption of chemical equilibrium between the solid phase of sediment and the interstitial water. In natural settings, equilibrium may not always exist or may be disturbed by episodic events. As such, the potential for disequilibrium and its impact on the interpretation of the equilibrium-based ESBs should be considered. For purposes of this discussion, two types of disequilibria are discussed: 1) disequilibrium between the solid phase sediment and interstitial water; and 2) disequilibrium between the sediment and overlying water column.

With regard to the first, ESBs are based on an assumption that nonionic organic chemicals

are in equilibrium with the sediment and interstitial water and are associated with sediment primarily through absorption to sediment organic carbon. When new chemical is introduced to a sediment, time is required for the chemical to distribute itself between interstitial water and sediment organic carbon. The time required for equilibrium to be achieved is dependent on the characteristics and concentration of the chemical. Sediment spiking experiments suggest that this is typically in the range of weeks.

In areas where sediment erosion and deposition are highly dynamic, equilibrium may be frequently disturbed. The degree to which this would affect the applicability of ESBs depends on the degree and frequency of equilibrium disruption. As noted above, even high K_{ow} nonionic organic compounds come to equilibrium in clean sediment in a period of days, weeks or months. Equilibrium times should be even shorter for mixtures of two sediments that each have previously been at equilibrium. This is particularly relevant in tidal situations where large volumes of sediments are eroded and deposited, even though near equilibrium conditions may predominate over large areas. While the potential for disequilibrium is recognized, it is probably unwise to deviate from the equilibrium assumption without strong evidence that disequilibrium exists over the long term to a sufficient degree to change the expected toxicity of sediment contamination. Recognize that even if there are short-term disturbances to equilibrium between sediment and interstitial water, conditions may quickly re-approach equilibrium between disturbances, such that an equilibrium-based approach is still reasonable, even if there are periods of disturbance/disequilibrium. If it is shown that disequilibrium exists to such an extent that equilibrium-based ESBs are inappropriate, site-specific experimentation may be useful in developing a modified approach (U.S. EPA 2003b).

Even where equilibrium exists between the solid phase sediment and interstitial water, there is often disequilibrium between the sediment and overlying water. This is particularly true for legacy pollution where input of new contamination to the water body has ceased or greatly decreased, and the sediment is now a source of contamination to the overlying water. Some have argued that such disequilibrium reduces exposure of sediment organisms, particularly for those that interact substantially with the overlying water. While the theoretical possibility is clear, the quantitative data from which an appropriate compensation could be calculated is lacking. Moreover, many toxicity test procedures used in the development and testing of EqP theory involve renewal of overlying water and thus include some degree of disequilibrium between the sediment and overlying water. Nonetheless, results from these tests are generally explicable through EqP predictions (e.g., Swartz et al. 1990, DeWitt et al. 1992, Hoke et al. 1994), suggesting that the degree to which this disequilibrium affects exposure is not exceptional, at least for those organisms. In instances where it is determined that EqP does not apply for a particular sediment because of the disequilibrium situations discussed above, site-specific experimentation may be useful in developing a modified approach (U.S. EPA 2003b).

A special case may be in spill situations, where there is a sudden, dramatic influx of new chemical into a system. Immediately following a spill, it can be expected that one or both types of disequilibrium might exist, that the overlying water might have higher chemical activity than in the sediment, and that the solid-phase sediment may not be in equilibrium with the interstitial water. In this situation there is a high potential for ESBs to be under protective.

In sediments where particles of undissolved chemical occur, disequilibrium exists and the benchmarks may be over protective in the sense that chemical concentrations in interstitial water may be lower than would be predicted based on chemical concentrations in sediment and f_{oc}. However, it is also true that in this situation basing an assessment solely on chemical concentrations in the interstitial water might

under-represent the degree of contamination. This is because sufficient chemical exists to contaminate a larger mass of sediment if the sediment containing as yet undissolved chemical is later mixed with other, less contaminated sediment.

Clearly, situations where substantial disequilibrium exists can result in several complexities for interpreting sediment chemistry in the context of ESBs. While it is true that ESBs may be less accurate for such situations, it is also important that an alternate assessment approach be developed that adequately accounts for the site-specific conditions. Disequilibrium should not be used as an excuse to dismiss ESB values without developing an alternate conceptual model on which to base the assessment.

4.3 Example Application of ESB_{Tier2}s Using Conventional and Narcosis Approaches and EqP-based Interpretation

Table 4-1 shows sediment chemistry data (in ug/g_{OC}) for four example marine sediments (i.e., A, B, C, D) along with the corresponding conventional and narcosis ESB_{Tier2} values. The sediment concentrations have been normalized for a TOC of 4.5% using Equation 3-9. Assuming a f_{Solids} of 0.20, ESB_{Tier2} values for benzene, 1,1,2,2-tetrachloroethane, and tetrachloroethene were adjusted using Equations 3-5 and 3-6. These values were compared to measured sediment chemistry. For each of the four sediments, Table 4-1 also shows the ratios of the measured concentration in sediment to the conventional and narcosis ESB_{Tier2}s. For the chemicals with modes of action in addition to narcosis (i.e., the pesticides in these examples), their narcosis contribution is not reported but was calculated to be very small and did not substantially affect the sum narcosis ESBTUs (see discussion in Section 2.3.2).

In sediment A (Table 4-1), all measured chemicals were below their conventional and narcosis ESB_{Tier2} values. In addition, the sum of the ratios of the measured concentrations to their narcosis ESB_{Tier2} (sum narcosis ESBTUs) was only 0.01, far below a value of 1 which would indicate concern for a narcotic effect caused by a mixture of chemicals. While these results themselves indicate no reason to suspect adverse effects to benthic organisms from these chemicals, it must be remembered that this conclusion is limited to the effects of these specific chemicals. It is, of course, still possible that other chemicals could be present in the sediment at concentrations that could cause adverse effects. Toxicity testing would be one way to address the potential for toxicity caused by unmeasured chemicals.

Sediment B (Table 4-1) has the same concentrations of all measured chemicals as in sediment A, except for diazinon and malathion, which exceed their conventional ESB_{Tier2} by factors of 3.9 and 11, respectively. These exceedances suggest concern for adverse effects of these chemicals on benthic organisms, subject to the assumptions underlying the ESB approach as discussed elsewhere in this document. Toxicity testing, particularly with species sensitive to these chemicals, could be used to further evaluate the presence of toxicity, as well as assessing the potential presence of toxicity from unmeasured chemicals. In addition, spiked sediment tests with these chemicals and/or sediment Toxicity Identification Evaluation (TIE) studies (U.S. EPA 2007b) may also be useful in evaluating the expected contribution of these chemicals at these concentrations to sediment toxicity.

For sediment C (Table 4-1), concentrations of the pesticides diazinon, alpha endosulfan and malathion are all below their conventional ESB_{Tier2} values, but three of the other measured chemicals, benzene, ethylbenzene and toluene, exceed their corresponding conventional ESB_{Tier2} values by factors of 4.3, 5.1, and 7.6, respectively. In contrast, these same chemicals do not exceed their narcosis ESB values, nor does the sum of narcosis ESBTUs exceed 1. The exceedance of the conventional ESB_{Tier2}s suggests that the levels of benzene, ethylbenzene, and toluene are high enough to be of potential concern when evaluated by the GLI

Tier 2 assessment approach (GLI 1995). However, the fact that the sum of narcosis ESBTUs does not exceed one raises the possibility that the exceedances for these chemicals may be influenced by conservatism in the GLI Tier 2 paradigm, particularly as it relates to narcotic chemicals (see Section 2.4 for additional discussion). Another issue to be considered relates to the likelihood that other narcotic chemicals, not listed in Table 4-1 may be present and contribute to an overall mixture toxicity. In particular, the elevated concentrations of benzene, ethylbenzene and toluene may suggest contamination with hydrocarbons such as refined petroleum products that may also contain PAHs or other hydrocarbons that could contribute to a narcotic mixture effect. Further analytical chemistry and toxicity testing would be logical supplements to the information in Table 4-1 for determining the overall likelihood of risk to benthic organisms. If PAHs are present, separate ESB guidance for PAH mixtures (U.S. EPA 2003e) can provide an approach to evaluate their potential contribution to narcotic toxicity. The theory underlying narcotic toxicity (Di Toro and McGrath 2000, Di Toro et al. 2000, U.S. EPA 2003e) suggests that the sum of ESBTUs for PAHs could be added to the sum of narcosis Tier 2 ESBTUs in Table 4.1 to assess the combined potency of those chemicals.

Finally, in sediment D (Table 4-1), concentrations of measured pesticides are again low, but concentrations of both BTEX compounds (i.e., benzene, toluene, ethylbenzene, xylene) and the measured chlorinated compounds are higher than for sediment C. Conventional ESB_{Tier2}s are exceeded for several compounds; although no individual narcosis ESB_{Tier2} values are exceeded, the sum of narcosis ESBTUs does exceed 1. In this case, both the conventional ESB_{Tier2}s and the narcosis mixture analysis suggests the potential for adverse effects to benthic organisms. Also, the finding that many compounds, including BTEX, chlorinated benzenes, and other chlorinated hydrocarbons are all present in concentrations approaching their narcosis ESB_{Tier2}s makes it likely that other, unmeasured chemicals in these families may also be present at toxicologically significant concentrations in this sediment, because typical sources of these chemicals to the environment often include many different related compounds (e.g., other di-, tri-, tetra-and hexachloro-benzenes). While this document does not address these additional compounds specifically, an approach for addressing their contribution in a way similar to that used in this document is provided by Di Toro and McGrath (2000) and Di Toro et al. (2000).

Table 4-1 Example applications of ESB_{Tier2} values with several nonionic organic chemicals using conventional and narcosis approaches. In this example, four marine sediments with 4.5% TOC and f_{Solids} of 0.20 are assessed. Sediment concentrations are shown with organic carbon normalization using Equation 3-9. ESB_{Tier2} values modified with Equations 3-5 and 3-6 to account for f_{Solids} for benzene, 1,1,2,2-tetrachloroethane and tetrachloroethene are shown rather than ESB_{Tier2} values in Table 3-1.

Appendix A

Description of the Derivation of Conventional Freshwater Chronic Toxicity Values using the Great Lakes Water Quality Initiative (GLI 1995) Approach

A.1 Acquisition and Review of Conventional Aquatic Toxicity Data

As discussed above, when possible, conventional ESBs were based on FCVs for aquatic life (Stephan et al.1985). When FCVs could not be derived, the ESBs were calculated from SCVs for aquatic life using the GLI approach (Suter and Mabrey 1994, GLI 1995, Suter and Tsao 1996). The purpose of this section is to describe the procedure used to derive SCVs from data in AQUIRE (now ECOTOX) and other sources.

The following restrictions on toxicity data and reference sources used were applied:

1. Acute toxicity data for only freshwater species were used (GLI, 1995), whereas acute-chronic ratios (ACRs) for both freshwater and saltwater species were used in order to expand the number of available ACRs.

2. Only the following were used as sources of references:

a. U.S. Environmental Protection Agency's AQUIRE (now ECOTOX) database.
b. Tables in existing documents from EPA's Office of Research and Development.

A preliminary review was conducted on test results obtained by means of a search of AQUIRE (now ECOTOX). Only information that could be retrieved from AQUIRE (now ECOTOX) was used in this review. Each test result was rejected if one or more of the reasons listed below applied. The first three reasons for rejection given below were addressed in the search strategy used to find test results in AQUIRE (now ECOTOX). All pertinent test results were printed and reviewed manually using the "Reasons for Rejection of a Test Result Based on Information in AQUIRE." For each test result that was not rejected, a copy of the original report was reviewed as described in the next section of this report, "Data Rejection Checklist."

Reasons for Rejection of a Test Result Based on Information in AQUIRE (now ECOTOX):

___ The test was not conducted in the laboratory (i.e., **Site** was not LAB).
___ Poor documentation (the documentation code (**Dc**) was not 1 or 2).
___ The endpoint was not reported (i.e., **Endpt** was left blank or was "NR").
___ The purity of the test chemical was less than 80% (i.e., **Chem_char** < 80%).
___ The test species (**Latin, Species**) was not an aquatic animal.
___ The test species (**Latin, Species**) was not a resident North American species.
___ The test species was *Wyeomyia smithii* (i.e., the pitcher plant mosquito) or was in the genus *Artemia* (i.e., it was a brine shrimp).

The following reasons for rejection applied only to acute toxicity tests:

___ The test exposure was not static, renewal, or flow-through (i.e., **Extype** was not S, R, or F).
___ The test was not conducted in freshwater (i.e., **Media** was not FW).
___ If the test species was Cladoceran (CLAD, water flea), copepod (COPE), midge or phantom midge (insect, family Chironomidae, order Diptera, DIPT), the **Duration** was less than 2 days (48 hr).
___ For all other animal species, the **Duration** was less than 4 days (96 hrs).
___ The **endpoint** was not LC_{50} or EC_{50} or IC_{50}.
___ The **effect** was not EQU, IMM, and/or MOR, except that SHD (incompletely developed shells, change in the ability to grow a shell) was acceptable for bivalve molluscs.

The following reasons for rejection applied only to chronic toxicity tests:

___ The concentrations of test material were not measured (i.e., **Method** was not M) in the test solution.
___ The test exposure was not flow-through or renewal (i.e., **Extype** was not F or R).

If the test species was a Cladoceran (CLAD, water flea) or copepod (COPE):

___ The **Life stage** was older than 24 hr.
___ The **Duration** was less than 21 days (except less than 7 days for *Ceriodaphnia*).
___ For all other species, the **Duration** was less than 24 days.

Stephan et al. (1985), references cited therein, and other pertinent publications (e.g., the American Fisheries Society guidebook series for North American fishes, molluscs, and crustacea) were used to determine whether a vertebrate or invertebrate aquatic species is resident in North America. Because of various constraints, some species listed below were assumed to be nonresident if a limited search did not demonstrate that they were resident. Any species that was said to have been field-collected in North America was considered resident.

Examples of resident species not in Stephan et al. (1985):

Chironomus riparius	midge
Gila elegans	bonytail
Gillia attilis	buffalo pebblesnail
Lestes congener	damselfly
Sigara alternata	water boatman
Stenonema interpunctatum	mayfly
Umbra pygmaea	eastern mudminnow

Examples of nonresident species not in Stephan et al. (1985):

Anguilla anguilla	common eel (assumed nonresident)
Anodonta anatina	fresh-water mussel
Anodonta cyanea	swan mussel
Barbus ticto	two-spotted; tic tac toe barb
Carassius carassius	Crucian carp
Chana punctatus or *gachua*	snake-head catfish
Cirrhinus mrigala	carp, hawkfish
Heteropneustes fossilis	Indian catfish
Macrobrachiu rosenbergii	giant freshwater prawn
Mystus vittatus	catfish
Notopterus notopterus	featherback
Paratelphusa jacquemontii	crab (probably)
Rasbora heteromorpha	harlequinfish/red rasbora
Spicodiaptomus chilospinus	calanoid copepod (assumed nonresident)

Resident status of organisms for which only the genus and "sp." were provided as the scientific name (e.g., *Peltodytes* sp.) was based on the location where the organisms were collected.

This checklist was used to review the acceptability of results of aquatic toxicity tests on nonionic organic chemicals including all references that were obtained from AQUIRE (now ECOTOX) and passed the "Preliminary Review of Records from AQUIRE." Because this second review was performed on all test results regardless of whether the reference came from AQUIRE (now ECOTOX), all items on the AQUIRE (now ECOTOX) review were also included here. This review was performed using the original publication and sources of supplemental information; this review was not performed using only secondary sources.

This final review covered both the quality of the test result and whether it was the kind of result that had been specified for use in this document. A test result that was deemed unacceptable for use in this document might be acceptable for another use. A result that was deemed unacceptable was not necessarily an incorrect result; it just might have been too questionable to use. For example, an LC_{50} obtained using unacceptable methodology might have been the same as an LC_{50} using acceptable methodology. The LC_{50} from the test using the unacceptable methodology, however, was unacceptable because it was questionable. In many cases, some test results in a publication were acceptable, whereas others were unacceptable. Similarly, one result from a test (e.g., a 24-hr LC_{50}) might not have been acceptable although another (e.g., a 48-hr LC_{50}) was acceptable.

Each test result was placed in one of three categories for the purposes of this review:

1. A test result was assumed acceptable if the test was conducted at EPA laboratories in Corvallis (OR), Duluth (MN), Gulf Breeze (FL), or Narragansett (RI); was conducted at the U.S. Fish and Wildlife Service laboratory in La Crosse, Wisconsin; was contained in Mayer and Ellersieck (1986); was conducted at the U.S. Department of the Interior laboratory in Columbia, Missouri, after the period covered by the report published by Mayer and Ellersieck (1986); or was contained in the University of Wisconsin-Superior data summary volumes (Brooke et al.1984; Geiger et al.1985, 1986, 1988, 1990). Reports from these sources usually contained information concerning methodology, but the result was assumed acceptable even if little information was available concerning methodology. Results in this category were rejected only if a major problem was known to exist.

2. A test result was assumed acceptable if the test was reported to have been conducted according to procedures described by such American Society for Testing and Materials (ASTM) standards as:

   ASTM Standard E 729, Guide for Conducting Acute Toxicity Tests with Fishes, Macroinvertebrates, and Amphibians

   ASTM Standard E 1241, Guide for Conducting Early Life-Stage Toxicity Tests with Fishes

   ASTM Standard E 1193, Guide for Conducting Renewal Life-Cycle Tests with *Daphnia magna*

   ASTM Standard E 1295, Guide for Conducting Three-brood, Renewal Toxicity Tests with *Ceriodaphnia dubia*

   Or procedures described by *Standard Methods*, the European Economic Community (EEC), the International Organization for Standardization, or the Organization for Economic Cooperation and Development (OECD), and if the description of the methodology at least mentioned such factors as acclimation, temperature control, controls, solvent and solvent control (if used), source of water, randomization, and duplication. Results in this category were, however, rejected if a single major problem was identified.

3. All other test results were in a third category. Whether they were accepted or rejected depended on the information available concerning the methodology and results. The result was rejected if insufficient information was available to evaluate the test. Identification of a single major problem, or at least three minor problems, were grounds for rejection of a test result, and most results with this number of identified problems were rejected. Best professional judgment was; however, applied to determine whether identified problems warranted rejection of the result.

The review of test results required judgments, starting with decisions about what items to include on the following list, and whether each one was major or minor. Applying the list also required judgment. For example, a test result was always rejected if a surfactant was used in the preparation of a stock solution or the test solutions, even if the test was conducted by Mount and Stephan (1967). If no information was given concerning the use of surfactants, test results in the first category above were deemed acceptable, but it was identified as a problem for other test results.

Reasons for Rejection (Asterisks indicate major problems; all others are minor problems.)

Report

___ * The test results were not available for public distribution in a dated and signed hard copy (e.g., publication, manuscript, letter, memorandum, etc.).

___ * The test results were from a secondary publication, except those results contained in the *Manual of Acute Toxicity: Interpretation and Data Base for 410 Chemicals and 66 Species of Freshwater Animals* (Mayer and Ellersieck 1986) were considered acceptable.

___ * Methodology and/or results were not adequately and clearly described, except for category 1. In some cases, other papers by the same or different authors provided the necessary information.

Test chambers

___ All test chambers and any compartments within the chambers were not identical.

___ * The test result was from a microcosm or model ecosystem study.

___ * The test chambers were made from or lined with PVC, except that the presence of PVC in chambers was acceptable if the test material was miscible with or very soluble in water or concentrations of the test material in solutions were measured.

Test material

___ The test material was not adequately described.

___ * The organisms were exposed to the test material via food, sediment, injection, gavage, etc.; exposure was not via only the test solutions.

___ * The test material was a component of a drilling mud, effluent, fly ash, mixture, formulation, sediment, or sludge.

___ The purity of the test material was less than <u>80 percent</u> (e.g., the test material contained less than 80 percent active ingredient); <u>analytical-grade, reagent-grade, or technical-grade</u> materials were considered acceptable unless known to be unacceptable.

Exception: The test material could contain less active ingredient if data were available to show that tests on the material produced the same results as tests on material that was at least 80 percent pure.

___ * The test material was an emulsifiable concentrate, a wettable powder, or a specially prepared mixture that contained a surfactant and/or an organic solvent that was not miscible with water.

___ * A surfactant or an organic solvent that was not miscible with water was used in the preparation of a stock solution or the test solutions.

___ If a water-miscible solvent was used to prepare the stock solution and/or test solutions, its concentration exceeded 0.5 mL/L in the test solutions.

___ * The test material was introduced into the test chamber by evaporating it onto the test chamber and adding dilution water.

Exception: This procedure was acceptable if the concentrations of test material in the test solutions were measured.

___ * Concentrations of test material in the test solutions were not measured for chronic toxicity tests (measurement was not necessary for acute tests).

___ Measured concentrations of test material during a flow-through test varied too much.

___ * For highly volatile, hydrolyzable, or degradable materials, the test was static or renewal (i.e., not flow-through) and/or concentrations of test material were not measured often enough using acceptable analytical methods.

___ * Exposure to the test material was intermittent, not continuous.

Test organisms

___ * The test species was not an aquatic animal.

___ * The test species was a single-celled organism.

___ * The test species was not a resident North American species.

___ * The test species was *Wyeomyia smithii* (i.e., the pitcher plant mosquito) or was in the genus *Artemia* (i.e., it was a brine shrimp).

___ * The test was not conducted using "whole" organisms; for example, the test was conducted using tissues or cell cultures.

___ * The test result was calculated for a mixture of species, especially if the species were in different genera.

___ * At least some of the test organisms were in a life stage that is not aquatic for at least part of the test.

___ * The test organisms were cladocerans that were obtained from a stock culture in which ephippia were being produced.

___ The test organisms showed signs of stress or disease before the test.

___ * The test was begun with organisms within 10 days after they were treated to cure or prevent disease and/or the organisms were treated during the test.

___ * Test organisms were previously exposed to substantial concentrations of the test material or other contaminants and were not held in clean water for at least 10 days before the beginning of the test.

___ * The test organisms were not acclimated

to or were not maintained in the dilution water at the test temperature for at least 48 hours before the beginning of the test.

___ The test organisms were mishandled or excessively disturbed before or during the test.

___ * The test organisms were fed during an acute toxicity test.

Exceptions:

1. Saltwater annelids and mysids could be fed during acute tests.
2. The test material does not sorb or complex readily with food.
3. Data were available to show that the presence of food probably would not affect the results of the test.

___ There were fewer than 10 test organisms per treatment.

___ There were not two or more replicates (groups of individuals of a species) tested for each concentration for chronic tests.

___ The test organisms were crowded in the test chambers.

___ * The test organisms reproduced during the test and all of the new organisms could not be distinguished from the initial organisms at the end of the test. (This has been a problem in some tests with rotifers.)

Controls

___ * There was no control treatment.

___ * There was a control treatment, but it was not comparable to the other treatments.

___ No data were reported for the controls.

___ * More than 10 percent of the control organisms died or showed signs of stress or disease or were otherwise adversely affected, except that a higher percentage was acceptable for a few species.

___ * Survival, growth, or reproduction in the control treatment for chronic tests were unacceptably low. (The limits of acceptability depended on the species.)

Dilution water

___ * Distilled or deionized water was used without addition of appropriate salts.

___ * Chlorinated water was used without adequate dechlorination.

___ * River water was used as the dilution water without appropriate treatment.

___ * The concentration of total organic carbon (TOC) or particulate matter (PM) in the dilution water exceeded 5 mg/L.

Exceptions:

1. TOC or PM could exceed 5 mg/L if a relationship was developed between toxicity and TOC or PM.
2. Data were available to show that TOC or PM probably would not affect the results of the test.

___ The dilution water contained unusual amounts or ratios of inorganic ions.

Test conditions

___ Turbulence in the test chamber, resulting from aeration, stirring, or design (of flow-through chambers), was excessive.

___ The temperature, pH, etc., of the test solutions were not adequately controlled.

___ * The pH of the dilution water was below 6.5 or above 9.0.

___ * The concentration of dissolved oxygen in a renewal or flow-through test was less than 60 percent of saturation.

___ * The concentration of dissolved oxygen during a static test was less than 60 percent saturation during the first 48 hours, or less than 40 percent of saturation from 48 to 96 hours.

___ Treatments, test organisms, and experimental units were not appropriately randomized.

___ * The dilution factor was greater than 9.

The toxicity tests that were not rejected were next evaluated to determine whether they provided the kinds of acute and chronic results that were to be used, as described in the next two sections.

A.2 Compilation of Acute Values

The following kinds of results of acute toxicity tests were used:

1. For midges, phantom midges, daphnids, and other cladocerans, the result used was the 48-hr EC_{50} based on percentage of organisms immobilized plus percentage of organisms killed. If such an EC_{50} was not available from a test, the 48-hr LC_{50} was used in place of the desired 48-hr EC_{50}. An EC_{50} or LC_{50} of longer

than 48 hours was used as long as the animals were not fed and the control animals were acceptable at the end of the test. Tests with daphnids and other cladocerans should have been started with organisms less than 24 hours old, and tests with midges and phantom midges should have been started with second- or third-instar larvae.

2. For embryos and larvae of barnacles, bivalve molluscs (clams, mussels, oysters, and scallops), sea urchins, lobsters, crabs, shrimp, and abalones, the result used was the 96-hr EC_{50} based on the percentage of organisms with incompletely developed shells plus the percentage of organisms killed. If such an EC_{50} was not available from a test, the lower of the 96-hr EC_{50} based on percentage of organisms with incompletely developed shells and the 96-hr LC_{50} was used in place of the desired 96-hr EC_{50}. If the duration of the test was between 48 and 96 hours, the EC_{50} or LC_{50} at the end of the test was used.

3. For all other freshwater and saltwater animal species and older life stages of barnacles, bivalve molluscs, sea urchins, lobsters, crabs, shrimp, and abalones, the result used was the 96-hr EC_{50} based on the percentage of organisms exhibiting loss of equilibrium plus the percentage of organisms immobilized plus the percentage of organisms killed. If such an EC_{50} was not available from a test, the 96-hr LC_{50} was used in place of the desired 96-hr EC_{50}.

Acceptable freshwater acute test results were entered in taxonomic order. If the tests were conducted properly, acute values reported as "greater than" values and those that were above the solubility of the test material were entered because rejection of such acute values would unnecessarily lower the Final Acute Value (FAV) by eliminating acute values for resistant species. Reported results were not rounded off to fewer than four significant digits.

In the case of a species for which at least one acceptable acute value was available, the species mean acute value (SMAV) was calculated as the geometric mean of the results of all flow-through tests in which the concentrations of test material were measured. In the case of a species for which no such result was available, the SMAV was calculated as the geometric mean of all available acute values (i.e., results of flow-through tests in which the concentrations were not measured and results of static and renewal tests based on initial concentrations of test material). (Nominal concentrations were acceptable for most test materials if measured concentrations were not available.) If only one acceptable acute value was available for a species, the SMAV was that value. The following information was also considered:

1. If the available data indicated that one or more life stages were more resistant than one or more other life stages of the same species by at least a factor of 2, the data for the more resistant life stages were not used in the calculation of the SMAV. This procedure was followed because a species can be considered protected from acute toxicity only if all life stages are protected.

2. The agreement of the data within and between species was considered. Acute values that appeared to be questionable in comparison with other acute and chronic data for the same species and for other species in the same genus usually were not used in the calculation of a SMAV. For example, if the acute values available for a species or genus differed by more than a factor of 10, some or all of the values usually were not used in calculations.

SMAVs were not rounded off to fewer than four significant digits.

The geometric mean of N numbers was calculated as the Nth root of the product of the N numbers. Alternatively, the geometric mean was calculated by adding the logarithms of the N numbers, dividing the sum by N, and taking the antilog of the quotient. Either natural (base e) or common (base 10) logarithms were used to calculate geometric means as long as they were used consistently within each set of data (i.e., the antilog used matched the logarithm used). The geometric mean of two numbers was usually calculated as the square root of the product of the two numbers. The geometric mean of one number was that number.

A.3 Compilation of Chronic Values

Results of three kinds of chronic toxicity tests were used:

1. *Life-cycle toxicity tests*. These tests consist of exposures of each of two or more groups of individuals of a species to a different concentration of the test material throughout a life cycle. To ensure that all life stages and life processes are exposed, tests with fish begin with embryos or newly hatched young less than 48 hours old, continue through maturation and reproduction, and end not less than 24 days (90 days for salmonids) after the hatching of the next generation. Tests with daphnids begin with young less than 24 hours old and continue until 7 days past the median time of first brood release in the controls.

   For fish, data are obtained and analyzed on survival and growth of adults and young, maturation of males and females, eggs spawned per female, embryo viability (salmonids only), and hatchability. For daphnids, data are obtained and analyzed on survival and young per female. For mysids, data are obtained and analyzed on survival, growth, and young per female.

2. *Partial life-cycle toxicity tests*. These tests consist of exposures of each of two or more groups of individuals of a species of fish to different concentrations of the test material through most portions of a life cycle. Partial life-cycle tests are allowed with fish species that require more than a year to reach sexual maturity, so that all major life stages are exposed to the test material in less than 15 months (i.e., the tests begin with immature juveniles at least 2 months prior to active gonad development and end not less than 24 days (90 days for salmonids) after hatching of the next generation).

   Data are obtained and analyzed on survival and growth of adults and young, maturation of males and females, eggs spawned per female, embryo viability (salmonids only), and hatchability.

3. *Early life-stage toxicity tests*. These tests consist of 28- to 32-day (60-days post hatch for salmonids) exposures of the early life stages of a species of fish from shortly after fertilization through embryonic, larval, and early juvenile development. Results of early life-stage tests in which the incidence of mortalities or abnormalities increased substantially near the end of the test are not used because the results of such tests are probably not good predictions of the results of comparable life-cycle or partial life-cycle tests.

   Data are obtained and analyzed on survival and growth. Results of early life-stage tests were used as predictions of results of life-cycle and partial life-cycle tests with the same species. Therefore, when results of a life-cycle or partial life-cycle test were available, results of an early life-stage test with the same species were not used.

Acceptable freshwater and saltwater chronic test results were sorted by taxonomic order. Reported results were not rounded off to fewer than four significant digits.

A chronic value was obtained either by calculating the geometric mean of the lower and upper chronic limits from a chronic test or by analyzing chronic data using regression analysis. A lower chronic limit was the highest tested concentration (a) in an acceptable chronic test, (b) that did not cause an unacceptable amount of adverse effect on any of the specified biological measurements, and (c) below which no tested concentration caused an unacceptable effect. An upper chronic limit was the lowest tested concentration (a) in an acceptable chronic test, (b) that did cause an unacceptable amount of adverse effect on one or more of the specified biological measurements, and (c) above which all tested concentrations also caused such an effect.

Because various authors have used a variety of terms and definitions to interpret and report results of chronic tests, reported results were reviewed carefully. The amount of effect that was considered unacceptable was based on a statistical hypothesis test and/or the percent reduction from the controls. For example, a small percent reduction (e.g., 3 percent) was considered acceptable even if it was statistically significantly different from the control, whereas a large percent reduction (e.g., 30 percent) was considered unacceptable even if it was not statistically significant.

A.4 Compilation of Acute-Chronic Ratios

Acceptable freshwater and saltwater ACRs and the test results on which they were based were recorded.

1. For each chronic value for which at least one corresponding appropriate acute value was available, an ACR was calculated, using for the numerator the geometric mean of the results of all acceptable flow-through acute tests in the same dilution water and in which the concentrations were measured. Static and renewal tests were acceptable for daphnids. Acute tests with fish should have been started with juveniles, whereas acute tests with daphnids should have been started with organisms less than 24 hr old.
2. Acute test(s) that were part of the same study as the chronic test were used if available. If acute tests were not conducted as part of the same study, acute tests conducted in the same laboratory and dilution water, but in a different study, were used. If no such acute tests were available, results of acute tests conducted in the same dilution water in a different laboratory were used. If no such acute tests were available, an ACR was not calculated.
3. For fish, if chronic test data for life-cycle or partial life-cycle tests were available for a species, they were used for the denominator instead of an early life-stage test for the same species.

For each species, the species mean acute-chronic ratio (SMACR) was calculated as the geometric mean of all ACRs available for that species.

A.5 Calculation Procedures

For each genus for which one or more SMAVs were available, the genus mean acute value (GMAV) was calculated as the geometric mean of the SMAVs available for the genus. The GMAVs were ranked from highest to lowest, with the lowest GMAV assigned rank 1. The associated SMAVs and freshwater SMACRs were also entered.

To derive a freshwater FAV (Stephan et al., 1985), it was necessary to have results of acceptable acute toxicity tests with at least one species of freshwater animal in eight different families, such that all of the following requirements were satisfied:

1. The family Salmonidae in the Class Osteichthyes.
2. A second family in the Class Osteichthyes, preferably a commercially or recreationally important warm-water species (e.g., bluegill, channel catfish).
3. A third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian, etc.).
4. A planktonic crustacean (e.g., cladoceran, copepod).
5. A benthic crustacean (e.g., ostracod, isopod, amphipod, crayfish).
6. An insect (e.g., mayfly, dragonfly, damselfly, stonefly, caddisfly, mosquito, midge).
7. A family in a phylum other than Arthropoda or Chordata (e.g., Rotifera, Annelida, Mollusca).
8. A family in any order of insect or any phylum not already represented.

If all eight of the minimum data requirements (MDRs) were satisfied, the FAV was calculated using the computer program given on page 98 of Stephan et al. (1985), using the total number of GMAVs and the four lowest. The calculated FAV was compared with the low SMAVs to determine whether the FAV should be lowered to protect a commercially or recreationally important species.

If all eight of the acute freshwater MDRs were not met, a freshwater secondary acute value (SAV) was calculated. To derive a freshwater SAV, it was necessary to have at least one acceptable acute toxicity test with a species in one of three genera (*Daphnia, Ceriodaphnia*, or *Simocephalus*) in the Family Daphnidae.

The SAV was calculated using the lowest GMAV and the secondary acute factor (SAF) corresponding to the number of minimum data requirements that were satisfied:

$$\textbf{SAV} = \frac{\text{lowest Genus Mean Acute Value}}{\text{Secondary Acute Factor}}$$

The SAFs from GLI (1995):

Number of MDRs Satisfied	SAF
1	21.9
2	13.0
3	8.0
4	7.0
5	6.1
6	5.2
7	4.3

If sufficient data are available, chronic values can be calculated in the same manner as acute values, without the use of an ACR. Genus mean chronic values (GMCVs) were then calculated as the geometric mean of available chronic values. If the necessary data were available, the chronic value was calculated using the computer program used to calculate the FAV. (This option is rarely used because the chronic MDRs are rarely satisfied.)

If the data were not available to allow use of the computer program (e.g., Stephan et al. 1985), a final acute-chronic ratio (FACR) was calculated if acceptable ACRs were available for at least one species of aquatic animal in at least three different families, and of the three species:

1. At least one was a fish.
2. At least one was an invertebrate.
3. At least one was an acutely sensitive freshwater species. (The other two could be saltwater species.)

If the MDRs for calculation of an FACR were satisfied, an FACR was calculated; otherwise an SACR was derived.

For some materials, the ACR seems to be the same for all species, but for other materials the ratio seems to increase or decrease as the SMAV increases. The FACR was obtained in one of four ways, depending on the data available:

1. If the SMACR seemed to increase or decrease as the SMAVs increased, the FACR was calculated as the geometric mean of the ACRs for species whose SMAVs were close to the FAV or SAV.
2. If no major trend was apparent and the ACRs for a number of species were within a factor of 10, the FACR was calculated as the geometric mean of the SMACRs that were within a factor of 10.
3. For acute tests conducted on metals and possibly other substances with embryos and larvae of barnacles, bivalve molluscs, sea urchins, lobsters, crabs, shrimp, and abalones, the ACR was usually assumed to be 2. Chronic tests are very difficult to conduct with most such species, but it is likely that the sensitivities of embryos and larvae would determine the results of life-cycle tests. Thus, if the lowest available SMAVs were obtained with embryos and larvae of such species, the FACR was assumed to be 2.
4. If the most appropriate SMACRs were less than 2.0, and especially if they were less than 1.0, acclimation had probably occurred during the chronic test. Because continuous exposure and acclimation cannot be assured to provide adequate protection in field situations, the FACR was assumed to be 2.

If the available SMACRs did not fit one of the above cases, an FACR could not be obtained and an SACR was derived if possible.

If the available ACRs did not satisfy the minimum data requirements for derivation of an FACR, sufficient ACRs of 18 were assumed so that the MDRs were satisfied. The SACR was then calculated as the geometric mean of the measured and assumed ACRs. If no experimentally determined ACRs were available, the SACR was 18 (GLI 1995).

Abstract

This equilibrium partitioning sediment benchmark (ESB) document describes procedures to derive concentrations of metal mixtures in sediment which are protective of the presence of benthic organisms. The equilibrium partitioning (EqP) approach was chosen because it accounts for the varying biological availability of chemicals in different sediments and allows for the incorporation of the appropriate biological effects concentration. This provides for the derivation of benchmarks that are causally linked to the specific chemical, applicable across sediments, and appropriately protective of benthic organisms.

EqP can be used to calculate ESBs for any toxicity endpoint for which there are water-only toxicity data; it is not limited to any single effect endpoint. For the purposes of this document, the ESB for mixtures of the metals cadmium, copper, lead, nickel, silver, and zinc, the $ESB_{AVS:WQC}$, is derived based on two complementary approaches. In the first approach, the $ESB_{AVS:WQC}$ is based on the solid phase and interstitial water phase of sediments. In sediments, these metals should not cause direct toxicity to benthic organisms if the ΣSEM-AVS is $\leq$ 0.0. In the second approach, sediments containing these metals should not cause direct toxicity to benthic organisms if the sum of the dissolved interstitial water concentrations for each of the metals ($\Sigma M_{i,d}$) divided by their respective Water Quality Criteria (WQC) Final Chronic Value (FCV) is $\leq$1.0. Uncertainty bounds on ΣSEM-AVS and (ΣSEM-AVS)/f_{OC} can be used to identify sediments where toxicity, because of these metals, is unlikely, uncertain, or likely. If the ΣSEM-AVS is > 0.0 or $\Sigma M_{i,d}$ divided by their respective FCVs is >1.0, effects may occur with increasing severity as the degree of exceedance increases. A procedure for addressing chromium toxicity in sediments is also included in an appendix.

The ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with metal mixtures or the potential for bioaccumulation and trophic transfer of metal mixtures to aquatic life, wildlife or humans.

Foreword

Under the Clean Water Act (CWA), the U.S. Environmental Protection Agency (EPA) and the States develop programs for protecting the chemical, physical, and biological integrity of the nation's waters. To support the scientific and technical foundations of the programs, EPA's Office of Research and Development has conducted efforts to develop and publish equilibrium partitioning sediment benchmarks (ESBs) for some of the 65 toxic pollutants or toxic pollutant categories. Toxic contaminants in bottom sediments of the nation's lakes, rivers, wetlands, and coastal waters create the potential for continued environmental degradation even where water column contaminant levels meet applicable water quality standards. In addition, contaminated sediments can lead to water quality impacts, even when direct discharges to the receiving water have ceased.

The ESBs and associated methodology presented in this document provide a means to estimate the concentrations of a substance that may be present in sediment while still protecting benthic organisms from the effects of that substance. These benchmarks are applicable to a variety of freshwater and marine sediments because they are based on the biologically available concentration of the substance in the sediments. These ESBs are intended to provide protection to benthic organisms from direct toxicity due to this substance. In some cases, the additive toxicity for specific classes of toxicants (e.g., metal mixtures or polycyclic aromatic hydrocarbon mixtures) is addressed. The ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with metal mixtures or the potential for bioaccumulation and trophic transfer of metal mixtures to aquatic life, wildlife or humans.

ESBs may be useful as a complement to existing sediment assessment tools, to help assess the extent of sediment contamination, to help identify chemicals causing toxicity, and to serve as targets for pollutant loading control measures.

This document provides technical information to EPA Program Offices, including Superfund, Regions, States, the regulated community, and the public. For example, ESBs when used in the Superfund process, would serve for screening purposes only, not as regulatory criteria, site specific clean-up standards, or remedial goals. The ESBs do not substitute for the CWA or EPA's regulations, nor is it a regulation itself. Thus, it cannot impose legally binding requirements on EPA, States, or the regulated community. EPA and State decision makers retain the discretion to adopt approaches on a case-by-case basis that differ from this technical information where appropriate. EPA may change this technical information in the future. This document has been reviewed by EPA's Office of Research and Development (Mid-Continent Ecology Division, Duluth, MN; Atlantic Ecology Division, Narragansett, RI), and approved for publication.

Mention of trade names or commercial products does not constitute endorsement or recommendation of use.

This is contribution AED-02-048 of the Office of Research and Development National Health and Environmental Effects Research Laboratory's Atlantic Ecology Division.

Executive Summary

This equilibrium partitioning sediment benchmark (ESB) document describes procedures to derive concentrations of metal mixtures in sediment which are protective of the presence of benthic organisms. The equilibrium partitioning (EqP) approach was chosen because it accounts for the varying biological availability of chemicals in different sediments and allows for the incorporation of the appropriate biological effects concentration U.S. EPA (2003a). This provides for the derivation of benchmarks that are causally linked to the specific chemical, applicable across sediments, and appropriately protective of benthic organisms.

Equilibrium partitioning theory predicts that these metals partition in sediment between acid volatile sulfide (AVS, principally iron monosulfide), interstitial (pore) water, benthic organisms, and other sediment phases such as organic carbon. Biological responses of benthic organisms to these metals in sediments are different across sediments when the sediment concentrations are expressed on a dry weight basis, but similar when expressed on a ΣSEM-AVS or interstitial water basis. The difference between the sum of the molar concentrations of simultaneously extracted metal (ΣSEM, the metal extracted in the AVS extraction procedure) minus the molar concentration of AVS accurately predicts which sediments are not toxic because of these metals. The use of (ΣSEM-AVS)/f_{OC} reduces variability associated with prediction of when sediments will be toxic.

EqP can be used to calculate ESBs for any toxicity endpoint for which there are water-only toxicity data; it is not limited to any single effect endpoint. For the purposes of this document, the ESB for mixtures of the metals cadmium, copper, lead, nickel, silver, and zinc is based on the solid phase and interstitial water phase of sediments. In sediments, these metals should not cause direct toxicity to benthic organisms if the ΣSEM-AVS is ≤ 0.0. Alternatively, sediments containing these metals should not cause direct toxicity to benthic organisms if the sum of the dissolved interstitial water concentrations for each of the metals ($\Sigma M_{i,d}$) divided by their respective water quality criteria final chronic value (FCV) is ≤ 1.0. Uncertainty bounds on ΣSEM-AVS and (ΣSEM-AVS)/f_{OC} can be used to identify sediments where toxicity, because of these metals, is unlikely, uncertain, or likely. If an FCV is not available, a secondary chronic value (SCV) can be substituted. Ancillary analyses conducted as part of this derivation suggest that the sensitivity of benthic/epibenthic organisms is not significantly different from pelagic organisms; for this reason, the FCV and the resulting $ESB_{AVS:WQC}$ should be fully applicable to benthic organisms. The $ESB_{AVS:WQC}$s should be interpreted as chemical concentrations below which adverse effects are not expected. At concentrations above the $ESB_{AVS:WQC}$s, effects may occur with increasing severity as the degree of exceedance increases. In principle, above the upper confidence limit effects are expected if the chemical is bioavailable as predicted by EqP theory. A sediment-specific site assessment would provide further information on chemical bioavailability and the expectation of toxicity relative to the $ESB_{AVS:WQC}$s and associated uncertainty limits. An appendix addresing chromium toxicity in sediments is also included in this document.

As discussed, while this document uses the WQC or AVS values, the EqP methodology can be used by environmental managers to derive a benchmark with any desired level of protection, so long as the water-only concentration affording that level of protection is known. Therefore, the resulting benchmark can be species or site-specific if the corresponding water-only information is available. For example, if a certain water-only effects concentration is known to be

economically important benthic species, the FCV or SCV for that benthic species could be used to derive the benchmark. Such a benchmark might be considered as providing "site-specific protection" for a species or endpoint, if the goal is to derive a benchmark for that particular site or species. Another way to make an ESB site-specific would be to incorporate information on unusual partitioning, if suspected, at the site (see U.S. EPA 2003b).

The ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with metal mixtures or the potential for bioaccumulation and trophic transfer of metal mixtures to aquatic life, wildlife or humans. Consistent with the recommendations of EPA's Science Advisory Board, publication of these documents does not imply the use of ESBs as stand-alone, pass-fail criteria for all applications; rather, ESB exceedances could be used to trigger the collection of additional assessment data. When using the AVS approach, the $ESB_{AVS:WQC}$ applies to sediments having AVS concentrations $\geq$ 0.1 µmol/g.

Tier 1 and Tier 2 ESB values were developed to reflect differing degrees of data availability and uncertainty. Tier 1 ESBs have been derived for metal mixtures in this document, and for the nonionic organic insecticides endrin and dieldrin, and polycyclic aromatic hydrocarbon (PAH) mixtures in U.S. EPA (2003c, d, e). Tier 2 ESBs are reported in U.S. EPA (2003f).

Glossary of Abbreviations

Ag	Silver
Ag_2S	Silver monosulfide
AVS	Acid volatile sulfide
CCC	Criteria continuous concentration
Cd	Cadmium
$\{Cd^{2+}\}$	Activity of ionic cadmium (mol/L)
$[Cd^{2+}]$	Concentration of ionic cadmium (mol/L)
$[Cd]_A$	Concentration of added cadmium (mol/L)
$[Cd]_B$	Concentration of bound cadmium (mol/L)
[CdS(s)]	Concentration of solid-phase cadmium sulfide (mol/L)
Cr	Chromium
C_S	Concentration of contaminant in sediment
C_s^*	Sediment LC50 Concentration
Cu	Copper
CWA	Clean Water Act

Section 1

Introduction

1.1 General Information

Toxic pollutants in bottom sediments of the Nation's lakes, rivers, wetlands, estuaries, and marine coastal waters create the potential for continued environmental degradation even where water column concentrations comply with established WQC. In addition, contaminated sediments can be a significant pollutant source that may cause water quality degradation to persist, even when other pollutant sources are stopped (Larsson, 1985; Salomons et al., 1987; Burgess and Scott, 1992). The absence of defensible equilibrium partitioning sediment benchmarks (ESBs) make it difficult to accurately assess the extent of the ecological risks of contaminated sediments and to identify, prioritize, and implement appropriate cleanup activities and source controls (U.S. EPA 1997a, b, c).

As a result of the need for a procedure to assist regulatory agencies in making decisions concerning contaminated sediment problems, the U.S. Environmental Protection Agency (EPA) Office of Science and Technology, Health and Ecological Criteria Division (OST/HECD) and Office of Research and Development National Health and Environmental Effects Research Laboratory (ORD/NHEERL) established a research team to review alternative approaches (Chapman, 1987). All of the approaches reviewed had both strengths and weaknesses, and no single approach was found to be applicable for the derivation of benchmarks in all situations (U.S. EPA, 1989, 1992). The equilibrium partitioning (EqP) approach was selected for nonionic organic chemicals because it presented the greatest promise for generating defensible, national, numeric chemical-specific benchmarks applicable across a broad range of sediment types. The three principal observations that underlie the EqP approach to establishing sediment benchmarks are as follows:

1. The concentrations of nonionic organic chemicals in sediments, expressed on an organic carbon basis, and in interstitial waters correlate to observed biological effects on sediment-dwelling organisms across a range of sediments.

2. Partitioning models can relate sediment concentrations for nonionic organic chemicals on an organic carbon basis to freely-dissolved concentrations in interstitial water.

3. The distribution of sensitivities of benthic organisms to chemicals is similar to that of water column organisms; thus, the currently established water quality criteria (WQC) final chronic values (FCV) or secondary chronic values (SCV) can be used to define the acceptable effects concentration of a chemical freely-dissolved in interstitial water.

Because of their widespread release and persistent nature, metals such as cadmium, copper, lead, nickel, silver, and zinc are commonly elevated in aquatic sediments. These metals, in addition to nonionic organic chemicals, are of potential concern to aquatic environments. Thus, there have been various proposals for deriving sediment benchmarks for protecting benthic communities using measurement of total sediment metals followed by comparison with background metal concentrations, or in some cases, an effects-based endpoint (Sullivan et al., 1985; Persaud et al., 1989; Long and Morgan, 1990; Ingersoll et al., 1996; MacDonald et al., 1996). An important limitation to these types of approaches is that the causal linkage between the measured concentration of metals and the observed toxicity cannot be established, in part because of the procedures used to derive correlative values, and because values derived are based on total rather than bioavailable metal concentrations. That is, for any given total metal concentration, adverse toxicological effects may or may not occur, depending on the physicochemical characteristics of the sediment of concern (Tessier and Campbell, 1987; Luoma, 1989; Di Toro et al., 1990).

Many researchers have used elaborate sequential extraction procedures to identify sedimentary physicochemical fractions with which metals are associated in an attempt to understand the biological availability of metals in sediments (Tessier et al., 1979; Luoma and Bryan, 1981). Key binding phases for metals in sediments included iron and manganese oxides and organic carbon. Shortcomings with these approaches have limited their application largely to aerobic sediments instead of anaerobic sediments, where metals are often found in the greatest concentrations (see Section 2).

In developing ESBs for metals that causally link metals concentrations to biological effects and that apply across all sediments, it is essential that bioavailability be understood. Therefore, the EqP approach was selected as the technical basis for deriving ESBs for metals. Different studies have shown that although total (dry weight) metal concentrations in anaerobic sediments are not predictive of bioavailability, metal concentrations in interstitial water are correlated with observed biological effects (Swartz et al., 1985; Kemp and Swartz, 1986). However, as opposed to the situation for nonionic organic chemicals and organic carbon (see Di Toro et al., 1991), sediment partitioning phases controlling interstitial water concentrations of metals were not readily apparent. A key partitioning phase controlling cationic metal activity and metal-induced toxicity in the sediment–interstitial water system is acid volatile sulfide (AVS) (Di Toro et al., 1990, 1992). AVS binds, on a molar basis, a number of cationic metals of environmental concern (cadmium, copper, lead, nickel, silver, and zinc), forming insoluble sulfide complexes with minimal biological availability. (Hereafter in this document, the use of the term "metals" will apply only to these six metals.)

The data that support the EqP approach for deriving sediment benthmarks for nonionic organic chemicals were reviewed by Di Toro et al. (1991) and U.S. EPA (1997a; 2003a). The utility of the EqP approach for deriving sediment benchmarks for metals (U.S. EPA, 1994a) was reviewed and endorsed by EPA's Science Advisory Board (SAB) in 1994 and 1999 (U.S. EPA, 1995a, 1999). The data that support the EqP approach for deriving sediment benchmarks for metals presented in this document were taken largely from a series of papers published in the December 1996 issue of *Environmental Toxicology and Chemistry* by Ankley et al. (1996), Berry et al. (1996), DeWitt et al. (1996), Di Toro et al. (1996a,b), Hansen et al. (1996a,b), Leonard et al. (1996a), Liber et al. (1996), Mahony et al. (1996), Peterson et al. (1996), and Sibley et al. (1996). In addition, publications by Di Toro et al. (1990, 1992), Ankley et al. (1994), U.S. EPA (1995a), and Berry et al. (1999) were of particular importance in the preparation of this document.

The same three general principles observed in applying the EqP approach to nonionic organic chemicals listed above also apply with only minor adjustments to deriving ESBs for mixtures of the cationic metals—cadmium, copper, lead, nickel, silver, and zinc:

1. The concentrations of these six metals in sediments, normalized to the concentration of AVS and simultaneously extracted metals (SEM) (the metals extracted with AVS) in sediments and dissolved in interstitial waters, correlate with observed biological effects to sediment-dwelling organisms across a range of sediments (Di Toro et al., 1992).

2. Partitioning models can relate sediment concentrations for cationic divalent metals (and monovalent silver) on an AVS basis to the absence of freely-dissolved concentrations in interstitial water.

3. The distributions of sensitivities of benthic and water column organisms to organic chemicals and metals are similar (U.S. EPA, 2003a); thus, the currently established WQC FCVs can be used to define the acceptable effects concentration of the metals freely dissolved in interstitial water.

The EqP approach, therefore, assumes that (1) the partitioning of the metal between sediment AVS (or any other binding factors controlling

bioavailability) and interstitial water approximates equilibrium; (2) organisms receive equivalent exposure from interstitial water–only exposure or from exposure to any other equilibrated sediment phase: either from interstitial water via respiration, sediment via ingestion, or sediment-integument exchange, or from a mixture of exposure routes; (3) for the cationic metals cadmium, copper, lead, nickel, zinc, and silver, partitioning of metal between the solid phase and interstitial water can be predicted based on the relative concentrations of AVS and SEM; (4) the WQC FCV concentration is an appropriate effects concentration for freely-dissolved metal in interstitial water; and (5) the toxicity of metals in interstitial water is no more than additive.

For the first time, the Agency is publishing ESBs that account for bioavailability in sediments and the potential for effects of a metal mixture in the aquatic environment, thus providing an ecologically relevant benchmark. Two equally applicable ESBs for metals, a solid phase and an interstitial water phase, are described. The solid-phase AVS ESBs is defined as the $\Sigma_i[SEM_i] \leq [AVS]$ (total molar concentration of simultaneously extracted metal is less than or equal to the total molar concentration of acid volatile sulfide). Note that cadmium, copper, lead, nickel, and zinc are divalent metals so that one mole of each metal can bind only with one mole of AVS. The molar concentrations of these metals are compared with AVS on a one-to-one basis. Silver, however, exists predominantly as a monovalent metal, so that silver monosulfide (Ag_2S) binds two moles of silver for each mole of AVS. Therefore, SEM_{Ag} by convention will be defined as the molar concentration of silver divided by two, [Ag]/2, which is compared with the molar AVS concentration. The interstitial water phase ESB is $\Sigma[M_{i,d}]/[FCV_{i,d}] \leq 1$ (the sum of cadmium, copper, nickel, lead, and zinc of the concentration of each individual metal dissolved in the interstitial water divided by the metal-specific FCV based on dissolved metal is less than or equal to one; note that at present EPA does not have an FCV for silver). This latter value is termed an interstitial water benchmark unit (IWBU). A requirement of the IWBUapproach is that the toxicities of interstitial water metal concentrations be additive. The data presented in this document support the additivity of the toxicity of metal mixtures in water.

Importantly, both the solid-phase AVS ESB and interstitial water ESB are no-effect benchmarks; that is, they predict sediments that are acceptable for the protection of benthic organisms. These ESBs, when exceeded, do not unequivocally predict sediments that are unacceptable for the protection of benthic organisms. The solid-phase AVS benchmark avoids the methodological difficulties of interstitial water sampling that may lead to an overestimate of exposure and provides information on the potential for additional metal binding. Because the AVS benchmark does not include other metal-binding phases of sediments, the interstitial benchmark is also proposed. The use of both the AVS and interstitial water benchmarks will improve estimates of risks of sediment-associated metals. For example, the absence of significant concentrations of metal in interstitial water in toxic sediments having SEM≤AVS and in nontoxic sediments having SEM>AVS demonstrates that metals in these sediments are unavailable. The $(\Sigma SEM\text{-}AVS)/f_{OC}$ correction, although not an ESB, can be used to refine the prediction of sediments where protection of benthic organisms is acceptable, uncertain, or unacceptable.

ESBs based on the EqP approach are developed using the latest available scientific data and are suitable for providing guidance to regulatory agencies because they are

- Numeric values
- Chemical-specific
- Applicable to most sediments
- Predictive of biological effects
- Protective of benthic organisms

It should be emphasized that these benchmarks are intended to protect benthic organisms from the direct effects of these six metals in sediments that are permanently inundated with water, intertidal, or inundated periodically for durations sufficient to permit

development of benthic assemblages. They do not apply to occasionally inundated soils containing terrestrial organisms. The ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with metal mixtures or the potential for bioaccumulation and trophic transfer of metal mixtures to aquatic life, wildlife or humans. The ESBs presented in this document are the recommended concentrations of cadmium, copper, lead, nickel, silver, and zinc in sediment that will not adversely affect most benthic organisms. ESB values may be adjusted to account for future data or site-specific considerations (U.S. EPA, 2003b).

This document includes the theoretical basis and the supporting data relevant to the derivation of an ESBfor cadmium, copper, lead, nickel, silver, and zinc and their mixture. An understanding of the "Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses" (Stephan et al., 1985); Response to Public Comment (U.S. EPA, 1985a); "Ambient Water Quality Criteria for Cadmium" (U.S. EPA, 1985b); "Ambient Water Quality Criteria for Copper" (U.S. EPA, 1985c); "Ambient Water Quality Criteria—Saltwater Copper Addendum" (U.S. EPA, 1995c); "Ambient Water Quality Criteria for Lead" (U.S. EPA, 1985d); "Ambient Water Quality Criteria for Nickel" (U.S. EPA, 1986); "Ambient Water Quality Criteria for Silver" (U.S. EPA, 1980); and "Ambient Water Quality Criteria for Zinc" (U.S. EPA, 1987) is necessary in order to understand the following text, tables, and calculations.

1.2 Applications of Sediment Benchmarks

ESBs are meant to be used with direct toxicity testing of sediments as a method of evaluation assuming the toxicity testing species is sensitive to the chemical of interest. They provide a chemical-by-chemical specification of what sediment concentrations are protective of benthic aquatic life. The EqP method should be applicable to nonionic organic chemicals with a K_{OW} above 3.0. Examples of other chemicals to which this methodology applies include endrin, dieldrin, and polycyclic aromatic hydrocarbon (PAH) mixtures.

For the toxic chemicals addressed by the ESB documents Tier 1 (U.S. EPA, 2003c, d, e, and this document) and Tier 2 (U.S. EPA, 2003f) values were developed to reflect the differing degrees of data availability and uncertainty. Tier 1 ESBs are more scientifically rigorous and data intensive than Tier 2 ESBs. The minimum requirements to derive a Tier 1 ESB include: (1) Each chemical's organic carbon-water partition coefficient (K_{OC}) is derived from the octanol-water partition coefficient (K_{OW}) obtained using the SPARC (SPARC Performs Automated Reasoning in Chemistry) model (Karickhoff et al., 1991) and the K_{OW}-K_{OC} relationship from Di Toro et al. (1991). This K_{OC} has been demonstrated to predict the toxic sediment concentration from the toxic water concentration with less uncertainty than K_{OC} values derived using other methods. (2) The FCV is updated using the most recent toxicological information and is based on the National WQC Guidelines (Stephan et al., 1985). (3) EqP-confirmation tests are conducted to demonstrate the accuracy of the EqP prediction that the K_{OC} multiplied by the effect concentration from a water-only toxicity test predicts the effect concentration from sediment tests (Swartz, 1991; DeWitt et al., 1992). Using these specifications, Tier 1 ESBs have been derived for metal mixtures in this document, the nonionic organic insecticides endrin and dieldrin (U.S. EPA, 2003c, d) and PAH mixtures (U.S. EPA, 2003e). In comparison, the minimum requirements for a Tier 2 ESB (U.S. EPA, 2003f) are less rigorous: (1) The K_{ow} for the chemical that is used to derive the K_{OC} can be from slow-stir, generator column, shake flask, SPARC or other sources. (2) FCVs can be from published or draft WQC documents, the Great Lakes Initiative or developed from AQUIRE. Secondary chronic values (SCV) from Suter and Mabrey (1994) or other effects concentrations from water-only toxicity tests can be used. (3) EqP cconfirmation tests are recommended, but are not required for the development of Tier 2 ESBs. Because of these lesser requirements, there is greater uncertainty in the EqP prediction of the sediment effect concentration from the water-only effect concentration, and in the level of protection afforded by Tier 2 ESBs. Examples of Tier 2 ESBs for nonionic organic chemicals are found in U.S. EPA (2003f).

1.3 Overview

Section 1 provides a brief review of the EqP methodology as it applies to the individual metals cadmium, copper, lead, nickel, silver, and zinc and their mixture. Section 2 reviews published experimental results that describe the toxicity associated with the partitioning and bioavailability of these metals in interstitial water of freshwater and marine sediments. Section 3 reviews the results of acute and chronic toxicity tests conducted with spiked and field sediments that demonstrate that the partitioning and bioavailability of metals in sediments can be used to accurately predict the absence of toxicity of sediment-associated metals. Section 4 describes the AVS benchmark and interstitial water benchmark approaches for the derivation of the ESB for individual metals and mixtures of metals. Published WQC values for five of these six dissolved metals (the silver FCV is not available) are summarized for use in calculating IWBUs as required in the interstitial water ESB approach. The $ESB_{AVS:WQC}$ for metals is then compared with chemical monitoring data on environmental occurrence of SEM, AVS, and interstitial metals in sediments from Lake Michigan, the Virginian Province from EPA's Environmental Monitoring and Assessment Program (EMAP), and the National Oceanic and Atmospheric Administration (NOAA) National Status and Trends monitoring program (NST). Section 5 describes recommended procedures for sampling, handling, and analysis of metals in sediments and interpretation of data from the sediment samples that is needed if the assessments of risks of sediment-associated metals are to be appropriately based on the EqP methodology. Section 6 concludes with the $ESB_{AVS:WQC}$ for a mixture of the metals: cadmium, copper, nickel, lead, silver, and zinc and discussion of their application and interpretation. The references cited in this document are listed in Section 7. Appendices A and B provide additional monitoring data. Appendix C reports on quality assurance for this document and Appendix D addresses chromium toxicity in sediments.

Section 2

Partitioning of Metals in Sediments

2.1 Metal Toxicity in Water-Only and in Interstitial Water of Sediment Exposures

The EqP approach for establishing sediment benchmarks (i.e., ESBs) requires that the chemicals be measured in phases that relate to chemical activity in sediment. The information provided in this section demonstrates that biological effects correlate to metal activity. Also, it demonstrates that biological response in sediment exposures is the same as in water-only exposures when sediment exposure is assessed on the basis of interstitial water concentrations. This is fundamental to satisfying the EqP approach for both metals and nonionic organic chemicals.

A direct method for establishing sediment benchmarks for metals would be to apply the WQC FCV to measured interstitial water concentrations. The validity of this approach depends both on the degree to which the interstitial water concentration represents free metal activity, and on whether free metal activity can be accurately measured in surface waters and water-only toxicity tests used to derive WQC, and in interstitial water of field sediments and sediments spiked with metals in the laboratory. For most metals, free metal activity cannot be directly measured at WQC concentrations. Therefore, present WQC are not based on free metal activity; rather, they are based on dissolved metals. However, many dissolved metals readily bind to dissolved (actually colloidal) organic carbon (DOC) forming complexes that do not appear to be bioavailable (Bergman and Dorward-King, 1997). Hence, sediment guidelines or benchmarks based on interstitial water concentrations of metals may be overly protective in cases where not all dissolved metal is bioavailable.

By implication, this difficulty extends to any complexing ligand that is present in sufficient quantity. Decay of sediment organic matter can cause substantial changes in interstitial water chemistry. In particular, bicarbonate increases because of sulfate reduction, which increases the importance of metal-carbonate complexes and further complicates the question of the bioavailable metal species (Stumm and Morgan, 1996).

Sampling sediment interstitial water for metals is not a routine procedure. The least invasive technique employs a diffusion sampler that has cavities covered with a filter membrane (Hesslein, 1976; Carignan, 1984; Carignan et al., 1985; Allen et al., 1993; Bufflap and Allen, 1995). The sampler is inserted into the sediment and the concentrations on either side of the membrane equilibrate. Because the sampler is removed after equilibration, the concentrations of metals inside the sampler should be equal to the concentrations of freely-dissolved metals in the interstitial water. The time required for equilibration, typically several days, depends on the size of the filter membrane and the geometry of the cavity.

An alternative technique for separating interstitial water is to obtain an undisturbed sediment sample as a whole sediment or core that can be sliced for vertical resolution, filter or centrifuge the sample, and then filter the resultant interstitial water twice. For anaerobic sediments, this must be done in a nitrogen atmosphere to prevent precipitation of iron hydroxide, which would scavenge the metals and yield artificially low dissolved concentrations of metals (Troup, 1974; Allen et al., 1993).

Although either technique is suitable for research investigations, they require more than the normally available sampling capabilities. If solid-phase chemical measurements were available

from which interstitial water metal activity could be deduced, this would obviate the need for interstitial water sampling and analysis, circumvent the need to deal with complexing ligands, and provide fundamental insight into metal-binding phases in sediments needed to predict bioavailability. The recommended procedures for suitable sampling, handling, and analytical techniques for interstitial water and sediments are provided in Section 5 of this document.

2.1.1 *Toxicity Correlates to Metal Activity*

A substantial number of water-only exposures indicate that biological effects can be correlated to divalent metal activity $\{M^{2+}\}$. Although other forms of metal may also be bioavailable (e.g., MOH^{+}), DOC and certain other ligand-complexed fractions of the metal render it unavailable to organisms. Results from some of these exposures are summarized below.

Acute toxicity of various concentrations of cadmium to grass shrimp (*Palaemonetes pugio*) has been determined in water containing the complexing ligand nitrilotriacetic acid (NTA) or chloride (as salinity), each of which forms cadmium complexes (Sunda et al., 1978). The concentration response curves as a function of total cadmium are quite different at varying concentrations of NTA and chloride (Figure 2-1, A and B). However, if the organism response is evaluated with respect to measured Cd^{2+} activity, a single concentration–response relationship results (Figure 2-1, C and D). Comparable results have been reported by Anderson and Morel (1978) for the dinoflagellate *Gonyaulax tamarensis* exposed to copper-ethylene diamine tetra-acetic acid (EDTA) complexes (Figure 2-2, A and C). Likewise, Allen et al. (1980) observed that when the concentration of zinc is held constant and the concentration of the complexing ligand NTA is varied, growth (cells/mL) of *Microcystis aeruginosa* decreases as the addition of NTA is

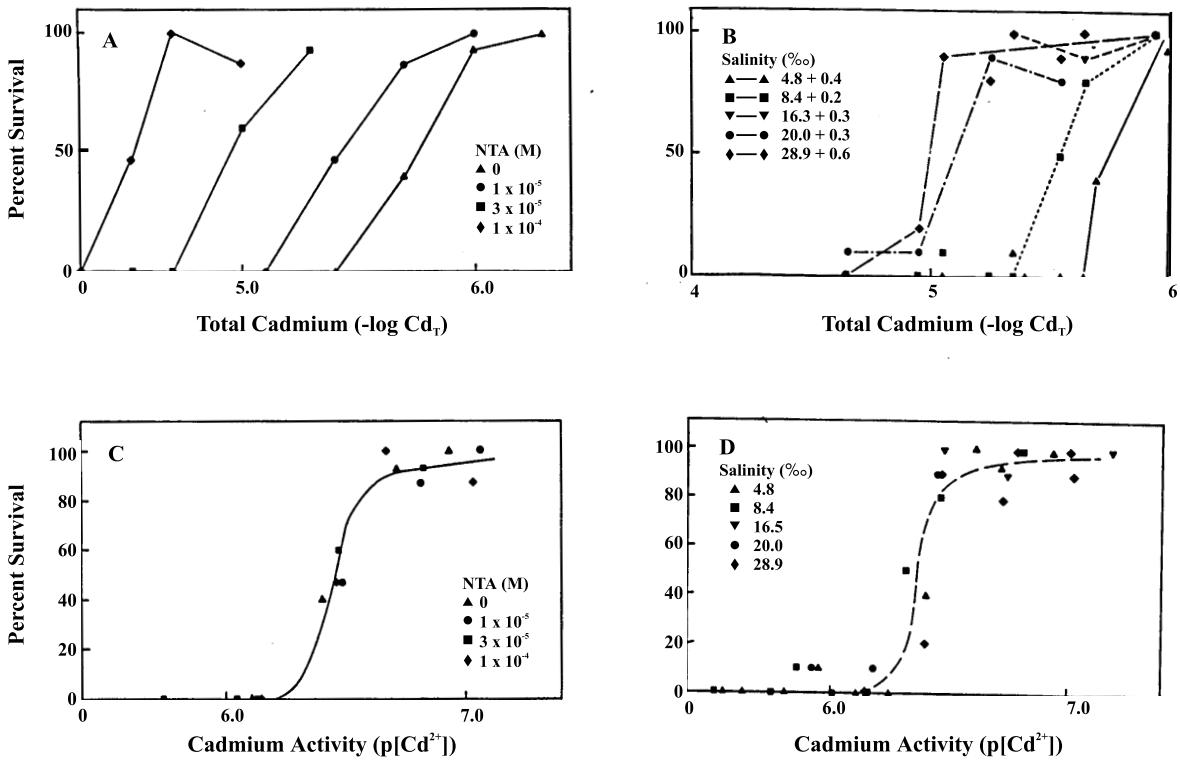

Figure 2-1. Acute toxicity to grass shrimp (*Palaemonetes pugio*) of total cadmium (top) and cadmium activity (bottom) with different concentrations of the complexing ligands NTA (left) and chloride as salinity (right) (figures from Sunda et al., 1978).

increased (Figure 2-2B). The authors correlated the effect to free zinc activity as shown in Figure 2-2D. A single concentration–response relationship is shown for the diatom, *Thalassiosira pseudonana*, and the unicellular alga, *Monochrysis lutheri*, exposed to copper and the complexing ligand Tris (Sunda and Guillard, 1976) as well as copper and DOC from natural river water (Sunda and Lewis, 1978) when exposure concentration is expressed as metal activity (Figure 2-3, A, B, C, and D, respectively).

Metal bioavailability, as measured by metal accumulation into tissues of organisms, has also

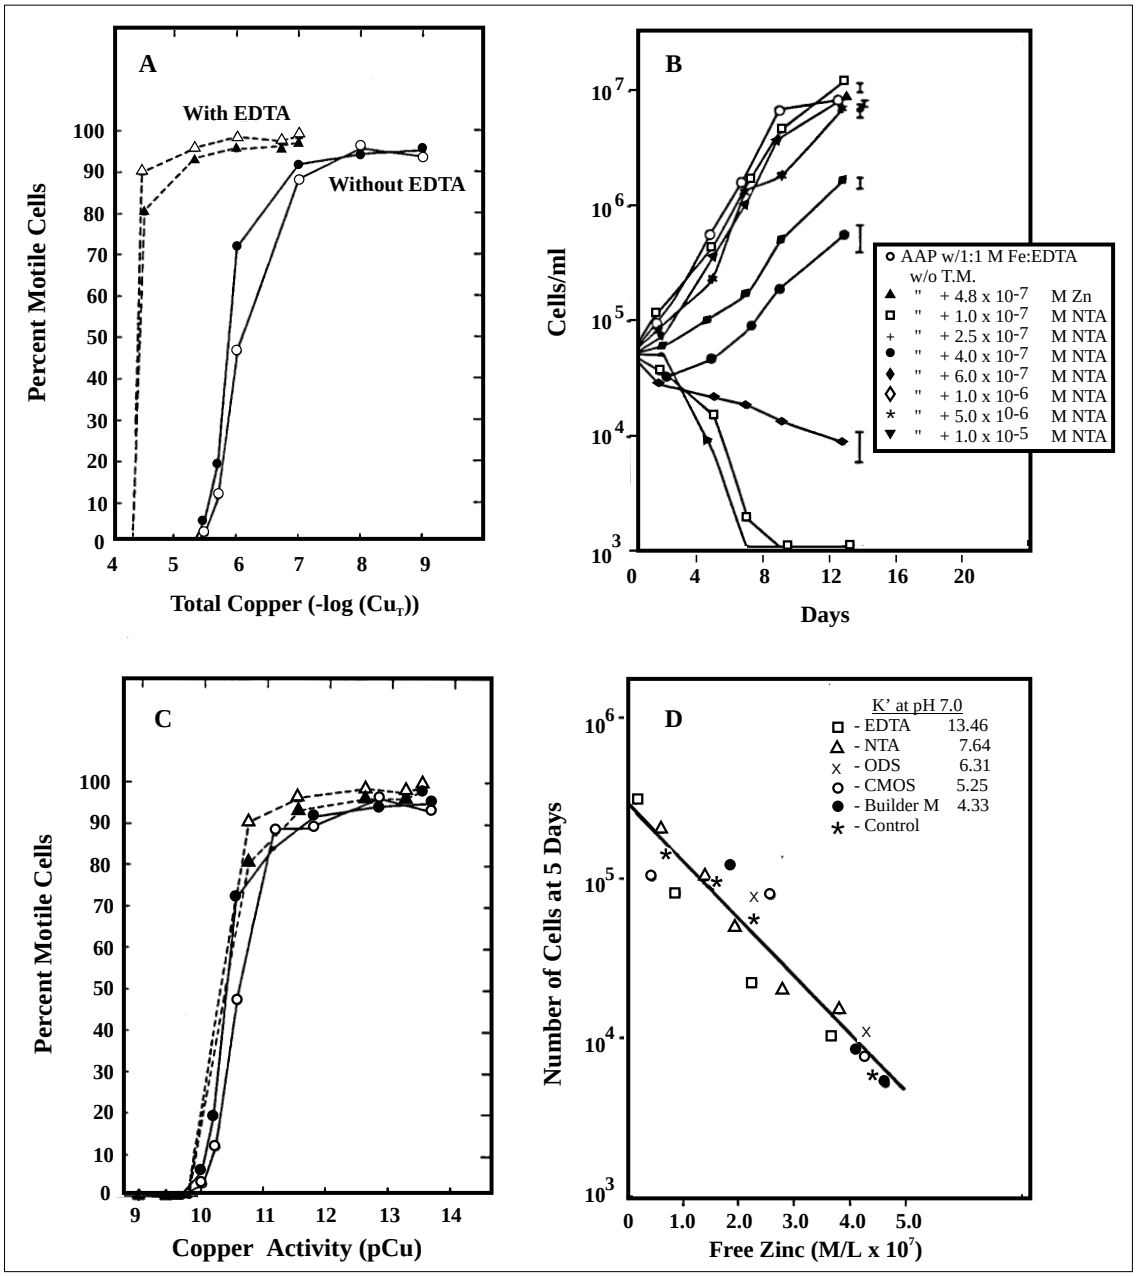

Figure 2-2. Acute toxicity of total copper (A) and copper activity (C) to the dinoflagellate *Gonyaulax tamarensis* with and without the complexing ligand EDTA (figures from Anderson and Morel, 1978). Toxicity of zinc to *Microcystis aeruginosa* showing growth of cells/mL versus time with different levels of the complexing ligands EDTA and NTA (B) and number of cells at 5 days as a function of free zinc concentration (D) (figures from Allen et al., 1980).

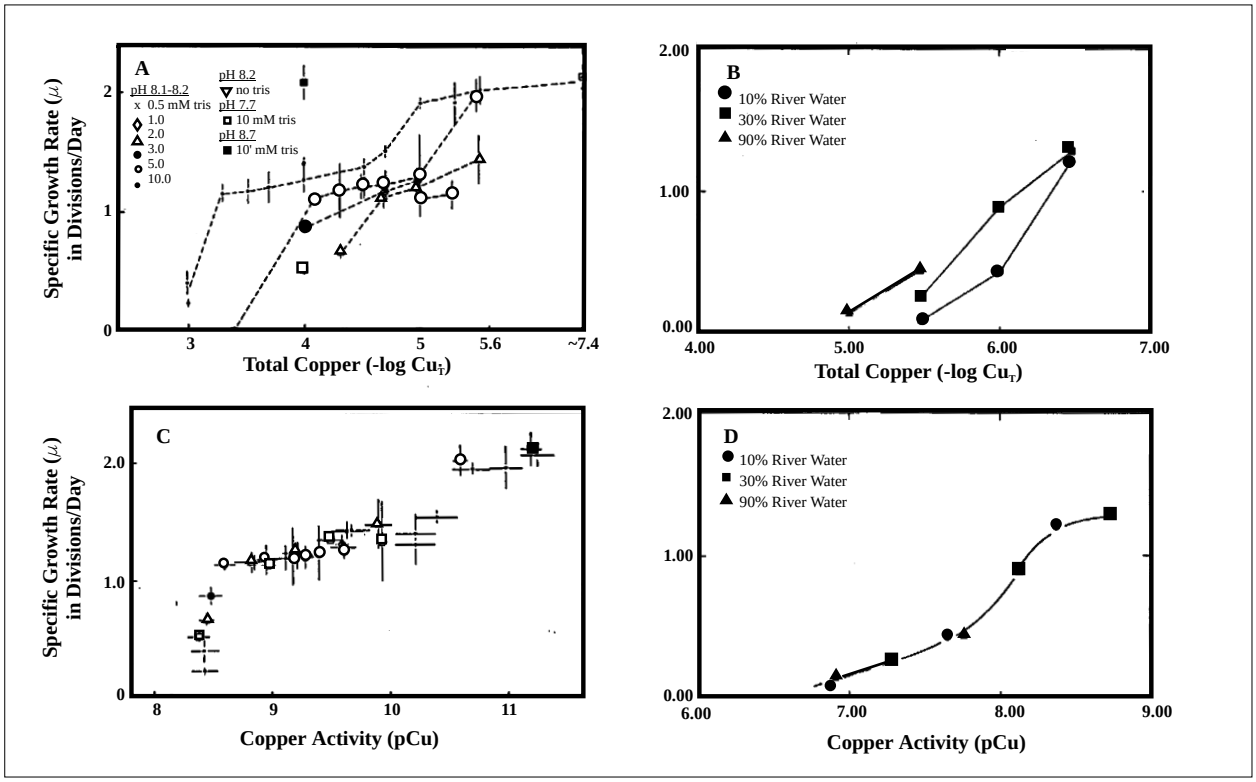

Figure 2-3. Specific growth rates of a diatom (*Thalassiosira pseudonana*) (left) and a unicellular algae (*Monochrysis lutheri*) (right) versus total copper (top) and copper activity (bottom) for a range of concentrations of the complexing ligands Tris (left; from Sunda and Guillard, 1976) and natural DOC in river water (right; from Sunda and Lewis, 1978).

been examined (Zamuda and Sunda, 1982). Uptake of copper by oysters is correlated not to total copper concentration (Figure 2-4A), but to copper activity (Figure 2-4B).

The implication to be drawn from these experiments is that the partitioning model required for establishing a sediment benchmark should predict dissolved metal activity in interstitial water, and that the benchmark based on dissolved metal would be conservative. The following subsection examines the utility of this idea.

2.1.2 *Toxicity Correlates to Interstitial Water Concentration*

This subsection presents early data that first indicated the equivalence of interstitial water concentrations and water-only exposures. Many more data of this sort are presented in Section 3. Swartz et al. (1985) tested the acute toxicity of cadmium to the marine amphipod *Rhepoxynius abronius* in sediment and water. An objective of the study was to determine the contributions of interstitial and particle-bound cadmium to toxicity. A comparison of the 4-day LC50 value of cadmium in interstitial water (1.42 mg/L) with the 4-day LC50 value of cadmium in water without sediment (1.61 mg/L) indicated no significant difference between the two (Figure 2-5). The LC50 represents the chemical concentration estimated to cause lethality to 50% of the test organisms within a specified time period.

Experiments were performed to determine the role of AVS in cadmium-spiked sediments using the amphipods *Ampelisca abdita* and *Rhepoxynius hudsoni* (Di Toro et al., 1990). Three sediments were used: a Long Island Sound sediment with high AVS, a Ninigret Pond sediment with low AVS concentration, and a 50/50 mixture of the two sediments Figure 2-6 presents a

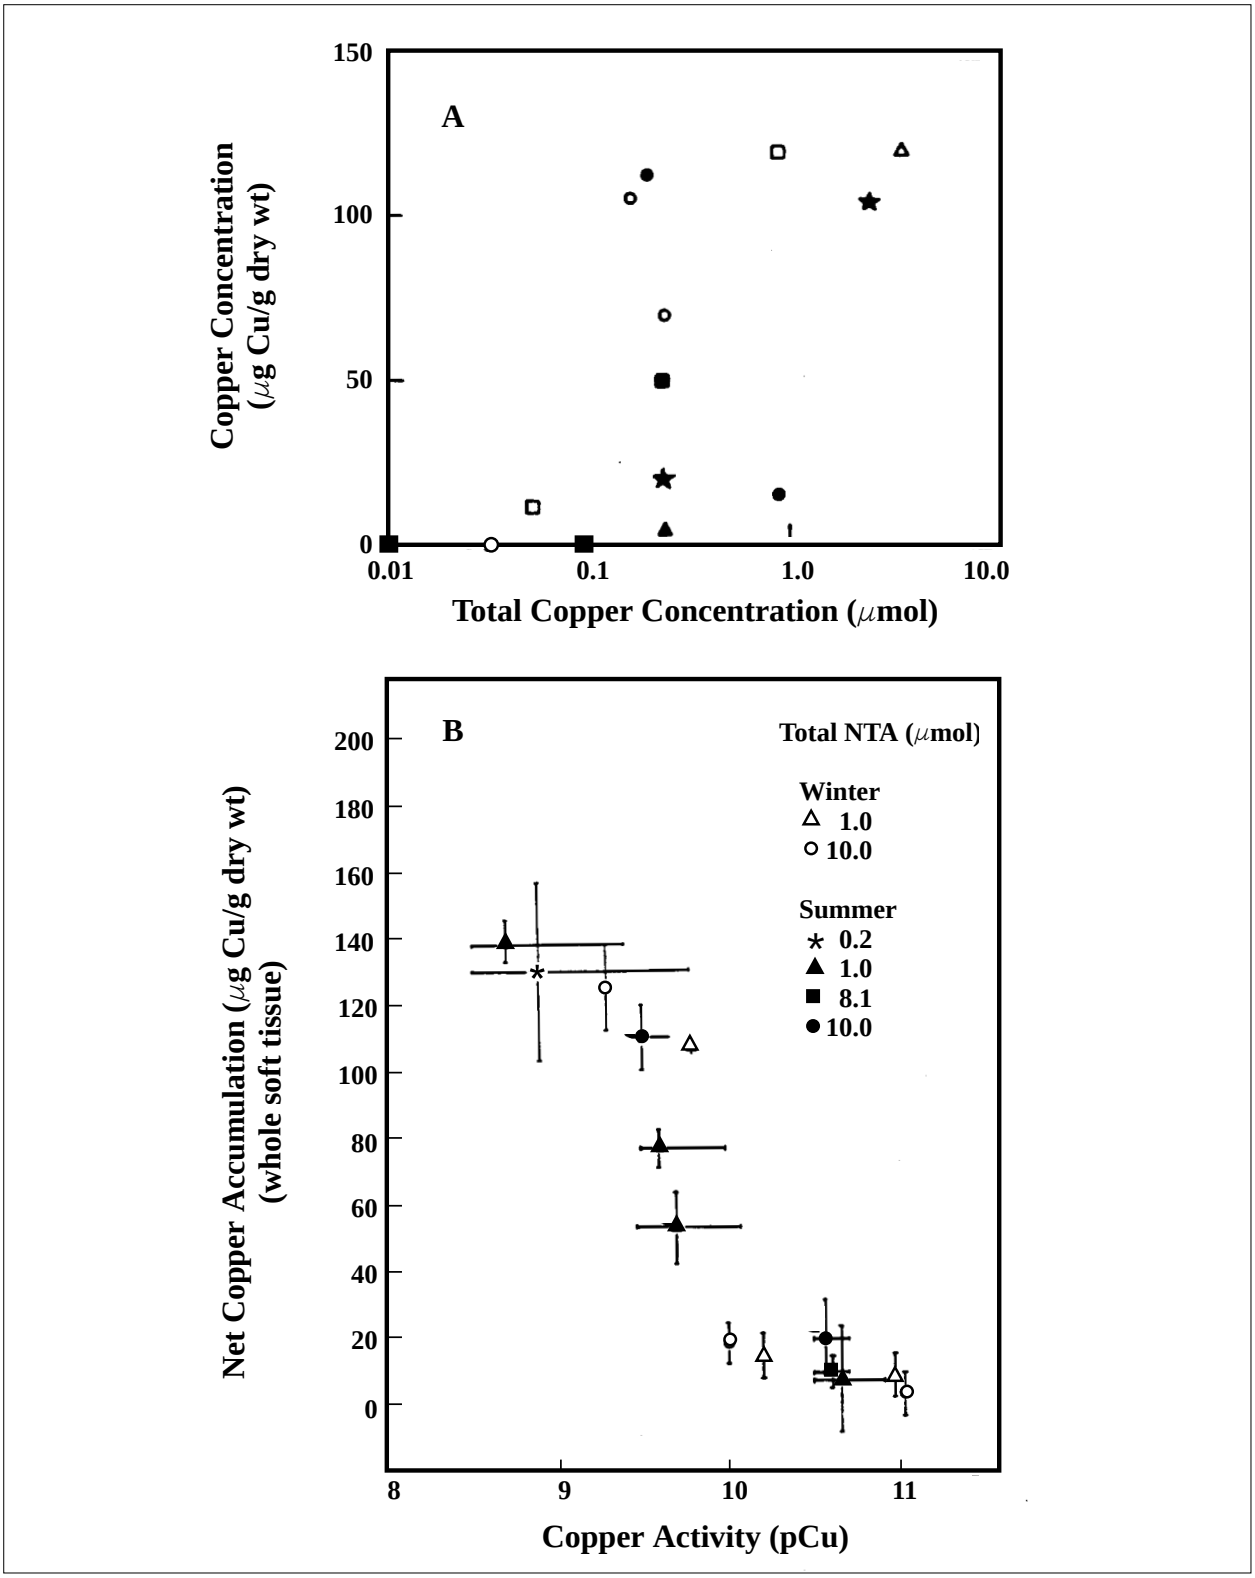

Figure 2-4. Copper accumulation in oysters (*Crassostrea virginica*) versus total copper (A) and copper activity (B) with different levels of the complexing ligand NTA (figures from Zamuda and Sunda, 1982).

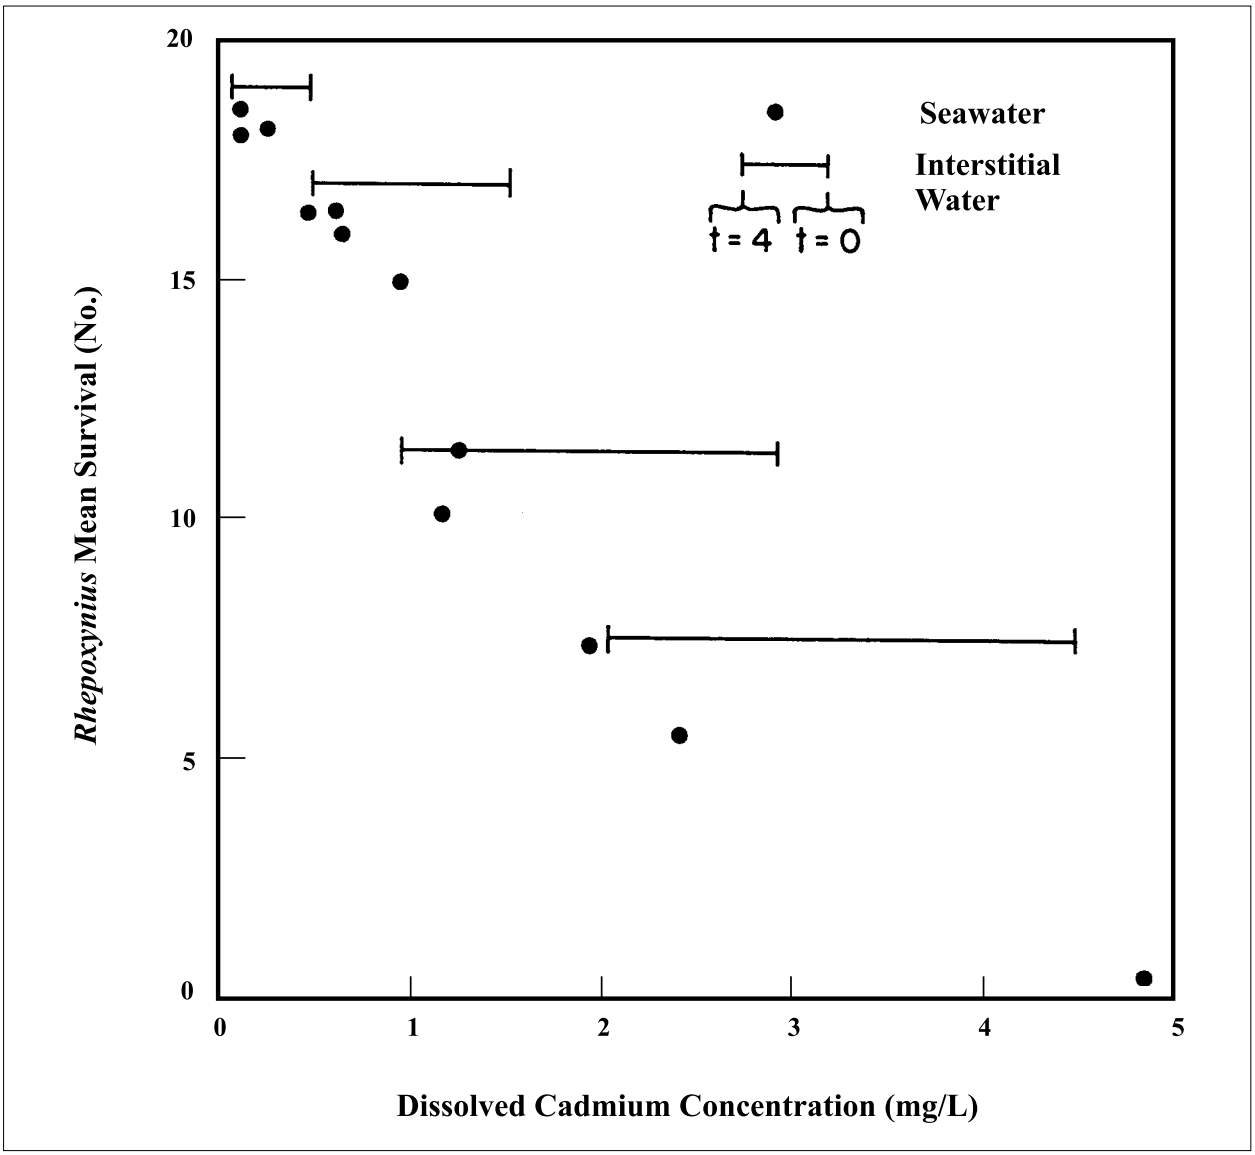

Figure 2-5. Mean survival of the amphipod *Rhepoxynius abronius* versus dissolved cadmium concentration for 4-day toxicity tests in seawater (symbols) and 0- and 4-day tests (bars) in interstitial water (figure from Swartz et al., 1985).

comparison of the observed mortality in three sediments with the interstitial water cadmium activity measured with a specific ion electrode. Four-day water-only and 10-day sediment toxicity tests were performed. The water-only response data for *A. abdita* and *R. hudsoni* are included for comparison although these data represent a shorter duration exposure. These experiments also demonstrate the equivalence of organism response to metal concentrations in interstitial water and in water-only exposures.

An elegant experimental design was employed by Kemp and Swartz (1986) to examine the relative acute toxicity of particle-bound and dissolved interstitial cadmium. They circulated water of the same cadmium concentration through different sediments. This resulted in different bulk sediment concentrations, but the same interstitial water concentrations. They found no statistically significant difference in organism response for the different sediments. Because the interstitial water concentrations were the same in each treatment,

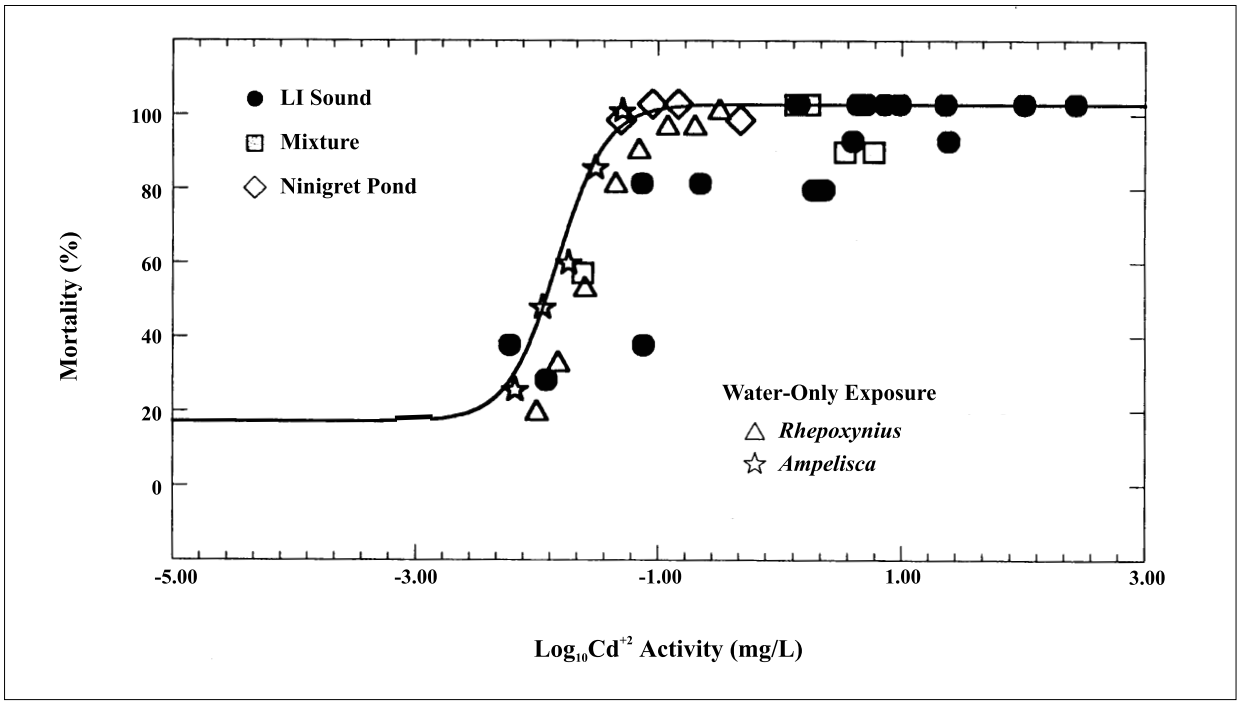

Figure 2-6. **Mortality versus interstitial water cadmium activity for sediments from Long Island Sound, Ninigret Pond, and a mixture of these two sediments. Water-only exposure data are from separate experiments with both *Ampelisca abdita* and *Rhepoxynius hudsoni*. The line is a joint fit to both water-only data sets (figure from Di Toro et al., 1990).**

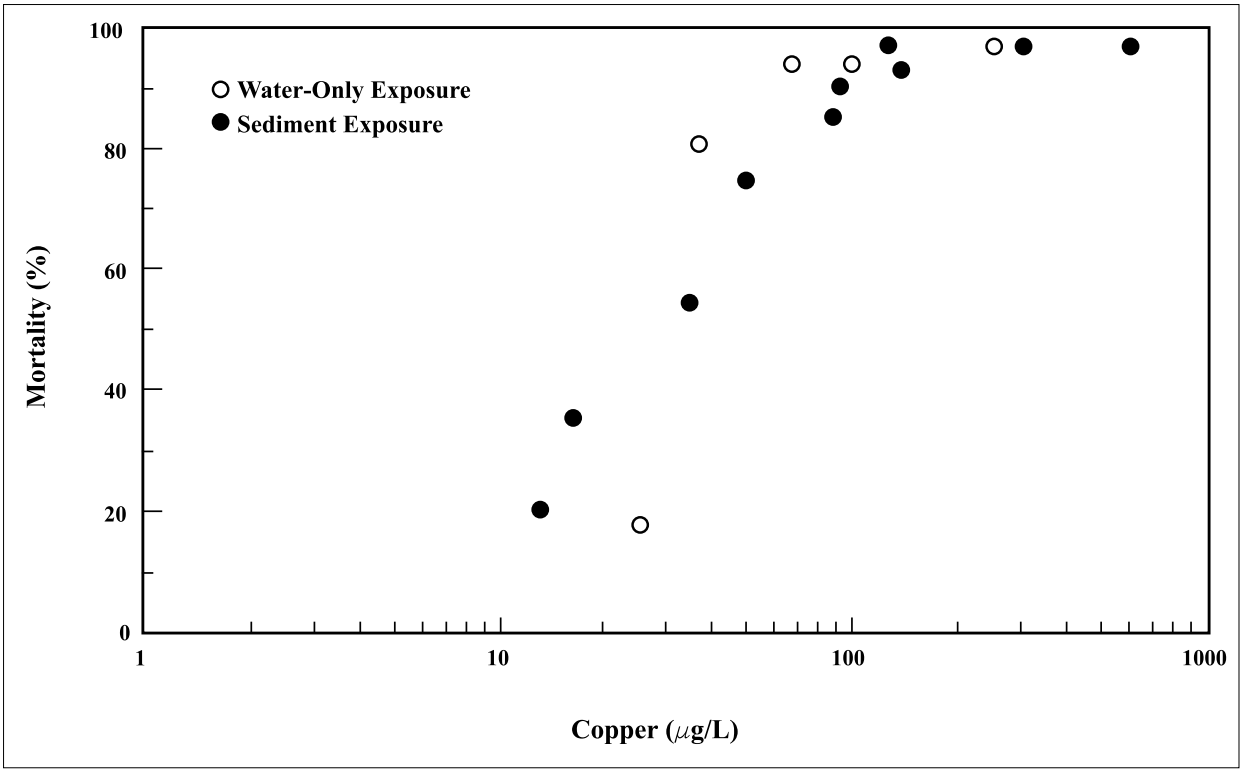

Figure 2-7. **Toxicity of copper to *Hyalella azteca* versus copper concentrations in a water-only exposure (○) and interstitial water copper concentrations in sediment exposures (●) using Keweenaw Watershed sediments (figure from Ankley et al., 1993).**

that is, the circulating water concentrations established the interstitial water concentrations, these experiments confirmed the hypothesis of equal response to concentrations in water-only and interstitial water.

A series of 10-day toxicity tests using the amphipod *Hyalella azteca* was performed to evaluate bioavailability of copper in sediments from two sites highly contaminated with this metal: Steilacoom Lake, WA, and Keweenaw Watershed, MI (Ankley et al., 1993). A water-only, 10-day copper toxicity test also was conducted with the same organism. The mortality resulting from the water-only test was strikingly similar to that from the Keweenaw sediment tests when related to interstitial water (Figure 2-7). The LC50 values show strong agreement for the water-only (31 μg/L) and the Keweenaw sediment test (28 μg/L) using the average of day 0 and day 10 interstitial water concentrations. Steilacoom Lake 10-day interstitial water concentrations were less than the 7 μg/L detection limit and were consistent with the observed lack of toxicity to *H. azteca*.

The data presented in this subsection, and the data in Section 3, demonstrate that in water-only exposures, metal activity and concentration can be used to predict toxicity. The results of the four experiments above demonstrate that mortality data from water-only exposures can be used to predict sediment toxicity using interstitial water concentrations. Therefore, the metal activity or dissolved concentration in interstitial water would be an important component of a partitioning model needed to establish sediment benchmarks. To complete the partitioning model, one would need to identify the solid metal-binding phase(s). The following subsection presents data that identifies solid-phase sulfides as the important metal-binding phase.

2.2 Solid-Phase Sulfide as the Important Binding Component

Modeling metal sorption to oxides in laboratory systems is well developed, and detailed models are available for cation and anion sorption (see Stumm [1987] and Dzombak and Morel [1990] for summaries). The models consider surface complexation reactions as well as electrical interactions by means of models of the double layer. Models for natural soil and sediment particles are less well developed. However, studies suggest that the models available for cation and anion sorption can be applied to soil systems (Allen et al., 1980; Barrow and Ellis, 1986a,b,c; Sposito et al., 1988). Because the ability to predict partition coefficients is required if interstitial water metal concentrations are to be inferred from the total concentration, some practical model is required. This subsection presents the state of the science in theoretical development of metal partitioning behavior in sediments.

2.2.1 *Metal Sorption Phases*

The initial difficulty selecting an applicable sorption model is that available models are complex and many of the parameter estimates may be specific to individual soils or sediments. However, the success of nonionic chemical sorption models based on organic carbon suggests that some model of intermediate complexity based on an identification of the dominant sorption phases may be more generally applicable.

A development in this direction has already been presented (Jenne et al., 1986; Di Toro et al., 1987). The basic idea was that instead of considering only one sorption phase, as is assumed for nonionic hydrophobic chemical sorption, multiple sorption phases must be considered. The conventional view of metal speciation in aerobic soils and sediments is that metals are associated with the exchangeable, carbonate and iron (Fe) and manganese (Mn) oxide forms, as well as organic matter, stable metal sulfides, and a residual phase. In oxic soils and freshwater sediments, sorption phases have been identified as particulate organic carbon (POC) and the oxides of Fe and Mn (Jenne, 1968, 1977; Oakley et al., 1980; Luoma and Bryan, 1981). These phases are important because they have a large sorptive capacity. Furthermore, they appear as coatings on the particles and occlude the other mineral

components. It was thought that they provided the primary sites for sorption of metals. These ideas have been applied to metal speciation in sediments. However, they ignore the critical importance of metal sulfide interactions, which dominate speciation in the anaerobic layers of the sediment.

2.2.2 *Titration Experiments*

The importance of sulfide in the control of metal concentrations in the interstitial water of marine sediments is well documented (Boulegue et al., 1982; Emerson et al., 1983; Davies-Colley et al., 1985; Morse et al., 1987). Metal sulfides are very insoluble, and the equilibrium interstitial water metal concentrations in the presence of sulfides are small. If the interstitial water sulfide

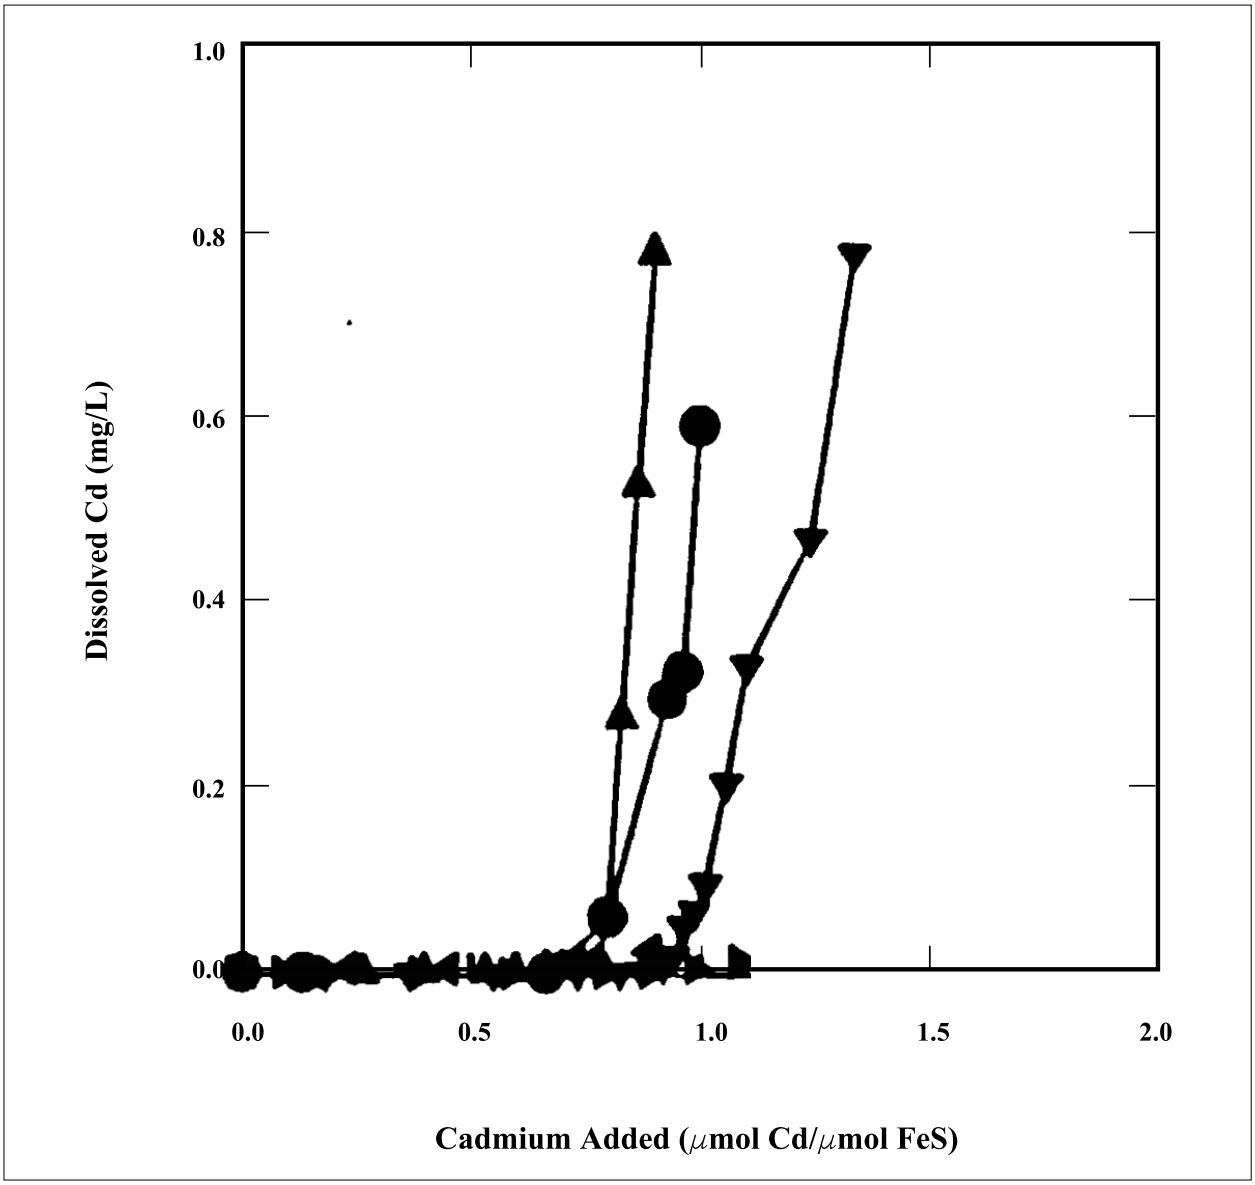

Figure 2-8. Cadmium titrations of amorphous FeS. The x-axis is the amount of cadmium added normalized by FeS initially present. The y-axis is total dissolved cadmium. The lines connecting the data points are an aid to visualizing the data. The different symbols represent replicate experiments (figure from Di Toro et al., 1990).

concentration, S^{2-}, in sediments is large, then the addition of metal, M^{2+}, to the sediment would precipitate metal sulfide (MS) following the reaction

$$M^{2+} + S^{2-} \rightleftharpoons MS(s) \qquad (2\text{-}1)$$

This appeared to be happening during a spiked cadmium sediment toxicity test (Di Toro et al., 1990) because a visible bright yellow cadmium sulfide precipitate formed as cadmium was added to the sediment. However, interstitial water sulfide activity, $\{S^{2-}\}$, measured with a sulfide electrode unexpectedly indicated that there was insufficient dissolved sulfide present in the unspiked sediment.

The lack of a significant quantity of dissolved sulfide in the interstitial water and the evident formation of solid-phase cadmium sulfide suggested the following possibility. The majority of the sulfide in sediments is in the form of solid-phase iron sulfides. Perhaps the source of the sulfide is from the solid-phase sulfide initially present. As cadmium is added to the sediment,

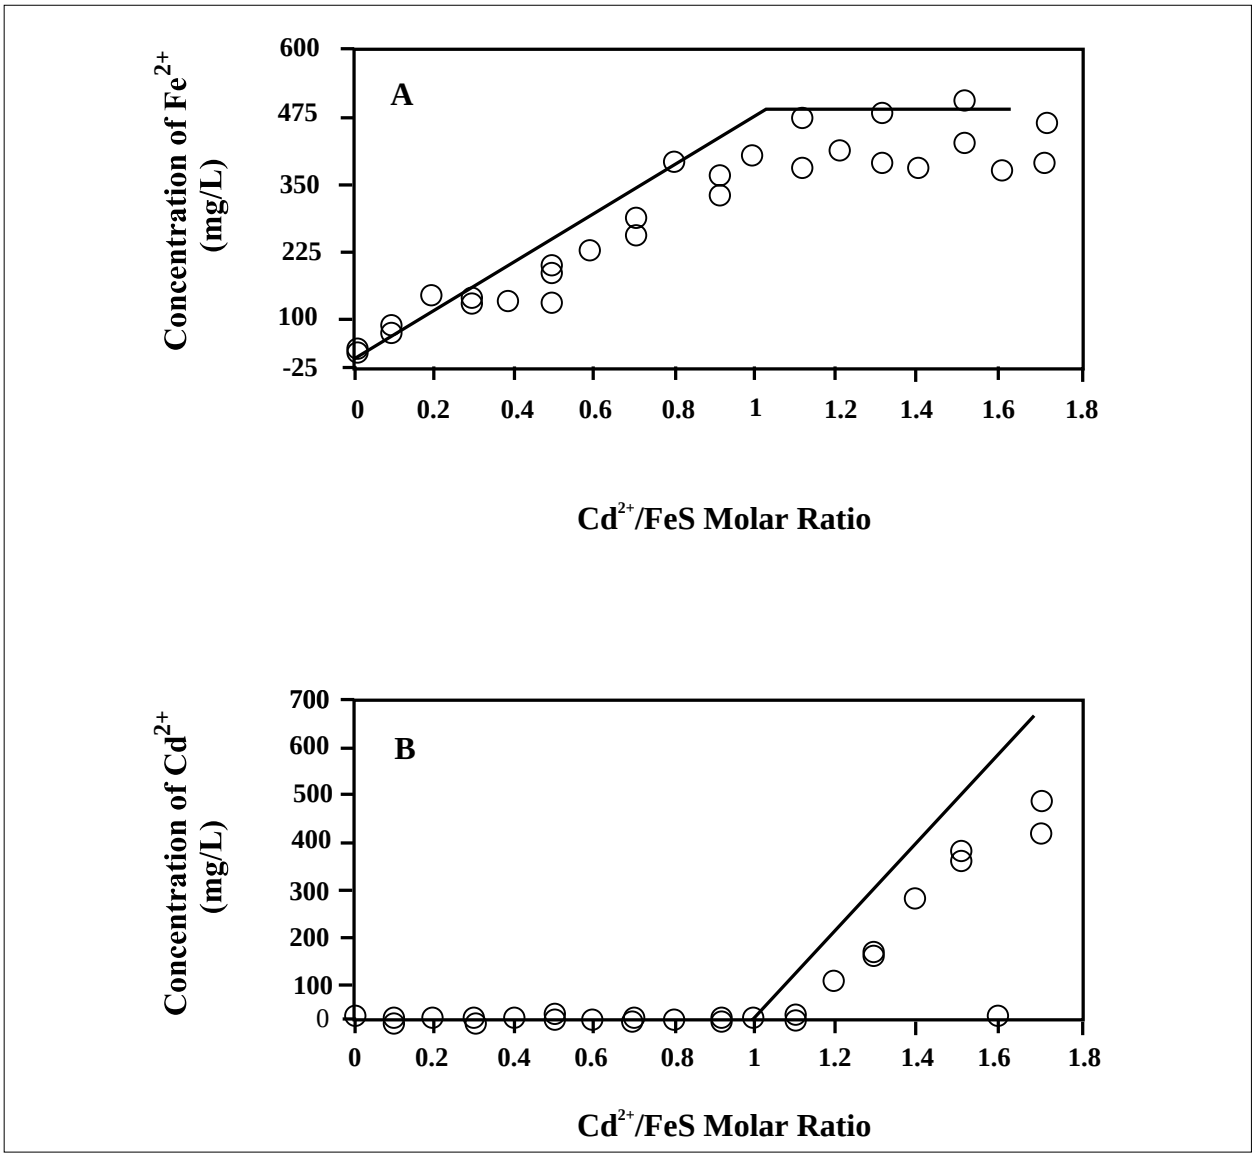

Figure 2-9. Concentrations of ionic iron (A) and cadmium (B) in the supernatant from titration of FeS by Cd^{2+} (Di Toro, unpublished data). The solid line represents the result expected from theory.

this causes the solid-phase iron sulfide to dissolve, releasing sulfide that is available for formation of cadmium sulfide. The reaction is

$$Cd^{2+} + FeS(s) \rightarrow CdS(s) + Fe^{2+} \quad (2\text{-}2)$$

Cadmium titrations with amorphous FeS and with sediments were performed to examine this possibility.

2.2.2.1 *Amorphous FeS*

A direct test of the extent to which this reaction takes place was performed (Di Toro et al., 1990). A quantity of freshly precipitated iron sulfide was titrated by adding dissolved cadmium. The resulting aqueous cadmium activity, measured with the cadmium electrode, versus the ratio of cadmium added $[Cd_A]$ to the amount of FeS initially present $[FeS(s)]_i$ is shown in Figure 2-8. The plot of dissolved cadmium versus cadmium added illustrates the increase in dissolved cadmium that occurs near $[Cd_A]/[FeS(s)]_i = 1$. It is interesting to note that these displacement reactions among metal sulfides have been observed by other investigators (Phillips and Kraus, 1965). The reaction was also postulated by Pankow (1979) to explain an experimental result involving copper and synthetic FeS.

These experiments plainly demonstrate that solid-phase amorphous iron sulfide can be readily displaced by adding cadmium. As a consequence, the source of available sulfide must be taken into account when evaluating the relationship between solid-phase and aqueous-phase cadmium in sediments.

A direct confirmation that the removal of cadmium was through the displacement of iron sulfide is shown in Figure 2-9. The supernatant from a titration of FeS by Cd^{2+} was analyzed for both iron and cadmium. The solid lines are the theoretical expectations based on the stoichiometry of the reaction.

2.2.2.2 *Sediments*

A similar titration procedure has been used to evaluate the behavior of sediments taken from four different marine environments: sediments from Black Rock Harbor and the Hudson River, and the sediments from Long Island Sound and Ninigret Pond used in the toxicity tests (Di Toro et al., 1990). The binding capacity for cadmium is estimated by extrapolating a straight line fit to the dissolved cadmium data. The equation is

$$[\Sigma Cd(aq)] = \max \{m([Cd_A] - [Cd_B])\} \quad (2\text{-}3)$$

where $[\Sigma Cd(aq)]$ is the total dissolved cadmium, $[Cd_A]$ is the cadmium added, $[Cd_B]$ is the bound cadmium, and m is the slope of the straight line. The different sediments exhibit quite different

Table 2-1. Cadmium binding capacity and AVS of sediments

Sediment	Initial AVS[a] (μmol/g)	Final AVS[b] (μmol/g)	Cd Binding Capacity[c] (μmol/g)
Black Rock Harbor	175 (41)	—	114(12)
Hudson River	12.6 (2.80)	—	8.58 (2.95)
LI Sound[d]	15.9 (3.30)	13.9 (6.43)	4.57 (2.52)

binding capacities for cadmium, listed in Table 2-1, ranging from approximately 1 μmol/g to more than 100 μmol/g. The question as to whether this binding capacity is explained by the solid-phase sulfide present in the samples is addressed in subsequent sections of this document.

2.2.3 *Correlation to Sediment AVS*

The majority of sulfide in sediments is in the form of iron monosulfides (mackinawite and greigite) and iron bisulfide (pyrite), of which the former is the most reactive. These sediment sulfides can be classified into three broad classes that reflect the techniques used for quantification (Berner, 1967; Goldhauber and Kaplan, 1974; Morse et al., 1987). The most labile fraction, AVS, is associated with the more soluble iron monosulfides. The more resistant sulfide mineral phase, iron pyrite, is not soluble in the cold acid extraction used to measure AVS. Neither is the third compartment, organic sulfide, which is associated with the organic matter in sediments (Landers et al., 1983).

The possibility that acid volatile sulfide is a direct measure of the solid-phase sulfide that reacts with cadmium is examined in Table 2-1, which lists the sediment-binding capacity for cadmium and the measured AVS for each sediment, and in Figure 2-10, which indicates the initial AVS concentration. The sediment cadmium-binding capacity appears to be somewhat less than the initial AVS for the sediments tested. However, a comparison between the initial AVS of the sediments and that remaining after the cadmium titration is completed suggests that some AVS is lost during the titration experiment (Table 2-1). In any case, the covariation of sediment-binding capacity and AVS is clear. This suggests that

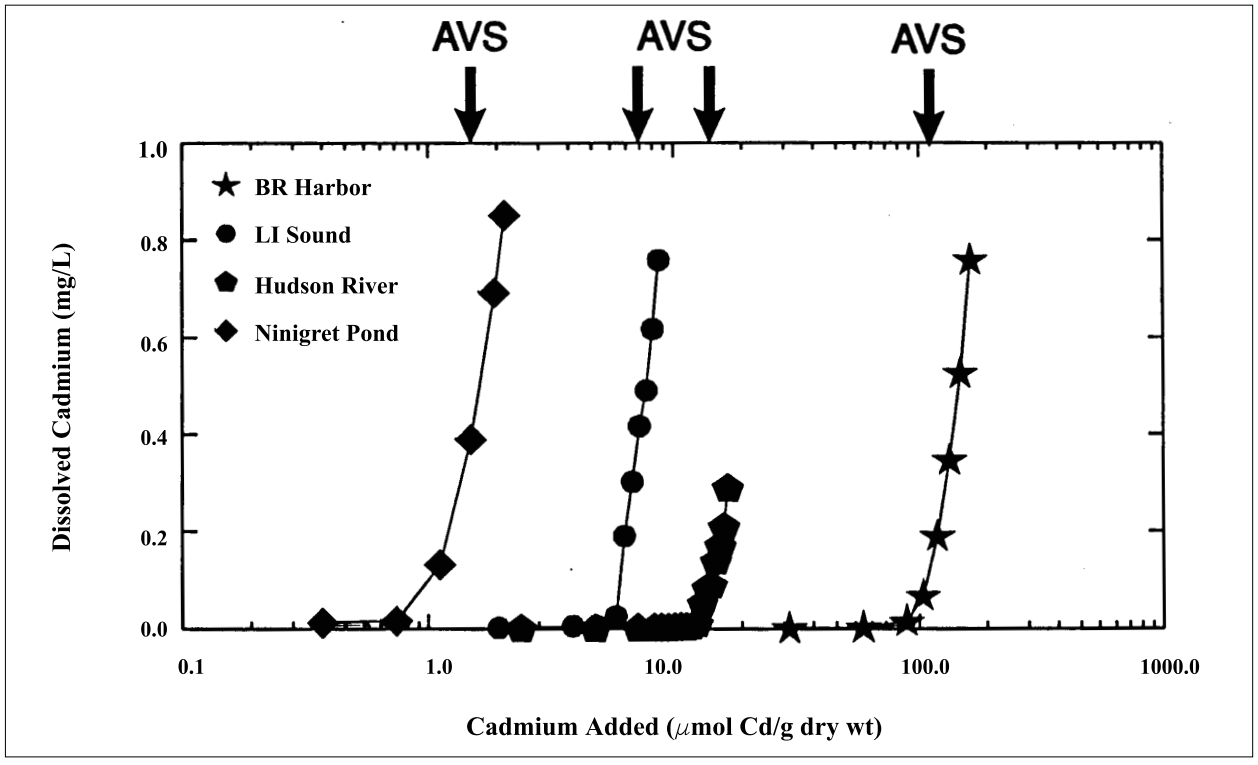

Figure 2-10. Cadmium titration of sediments from Black Rock Harbor, Long Island Sound, Hudson River, and Ninigret Pond. Cadmium added per unit dry weight of sediment versus dissolved cadmium. Arrows are the measured AVS concentrations for the four sediments (figure from Di Toro et al., 1990).

Table 2-2. Metal sulfide solubility products and ratios

Metal Sulfide	$\text{Log}_{10}K_{sp,2}$ [a]	$\text{Log}_{10}K_{sp}$ [b]	$\text{Log}_{10}(K_{MS}/K_{FeS})$
FeS	−3.64	−22.39	—
NiS	−9.23	−27.98	−5.59
ZnS	−9.64	−28.39	−6.00
CdS	−14.10	−32.85	−10.46
PbS	−14.67	−33.42	−11.03
CuS	−22.19	−40.94	−18.55
Ag_2S	−36.14	−54.71	−32.32

[a]Solubility products, $K_{sp,2}$ for the reaction $M^{2+} + HS^- \leftrightarrow MS(s) + H^+$ for FeS (mackinawite), NiS (millerite), and CdS (greenockite) from Emerson et al. (1983). Solubility products for ZnS (wurtzite), PbS (galena), CuS (covellite), and Ag_2S (acanthite) and $pK_2 = 18.57$ for the reaction $HS^- \leftrightarrow H^+ + S^{2-}$ from Schoonen and Barnes (1988).
[b]K_{sp} for the reaction $M^{2+} + S^{2-} \leftrightarrow MS(s)$ is computed from log $K_{sp,2}$ and pK_2.

measurement of AVS is the proper quantification of the solid-phase sulfides that can be dissolved by the addition of ionic cadmium. The chemical basis for this is examined below.

2.2.4 *Solubility Relationships and Displacement Reactions*

Iron monosulfide, FeS(s), is in equilibrium with aqueous-phase sulfide and iron via the reaction

$$FeS(s) \leftrightarrow Fe^{2+} + S^{2-} \quad (2\text{-}4)$$

If cadmium is added to the aqueous phase, the result is

$$Cd^{2+} + FeS(s) \leftrightarrow Cd^{2+} + Fe^{2+} + S^{2-} \quad (2\text{-}5)$$

As the cadmium concentration increases, $[Cd^{2+}][S^{2-}]$ will exceed the solubility product of cadmium sulfide and CdS(s) will start to form. Since the cadmium sulfide is more insoluble than iron monosulfide, FeS(s) should start to dissolve in response to the lowered sulfide concentration in the interstitial water. The overall reaction is

$$Cd^{2+} + FeS(s) \leftrightarrow CdS(s) + Fe^{2+} \quad (2\text{-}6)$$

The iron in FeS(s) is displaced by cadmium to form soluble iron and solid cadmium sulfide, CdS(s). The consequence of this replacement reaction can be seen using the analysis of the M(II)-Fe(II)-S(-II) system with both MS(s) and FeS(s) presented in Di Toro et al. (1992). M^{2+} represents any divalent metal that forms a sulfide that is more insoluble than FeS. If the added metal, $[M]_A$, is less than the AVS present in the sediment then the ratio of metal activity to total metal in the sediment–interstitial water system is less than the ratio of the MS to FeS solubility product constant

$$\{M^{2+}\}/[M]_A < K_{MS}/K_{FeS} \quad (2\text{-}7)$$

This general result is independent of the details of the interstitial water chemistry. In particular, it is independent of the Fe^{2+} activity. Of course, the actual value of the ratio $\{M^{2+}\}/[M]_A$ depends on aqueous speciation, as indicated by Equation 2-6. However, the ratio is still less than the ratio of the sulfide solubility products.

This is an important finding because the data presented in Section 2.1.1 indicate that toxicity is related to metal activity, $\{M^{2+}\}$. This inequality guarantees that the metal activity, in contrast to the total dissolved metal concentration, is regulated by the iron sulfide–metal sulfide system.

The metal sulfide solubility products and the ratios are listed in Table 2-2. For example, the ratio of cadmium activity to total cadmium is less

than $10^{-10.46}$. For nickel, the ratio is less than $10^{-5.59}$. By inference, this reduction in metal activity will occur for any other metal that forms a sulfide that is significantly more insoluble than iron monosulfide. The ratios for the other metals in Table 2-2 (Cu, Pb, Ag, and Zn) indicate that metal activity for these metals will be very small in the presence of excess AVS.

2.2.5 *Application to Mixtures of Metals*

A conjecture based on the sulfide solubility products for the metals listed in Table 2-2 is that the sum of the molar concentrations of metals should be compared with AVS. Because all these metals have lower sulfide solubility parameters than FeS, they would all exist as metal sulfides if their molar sum (and using [Ag]/2 because it is monovalent) is less than the AVS. For this case

$$\Sigma_i[M_T]_i < AVS \qquad (2\text{-}8)$$

no metal toxicity would be expected, where $[M_T]_i$ is the total cold acid extractable i^{th} metal molar concentration in the sediment (divided by 2 for silver). On the other hand, if their molar sum is greater than the AVS concentration, then a portion of the metals with the largest sulfide solubility parameters would exist as free metal and potentially cause toxicity. For this case the following would be true

$$\Sigma_i[M_T]_i > AVS \qquad (2\text{-}9)$$

These two equations are precisely the formulas that could be employed to determine the extent of metal toxicity in sediments assuming additive behavior and neglecting the effect of partitioning to other sediment phases. Whether the normalized sum is less than or greater than 1.0 discriminates between nontoxic and potentially toxic sediments. The additivity does not come from the nature of the mechanism that causes toxicity. Rather, it results from the equal ability of the metals to form metal sulfides with the same stoichiometric ratio of M and S (except silver).

The appropriate quantity of metals to use in the metals and AVS comparison is referred to as SEM, that is, the metal extracted with the cold acid used in the AVS procedure. This is the appropriate quantity to use because some metals form sulfides that are not labile in the AVS extraction (e.g., nickel, copper). If a more rigorous extraction were used to increase the fraction of metal extracted that did not also capture the additional sulfide extracted, then the sulfide associated with the additional metal release would not be quantified. This would result in an erroneously high metal value relative to AVS (Di Toro et al., 1992).

The above discussion is predicated on the assumption that all the metal sulfides behave similarly to cadmium sulfide. Furthermore, it has been assumed that only acid-soluble metals are reactive enough to affect the free metal activity. That is, the proper metal concentration to be used is the SEM. Both of these hypotheses were tested directly with benthic organisms using sediment toxicity tests. Results of these sediment-spiking experiments with cadmium, copper, lead, nickel, silver, zinc, and a mixture of these metals are presented in Section 3.

Section 3

Toxicity of Metals in Sediments

3.1 General Information

This section summarizes data from acute and chronic toxicity tests that demonstrate that absence of sediment toxicity caused by metals can be predicted by (a) the use of interstitial water concentrations of metals or (b) comparison of molar concentrations of AVS and SEM. Furthermore, they demonstrate that use of $(\Sigma SEM\text{-}AVS)/f_{OC}$ reduces the variability associated with prediction of when sediments will be toxic. The ability to predict toxicity of metals in sediments, through a fundamental understanding of chemical bioavailability, is demonstrated using results of toxicity tests with benthic organisms in spiked or field sediments. A wide variety of individual benthic species having different habitat requirements have been tested in 10-day experiments in spiked and field sediments, including the following: an oligochaete (*Lumbriculus variegatus*), polychaetes (*Capitella capitata* and *Neanthes arenaceodentata*), amphipods (*A. abdita, R. hudsoni, Leptocheirus plumulosus,* and *Hyalella azteca*), a harpacticoid copepod (*Amphiascus tenuiremis*), a midge (*Chironomus tentans*), and a gastropod (*Helisoma* sp.). In addition, the approach was tested in life-cycle tests with *L. plumulosus* and *C. tentans*. Many other benthic species were tested in freshwater and saltwater benthic colonization studies.

3.1.1 *Terminology*

Early studies on use of AVS in prediction of biological effects (e.g., Di Toro et al., 1990) involved the ratio of SEM to AVS, expressed as SEM/AVS. The ratio appeared more useful in the early laboratory tests because it caused concentration-response data from spiking experiments with different sediments to fall on the same line (Di Toro et al., 1990, 1992; Casas and Crecelius, 1994; Pesch et al., 1995; Berry et al., 1996). Later studies, however, showed several advantages to the use of the difference, expressed as SEM-AVS (Hansen et al., 1996a). The two expressions—SEM/AVS ≤ 1 and SEM-AVS ≤ 0—are functionally equivalent. Both indicate an excess of AVS over SEM. The advantages to using SEM-AVS are that it does not get very large when AVS is very low (as the ratio does), and that it can be used to develop partitioning relationships that include other phases, such as total organic carbon (TOC) (see Section 3.4; see also the discussion in Section 3.2.5). For these reasons, the use of the SEM-AVS difference is the recommended method, and it will be used throughout the rest of this document except in the discussion of the historical development of AVS theory that follows. In the ensuing discussion, SEM/AVS ratios are presented because they were originally presented in this form.

3.2 Predicting Metal Toxicity: Short-Term Studies

3.2.1 *Spiked Sediments: Individual Experiments*

A key to understanding the bioavailability of sediment-associated contaminants was provided by Adams et al. (1985), who observed that the effects of kepone, a nonionic organic pesticide, were similar across sediments when toxicity was related to interstitial water concentrations. Swartz et al. (1985) and Kemp and Swartz (1986) first observed that metal concentrations in interstitial waters of different sediments were correlated with observed biological effects. However, as opposed to the situation for nonionic organic chemicals and organic carbon (see Di Toro et al., 1991), the sediment-partitioning phases that controlled interstitial water concentrations of metals and metal-induced sediment toxicity were initially not apparent.

Di Toro et al. (1990) first investigated the significance of sulfide partitioning in controlling metal bioavailability and metal-induced toxicity in marine sediments spiked with cadmium. In these experiments, the operational definition of Cornwell and Morse (1987) was used to identify that fraction of amorphous sulfide, or AVS, available to interact with cadmium in the sediments. Specifically, AVS was defined as the sulfide liberated from wet sediment when treated with cold 1N HCl acid. Di Toro et al. (1990) found that, when expressed on a dry weight basis, the toxicity of cadmium in sediments in 10-day tests with the amphipods *R. hudsoni* or *A. abdita* was sediment specific (Figure 3-1A; from Di Toro et al., 1990).

Toxicity increased with increasing cadmium concentration, but the concentration-response relationships were different for each sediment. Thus, it would not be possible to predict whether a particular sediment would be toxic or not. If the cadmium concentration is expressed on an interstitial water basis (Figure 3-1B), however, concentration response is not sediment specific. Similar results are observed when cadmium concentration is expressed as SEM/AVS (Figure 3-1C). Note that when the ratio of μmol Cd/μmol AVS was less than 1.0, the sediments were not toxic, and when the ratio was greater than 1.0, the sediments became increasingly toxic. Studies by Carlson et al. (1991) with cadmium-spiked freshwater sediments yielded similar results; when there was more AVS than total cadmium, significant toxicity was not observed in 10-day tests with an oligochaete (*L. variegatus*) or snail (*Helisoma* sp). Di Toro et al. (1992), in their studies with nickel-spiked sediments using *A. abdita* and field sediments contaminated with cadmium and nickel using the freshwater amphipod *H. azteca*, provided further support to the importance of AVS in controlling metal bioavailability in sediments. These studies suggested that it may be feasible to derive an ESB for mixtures of metals by direct comparison of molar AVS concentrations to the molar sum of the concentrations of cationic metals (specifically, cadmium, copper, lead, nickel, and zinc) extracted with the AVS (i.e., ΣSEM). They observed that expression of metals concentrations based on the sum of SEM concentrations is required because a significant amount of nickel sulfide is not completely soluble in the AVS extraction. Hence, AVS must be used as the measure of reactive sulfide and the sum of SEM as the measure of total reactive metal.

Casas and Crecelius (1994) further explored the relationship of SEM and AVS, interstitial water concentrations, and toxicity by conducting 10-day toxicity tests with the marine polychaete *C. capitata* exposed to sediments spiked with zinc, lead, and copper. As was true in earlier studies, elevated interstitial water metal concentrations were observed only when SEM concentrations exceeded those of AVS. Sediments were not toxic when SEM concentrations were less than AVS and when the concentrations in interstitial water were less than the water-only LC50 values. Green et al. (1993) reported results of another spiking experiment supporting this general EqP approach to deriving an ESB for metals. In their study, metal–sulfide partitioning was not directly quantified, but it was found that toxicity of cadmium-spiked marine sediments to the meiobenthic copepod *A. tenuiremis* was predictable based on interstitial water, but not sediment dry weight cadmium concentrations. Further spiking experiments by Pesch et al. (1995) demonstrated that 10-day survival of the marine polychaete *N. arenceodentata* was comparable to controls in cadmium- or nickel-spiked sediments with more AVS than SEM.

Berry et al. (1996) described experiments in which *A. abdita* were exposed for 10 days to two or three sediments spiked either singly, or in combination, with cadmium, copper, lead, nickel, and zinc. As in previous studies, significant toxicity to the amphipod did not occur when AVS concentrations exceeded those of SEM. They compared observed mortality with interstitial water metal concentrations expressed as interstitial water toxic units (IWTUs)

$$IWTU = [M_d]/LC50 \quad (3\text{-}1)$$

where $[M_d]$ is the dissolved metal concentration in the interstitial water, and the LC50 is the concentration of the metal causing 50% mortality of the test species in a water-only test. If interstitial water exposure in a sediment test is indeed equivalent to that in a water-only test, then 1.0 IWTU should result in 50% mortality of the test animals. Berry et al. (1996) reported that significant (>24%) mortality of the saltwater amphipod occurred in only 3.0% of sediments with less than 0.5 IWTU, whereas samples with greater than 0.5 IWTUs were toxic 94.4% of the time. Berry et al. (1996) also made an important observation relative to interstitial water metal chemistry in their mixed-metals test; chemical equilibrium calculations suggest that the relative affinity of metals for AVS should be silver> copper>lead>cadmium>zinc>nickel (Emerson et al., 1983; Di Toro et al., 1992); hence, the appearance of the metals in interstitial water as AVS is exhausted should occur in an inverse order. For example, zinc would replace nickel in a monosulfide complex and nickel would be liberated to the interstitial water, and so on. Berry et al. (1996) observed this trend in sediments spiked with cadmium, copper, nickel, and zinc (Figure 3-2). Furthermore, an increase in the concentration of a metal in a sediment with a low sulfide solubility product constant (K_{sp}) theoretically would displace a previously unavailable and nontoxic metal with a higher K_{sp}, making that metal available to bind to other sediment phases or enter interstitial water to become toxic. Berry et al. (1999) exposed the saltwater amphipod *A. abdita* to sediments spiked with silver. When AVS was detected in the sediments, they were not toxic and interstitial water contained no detectable silver. For sediments that contain no detectable AVS,

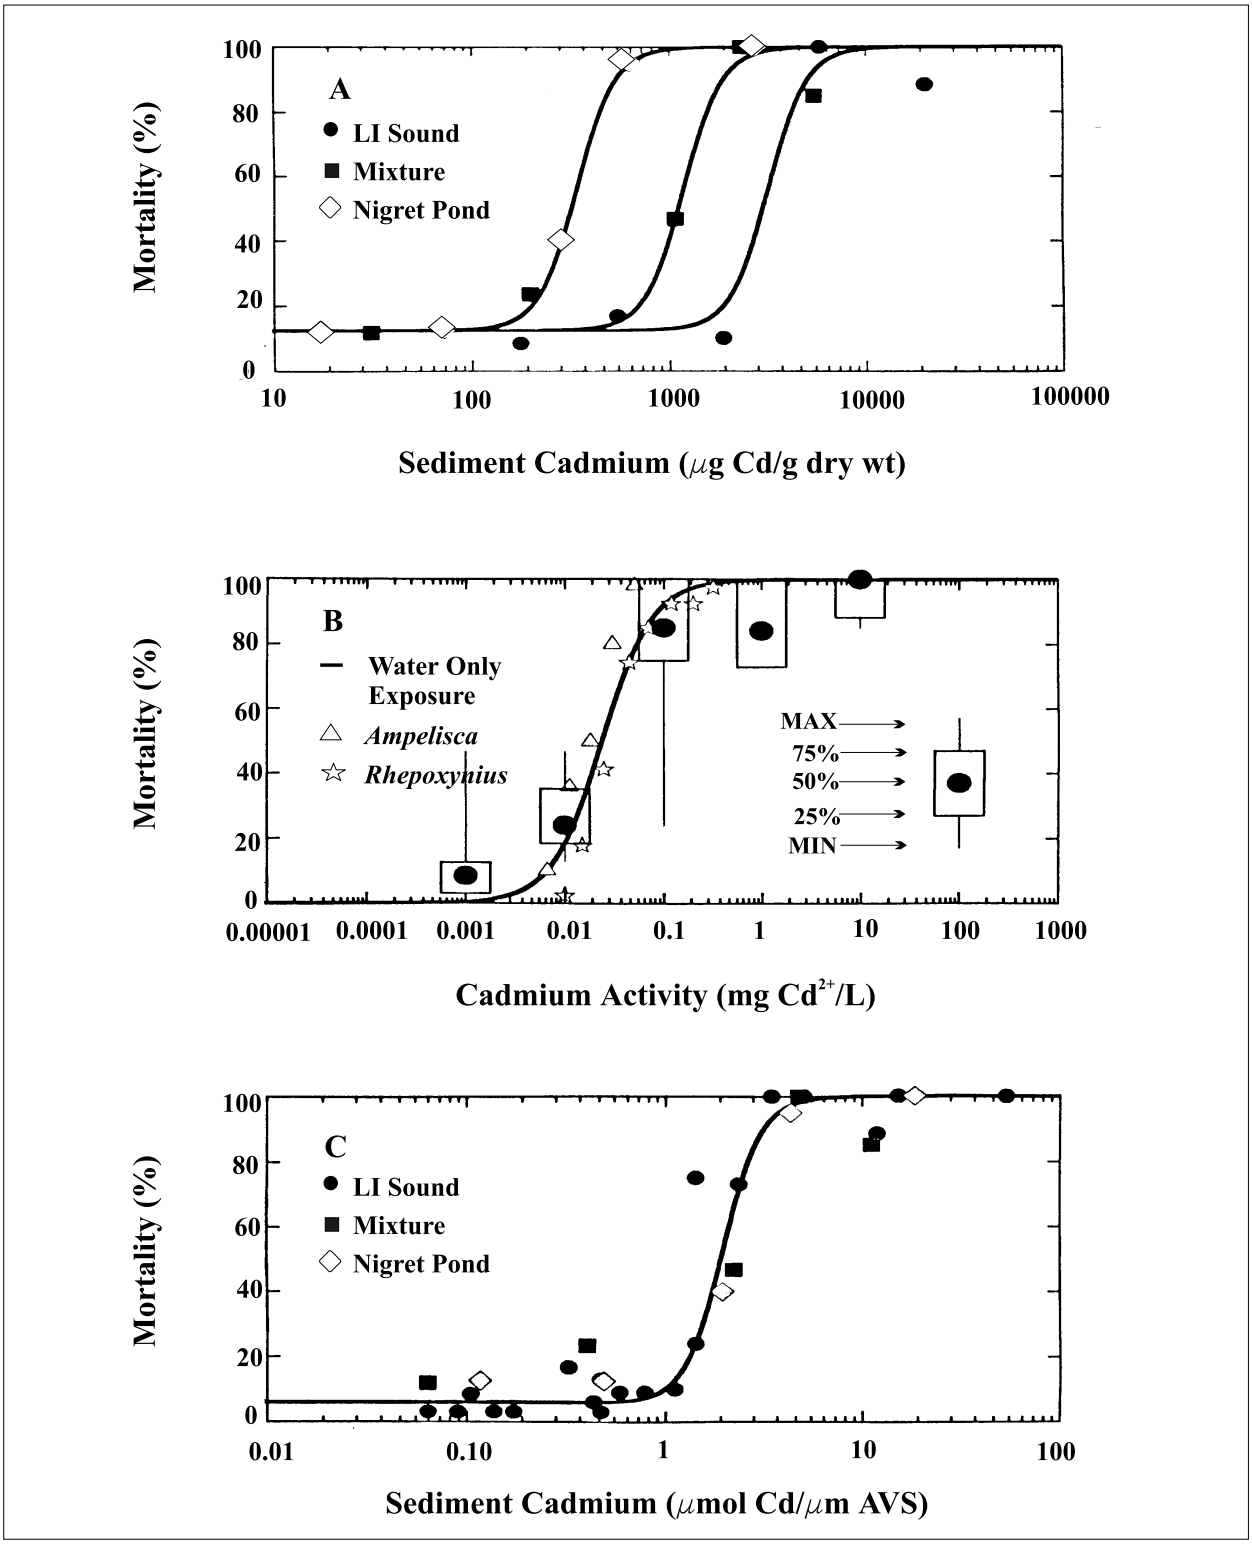

Figure 3-1. Percentage mortality of amphipods (*Ampelisca abdita* and *Rhepoxynius hudsoni*) exposed to sediments from Long Island Sound, Ninigret Pond, and a mixture of these two sediments as a function of the sum of the concentrations of metals in sediments expressed as: (A) dry weight, (B) interstitial water cadmium activity, and (C) the sediment cadmium/AVS ratio (figures from Di Toro et al., 1990).

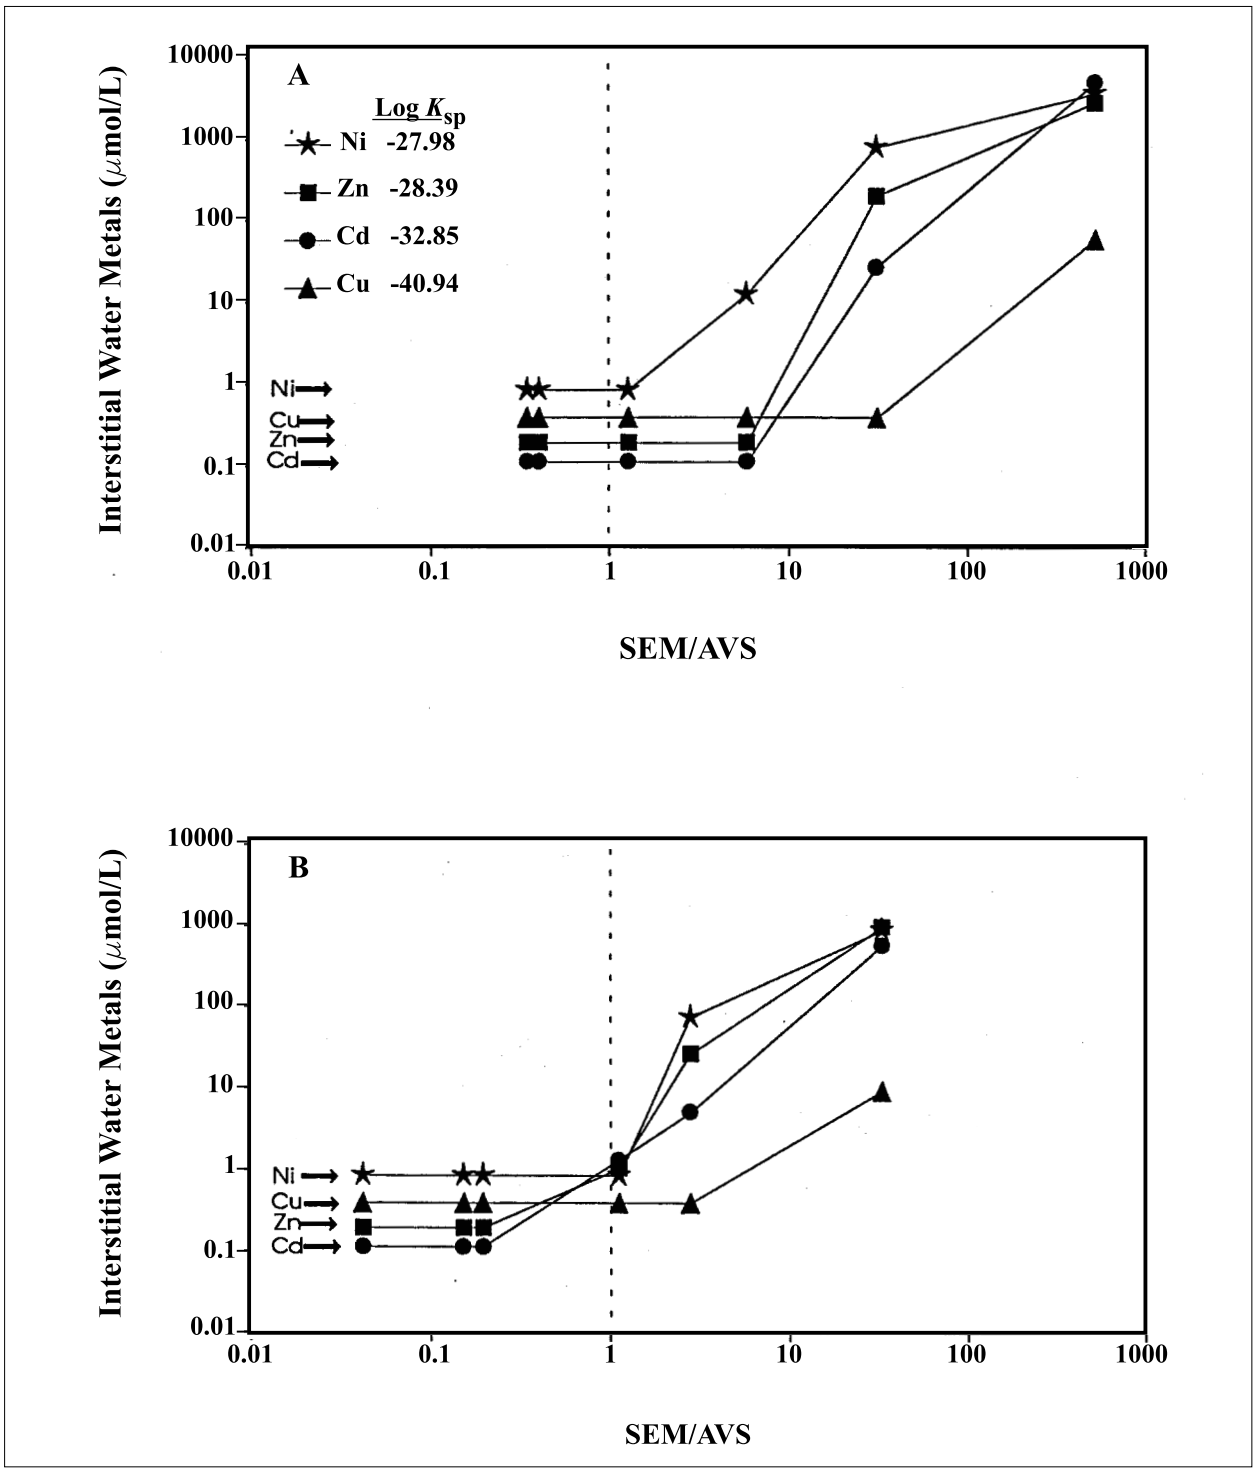

Figure 3-2. **Concentrations of individual metals in interstitial water of sediments from Long Island Sound (A) and Ninigret Pond (B) in the mixed metals experiment as a function of SEM/AVS ratio. Concentrations below the interstitial water detection limits, indicated by arrows, are plotted at one-half the detection limit. K_{SP} is the sulfide solubility product constant (figures from Berry et al., 1996).**

any SEM silver that is detected is dissolved interstitial silver, because silver sulfide and silver chloride precipitate are not extracted using the standard AVS procedure.

3.2.2 *Spiked Sediments: All Experimental Results Summarized*

This summary includes data from amphipods exposed in 10-day toxicity tests to saltwater sediments spiked with cadmium, copper, lead, nickel, silver, or zinc and their mixtures (Di Toro et al., 1990; Berry et al., 1996, 1999); polychaetes exposed to sediments spiked with cadmium, copper, lead, nickel, or zinc (Casas and Crecelius, 1994; Pesch et al., 1995); copepods exposed to sediments spiked with cadmium (Green et al., 1993; measured interstitial cadmium but not AVS); and freshwater tests using oligochaetes and snails exposed to sediments spiked with cadmium (Carlson et al., 1991). Seven species (freshwater and saltwater) and sediments from seven different locations were described. AVS concentrations ranged from 1.9 to 65.7 μmol/g dry weight, and TOC ranged from 0.15% to 10.6% in these sediments.

Overall, the results of these experiments demonstrate that predictions of the toxicity of sediments spiked with metals using the total metal concentration on a dry weight basis are not based on scientific theories of bioavailability and will have considerable error (Figures 3-3A and 3-4A). Sediments having $\leq$24% mortality are considered nontoxic as defined by Berry et al. (1996), which is indicated by the horizontal line in Figure 3-3. Furthermore, the concentration range where it is 90% certain that the sediment may be either toxic or nontoxic, shown as dashed lines in Figure 3-3, is almost two orders of magnitude for dry weight metals, a little over an order of magnitude for IWTUs, and only a half order of magnitude for SEM/AVS (see Section 3.4 for a description of the derivation of the uncertainty limits). The uncertain range for dry weight metals is approximately equal to the sum of the uncertainty range for SEM/AVS plus the range in the AVS concentrations of the spiked sediments in the database. If sediments with a lower AVS concentration had been tested, effects would have occurred at a lower dry weight concentration, and if sediments with lower or higher AVS concentrations had been tested, the uncertainty range would increase. Importantly, the uncertainty range for IWTUs or SEM/AVS would likely not be altered.

Even given the above, it is visually tempting to select a cutoff at a dry weight concentration of 1.0 μmol/g to indicate the separation of sediments that are toxic or nontoxic. This would be inappropriate because toxicity of metals in sediments when concentrations are expressed as dry weights have been shown to be sediment specific (Figure 3-1A). Also, had sediments with lower or higher AVS concentrations been tested, the cutoff would have been at lower or higher dry weight concentrations. However, to further demonstrate the risks of establishing a dry weight cutoff, the data from the 184 spiked sediments in Figure 3-3 were re-analyzed. A visually based cutoff of 1.0 μmol/g dry weight, and theoretically based cutoffs of 0.5 IWTU and 1.0 SEM/AVS were selected. Sediment concentrations were numerically ordered. Those with concentrations less than the cutoffs were divided into three groups containing approximately the same number of sediments (15, 22, or 25 sediments per group for dry weight metal concentrations, IWTUs, and SEM/AVS, respectively). Similarly, sediments containing greater concentrations were divided into six groups (21, 16, or 14 sediments per group for dry weight metal concentrations, IWTUs, and SEM/AVS, respectively). The percentages of nontoxic ($\leq$24% mortality) and toxic (>24% mortality) sediments in each group are plotted in a stacked bar plot (Figure 3-4). Not surprisingly, because the distribution was visually selected, most sediments having less than 1.0 μmol/g dry weight metal were not toxic. The same was true for the toxicologically selected cutoffs of 0.5 IWTUs and SEM/AVS ratios of 1.0. The advantage of using IWTUs and SEM/AVS becomes more clear when the sediments above the cutoffs are considered. For dry weight metal concentrations, more of the sediments in the first four sediment groups (up to 26.8 μmol/g dry weight) were nontoxic than were toxic. It was only in the two sediment groups that contained the highest concentrations, >27.6 μmol/g dry weight, that toxic sediments predominated after the first two sediment groups. In contrast, toxic sediments predominated in only the first two sediment groups above the IWTU cutoff and after the first sediment group above the SEM/AVS ratio cutoff.

In some cases, the dry weight metal concentrations required to cause acute mortality in these experiments were very high relative to those often suspected to be of toxicological significance in field sediments (e.g., Figures 3-1A and 3-3A). This has sometimes been interpreted as a limitation of the use of SEM and AVS to predict metal-induced toxicity. However, the range of AVS in these sediments spiked with metals is similar to

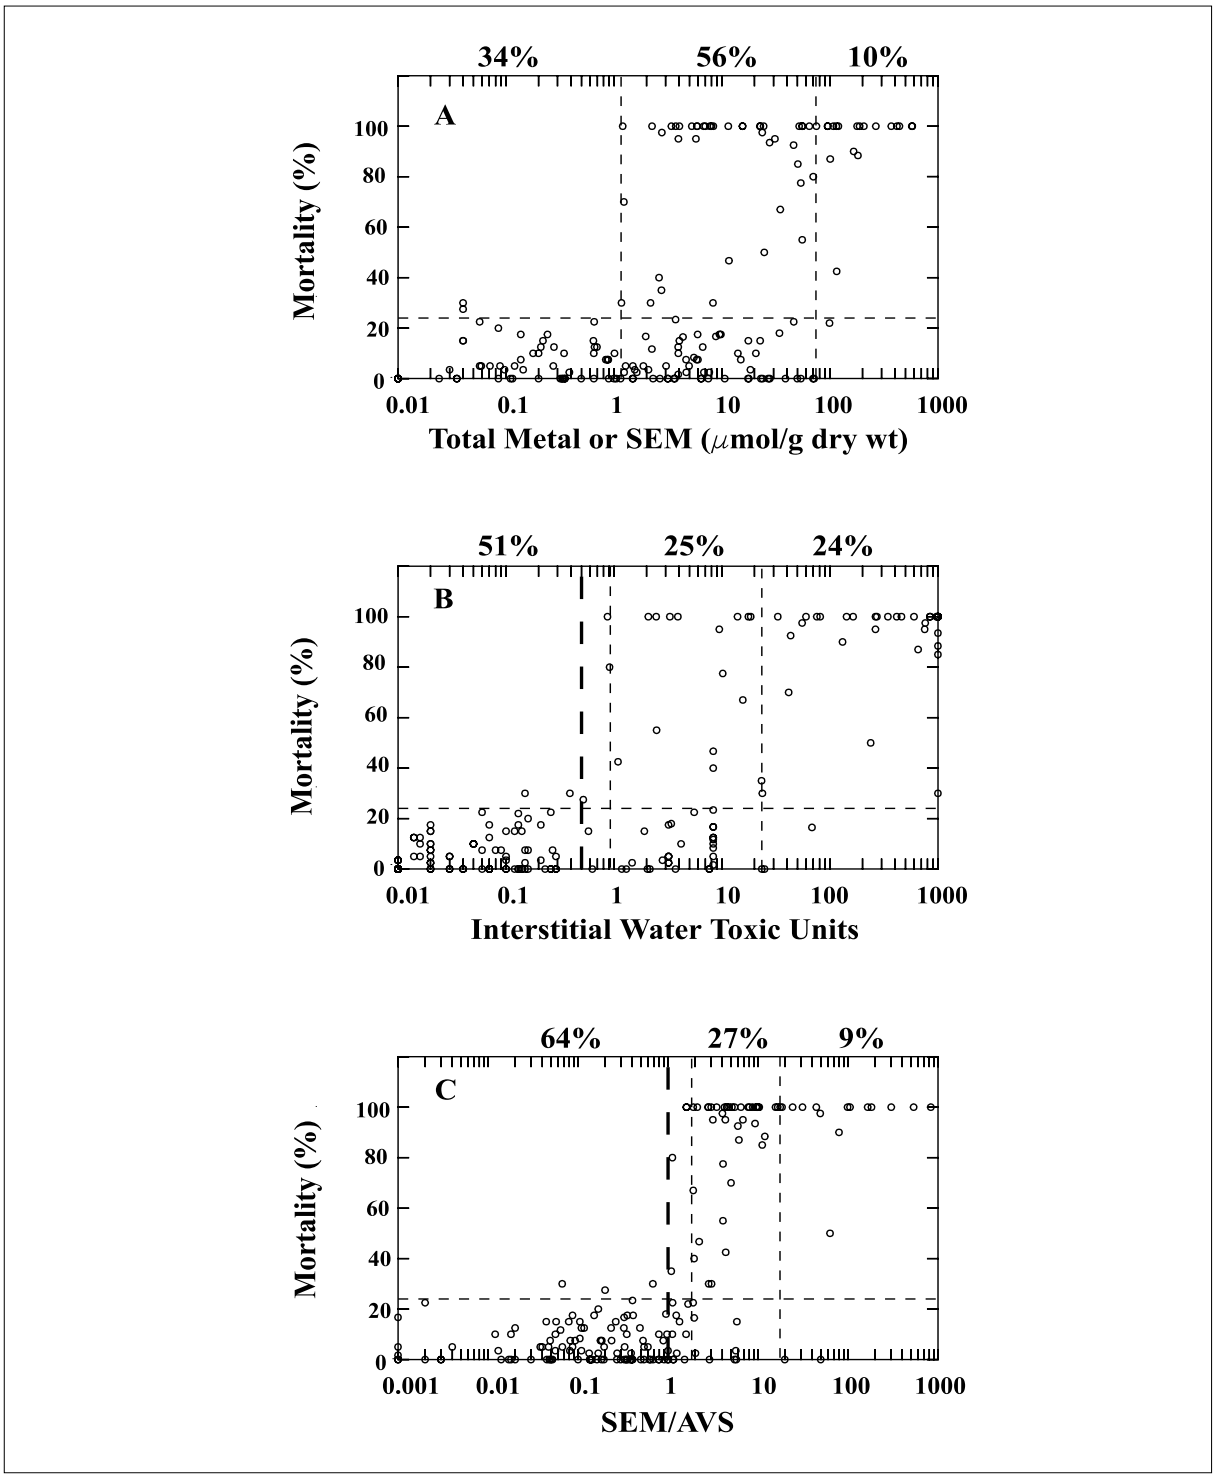

Figure 3-3. Percentage mortality of freshwater and saltwater benthic species in 10-day toxicity tests in sediments spiked with individual metals (Cd, Cu, Pb, Ni, Ag, or Zn) or a metal mixture (Cd, Cu, Ni, and Zn). Mortality is plotted as a function of: (A) the sum of the concentrations of the respective metal or metal mixture in μmol metal per gram dry weight of sediment; (B) IWTU; and (C) SEM/AVS ratio. Data below the detection limits are plotted at IWTU=0.01 and SEM/AVS=0.001. Heavy dashed lines are the theoretically based cutoffs of 0.5 IWTU and a SEM/AVS ratio of 1.0. Light vertical dashed lines are the 90% uncertainty bound limits derived as in Section 3.4. The percentage of the total number of sediments (n = 184) within the bounded limits is provided above each of the three panels for the purpose of comparison (silver data from Berry et al., 1999; all other data modified after Berry et al., 1996).

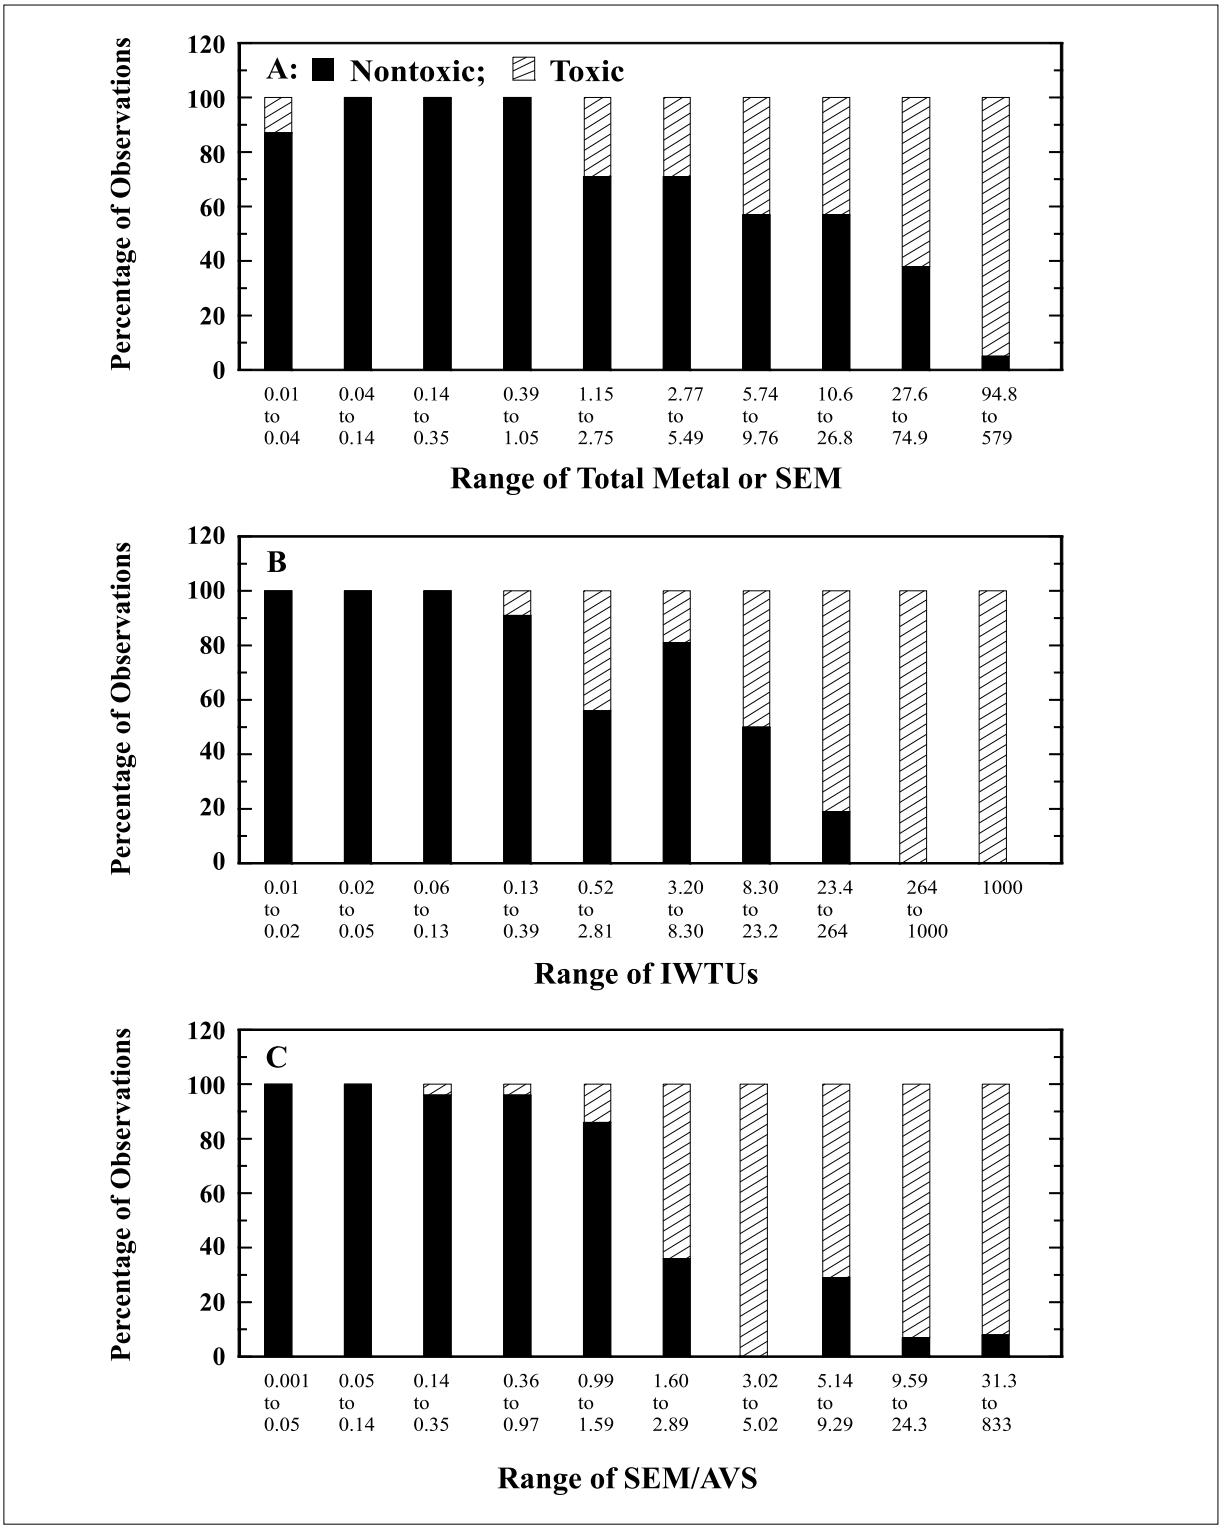

Figure 3-4. Percentage of the 184 spiked sediments from Figure 3-3 that were nontoxic or toxic over various intervals of (A) concentrations of metal based on sediment dry weight (μmol/g), (B) IWTU, and (C) SEM/AVS.

that of sediments commonly occurring in the field. The important point here is that even a sediment with only a moderate concentration of AVS has a considerable capacity for sequestering metals as a metal sulfide, a form that is not bioavailable (Di Toro et al., 1990).

In contrast, the combined data from all available freshwater and saltwater spiked-sediment experiments support the use of IWTUs to predict mortality of benthic species in spiked-sediment toxicity tests (Figure 3-3B). Mortality in these experiments was sediment independent when plotted against IWTUs. Sediments with IWTUs of <0.5 were generally not toxic. Of the 96 sediments with IWTUs <0.5, 96.9% were not toxic, whereas 76.4% of the 89 sediments with IWTUs ≥0.5 were toxic (Table 3-1). This close relationship between IWTUs and sediment toxicity in sediments spiked with metals was also observed in studies with field sediments contaminated with metals (see Section 3.2.3 below), as well as sediments spiked with nonionic organic chemicals (Adams et al., 1985; Swartz et al., 1990; Di Toro et al., 1991), and field sediments contaminated with nonionic organic chemicals (Hoke et al., 1994; Swartz et al., 1994).

Table 3-1. Toxicity of sediments from freshwater and saltwater lab-spiked sediment tests, field locations, and combined lab-spiked and field sediment tests as a function of the molar concentrations of SEM and AVS (SEM/AVS or the SEM-AVS), interstitial water toxic units (IWTUs), and both SEM/AVS or SEM-AVS and IWTUs

			Percent of Sediments	
Study Type/Parameter	Value	n	Nontoxic[a]	Toxic[b]
Laboratory Spike:				
SEM/AVS or SEM-AVS[c]	≤1.0 or ≤0.0	101	98.0	2.0
	>1.0 or >0.0	95	26.3	73.7

	>1.0 or >0.0; ≥0.5	123	21.1	78.9

[a]Nontoxic sediments ≤24% mortality.
[b]Toxic sediments >24% mortality.
[c]An SEM/AVS ratio of ≤1.0 or an SEM-AVS difference of ≤0.0 indicates an excess of sulfide and probable nontoxic sediments. An SEM/AVS ratio of >1.0 or an SEM-AVS difference of >0.0 indicates an excess of metal and potentially toxic sediments.
[d]An IWTU of <0.5 indicates a probable nontoxic interstitial water concentration of less than one-half of the water-only LC50 of the same duration. An IWTU of ≥0.5 indicates a possibly toxic interstitial water concentration of greater than one-half of the water-only LC50 of the same duration.

Source: Modified from Hansen et al., 1996a.

The interstitial water metal concentrations in spiked-sediment studies were most often below the limit of analytical detection in sediments with SEM/AVS ratios below 1.0 (Berry et al., 1996). Above an SEM/AVS ratio of 1.0, the interstitial metals concentrations increased up to five orders of magnitude with increasing SEM/AVS ratio. This increase of several orders of magnitude in interstitial water metals concentration with an increase of only a factor of two or three in sediment concentration is the reason why mortality is most often complete in these sediments, and why the chemistry of anaerobic sediments controls the toxicity of metals to organisms living in aerobic microhabitats. It also explains why toxicities of different metals in the same sediment to different species when expressed on the basis of sediment metals concentration are so similar. Interstitial water metals were often below or near detection limits when SEM/AVS ratios were only slightly above 1.0, indicating the presence of other metal-binding phases in sediments.

The combined data from all available freshwater and saltwater spiked-sediment experiments also support the use of SEM/AVS ratios to predict sediment toxicity to benthic species in spiked-sediment toxicity tests. All tests yield similar results when mortality is plotted against SEM/AVS ratios (Figure 3-3C). Mortality in these experiments was sediment independent when plotted on an SEM/AVS basis. With the combined data, 98.0% of the 101 metals-spiked sediments with SEM/AVS ratios $\leq$1.0 were not toxic, whereas 73.7% of the 95 sediments with SEM/AVS ratios >1.0 were toxic (Table 3-1).

The overall data show that when both SEM/AVS ratios and IWTUs are used, predictions of sediments that would be toxic were improved. Of the 83 sediments with SEM/AVS ratios $\leq$1.0 and IWTUs <0.5, 97.6% were not toxic, whereas 85.9% of the 78 sediments with SEM/AVS ratios >1.0 and IWTUs $\geq$0.5 were toxic (Table 3-1).

These results show that SEM/AVS and IWTUs are accurate predictors of the absence of mortality in sediment toxicity tests; however, predictions of sediments that might be toxic are less accurate. The fact that a significant number of sediments (26.3%) tested had SEM/AVS ratios of >1.0 but were not toxic indicates that other binding phases, such as organic carbon (Mahony et al., 1996), may also control bioavailability in anaerobic sediments.

Organism behavior may also explain why some sediments with SEM/AVS ratios of >1.0 were not toxic. Many of the sediments that had the highest SEM/AVS ratios in excess of 1.0 that produced little or no mortality were from experiments using the polychaete *N. arenaceodentata* (see Pesch et al., 1995). In these experiments, this polychaete did not burrow into some of the test sediments with the highest concentrations, thereby limiting its exposure to the elevated concentrations of metals in the interstitial water and sediments. This same phenomenon may also explain the low mortality of snails, *Heliosoma* sp., in freshwater sediments with high SEM/AVS ratios. These snails are epibenthic and crawl onto the sides of test beakers to avoid contaminated sediments (G.L. Phipps, U.S. EPA, Duluth, MN, personal communication). Increased mortality was always observed in sediments with SEM/AVS ratios >5.9 in tests with the other five species.

Similarly, a significant number of sediments (23.6%) with $\geq$0.5 IWTUs were not toxic. This is likely the result of interstitial water ligands, which reduces the bioavailability and toxicity of dissolved metals; sediment avoidance by polychaetes or snails; or methodological problems in contamination-free sampling of interstitial water. Ankley et al. (1991) suggested that a toxicity correction for the hardness of the interstitial water for freshwater sediments is needed to compare toxicity in interstitial water with that in water-only tests. Absence of a correction for hardness would affect the accuracy of predictions of metal-induced sediment toxicity using IWTUs. Furthermore, a significant improvement in the accuracy of metal-induced toxicity predictions using IWTUs might be achieved if DOC binding in the interstitial water is taken into account. Green et al. (1993) and Ankley et al. (1991) hypothesized that increased DOC in the interstitial water reduced the bioavailability of cadmium in sediment exposures, relative to the water-only exposures. Green et al. (1993) found that the LC50 value for cadmium in an interstitial water exposure without sediment was more than twice that in a water-only exposure, and that the LC50 value for cadmium in interstitial water associated with sediments was more than three times that in a water-only exposure.

3.2.3 *Field Sediments*

In addition to short-term laboratory experiments with spiked sediments, there have been several published studies of laboratory toxicity tests with metal-contaminated sediments from the field. Ankley et al. (1991) exposed *L. variegatus* and the amphipod *H. azteca* to 17 sediment samples along a gradient of cadmium and nickel contamination from a freshwater/

estuarine site in Foundry Cove, NY. In 10-day toxicity tests, *H. azteca* mortality was not significantly different from controls in all sediments where SEM (cadmium plus nickel) was less than AVS. Mortality was greater than controls only in sediments with more SEM than AVS. *L. variegatus* was far less sensitive to the sediments than *H. azteca*, which correlates with the differential sensitivity of the two species in water-only tests with cadmium and nickel.

In 10-day toxicity tests with the saltwater amphipod *A. abdita* in these same sediments, Di Toro et al. (1992) observed that metals concentrations ranging from 0.1 to 28 μmol SEM/g sediment were not toxic in some sediments, whereas metals concentrations ranging from 0.2 to 1,000 μmol SEM/g sediment were lethal in other sediments. These results indicate that the bioavailable fraction of metals in sediments varies from sediment to sediment. In contrast, the authors also observed a clearly discernible mortality-concentration relationship when mortality was related to the SEM/AVS molar ratio (i.e., there was no significant mortality where SEM/AVS ratios were <1.0, mortality increased in sediments having SEM/AVS ratios of 1.0 to 3.0, and there was 100% mortality in sediments with ratios >10). The sum of the IWTUs for cadmium and nickel ranged from 0.08 to 43.5. Sediments with ≤0.5 IWTUs were always nontoxic, those with >2.2 IWTUs were always toxic, and two of seven sediments with intermediate IWTUs (0.5 to 2.2) were toxic. Molar concentrations of cadmium and nickel in the interstitial water were similar. However, cadmium contributed over 95% to the sum of the toxic units because cadmium is 67 times more toxic to *A. abdita* than nickel. The latter illustrates the utility of interstitial water concentrations of individual metals in assigning the probable cause of mortality in benthic species (Hansen et al., 1996a).

In tests with the same sediments from Foundry Cove, Pesch et al. (1995) observed that 6 of the 17 sediments tested had SEM/AVS ratios <1.0 and IWTUs <0.5, and none of the 6 were toxic to the polychaete *N. arenaceodentata*. Interestingly, the other 11 sediments containing SEM/AVS ratios >1.0 were also not toxic. The results are not surprising given that in these particular tests only one sediment had >0.5 IWTUs, *N. arenaceodentata* is not sensitive to cadmium and nickel, and the polychaetes did not burrow into sediments containing toxic concentrations of these metals.

Ankley et al. (1993) examined the significance of AVS as a binding phase for copper in freshwater sediments from two copper-impacted sites. Based on interstitial water copper concentrations in the test sediments, the 10-day LC50 for *H. azteca* was 31 μg/L; this compared favorably with a measured LC50 of 28 μg/L in a 10-day water-only test. Sediments having SEM/AVS ratios <1.0 were not toxic. They also observed no toxicity in several sediments with markedly more SEM than AVS, suggesting that copper was not biologically available in these sediments. Absence of copper in interstitial water from these sediments corroborated this lack of bioavailability. This observation suggested the presence of binding phases in addition to AVS for copper in the test sediments. Two studies suggest that an important source of the extra binding capacity in these sediments was organic carbon (U.S. EPA, 1994a; Mahony et al., 1996).

Hansen et al. (1996a) investigated the biological availability of sediment-associated divalent metals to *A. abdita* and *H. azteca* in sediments from five saltwater locations and one freshwater location in the United States, Canada, and China using 10-day lethality tests. Sediment toxicity was not related to dry weight metals concentrations. In the locations where metals might be likely to cause toxicity, 49 sediments had less SEM than AVS and <0.5 IWTUs, and no toxicity was observed. In contrast, one-third of the 45 sediments with more SEM than AVS and >0.5 IWTUs were toxic (Table 3-1).

Hansen et al. (1996a) made an observation that is important to interpretation of toxicity of sediments from field locations, particularly those from industrial harbors. They observed that if sediments with SEM/AVS ratios <1.0 are toxic, even if metals concentrations on a dry weight basis are very high, the toxicity is not likely to be caused by metals. Furthermore, it is incorrect to use such data to reach the conclusion that the EqP approach is not valid. This is because when SEM/AVS ratios were <1.0, there was an almost complete absence of toxicity in both spiked sediments and field sediments where metals were the only known source of contamination and IWTUs for metals were <0.5. When metals concentrations expressed as the sum of the IWTUs are used in conjunction with SEM/AVS ratios, they together provide insight that can explain apparent anomalies between SEM/AVS ratios <1.0 and sediment toxicity in field sediments. Joint use of both SEM/AVS ratios and interstitial water concentrations is also a powerful tool for explaining absence of toxicity when SEM/AVS ratios are >1.0. Overall, when freshwater and saltwater field sediments were tested in the laboratory, 100% were not toxic when SEM/AVS was ≤1.0 and IWTUs were <0.5, and 66.7% were toxic

when SEM/AVS was >1.0 and IWTUs were ≥0.5 (Table 3-1).

Therefore, because AVS can bind divalent metals in proportion to their molar concentrations, Hansen et al. (1996a) proposed the use of the difference between the molar concentrations of SEM and AVS (SEM-AVS) rather than SEM/AVS ratios used previously. The molar difference provides important insight into the extent of additional available binding capacity and the magnitude by which AVS binding has been exceeded (Figure 3-5). Further, absence of organism response when AVS binding is exceeded can indicate the potential magnitude of other important binding phases in controlling bioavailability. Figure 3-5 shows that for most nontoxic freshwater and saltwater field sediments, 1 to 100 μmol of additional metal would be required to exceed the sulfide-binding capacity (i.e., SEM-AVS = −100 to −1 μmol/g). In contrast, most toxic field sediments contained 1 to 1,000 μmol of metal beyond the binding capacity of sulfide alone. Data on nontoxic field sediments whose sulfide-binding capacity is exceeded (SEM-AVS is >1.0 μmol/g) indicate that other sediment phases, in addition to AVS, have significance in controlling metal bioavailability. In comparison to SEM/AVS ratios, use of SEM-AVS differences is particularly informative where AVS concentrations are low, such as those from Steilacoom Lake and the Keweenaw Watershed, where the SEM-AVS difference is numerically low and SEM/AVS ratios are high (Ankley et al., 1993). For these reasons, SEM-AVS is used instead of the SEM/AVS ratio almost exclusively for the remainder of this document.

3.2.4 *Field Sites and Spiked Sediments Combined*

Figure 3-6 and Table 3-1 summarize available data from freshwater and saltwater sediments spiked with individual metals or metal mixtures, freshwater field sites, and saltwater field sites on the utility of metals concentrations in sediments normalized by dry weight, IWTUs, and SEM-AVS. These data explain the

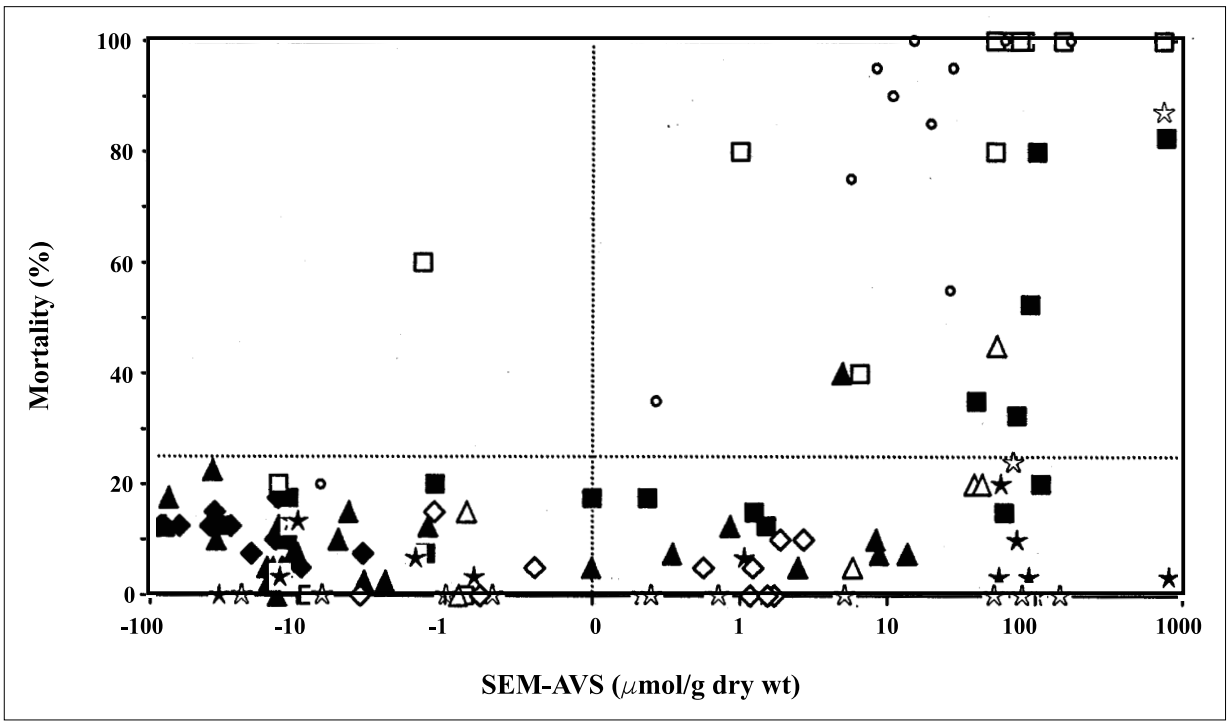

Figure 3-5. Percentage mortality of amphipods, oligochaetes, and polychaetes exposed to sediments from four freshwater and three saltwater field locations as a function of the sum of the molar concentrations of SEM minus the molar concentration of AVS (SEM-AVS). Sediments having ≤24% mortality are considered nontoxic as defined by Berry et al. (1996), which is indicated by the horizontal dotted line in the figure. The vertical dotted line at SEM-AVS = 0.0 μmol/g dry wt indicates the boundary between sulfide-bound unavailable metal and potentially available metal. The different symbols represent field sediments from different locations (figure from Hansen et al., 1996a).

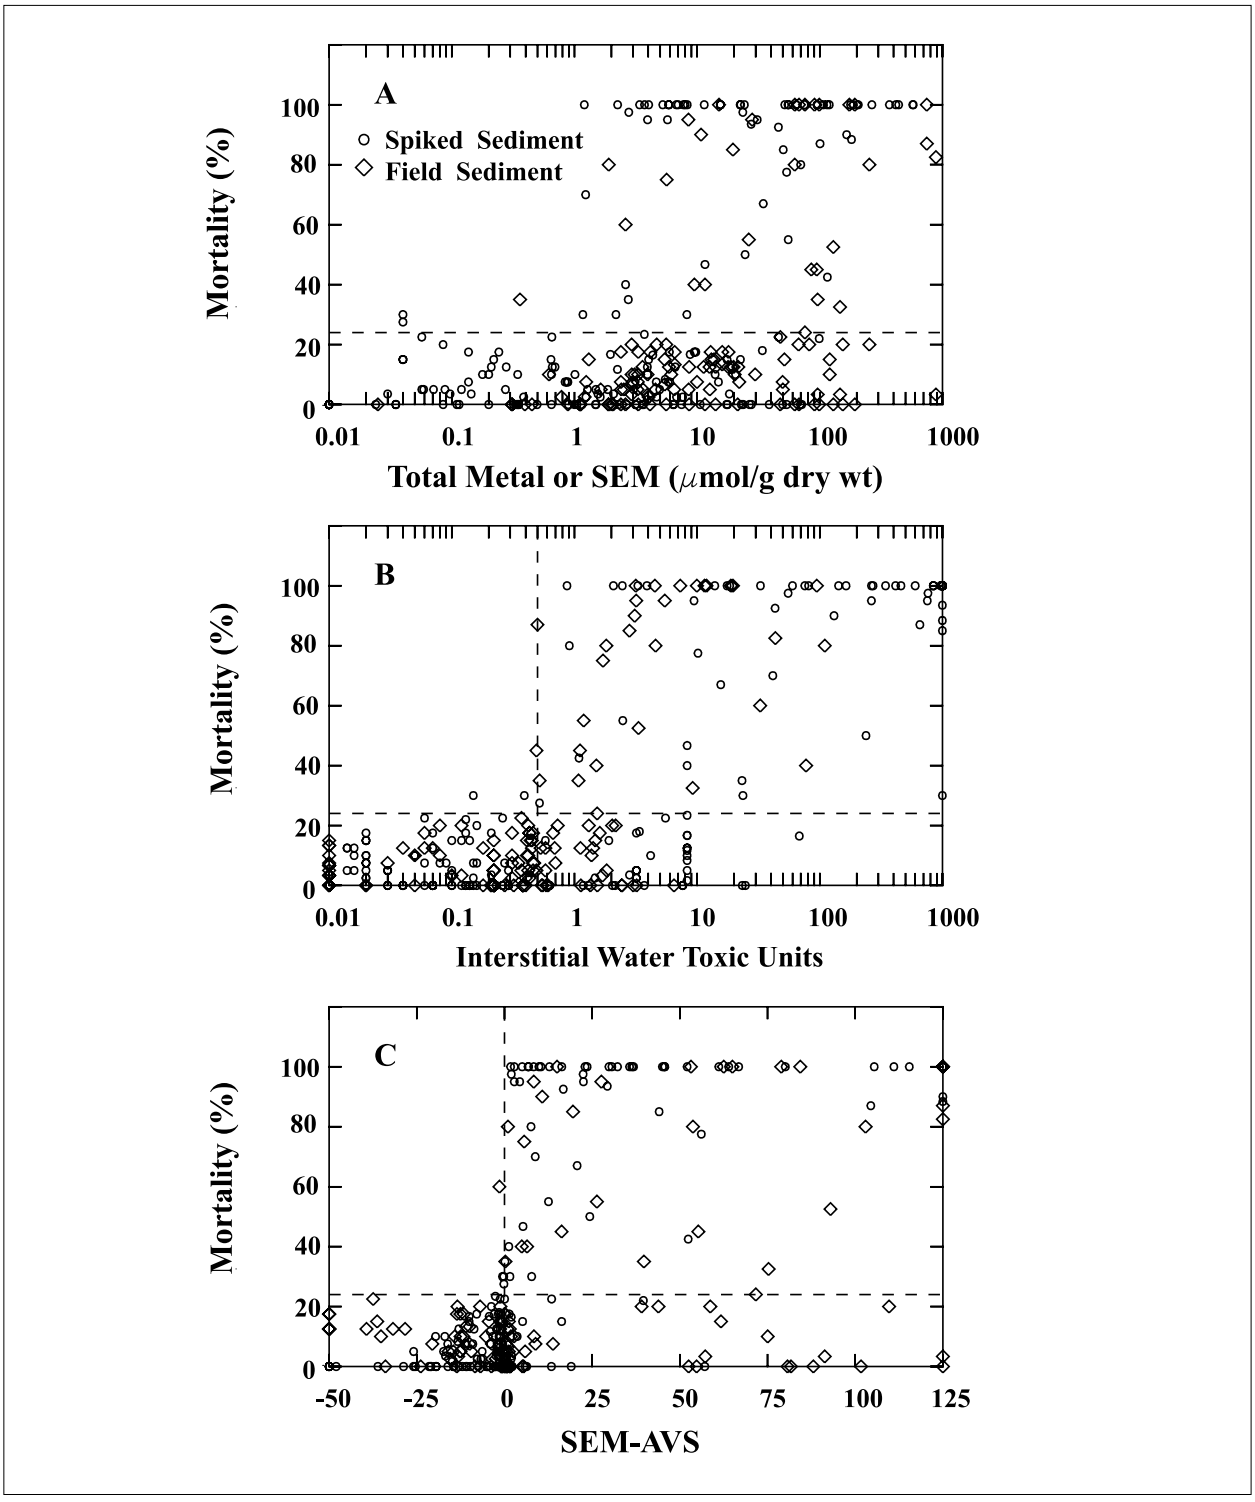

Figure 3-6. Percentage mortality of freshwater and saltwater benthic species in 10-day toxicity tests in spiked sediments and sediments from the field. Mortality is plotted as a function of: (A) the sum of the concentrations of the respective metal (Cd, Cu, Pb, Ni, Ag, or Zn) or metal mixture in μmol metal per gram dry weight of sediment; (B) IWTU; and (C) SEM-AVS difference. Data below the detection limits are plotted at IWTU = 0.01 and SEM-AVS = -50 μmol/g dry wt (silver data from Berry et al., 1999; all other data modified after Hansen et al., 1996a).

bioavailability and acute toxicity of metals in sediments (Hansen et al., 1996a; Berry et al., 1999). This analysis contains all available data from 10-day lethality tests where mortality, IWTUs, SEM, and AVS are known from experiments with sediments toxic only because of metals. The relationship between benthic organism mortality and total dry weight metals concentrations in spiked and field sediments is not useful to causally relate metal concentrations to organism response (Figures 3-4A and 3-6A). The overlap is almost four orders of magnitude in the bulk metals concentrations that cause no toxicity and those that are 100% lethal for these sediments where metals are the only source of toxicity (see discussion in Section 3.2.2).

Data in Figure 3-6B show that over all tests, the toxicity of sediments whose concentrations are normalized on an IWTU basis are typically consistent with the IWTU concept; that is, if IWTUs are $\leq$1.0, then sediments should be lethal to $\leq$50% of the organisms exposed, and significant mortality probably should be absent at <0.5 IWTUs. Of the spiked and field sediments evaluated that had IWTUs <0.5, 97.7% of 175 sediments were nontoxic (Table 3-1). For the 142 sediments having IWTUs $\geq$0.5, 68.3% were toxic. However, and as stated above, given the effect on toxicity or bioavailability of the presence of other binding phases (e.g., DOC) in interstitial water, water quality (hardness, salinity, etc.), and organism behavior, it is not surprising that many sediments having IWTUs $\geq$0.5 are not toxic.

Data in Figure 3-6C show that over all tests, organism response in sediments whose concentrations are normalized on an SEM-AVS basis is consistent with metal-sulfide binding on a mole to mole basis as first described by Di Toro et al. (1990), and later recommended for assessing the bioavailability of metals in sediments by Ankley et al. (1994). Saltwater and freshwater sediments either spiked with metals or from field locations with SEM-AVS differences $\leq$0.0 were uniformly nontoxic (98.1% of 158 sediments) (Table 3-1). The majority (58.0%) of 174 sediments having SEM-AVS >0.0 were toxic. It is not surprising that many sediments having SEM-AVS >0.0 are not toxic given the effect on toxicity or bioavailability of the presence of other sediment phases that also affect bioavailability (see Section 3-4; Di Toro et al., 1987, 2000; Mahony et al., 1996).

Over all tests, the data in Figure 3-6 indicate that use of both IWTUs and SEM-AVS together did not improve the accuracy of predictions of sediments that were nontoxic (98.5% of 132 sediments; Table 3-1). However, it is noteworthy that 78.9% of the 123 sediments with both SEM-AVS >0.0 and IWTUs $\geq$0.5 were toxic. Therefore, the approach of using SEM-AVS, IWTUs, and especially both indicators to identify sediments of concern is very useful.

The results of all available data demonstrate that using SEM, AVS, and interstitial water metals concentrations to predict the lack of toxicity of cadmium, copper, lead, nickel, silver, and zinc in sediments is certain. This is very useful, because the vast majority of sediments found in the environment in the United States have AVS concentrations that exceed the SEM concentration (SEM-AVS <0.0) (see Section 4.4). This may incorrectly suggest that there should be little concern about metals in sediments on a national basis, even though localized areas of biologically significant metal contamination do exist (Wolfe et al., 1994; Hansen et al., 1996a; Leonard et al., 1996a). It is potentially important that most of these data are from field sites where sediment samples were collected in the summer. At this time of year, the seasonal cycles of AVS produce the maximum metal-binding potentials (Boothman and Helmstetter, 1992; Leonard et al., 1993). Hence, sampling at seasons and conditions when AVS concentrations are at a minimum is a must in establishing the true overall level of concern about metals in the nation's sediments and in evaluations of specific sediments of local concern.

Predicting which sediments with SEM-AVS >0.0 will be toxic is presently less certain. Importantly, the correct classification rate seen in these experiments is high; that is, the accuracy of predicting which sediments were toxic was 58.0% using the SEM and AVS alone, 68.3% using IWTUs, and 78.9% using both indicators. An SEM-AVS >0.0, particularly at multiple adjacent sites, should trigger additional tiered assessments. These might include characterization of the spatial (both vertical and horizontal) and temporal distribution of chemical concentration (AVS and SEM) and toxicity, measurements of interstitial water metal, and toxicity identification evaluations (TIEs). In this context, the combined SEM-AVS and IWTU approach should be viewed as only one of the many sediment evaluation methodologies.

3.2.5 *Conclusions from Short-Term Studies*

Results from tests using sediments spiked with metals and sediments from the field in locations where toxicity is associated with metals demonstrate the value of explaining the biological availability of metals

concentrations normalized by SEM-AVS and IWTUs instead of dry weight metal concentrations. Importantly, data from spiked-sediment tests strongly indicate that metals are not the cause of most of the toxicity observed in field sediments when both SEM-AVS is $\leq$0.0 and IWTUs are <0.5 (Table 3-1). Expressing concentrations of metals in sediments on an SEM-AVS basis provides important insight into the available additional binding capacity of sediments and the extent to which sulfide binding has been exceeded.

SEM-AVS and interstitial water concentrations of metals can aid in identifying the specific metal causing toxicity. For example, the metal(s) in excess of AVS can be identified by subtracting from the molar concentration of AVS the molar concentrations of specific metals in the SEM in order of their sulfide solubility product constants ($K_{sp,2}$) in the SEM. Alternatively, interstitial water concentrations of metals can be used to identify a specific metal causing sediment toxicity using the toxic unit concept, if appropriate water-only toxicity data for the tested species are available (Hansen et al., 1996a).

Predictions of sediments not likely to be toxic, based on use of SEM-AVS and IWTUs for all data from freshwater or saltwater field sediment and spiked-sediment tests, are extremely accurate (98.5%) using both parameters. Predictions of sediments likely to be toxic are less accurate. Nevertheless, SEM-AVS is extremely useful in identifying sediments of potential concern. Data were summarized from amphipod tests using freshwater and saltwater laboratory metals-spiked sediments and field sediments where metals were a known problem by comparing the percentage of sediments that were toxic with the SEM-AVS concentration (tests with polychaetes and gastropods were excluded because these organisms avoid exposure) (Hansen, 1995). Seventy percent of the sediments in these amphipod studies with an SEM-AVS concentration of $\geq$0.76 μmol of excess SEM/g were toxic. The corresponding values for 80%, 90%, and 100% of the sediments being toxic were 2.7, 16, and 115 μmol of excess SEM/g, respectively.

Of course, SEM, AVS, and IWTUs can only predict toxicity or the lack of toxicity caused by *metals* in sediments. They cannot be used alone to predict toxicity of sediments contaminated with toxic concentrations of other contaminants. However, SEM and AVS have been used in sediment assessments to rule out metals as probable causative agents of toxicity (Wolfe et al., 1994). Also, the use of SEM and AVS to predict biological availability and toxicity of cadmium, copper, lead, nickel, silver, and zinc is applicable only to anaerobic sediments that contain AVS; binding factors other than AVS control bioavailability in aerobic sediments (Di Toro et al., 1987; Tessier et al., 1993). Measurement of interstitial water metal may be useful for evaluations of these and other metals in aerobic and anaerobic sediments (Ankley et al., 1994). Even with these caveats, the combined use of SEM, AVS, and interstitial measurements is preferable to all other currently available sediment evaluation procedures to causally assess the implications to benthic organisms of these six metals associated with sediments (see discussion in Section 5, Sampling and Analytical Chemistry, for further guidance).

3.3 Predicting Metal Toxicity: Long-Term Studies

Taken as a whole, the short-term laboratory experiments with metal-spiked and field-collected sediments present a strong argument for the ability to predict the absence of metal toxicity based on sediment SEM and AVS relationships and/or interstitial water metal concentrations. However, if this approach is to serve as a valid basis for ESB derivation, comparable predictive success must be demonstrated in long-term laboratory and field experiments where chronic effects could be manifested (Luoma and Carter, 1993; Meyer et al., 1994). This demonstration was the goal of experiments described by Hare et al. (1994), DeWitt et al. (1996), Hansen et al. (1996b), Liber et al. (1996), and Sibley et al. (1996). An important experimental modification to these long-term studies, as opposed to the short-term tests described in Section 3.2, was the collection of horizon-specific chemistry data. This is required because AVS concentrations often increase, and SEM-AVS differences decrease, with an increase in sediment depth (Howard and Evans, 1993; Leonard et al., 1996a); hence, chemistry performed on homogenized samples might not reflect the true exposure of benthic organisms dwelling in surficial sediments (Luoma and Carter, 1993; Hare et al., 1994; Peterson et al., 1996).

3.3.1 *Life-Cycle Toxicity Tests*

DeWitt et al. (1996) conducted an entire life-cycle toxicity test with the marine amphipod *L. plumulosus* exposed for 28 days to cadmium-spiked estuarine sediments (Table 3-2). The test measured effects on survival, growth, and reproduction of newborn amphipods relative to interstitial water and SEM/AVS

Table 3-2. Summary of the results of full life-cycle and colonization toxicity tests conducted in the laboratory and field using sediments spiked with individual metals and metal mixtures

Toxicity Test	Metal(s)	Duration (days)	Measured SEM-AVS[a] (μmol/g) NOEC(s)[b]	OEC(s)[c]	Effect	Reference
Life Cycle:						
Leptocheirus plumulosus	Cadmium	28	-3.5, -2.0, 0.78, 2.0	8.9, 15.6	Mortality 100%	DeWitt et al., 1996
Chironomus tentans	Zinc	56	-2.6, -1.4, 6.4	21.9, 32.4	Larval mortality 85%-100% Weight, emergence, and reproduction reduced	Sibley et al., 1996
Colonization:						
Laboratory-saltwater	Cadmium	118	-13.4	8.0, 27.4	Fewer polychaetes, shifts in community composition, fewer species, bivalves absent, tunicates increased	Hansen et al., 1996b
Field-saltwater	Cadmium, copper, lead, nickel, zinc	120	-0.31, -0.06, 0.02	—	No effects observed	Boothman et al., 2001
Field-freshwater	Cadmium	~365	-0.07, 0.08, 0.34	2.2	Reduced *Chironomus salinarius* numbers Bioaccumulation	Hare et al., 1994
Field-freshwater	Zinc	368	-3.6, -3.5, -2.9, -2.0, 1.0[d]	—	No effects observed	Liber et al., 1996

[a]SEM-AVS differences are used instead of SEM/AVS ratios to standardize across the studies referenced. An SEM-AVS difference of ≤0.0 is the same as an SEM/AVS ratio of ≤1.0. An SEM-AVS difference of >0.0 is the same as an SEM/AVS ratio of >1.0.
[b]NOECs = no observed effect concentration(s); all concentrations where response was not significantly different from the control.
[c]OECs = observed effect concentration(s); all concentrations where response was significantly different from the control.
[d]Occasional minor reductions in oligochaetes (Naididae).

normalization. Seven treatments of Cd were tested: 0 (control), −3.5, −2.0, 0.78, 2.0, 8.9, and 15.6 SEM_{Cd}-AVS differences (measured concentrations). Gradients in AVS concentration as a function of sediment depth were greatest in the control treatment, decreased as the SEM_{Cd} ratio increased, and became more pronounced over time. Depth gradients in SEM_{Cd}-AVS differences were primarily caused by the spatial and temporal changes in AVS concentration, because SEM_{Cd} concentrations changed very little with time or depth. Thus in most treatments SEM_{Cd}-AVS differences were smaller at the top of sediment cores than at the bottom. This is expected because the oxidation rate of iron sulfide in laboratory experiments is very rapid (100% in 60 to 90 minutes) but for cadmium sulfide it is slow (10% in 300 hours) (Mahony et al., 1993; Di Toro et al., 1996a). Interstitial cadmium concentrations increased in a dramatic stepwise fashion in treatments having a SEM-AVS difference of ≥8.9 μmol of excess SEM, but were below the 96-hour LC50 value for this amphipod in lesser treatments. There were no significant effects on survival, growth, or reproduction in sediments containing more AVS than cadmium (−3.5 and −2.0 μmol/g) and those with a slight excess of SEM_{Cd} (0.78 and 2.0 μmol/g), in spite of the fact that these samples contained from 183 to 1,370 μg cadmium/g sediment. All amphipods died in sediments having SEM-AVS differences ≥8.9 μmol excess SEM/g. These results are

consistent with predictions of metal bioavailability from 10-day acute tests with metal-spiked sediments (i.e., that sediments with SEM_{Cd}-AVS differences $\leq$0.0 are not toxic, interstitial water metal concentrations are related to organism response, and sediments with SEM_{Cd}-AVS differences >0.0 may be toxic).

Sibley et al. (1996) reported similar results from a 56-day life-cycle test conducted with the freshwater midge *C. tentans* exposed to zinc-spiked sediments (Table 3-2). The test was initiated with newly hatched larvae and lasted one complete generation, during which survival, growth, emergence, and reproduction were monitored. In sediments where the molar difference between SEM and AVS (SEM-AVS) was <0.0 (dry weight zinc concentrations were as high as 270 mg/kg), concentrations of zinc in the sediment interstitial water were low and no adverse effects were observed for any of the biological endpoints measured. Conversely, when SEM-AVS was 21.9 and 32.4 μmol of excess SEM/g, interstitial water concentrations of zinc increased (being highest in surficial sediments), and reductions in survival, growth, emergence, and reproduction were observed. Over the course of the study, the absolute concentration of zinc in the interstitial water in these treatments decreased because of the increase in sediment AVS and loss of zinc from twice-daily renewals of the overlying water.

3.3.2 *Colonization Tests*

Hansen et al. (1996b) conducted a 118-day benthic colonization experiment in which sediments were spiked to achieve nominal cadmium/AVS molar ratios of 0.0 (control), 0.1, 0.8, and 3.0 and then held in the laboratory in a constant flow of unfiltered seawater (Table 3-2). Oxidation of AVS in the surficial 2.4 cm of the control treatment occurred within 2 to 4 weeks and resulted in sulfide profiles similar to those occurring in sediments in nearby Narragansett Bay, RI (Boothman and Helmstetter, 1992). In the nominal 0.1 cadmium/AVS treatment, measured SEM_{Cd} was always less than AVS (SEM-AVS = $-$13.4 μmol AVS/g in the surficial 2.0 cm), interstitial cadmium concentrations (<3 to10 μg/L) were less than those likely to cause biological effects, and no significant biological effects were detected. In the nominal 0.8 cadmium/AVS treatment (SEM-AVS = 8.0 μmol SEM/g), measured SEM_{Cd} commonly exceeded AVS in the surficial 2.4 cm of sediment, and interstitial cadmium concentrations (24 to 157 μg/L) were sufficient to be of toxicological significance to highly sensitive species. In this treatment, shifts in the presence or absence of organisms were observed over all taxa, and there were fewer macrobenthic polychaetes (*Mediomastus ambiseta*, *Streblospio benedicti*, and *Podarke obscura*) and meiofaunal nematodes. In the nominal 3.0 cadmium/AVS treatment (SEM-AVS of 27.4 μmol SEM/g), concentrations of SEM_{Cd} were always greater than AVS throughout the sediment column. Interstitial cadmium ranged from 28,000 to 174,000 μg/L. In addition to the effects observed in the nominal 0.8 cadmium/AVS treatment, the following effects were observed: (a) sediments were colonized by fewer macrobenthic and polychaete species and harpacticoids, (b) the sediments had lower densities of diatoms, and (c) bivalve molluscs were absent. Over all treatments, the observed biological responses were consistent with predicted possible adverse effects resulting from elevated SEM_{Cd}-AVS differences in surficial sediments and interstitial water cadmium concentrations.

Boothman et al. (2001) conducted a field colonization experiment in which sediments from Narragansett Bay, RI, were spiked with an equimolar mixture of cadmium, copper, lead, nickel, and zinc at nominal SEM/AVS ratios of 0.1, 0.8, and 3.0; placed in boxes; and replaced in Narragansett Bay (Table 3-2). The AVS concentrations decreased with time in surface sediments (0 to 3 cm) in all treatments where the nominal SEM/AVS ratio was <1.0 (SEM-AVS decreased from $-$0.31 to $-$0.06 μmol SEM/g in the surficial 2.0 cm) but did not change in subsurface (6 to 10 cm) sediments or in the entire sediment column where nominal SEM/AVS ratios exceeded 1.0 (SEM-AVS = 0.02 μmol AVS/g). SEM decreased with time only where SEM exceeded AVS. The concentration of metals in interstitial water was below detection limits when there was more AVS than SEM. When SEM exceeded AVS, significant concentrations of metals were present in interstitial water, and appeared in the order of their sulfide solubility product constants. Interstitial water concentrations in these sediments decreased with time, although they exceeded the WQC in interstitial water for 60 days for all metals, 85 days for cadmium and zinc, and 120 days for the entire experiment for zinc. Benthic faunal assemblages in the spiked-sediment treatments were not different from those of the control treatment. Lack of biological response was consistent with the vertical profiles of SEM and AVS. AVS was greater than SEM in all surface sediments, including the top 2 cm of the 3.0 nominal SEM/AVS treatment, because of oxidation of AVS and loss of SEM. The authors speculated that interstitial metal was likely absent in the surficial sediments in spite of data demonstrating the presence of significant measured concentrations.

Interstitial water in the 3.0 nominal SEM/AVS treatment was sampled from sediment depths where SEM was in excess, rather than in the surficial sediments. Important to the biological data are the surficial sediments, where settlement by saltwater benthic organisms first occurs. Also, there was a storm event that allowed a thin layer of clean sediment to be deposited on top of the spiked sediment (W.S. Boothman, U.S. EPA, Narragansett, RI, personal communication). These data demonstrate the importance of sampling sediments and interstitial water in sediment horizons where benthic organisms are active.

Hare et al. (1994) conducted an approximately 1-year field colonization experiment in which uncontaminated freshwater sediments were spiked with cadmium and replaced in the oligotrophic lake from which they originally had been collected (Table 3-2). Cadmium concentrations in interstitial waters were very low at cadmium-AVS molar differences <0.0, but increased markedly at differences >0.0. The authors reported reductions in the abundance of only the chironomid *Chironomus salinarius* in the 2.2 μmol excess SEM/g treatment. Cadmium was accumulated by organisms from sediments with surficial SEM concentrations that exceeded those of AVS. These sediments also contained elevated concentrations of cadmium in interstitial water.

Liber et al. (1996) performed a field colonization experiment using sediments having 4.46 μmol of sulfide from a freshwater mesotrophic pond (Table 3-2). Sediments were spiked with 0.8, 1.5, 3.0, 6.0, and 12.0 μmol of zinc, replaced in the field, and chemically and biologically sampled over 12 months. There was a pronounced increase in AVS concentrations with increasing zinc concentration; AVS was lowest in the surficial 0 to 2 cm of sediment with minor seasonal variations. With the exception of the highest spiking concentration (approximately 700 mg/kg, dry weight), AVS concentrations remained larger than those of SEM. Interstitial water zinc concentrations were rarely detected in any treatment, and were never at concentrations that might pose a hazard to benthic macroinvertebrates. The only observed difference in benthic community structure across the treatments was a slight decrease in the abundance of Naididae oligochaetes at the highest spiking concentration. The absence of any noteworthy biological response was consistent with the absence of interstitial water concentrations of biological concern. The lack of biological response was attributed to an increase in concentrations of iron and manganese sulfides produced during periods of diagenesis, which were replaced by the more stable zinc sulfide, which is less readily oxidized during winter months. In this experiment, and theoretically in nature, excesses of sediment metal might be overcome over time because of the diagenesis of organic material. In periods of minimal diagenesis, oxidation rates of metal sulfides, if sufficiently great, could release biologically significant concentrations of the metal into interstitial waters. The phenomenon should occur metal by metal in order of their sulfide solubility product constants.

3.3.3 *Conclusions from Chronic Studies*

Over all full life-cycle and colonization toxicity tests conducted in the laboratory and field using sediments spiked with individual metals and metal mixtures (Table 3-2), no sediments with an excess of AVS (SEM-AVS $\leq$ 0.0) were toxic (Figure 3-7). Conversely, all sediments where chronic effects were observed, and 7 of 19 sediments where no effects were observed, had an excess of SEM (SEM-AVS >0.0) (Table 3-2; Figure 3-7). Therefore, the results from all available acute and chronic toxicity tests support the use of SEM-AVS $\leq$ 0.0 as an ESB that can be used to predict sediments that are unlikely to be toxic.

3.4 Predicting Toxicity of Metals in Sediments

3.4.1 *General Information*

The SEM-AVS method for evaluating toxicity of metals in sediments (Di Toro et al., 1990, 1992) has proven to be successful at predicting the lack of metal toxicity in spiked and field-contaminated sediments (Berry et al., 1996; Hansen et al., 1996a). However, because SEM-AVS does not explicitly consider the other sediment phases that influence interstitial water–sediment partitioning, and in spite of its utility in identifying sediments of possible concern, it was never intended to be used to predict the occurrence of toxicity. The proposed sediment quality criteria for metals using SEM, AVS, and IWTUs in Ankley et al. (1996)—now referred to as ESBs or equilibrium partitioning sediment benchmarks—were constructed as "one-tailed" guidelines. They should be used to predict the lack of toxicity but not its presence. Thus the problem of predicting the onset of toxicity in metal-contaminated sediments remained unsolved.

This section introduces a modification of the SEM-AVS procedure in which the SEM-AVS difference is

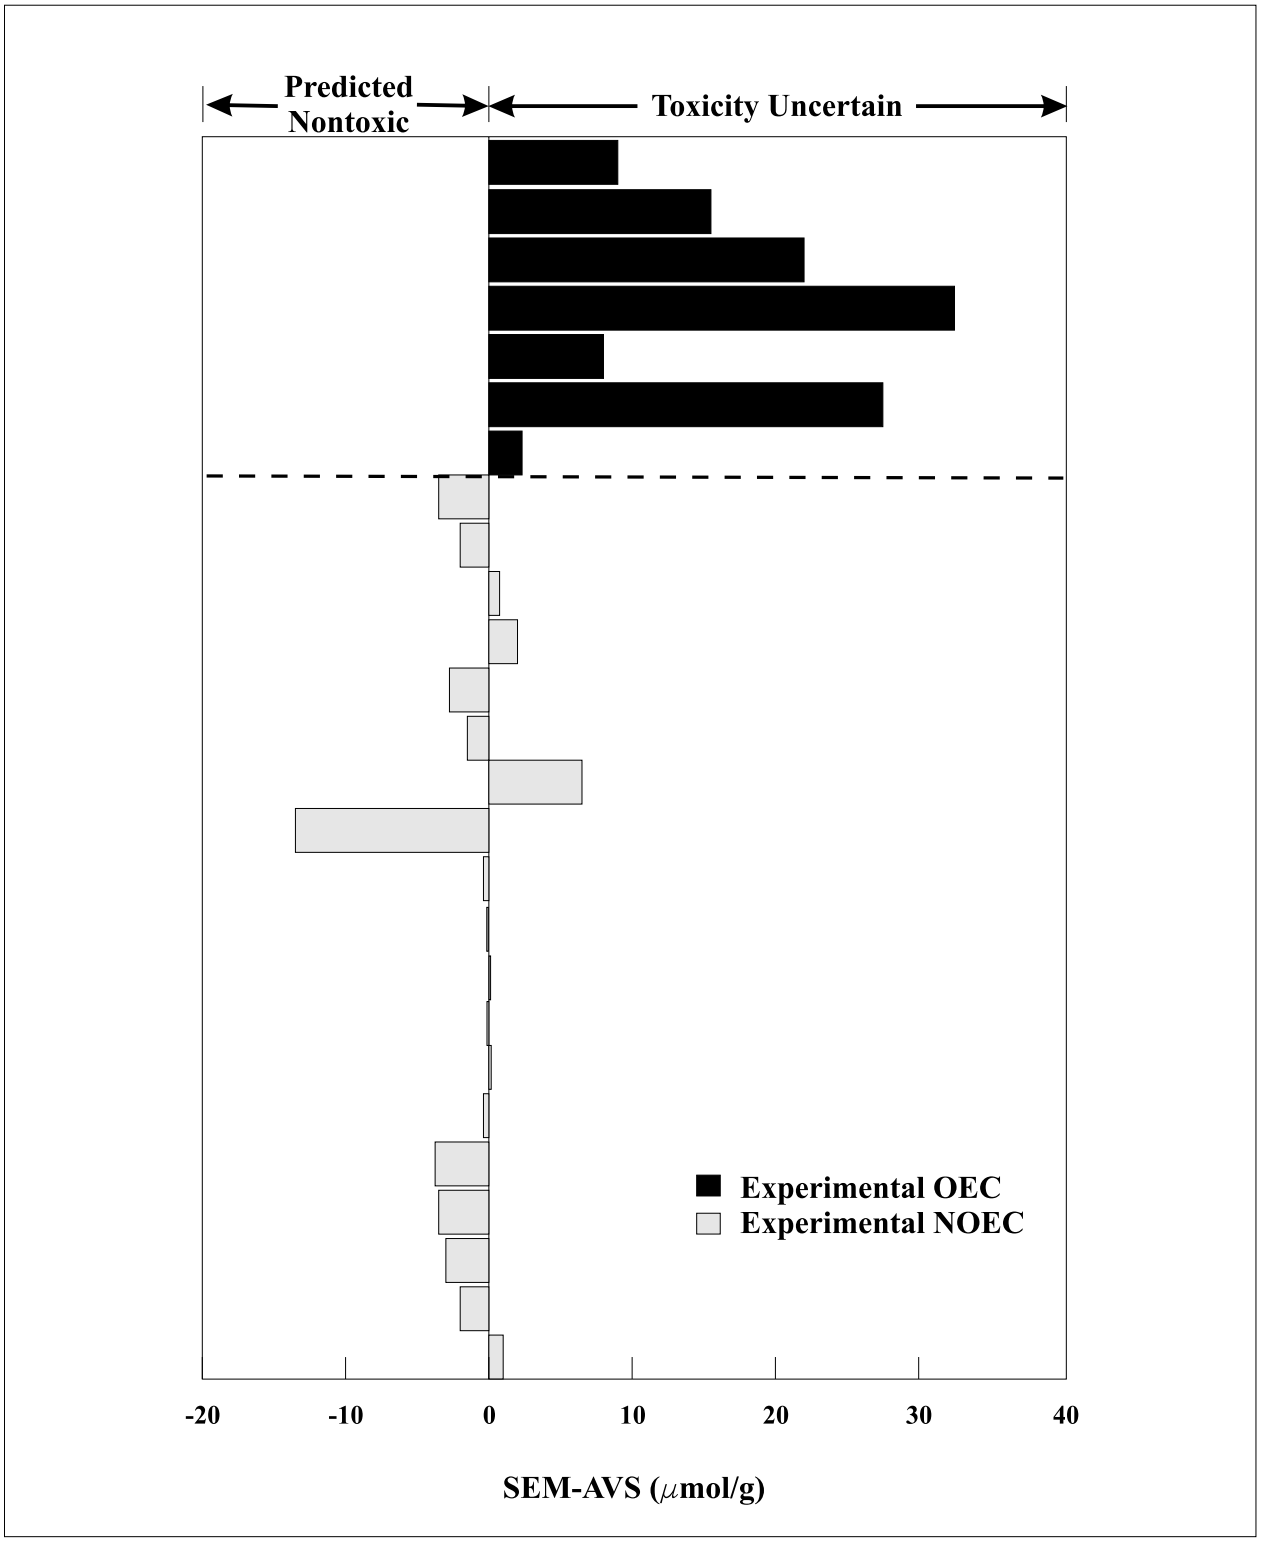

Figure 3-7. **Comparison of the chronic toxicity of sediments spiked with individual metals or metal mixtures to predicted toxicity based on SEM-AVS (data from Table 3-2). Horizontal dashed line separates experimental observed effect concentrations (solid columns) from no observed effect concentrations (shaded columns). Values at SEM-AVS ≤ 0.0 μmol/g_{OC} are predicted to be nontoxic. Values at SEM-AVS >0.0 μmol/g_{OC} are indicative of sediments that are likely to be toxic or toxicity is uncertain.**

normalized by the fraction of organic carbon, f_{OC}, in a sediment. This section is largely taken from Di Toro et al. (2000). Their publication should be consulted for additional information about the utility of the f_{OC} procedure and comparison of this procedure with the sediment guidelines of Long et al. (1995a) and MacDonald et al. (1996). The $(\Sigma SEM\text{-}AVS)/f_{OC}$ procedure significantly improves prediction of mortality by accounting for partitioning of metals to sediment organic carbon, as well as the effect of AVS. In addition, the approach used by Di Toro et al. (2000) to derive $(\Sigma SEM\text{-}AVS)/f_{OC}$ uncertainty bounds for identifying sediments that are likely to be toxic, are of uncertain toxicity, or are nontoxic has applicability to SEM/AVS ratios, SEM-AVS differences, and IWTUs. Although not used as an ESB, the uncertainty bounds should be useful in prioritizing sediments of concern for further evaluations.

3.4.2 *EqP Theory for SEM, AVS, and Organic Carbon*

The EqP model provides for the development of causal sediment concentrations that predict toxicity or lack of toxicity in sediments (Di Toro et al., 1991). The sediment concentration C_S that corresponds to a measured LC50 in a water-only exposure of the test organism is

$$C_S^* = K_p \, LC50 \tag{3-2}$$

where C_S^* is the sediment LC50 concentration (μg/kg dry wt), K_p (L/kg) is the partition coefficient between interstitial water and sediment solids, and LC50 is the concentration causing 50% mortality (μg/L). For application to metals that react with AVS to form insoluble metal sulfides, Equation 3-2 becomes

$$C_S^* = AVS + K_p \, LC50 \tag{3-3}$$

where AVS is the sediment concentration of acid volatile sulfides. Equation 3-3 simply states that because AVS can bind the metal as highly insoluble sulfides, the concentration of metal in a sediment that will cause toxicity is at least as great as the AVS that is present. The sediment metal concentration that should be employed is the SEM concentration, because any metal that is bound so strongly that 1N of hydrochloric acid cannot dissolve it is not likely to be bioavailable (Di Toro et al., 1992). Of course, this argument is theoretical, which is why so much effort has been expended to demonstrate experimentally that this is actually the case (Di Toro et al., 1992; Hare et al., 1994; Berry et al., 1996; Hansen et al., 1996a; Sibley et al., 1996). Therefore, the relevant sediment metal concentration is SEM, and Equation 3-3 becomes

$$SEM = AVS + K_p \, LC50 \tag{3-4}$$

The basis for the AVS method is to observe that if the second term in Equation 3-4 is neglected, then the critical concentration is SEM = AVS, and the criterion for toxicity or lack of toxicity is SEM-AVS $\leq$ 0.0 (μmol/g dry wt).

The failure of the difference to predict toxicity when there is an excess of SEM is due to neglect of the partitioning term K_pLC50. Note that ignoring the term does not affect the prediction of lack of toxicity in that it makes the condition conservative (i.e., smaller concentrations of SEM are at the boundary of toxicity and no toxicity).

The key to improving prediction of toxicity is to approximate the partitioning term rather than ignore it (Di Toro et al, *in prep.*). In sediments, the organic carbon fraction is an important partitioning phase, and partition coefficients for certain metals at certain pHs have been measured (Mahony et al., 1996). This suggests that the partition coefficient K_p in Equation 3-4 can be expressed using the organic carbon–water partition coefficient, K_{OC}, together with the fraction organic carbon in the sediment, f_{OC}

$$K_p = f_{OC} \, K_{OC} \tag{3-5}$$

Using this expression in Equation 3-4 yields

$$SEM = AVS + f_{OC} \, K_{OC} \, LC50 \tag{3-6}$$

Moving the known terms to the left side of this equation yields

$$\frac{SEM - AVS}{f_{OC}} = K_{OC} LC50 \tag{3-7}$$

If both K_{OC} and LC50 are known, then Equation 3-7 can be used to predict toxicity.

The method evaluated below uses $(\Sigma SEM\text{-}AVS)/f_{OC}$ as the predictor of toxicity and evaluates the critical concentrations (the right side of Equation 3-7) based on observed SEM, AVS, f_{OC}, and toxicity data (Di Toro et al, *in prep.*). If multiple metals are present, it is necessary to use the total SEM

$$\Sigma SEM = \sum_{i=1}^{N} [SEM_i] \tag{3-8}$$

to account for all the metals present. Note that (ΣSEM-AVS)/f_{OC} is the organic carbon–normalized excess SEM for which we use the notation

$$\left(\sum \text{SEM} - \text{AVS}\right)/f_{OC} = \left(\sum \frac{\text{SEM} - \text{AVS}}{f_{OC}}\right) \qquad (3\text{-}9)$$

3.4.3 *Data Sources*

Data from toxicity tests using both laboratory-spiked and field-collected sediments were compiled from the literature. Four sources of laboratory-spiked tests using marine sediments (Casas and Crecelius, 1994; Pesch et al., 1995; Berry et al., 1996, 1999) and one using freshwater sediments (Carlson et al., 1991) were included. Two sources for metal-contaminated field sediments were included (Hansen et al., 1996a; Kemble et al., 1994). The field data from the sediments where metals were not the probable cause of toxicity (Bear Creek and Jinzhou Bay) (Hansen et al., 1996a) were excluded. Data reported included total metals, SEM, AVS, f_{OC}, and 10- or 14-day mortality. In Hansen et al. (1996a), data were reported for five saltwater and four freshwater locations, but organic carbon concentrations were not available for freshwater field sediments from three locations. Organic carbon data for the Keweenaw Watershed were obtained separately (E.N. Leonard, U.S. EPA, Duluth, MN, personal communication).

Laboratory-spiked and field sediment data were grouped for analysis. Mortality data were compared against the SEM-AVS difference and the SEM-AVS difference divided by the f_{OC}. For each comparison, two uncertainty bounds were computed: a lower-bound concentration equivalent to a 95% chance that the mortality observed would be less than 24% (the percentage mortality considered to be toxic) (see Berry et al., 1996) and an upper-bound concentration equivalent to a 95% chance that the observed mortality would be greater than 24%. The lower-bound uncertainty limit was computed by evaluating the fraction of correct classification starting from the lowest x-axis value. When the fraction correct dropped to below 95%, the 95th percentile was interpolated. The same procedure was applied to obtain the upper-bound uncertainty limit. These uncertainty bounds are the concentration range where it is 90% certain that the sediment may be either toxic or not toxic.

3.4.4 *Acute Toxicity Uncertainty*

Mortality in the laboratory-spiked and field-contaminated sediment tests were both organism and metal independent when plotted against the SEM-AVS difference (Figure 3-8A). The horizontal dashed line indicating 24% mortality is shown for reference. The 90% lower and upper uncertainty bound limits for the SEM-AVS difference are from 1.7 and 120 μmol/g, a factor of 70. Thus, it appears that for both laboratory and spiked-sediment data, toxicity is likely when the SEM-AVS difference is >120, uncertain when the difference is from 1.7 to 120 μmol/g, and not likely when the difference is <1.7 μmol/g.

Although use of SEM-AVS differences to predict toxicity is not based on any theoretical foundation, use of SEM-AVS $\leq$0.0 to predict lack of toxicity is based on the equilibrium partitioning model (Di Toro et al., 1991) and the chemistry of metal–sulfide interactions. The stoichiometry of the uptake of divalent metals by AVS is such that 1 mol of AVS will stabilize 1 mol of SEM, except for silver, where the ratio is 2:1, hence the use of the difference of 0.0 μmol/g dry weight to predict lack of toxicity. In fact it is the very low solubility of the resulting metal sulfides that limits the interstitial water concentrations to below toxic levels regardless of the details of the sediment chemistry (e.g., pH, iron concentration) as has been demonstrated in this document and detailed in the Appendix in Di Toro et al. (1992).

The (ΣSEM-AVS)/f_{OC} approach provides an equivalent theoretical basis that is needed to derive an appropriately normalized sediment concentration that predicts occurrence of toxicity that is causally linked to bioavailable metal. When percent mortality is plotted against the organic carbon–normalized excess SEM (ΣSEM-AVS)/f_{OC}) for the same data as contained in Figure 3-8A, toxicity is likely when the (ΣSEM-AVS)/f_{OC} is >3,000 μmol/g_{OC}, uncertain when the concentration is between 130 and 3,000 μmol/g_{OC}, and not likely when the concentration is <130 μmol/g_{OC} (Figure 3-8B). Thus, the width of the uncertainty bound is a factor of 70 for SEM-AVS differences and 23 for (ΣSEM-AVS)/f_{OC}.

If the (ΣSEM-AVS)/f_{OC} approach improves predictions of sediment toxicity caused by metals, the uncertainty bounds should narrow and the percentages of sediments where toxicity predictions are uncertain should decrease. If the uncertainty bound analysis is not conducted, and SEM-AVS>0.0 is used as proposed in Sections 3.2 and 3.3, predictions of sediment toxicity

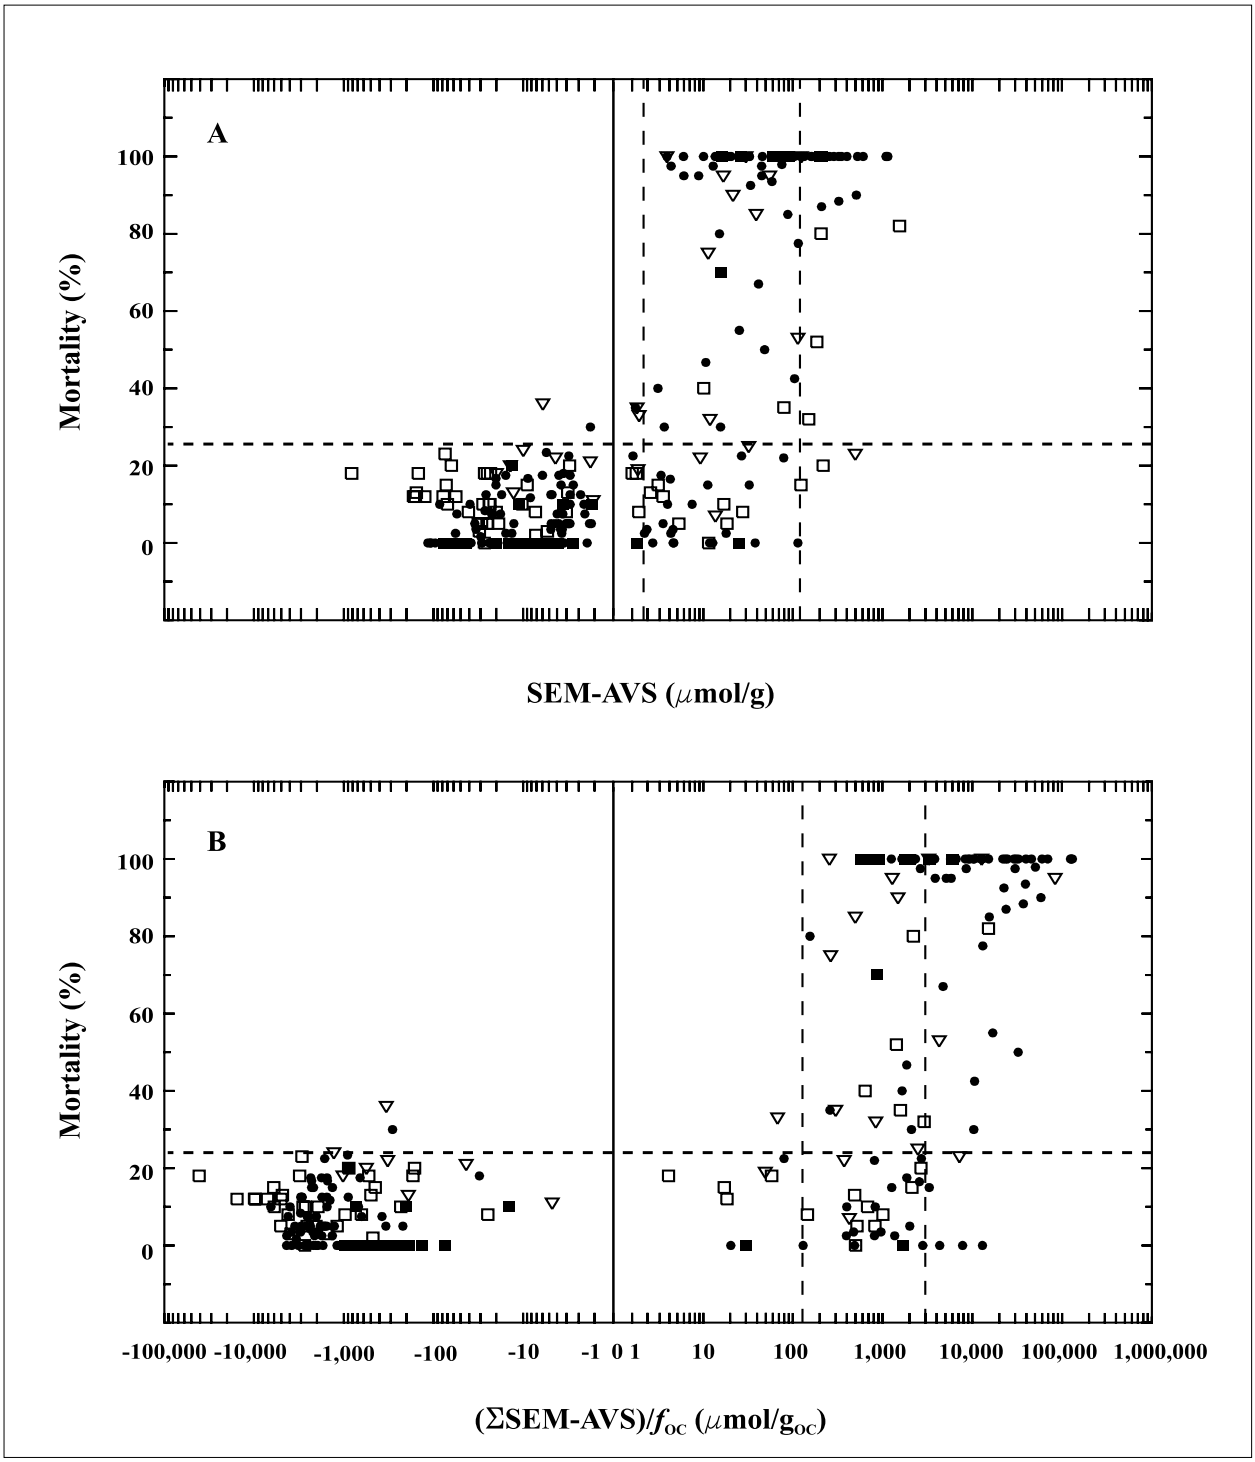

Figure 3-8. Percent mortality versus SEM-AVS (A) and (ΣSEM-AVS)/f_{oc} (B) for saltwater field data without Bear Creek and Jinzhou Bay (□), freshwater field data (▽), freshwater spiked data (≃), and saltwater spiked data (●); silver data excluded. Vertical dashed lines are the 90% uncertainty bound limits (figure from Di Toro et al., 2000).

for the 267 spiked sediments are classified as uncertain for 47.2% of the sediments. Using the uncertainty bounds on SEM-AVS of 1.7 to 120 μmol/g as described in this section results in reduction in the percentage of sediments where toxicity predictions are uncertain, to 34.1%. Use of $(\Sigma SEM\text{-}AVS)/f_{OC}$ with uncertainty bounds of 130 to 3,000 $\mu mol/g_{OC}$ results in further reduction in the percentage of sediments where toxicity predictions are uncertain, to 25.5%. Therefore, use of the uncertainty limits of the $(\Sigma SEM\text{-}AVS)/f_{OC}$ approach classifies 33.7% more sediments as toxic or nontoxic than using the uncertainty limits of SEM-AVS, and 85% more than use of SEM-AVS without uncertainty limits. This improvement highlights the advantages of using $(\Sigma SEM\text{-}AVS)/f_{OC}$ in assessing toxicity of metal-contaminated sediments.

Use of $(\Sigma SEM\text{-}AVS)/f_{OC}$ uncertainty limits applies to all the metals regardless of their identity. Figure 3-9 presents the spiked-sediment data categorized by identity of the metal. The field-contaminated data cannot be included because the identity of the metal causing toxicity cannot be unambiguously determined. There is no apparent difference for any of the metals in the region of overlapping survival and mortality data between 130 and 3,000 $\mu mol/g_{OC}$.

It is interesting to note that organic carbon normalization appears not to work for silver. The spiked-sediment test data are presented in Figure 3-10A (Berry et al., 1999). Note that there is almost a complete overlap of mortality and no mortality data. This suggests that organic carbon is not a useful normalization for silver partitioning in sediments. Perhaps this is not surprising because the role of sulfur groups is so prominent in the complexation chemistry of silver (Bell and Kramer, 1999).

To not depend on the identity of the metal is an advantage in analyzing naturally contaminated sediments in that it is difficult to decide which metal is potentially causing the toxicity. Of course it can be done using the sequence of solubilities of the metal sulfides or interstitial metal concentrations (Di Toro et al., 1992; Ankley et al., 1996). The metal-independent method can be tested using the results of an experiment with an equimolar mixture of cadmium, copper, nickel, and zinc (see Figure 3-10B). The area of uncertainty falls within the carbon-normalized excess SEM boundaries above.

3.4.5 *Chronic Toxicity Uncertainty*

The results of chronic toxicity tests with metals-spiked sediments can also be compared to $(\Sigma SEM\text{-}AVS)/f_{OC}$ (Figure 3-11; Table 3-3). Note that Figure 3-11 indicates a category for "predicted toxic." Significant chronic effects were observed in only 1 of the 19 sediments, where the uncertainty analysis of acute toxicity tests indicated that effects were not expected at $(\Sigma SEM\text{-}AVS)/f_{OC} < 130\ \mu mol/g_{OC}$. The concentration in the sediment where chronic effects were observed but not expected, i.e., $(\Sigma SEM\text{-}AVS)/f_{OC} = 28\ \mu mol$ excess SEM/g_{OC}. The previous analysis of the results of chronic toxicity tests using SEM-AVS indicated that concentrations of SEM exceeded AVS in 7 of 19 nontoxic sediments. Sediment concentrations based on $(\Sigma SEM\text{-}AVS)/f_{OC}$ placed these sediments in the uncertain toxicity category. Importantly, use of $(\Sigma SEM\text{-}AVS)/f_{OC}$ to classify sediments resulted in six of these same seven sediments being correctly classified as probably nontoxic. Chronic effects were observed in six of the seven sediments where predictions of effects are uncertain (130 to 3,000 $\mu mol/g_{OC}$). This suggests that chronic toxicity tests with sensitive benthic species will be a necessary part of the evaluations of sediments predicted to have uncertain effects.

3.4.6 *Summary*

The uncertainty bounds on SEM-AVS differences and organic carbon–normalized excess SEM ($(\Sigma SEM\text{-}AVS)/f_{OC}$) can be used to identify sediments that are likely to be toxic, are of uncertain toxicity, or are nontoxic. Use of $(\Sigma SEM\text{-}AVS)/f_{OC}$ as a correction factor for excess SEM is attractive because it is based on the theoretical foundation of equilibrium partitioning. Likewise, it reduces the uncertainty of the prediction of toxicity over that of SEM-AVS differences.

Section 4

Derivation of Metal Mixtures $ESB_{AVS:WQC}s$

4.1 General Information

Section 4 of this document presents the technical basis for establishing the ESB for cadmium, copper, lead, nickel, silver, and zinc. The basis of the overall approach is the use of EqP theory linked to the concept of maintaining metal activity for the sediment interstitial water system below concentrations that cause adverse effects. Extensive toxicological concentration-response data from short-term and chronic laboratory and field experiments, with both marine and freshwater sediments and a variety of species, indicate that it is possible to reliably predict absence of metal toxicity based on EqP theory and derive ESBs for metals in sediments using either of two approaches referred to as $ESB_{AVS:WQC}s$. The $ESB_{AVS:WQC}s$ for the six metals that collectively predicts absence of their toxicity in sediments can be derived by (a) comparing the sum of their molar concentrations, measured as SEM, with the molar concentration of AVS in sediments (solid-phase AVS benchmark); or (b) summing the measured interstitial water concentrations of the metals divided by their respective WQC FCVs (interstitial water benchmark). Lack of exceedence of the $ESB_{AVS:WQC}$ based on either of these two procedures indicates that metal toxicity should not occur.

At present, the technical basis for implementing these two approaches is supportable. The approaches have been presented to and reviewed by the SAB (U.S. EPA, 1994a, 1995a, 1999).

Additional research required to fully implement other approaches for deriving an $ESB_{AVS:WQC}$ for these metals and to derive an ESB for other metals such as mercury, arsenic, and chromium includes the development of uncertainty estimates; part of this would include their application to a variety of field settings and sediment types. Finally, the ESB approaches are intended to protect benthic organisms from direct toxicity associated with exposure to metal-contaminated sediments. The ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with metal mixtures or the potential for bioaccumulation and trophic transfer of metal mixtures to aquatic life, wildlife or humans. They are not designed to protect aquatic systems from metal release associated with, for example, sediment suspension, or the transport of metals into aquatic food webs. In particular, studies are needed to understand the toxicological significance of the biomagnification of metals that occurs when predators consume benthic organisms that have accumulated metals from sediments with more AVS than SEM (Ankley, 1996).

The following nomenclature is used in subsequent discussions of the $ESB_{AVS:WQC}s$ derivation for metal mixtures. The $ESB_{AVS:WQC}$ for the metals, based on AVS, is expressed in molar units because of the molar stoichiometry of metal binding to AVS. Thus, solid-phase constituents (AVS, SEM) are in μmol/g dry weight. The interstitial water metal concentrations are expressed in μmol/L or μg/L, either as dissolved concentrations $[M_d]$ or activities $\{M^{2+}\}$ (Stumm and Morgan, 1981). The subscripted notation, M_d, is used to distinguish dissolved aqueous-phase molar concentrations from solid-phase molar concentrations with no subscript. For the combined concentration, $[SEM_T]$, the units are μmol of total metal per gram of dry weight sediment. Note also that when $[SEM_{Ag}]$ is summed and/or compared with AVS, one-half the molar silver concentration is applied.

One final point should be made with respect to nomenclature. The terms *nontoxic* and *having no effect* are used only with respect to the six metals considered in this document. Toxicity of field- collected sediments can be caused by other chemicals. Therefore, avoiding exceedences of the $ESB_{AVS:WQC}$ for metal mixtures does not mean that the sediments are nontoxic. It only ensures that the six metals being considered should not cause direct toxicity to benthic organisms. Moreover, as discussed in detail below, exceedence of the benchmarks for the six metals does not necessarily indicate that metals will cause toxicity. For these reasons,it is strongly recommended that the combined use of both AVS and interstitial water measurements; toxicity tests; TIEs; chemical monitoring in vertical, horizontal, and temporal scales; and other assessment methodologies as integral parts of any evaluation of the effects of sediment-associated contaminants (Ankley et

al., 1994; Lee et al., 2000).

4.2 Sediment Benchmarks for Multiple Metals

It is neither sufficient nor appropriate to derive an ESB that considers each metal separately, because metals almost always occur as mixtures in field sediments and metal–sulfide binding is interactive.

4.2.1 *AVS Benchmarks*

Results of calculations using chemical equilibrium models indicate that metals act in a competitive manner when binding to AVS. That is, the six metals—silver, copper, lead, cadmium, zinc, and nickel— will bind to AVS and be converted to their respective sulfides in this sequence (i.e., in the order of increasing solubility). Therefore, they must be considered together. There cannot be a benchmark for just nickel, for example, because all the other metals may be present as metal sulfides, and therefore, to some extent, as AVS. If these other metals are not measured as a mixture, then the ΣSEM will be misleadingly small, and it might appear that Σ[SEM]<[AVS] when in fact this would not be true if all the metals are considered together. It should be noted that this document currently restricts this discussion to the six metals listed above; however, in situations where other sulfide-forming metals (e.g., mercury) are present at high concentrations, they also must be considered.

The equilibrium model used to derive the $ESB_{AVS:WQC}$ for a mixture of the metals is presented below (see Ankley et al., 1996, for details). If the molar sum of SEM for the six metals is less than or equal to the AVS, that is, if

$$\Sigma_i [SEM_i] \leq [AVS] \quad (4\text{-}1)$$

where

$$\Sigma_i [SEM_i] = [SEM_{Cd}] + [SEM_{Cu}] + [SEM_{Pb}] + [SEM_{Ni}] + [SEM_{Zn}] + 1/2[SEM_{Ag}]$$

then the concentrations of the mixtures of metals in the sediment are acceptable for protection of benthic organisms from acute or chronic metal toxicity.

4.2.2 *Interstitial Water Benchmarks*

The application of the interstitial water benchmark to multiple metals is complicated, not by the chemical interactions of the metals in the sediment-interstitial water system (as in the case with the AVS benchmark), but rather because of possible toxic interactions. Even if the individual concentrations do not exceed the water quality final chronic value (FCV) of each metal

Table 4-1. Water quality criteria (WQC) final chronic value (FCV) based on the dissolved concentration of metal[a]

Metal	Saltwater FCV (μg/L)	Freshwater FCV (μg/L)[b]
Cadmium	9.3	CF[c] $[e^{(0.7852[\ln(\text{hardness})]-3.490}]$
Copper[d]	3.1	$0.960[e^{(0.8545[\ln(\text{hardness})]-1.465)}]$
Lead	8.1	$0.791[e^{(1.273[\ln(\text{hardness})]-4.705)}]$
Nickel	8.2	$0.997[e^{(0.8460[\ln(\text{hardness})]+1.1645)}]$
Silver	NA[e]	NA[e]
Zinc	81	$0.986[e^{(0.8473[\ln(\text{hardness})]+0.7614)}]$

[a] These WQC FCV values are for use in the interstitial water benchmarks approach for deriving $ESBs_{AVS:WQC}$ based on the dissolved metal concentrations in interstitial water (U.S. EPA, 1995b).

[b] For example, the freshwater FCV at a hardness of 50, 100, and 200 mg $CaCO_3$/L are 0.62, 1.0, and 1.7 μg cadmium/L; 6.3, 10, and 20 μg copper/L; 1.0, 2.5, and 6.1 μg lead/L; 87, 160, and 280 μg nickel/L; and 58, 100, and 190 μg zinc/L.

[c] CF = conversion factor to calculate the dissolved FCV for cadmium from the total FCV for cadmium: CF=1.101672–[(ln hardness)(0.041838)].

[d] The saltwater FCV for copper is from U.S. EPA (1995c).

[e] The silver criteria are currently under revision to reflect water quality factors that influence the criteria such as hardness, DOC, chloride, and pH, among other factors.

presented in Table 4-1, the metals could exert additive effects that might result in toxicity (Biesinger et al., 1986; Spehar and Fiandt, 1986; Enserink et al., 1991; Kraak et al., 1994). Therefore, in order to address this potential additivity, the interstitial water metal concentrations are converted to interstitial water benchmark units (IWBUs). This conversion is done by dividing the individual metal interstitial water concentrations by their respective WQC FCV and summing these values for all the metals. IWBUs are conceptually similar to toxic units; however, the term IWBU was adopted because it is derived using the FCV, which is intended to be a "no effect" concentration (i.e., toxicity would not usually be expected at 1.0 IWBUs).

For freshwater sediments, the FCVs are hardness dependent for all of the divalent metals under consideration, and thus, need to be adjusted to the hardness of the interstitial water of the sediment being considered. Because there are no FCVs for silver in freshwater or saltwater, this approach is not applicable to sediments containing significant concentrations of silver (i.e., ΣSEM>AVS). Because silver has the smallest solubility product (see Table 2-2) and the greatest affinity for AVS, it would be the last metal to be released from the AVS or the first metal to bind with AVS. Therefore, it is unlikely that silver would occur in the interstitial water of any sediment with measurable AVS (Berry et al., 1996).

For the ith metal with a total dissolved concentration, $[M_{i,d}]$, the IWBU is

$$\sum_i \frac{[M_{i,d}]}{FCV_{i,d}} \le 1.0 \qquad (4\text{-}2)$$

where

$$\sum_i \frac{[M_{i,d}]}{[FCV_{i,d}]} = \frac{[M_{Cd,d}]}{[FCV_{Cd,d}]} + \frac{[M_{Cu,d}]}{[FCV_{Cu,d}]} + \frac{[M_{Pb,d}]}{[FCV_{Pb,d}]} + \frac{[M_{Ni,d}]}{[FCV_{Ni,d}]} + \frac{[M_{Zn,d}]}{[FCV_{Zn,d}]}$$

4.2.3 *Summary*

In summary, the sediment benchmarks for these six metals are not exceeded, and benthic organisms are sufficiently protected, if the sediment meets either one of the following benchmarks.

$$\Sigma_i[SEM_i] \le [AVS] \qquad (4\text{-}1)$$

or

$$\sum_i \frac{[M_{i,d}]}{FCV_{i,d}} \le 1.0 \qquad (4\text{-}2)$$

If the AVS or interstitial water $ESB_{AVS:WQC}$s are exceeded, there is reason to believe that the sediment *might* be unacceptably contaminated by these metals. Further evaluation and testing would, therefore, be necessary to assess actual toxicity and its causal relationship to the metals of concern. If data on the sediment-specific SEM, AVS, and organic carbon concentrations are available, the uncertainty bounds for $(\Sigma SEM\text{-}AVS)/f_{OC}$ described in Section 3.4 could be used to further classify sediments as those in which metals are not likely to cause toxicity, metal toxicity predictions are uncertain, or metal toxicity is likely. For sediments in which toxicity is likely or uncertain, acute and chronic tests with species that are sensitive to the metals suspected to be of concern, acute and chronic sediment TIEs, in situ community assessments, and seasonal and spatial characterizations of the SEM, AVS, and interstitial water concentrations would be appropriate (Ankley et al., 1994).

4.3 Example Calculation of $ESB_{AVS:WQC}$s for Metals and EqP-Based Interpretation

To assist users of these $ESB_{AVS:WQC}$s for mixtures of metals, example calculations for deriving solid-phase and interstitial water $ESB_{AVS:WQC}$s are provided in Table 4-2. For each of the three sediments, the calculations began with measured concentrations (in bold) of AVS (μg/g), SEM_i (μg/g), and interstitial water metal (μg/L). All other values were calculated. The specific concentrations in each of the these sediments were selected to provide examples of how the chemical measurements are used with the $ESB_{AVS:WQC}$ to determine the acceptability of a specific sediment and how the risks of sediment-associated metals can be evaluated within the technical framework of the EqP approach. Sediments are arranged in the table in decreasing order of their sulfide solubility product constants (see Section 2.2.5).

Sediment A contains relatively high concentrations of metals in the SEM, between 14.2 and 16.5 μg/g for copper, lead, and zinc. However, because there is sufficient AVS (0.96 μmol/g) in the sediment, the solid-phase $ESB_{AVS:WQC}$ is –0.343 (μmol/g), and there is no

Table 4-2. Example calculations of $ESB_{AVS:WQC}$s for metal mixtures: three sediments.

	Sediment Concentration			Interstitial Water Concentration				$ESB_{AVS:WQC}$	
Sediment	Analyte	$\mu g/g^a$	$\mu mol/g$	Metal ($M_{i,d}$)	$\mu g/L$	FCV[b]	IWBU	SEM-AVS ($\mu mol/g$)	IW

metal detected in the interstitial water. This sediment is acceptable for protection of benthic organisms from direct toxicity of the metals in the sediment. Silver was not measured in this sediment. However, because AVS is present, any silver in the sediment is not of toxicological concern and none should occur in interstitial water. One final consideration is the need for detection limits for metals in the sediment that are significantly below their respective WQC FCVs. For this sediment there were no detectable metals in the interstitial water and ΣIWBU was <0.46.

Sediment B is from a Superfund site heavily contaminated with all of the metals (ΣSEM = 46.5

μmol/g), but most severely with zinc (2,630 μg/g). There is an excess of SEM in this sediment (SEM-AVS = 5.71 μmol/g). Importantly for sediment B, the interstitial concentrations of the metals were all less than the WQC FCVs and the ΣIWBU was <1.0 (~ 0.46). Therefore, this sediment is acceptable for protection of benthic organisms from direct toxicity of this mixture of metals in the sediment. It should be noted that, if interstitial metal concentrations had not been quantified, the sediment would have exceeded the $ESB_{AVS:WQC}$ and additional testing would be advisable. A possible explanation for the absence of significant metals in the interstitial water of this sediment is its higher organic carbon concentration (f_{OC} = 0.05). The (ΣSEM-AVS)/f_{OC} of 114 μmol excess SEM/g_{OC} for this sediment is, therefore, predicted to be nontoxic because it is <130 μmol excess SEM/g_{OC} (see Section 3.4.4).

Sediment C is heavily contaminated with approximately equimolar concentrations of cadmium and nickel. It exceeds the $ESB_{AVS:WQC}$ for metals for both solid and interstitial water phases. The ΣSEM (10.28 μmol/g) exceeds the AVS (4.57 μmol/g); therefore, SEM-AVS = 5.71 μmol excess SEM/g, a concentration identical to that of sediment B. Although lead and copper are found in the sediment, they are not found in detectable concentrations in the interstitial water. This is because they have the lowest sulfide solubility product constants and the sum of their SEM concentrations (0.39 μmol/g) is less than AVS. If the dry weight concentrations of metals had been analyzed, silver and additional copper and nickel might have been detected. Silver will not be detected in the SEM or interstitial water when AVS is present (see Section 3.2.1). Nickel, cadmium, and zinc occur in interstitial water because in the sequential summation of the SEM_i concentrations in order of increasing sulfide solubilities, the concentrations of these metals exceed the AVS. Therefore, these three metals are found in the SEM that is not a metal sulfide and in the interstitial water, and contribute to the ΣIWBU (~40.47) as well as to the overall exposure of benthic organisms. Because only cadmium concentrations exceed the WQC FCV, any effects observed in toxicity tests or in faunal analyses with this sediment should principally be a result of cadmium. This sediment is low in organic carbon concentration (TOC = 0.2%; f_{OC} = 0.002). The organic carbon–normalized concentration (ΣSEM-AVS/f_{OC}) of 2,855 μmol excess SEM/g_{OC} was within the uncertainty bounds of 130 to 3,000 μmol excess SEM/g_{OC}, suggesting that additional evaluations should be conducted (see Section 3.4.4).

4.4 $ESB_{AVS:WQC}$ for Metals vs. Environmental Monitoring Databases

This section compares the $ESB_{AVS:WQC}$ based on AVS or IWBUs with chemical monitoring data from freshwater and saltwater sediments in the United States. This comparison of AVS-SEM and interstitial water concentrations is used to indicate the frequency of sediments in the United States where metals toxicity is unlikely. When data were available in the monitoring programs, (ΣSEM-AVS)/f_{OC} is used to indicate sediments where toxicity is unlikely, likely, or uncertain. When toxicity or benthic organism community health data are available in conjunction with these concentrations it is possible to speculate as to potential causes of the observed effects. These data, however, cannot be used to validate the usefulness of the AVS approach because sediments that exceed the benchmarks are not always toxic, and because observed sediment toxicity may be the result of unknown substances.

4.4.1 *Data Analysis*

Three monitoring databases were identified that contain AVS, SEM, and f_{OC} information; one also had data on concentrations of metals in interstitial water. Toxicity tests were conducted on all sediments from these sources. The sources are the Environmental Monitoring and Assessment Program (EMAP) (Leonard et al., 1996a), the National Oceanographic and Atmospheric Administration National Status and Trends monitoring program (NOAA NST) (Wolfe et al., 1994; Long et al., 1995b, 1996), and the Regional Environmental Monitoring and Assessment Program (REMAP) (Adams et al., 1996).

4.4.1.1 *Freshwater Sediments*

The AVS and SEM concentrations in the 1994 EMAP database from the Great Lakes were analyzed by Leonard et al. (1996a). A total of 46 sediment grab samples and 9 core samples were collected in the summer from 42 locations in Lake Michigan. SEM, AVS, TOC, interstitial water metals (when sufficient volumes were present), and 10-day sediment toxicity to the midge *C. tentans* and the amphipod *H. azteca* were measured in the grab samples (the concentrations are listed in Appendix A).

The AVS concentrations versus SEM-AVS differences from Appendix A are plotted in Figure 4-1. Grab sediment samples containing AVS concentrations

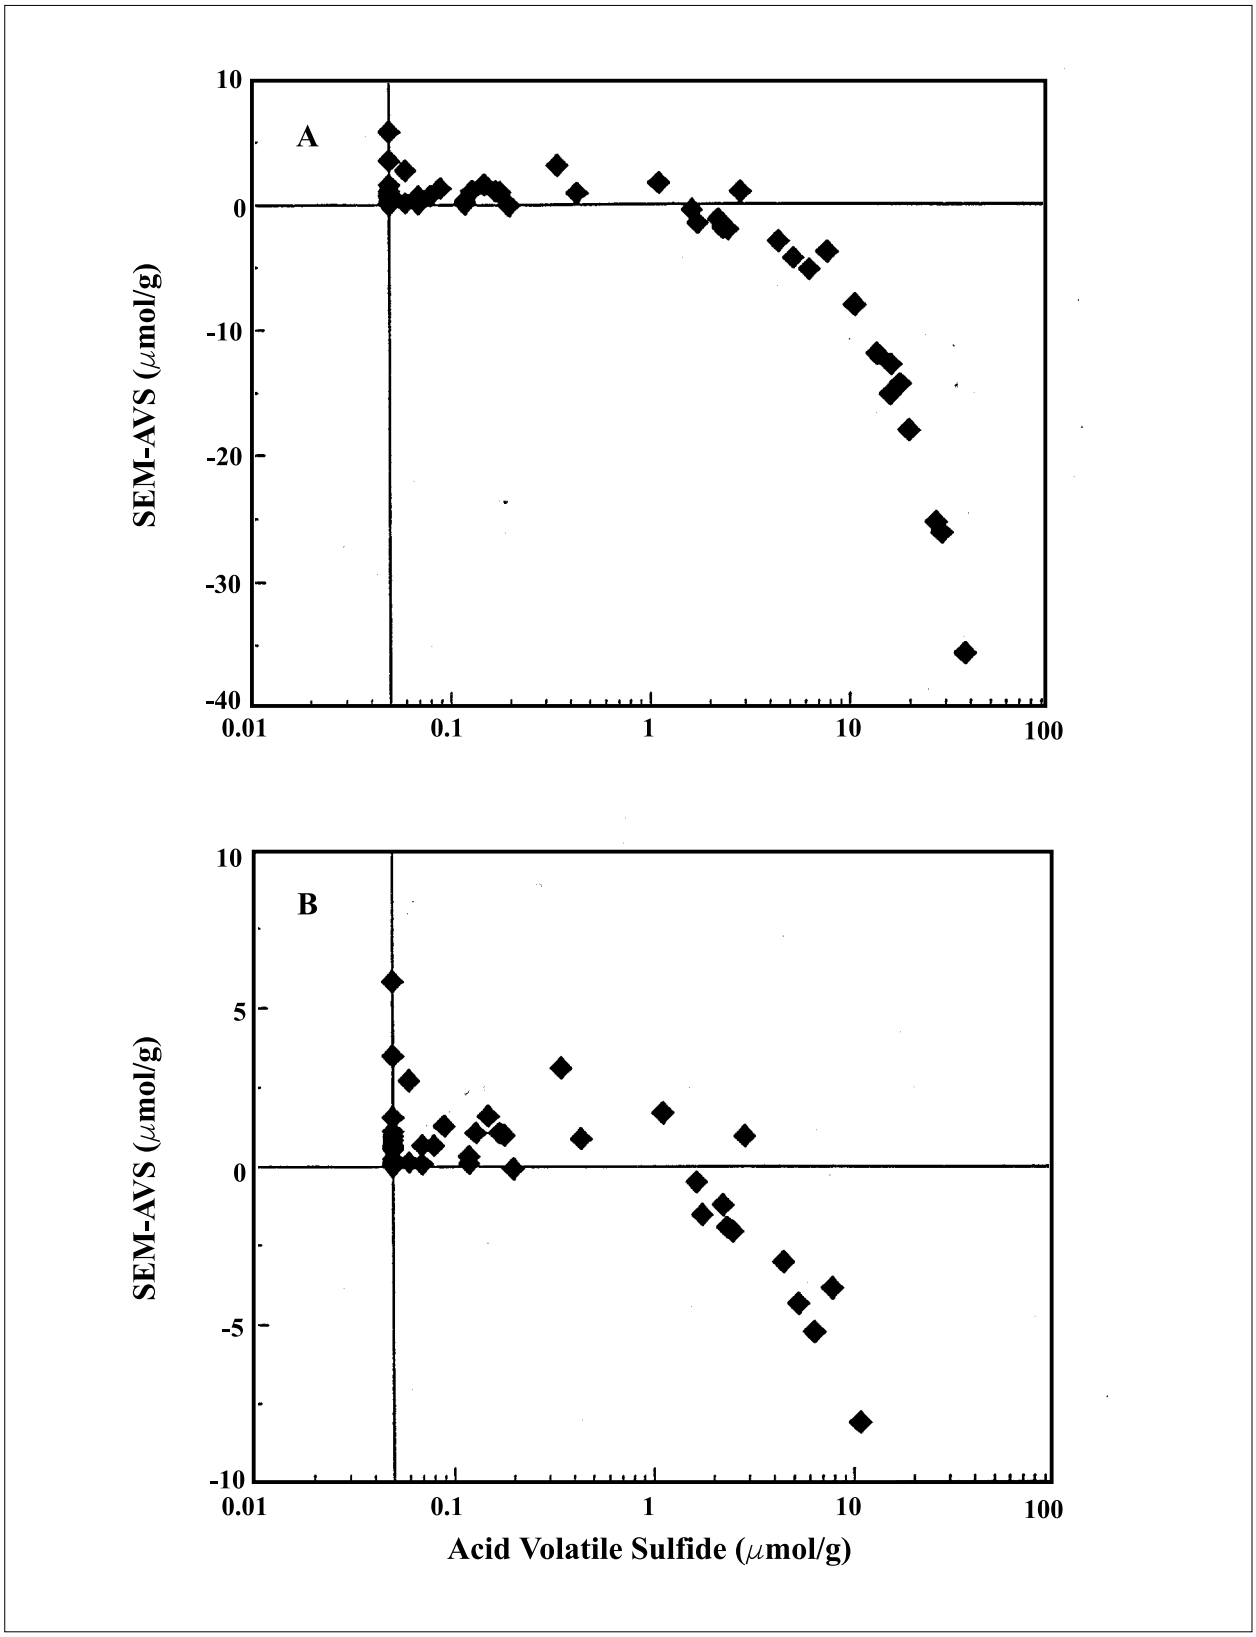

Figure 4-1. SEM-AVS values versus AVS concentrations in EMAP-Great Lakes sediments from Lake Michigan. Data are from surficial grab samples only. Plot (A) shows all values; plot (B) has the ordinate limited to SEM-AVS values between –10 and +10 μmol/g.

below the detection limit of 0.05 μmol/g AVS are plotted at that concentration. Forty-two of the 46 samples (91%) had SEM-AVS differences greater than 0.0. Thirty-six of these had less than 1.0 μmol of excess SEM/g sediment; and none had over 5.8 μmol excess SEM/g sediment. Sediments with SEM concentrations in excess of that for AVS have the potential to be toxic because of metals. However, the majority of sediments with an excess of SEM had low concentrations of both AVS and SEM. For 20 of these Lake Michigan sediments, interstitial water metals concentrations were measured. The sum of the IWBUs for cadmium, copper, lead, nickel, and zinc was always less than 0.4 (Leonard et al., 1996a). In 10-day toxicity tests using *C. tentans* and *H. azteca*, no toxicity was observed in 81% of the 21 sediments not exceeding the $ESB_{AVS:WQC}$, Leonard et al. (1996a) concluded that when toxicity was observed it was not likely from metals, because of the low interstitial water metals concentrations. These data demonstrate the value of using both SEM-AVS and IWBUs to evaluate the risks of metals in sediments.

4.4.1.2 *Saltwater Sediments*

Saltwater data from a total of 398 sediment samples from 5 monitoring programs representing the eastern coast of the United States are included in Appendix B. The EMAP Virginian Province database (U.S. EPA, 1996) consists, in part, of 127 sediment samples collected from August to mid-September 1993 from randomly selected locations in tidal rivers and small and large estuaries from the Chesapeake Bay to Massachusetts (Strobel et al., 1995). The NOAA data are from Long Island Sound, Boston Harbor, and the Hudson River Estuary. Sediments were collected from 63 locations in the coastal bays and harbors of Long Island Sound in August 1991 (Wolfe et al., 1994). Sediment samples from 30 locations in Boston Harbor were collected in June and July 1993 (Long et al., 1996). Sediment samples from 38 locations in the Hudson River Estuary were collected from March to May 1991 (Long et al., 1995b). Sediment samples were collected in the REMAP program from 140 locations from the New York/New Jersey Harbor Estuary System (Adams et al., 1996). All of the above sediment grab samples were from approximately the top 2 cm of undisturbed sediment.

For saltwater sediments, the molar concentration of AVS typically exceeds that for SEM (SEM-AVS $\leq$0.0 μmol/g) for most of the samples across the entire range of AVS concentrations (Figure 4-2). A total of 68 of the 398 saltwater sediments (17%) had an excess of metal, and only 4 of the 68 (6%) had over 2 μmol excess SEM/g. As AVS levels increase, fewer and fewer sediments have SEM-AVS differences that are positive; none occurred when AVS was >8.1 μmol/g. Interstitial water metal was not measured in these saltwater sediments. Only 5 of the 68 sediments (7%) having excess of up to 0.9 μmol SEM/g were toxic in 10-day sediment toxicity tests with the amphipod *A. abdita*, whereas 79 of 330 sediments (24%) having an excess of AVS were toxic. Toxicity was not believed to be metals related in the 79 toxic sediments where AVS was in excess over SEM. Metals were unlikely the cause of toxicity in those sediments having an excess of SEM because there was only $\leq$0.9 μmol excess SEM/g. Finally, the absence of toxicity in sediments having an excess of SEM of up to 4.4 μmol/g indicates significant metal-binding potential over that of AVS in some sediments. Organic carbon concentrations from 0.05% to 15.2% (average 1.9%) provide for some of this additional metal binding.

Organic carbon, along with SEM and AVS, was measured in these 398 saltwater sediments. Therefore, the $(\Sigma SEM\text{-}AVS)/f_{OC}$ concentrations of concern can be compared with the organic carbon–normalized concentrations of SEM-AVS differences (Figure 4-3). No sediments containing an AVS concentration in excess of 10 μmol/g had an excess of SEM; that is, all $(\Sigma SEM\text{-}AVS)/f_{OC}$ values were negative. Excess of SEM relative to AVS became more common as sediment AVS decreased. None of the sediments contained greater than 130 μmol excess SEM/g_{OC}, the lower uncertainty bound from Section 3.4. This indicates that metals concentrations in all of the sediments monitored in the summer by EPA EMAP and REMAP and by NOAA are below concentrations of concern for benthic organisms.

4.5 Bioaccumulation

The data appear to suggest that, for these sediments collected from freshwater and marine locations in the United States, direct toxicity caused by metals in sediments is expected to be extremely rare. Although this might be true, these data by themselves are inconclusive. Importantly, it would be inappropriate to use the data from the above studies to conclude that metals in sediments are *not* a problem. In all of the above studies, the sediments were conducted in the summer when the seasonal biogeochemical cycling of sulfur should produce the highest concentrations of iron monosulfide, which

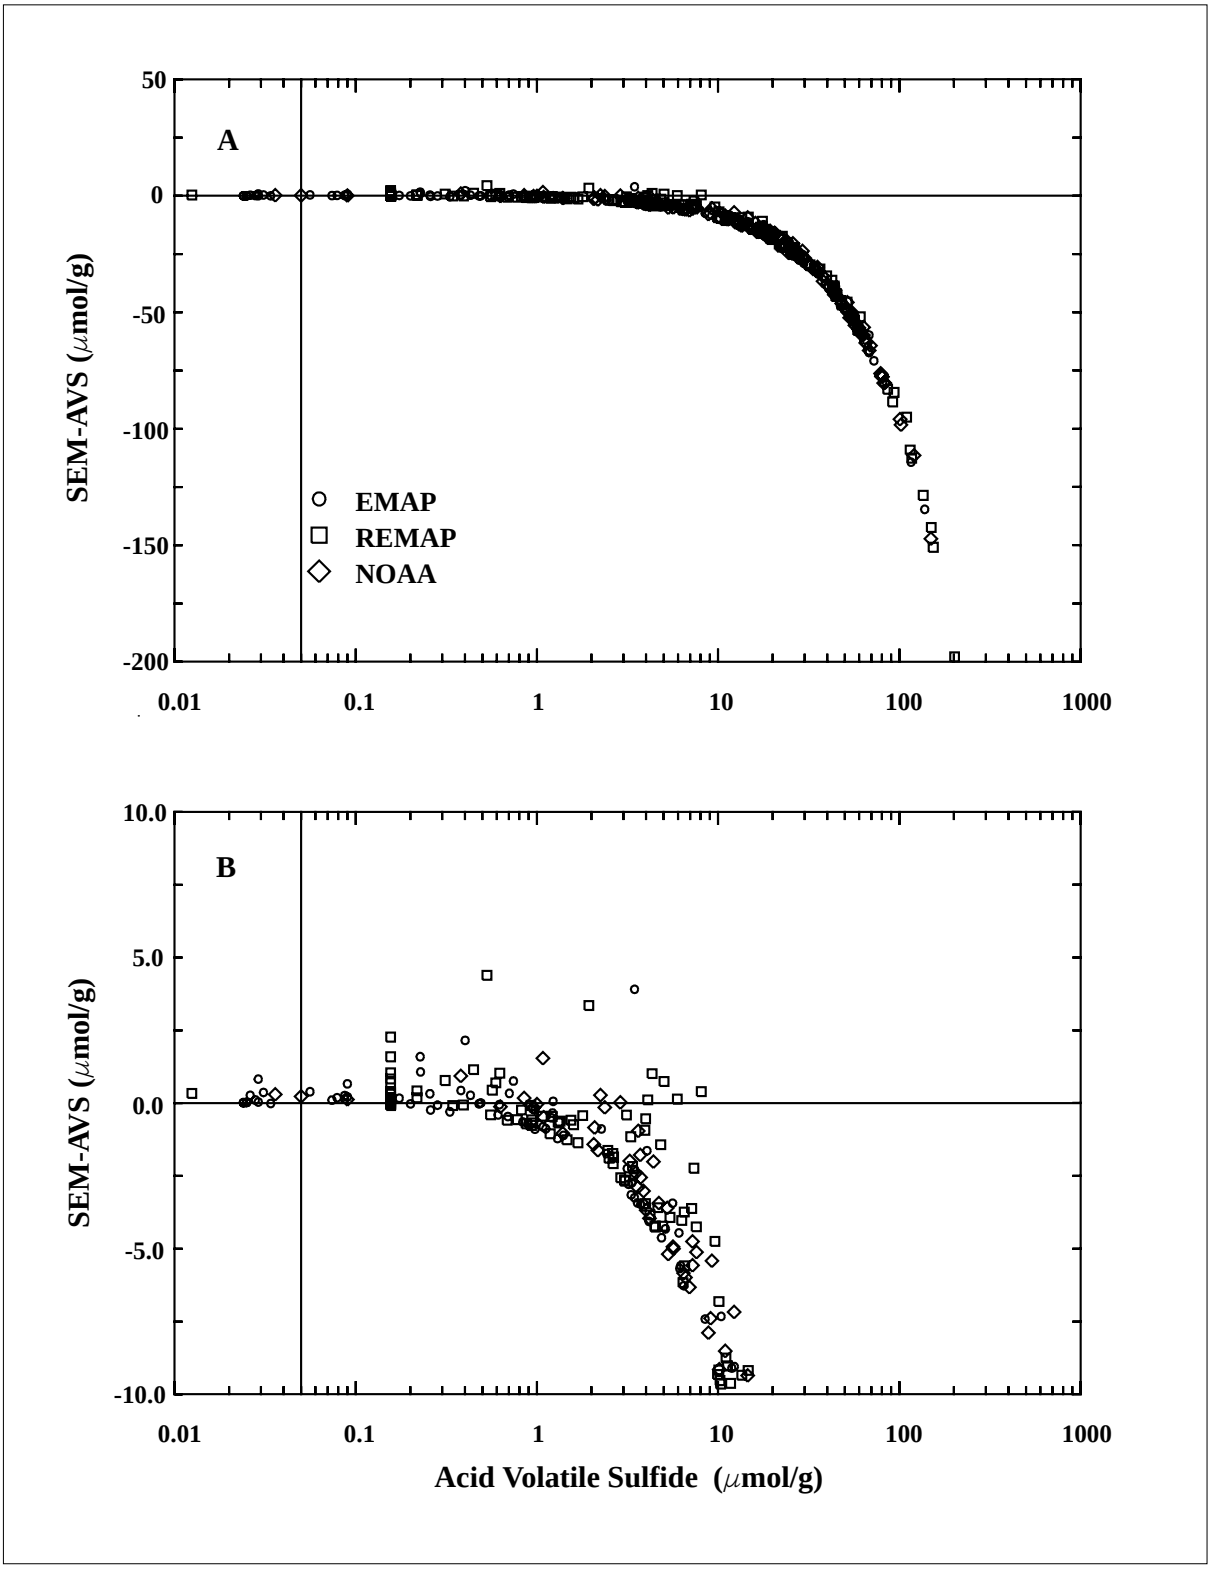

Figure 4-2. **SEM-AVS values versus AVS concentrations in EMAP-Estuaries Virginian Province (U.S. EPA, 1996); REMAP-NY/NJ Harbor Estuary (Adams et al., 1996); NOAA NST-Long Island Sound (Wolfe et al., 1994); Boston Harbor (Long et al., 1996); and Hudson-Raritan Estuaries (Long et al., 1995b). Plot A shows all values; plot B has the ordinate limited to SEM-AVS values between -10 and +10 μmol/g (see data in Appendix B).**

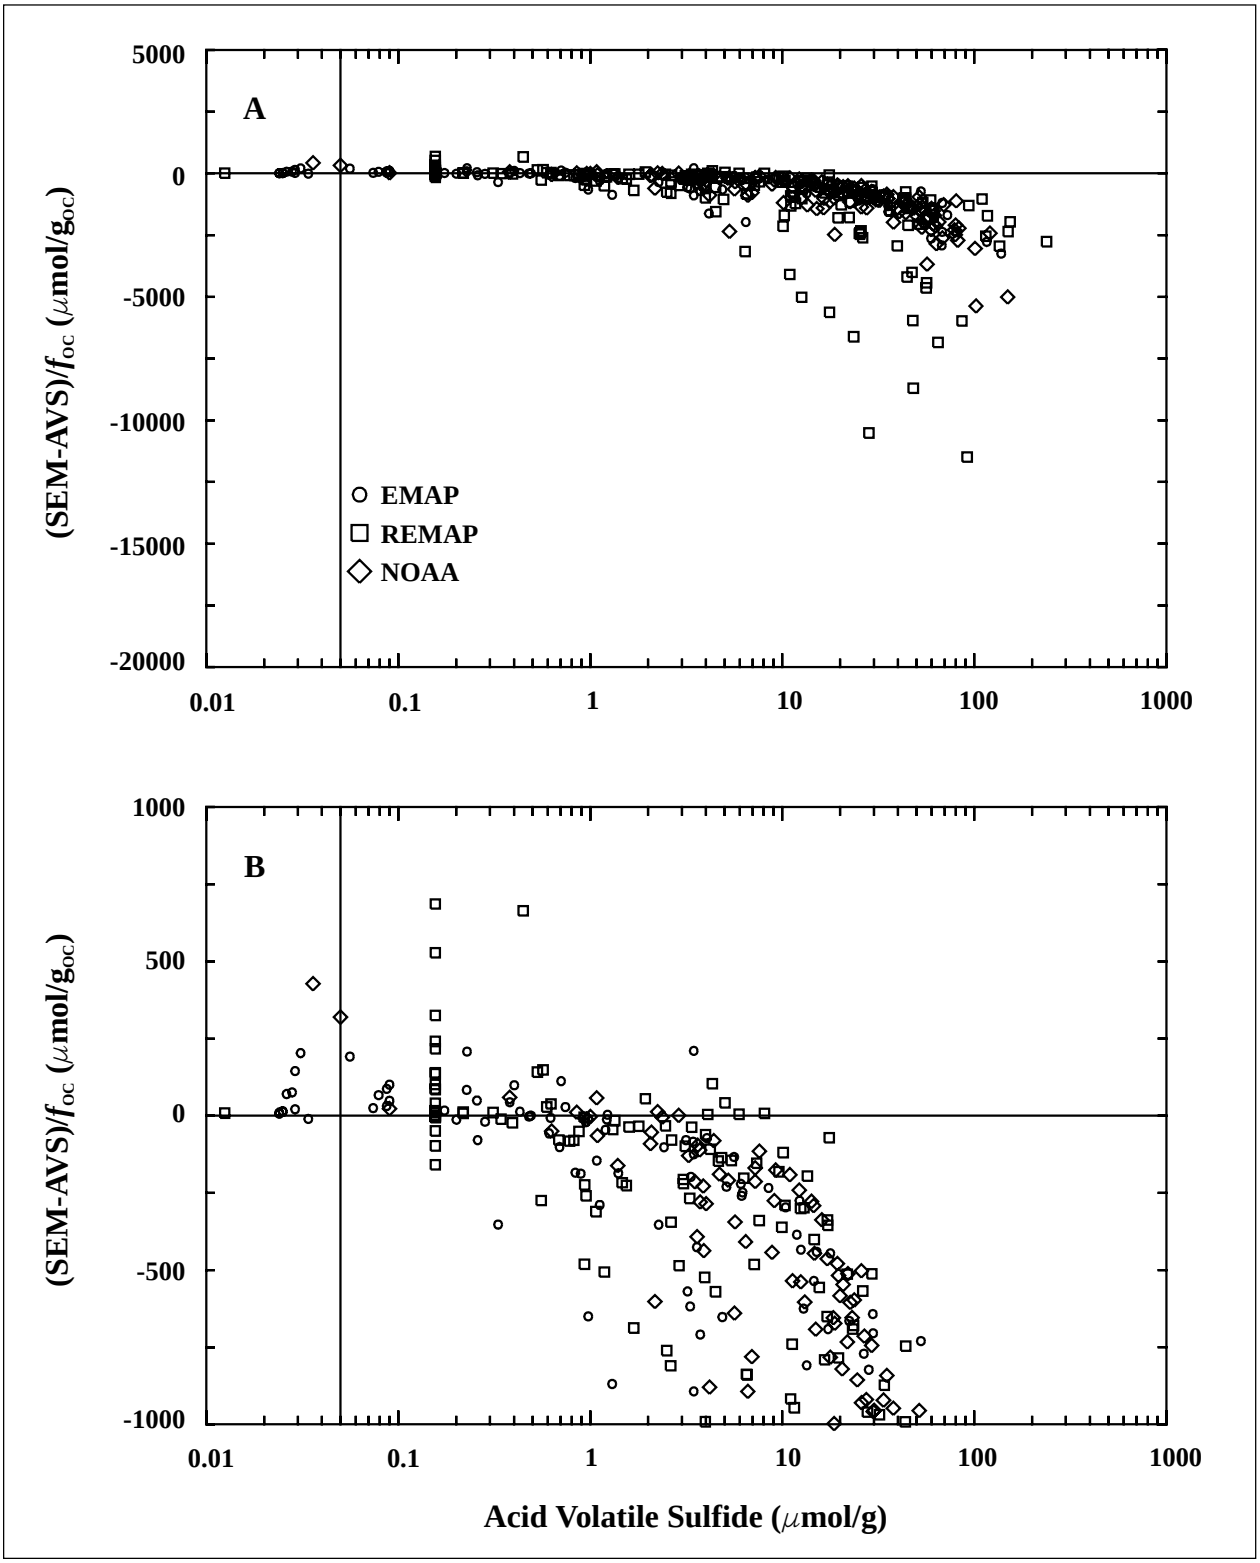

Figure 4-3. **(ΣSEM-AVS)/f_{OC} versus AVS concentrations in EMAP-Estuaries Virginian Province (U.S. EPA, 1996); REMAP-NY/NJ Harbor Estuary (Adams et al., 1996); NOAA NST-Long Island Sound (Wolfe et al., 1994); Boston Harbor (Long et al., 1996); and Hudson-Raritan Estuaries (Long et al., 1995b). Plot A shows all values; plot B has the ordinate limited to (ΣSEM-AVS)/f_{OC} values between -10 and +10 μmol/g (see data in Appendix B).**

might make direct metal-associated toxicity less likely than in the winter/spring months. Accurate assessment of the extent of the direct ecological risks of metals in sediments requires that sediment monitoring occur in the months of minimum AVS concentration; typically, but not always, in November to early May. These yet-to-be-conducted studies must monitor, at a minimum, SEM, AVS, f_{OC}, interstitial water metal, and toxicity.

Bioaccumulation of metals from sediments when SEM is less than AVS was not expected based on EqP theory. However, there is a significant database that demonstrates that metals concentrations in benthic organisms increase when metals concentrations in sediments on a dry weight basis increase (Ankley, 1996). This has caused considerable debate (Lee et al., 2000a,b) because it suggests that metal bioavailability may be related to dry weight metals concentrations, and if the increase in bioaccumulated metal is related to effects, then effects may be related to dry weight metals concentrations. Most importantly, these studies, and all other AVS-related testing, has overwhelming demonstrated that toxic effects of metals are absent in sediments when SEM is less than AVS, even when bioaccumulation is observed, and that toxicity is not related to dry weight metals concentrations. For example, careful evaluation of Lee et al. (2000b) results, demonstrates that in order to understand and predict metal toxicity AVS normalization is critical. Although Lee et al. (2000b) note the accumulation of metal by the test organisms, no adverse effects were reported. This suggests that the bioaccumulated metals may not be toxicologically available or of sufficient concentration in the organism to cause effects. In addition, these metals do not biomagnify to higher trophic levels in aquatic ecosystems (Suedel et al., 1994). Therefore, an $ESB_{AVS:WQC}$ based on the difference between the concentrations of SEM and AVS is appropriate for protecting benthic organisms from the direct effects of sediment-associated metals, and not for protecting against metal bioaccumulation.

Section 5

Sampling and Analytical Chemistry

5.1 General Information

This section provides guidance on procedures for sampling, handling, and analysis of metals in sediments, and on the interpretation of data from the sediment samples that are needed if the assessments of the risks of sediment-associated metals are to be appropriately based on the EqP methodology. The design of any assessment should match the goal of the specific assessment and how evaluation tools such as $ESB_{AVS:WQC}$s are to be applied.

Results of the short- and long-term laboratory and field experiments conducted to date using sediments spiked with individual metals and mixtures of metals represent convincing support for the conclusion that absence (but not necessarily presence) of metal toxicity can be reliably predicted based on metal–sulfide relationships or interstitial water metal concentrations. In contrast, much confusion exists on how to use this convincing evidence to interpret the significance of metals concentrations in sediments from the field. Using these observations as a basis for predicting metal bioavailability, or deriving an $ESB_{AVS:WQC}$, raises a number of conceptual and practical issues related to sampling, analytical measurements, and effects of additional binding phases. Many of these were addressed by Ankley et al. (1994). Those most salient to the proposed derivation of the $ESB_{AVS:WQC}$s are described below.

5.2 Sampling and Storage

Accurate prediction of exposure of benthic organisms to metals is critically dependent on sampling appropriate sediment horizons at appropriate times. This is because of the relatively high rates of AVS oxidation caused by natural processes in sediments and the requirement that oxidation must be avoided during sampling of sediments and interstitial water. In fact, the labile nature of iron monosulfides has led some to question the practical utility of using AVS as a basis for an EqP-derived ESB for metals (Luoma and Carter, 1993; Meyer et al., 1994). For example, there have been many observations of spatial (depth) variations in AVS concentrations, most of which indicate that surficial AVS concentrations are less than those in deeper sediments (Boothman and Helmstetter, 1992; Howard and Evans, 1993; Brumbaugh et al., 1994; Hare et al., 1994; Besser et al., 1996; Hansen et al., 1996b; Leonard et al., 1996a; Liber et al., 1996; Boothman et al., 2001). This is likely because of oxidation of AVS (principally FeS) at the sediment surface, a process enhanced by bioturbation (Peterson et al., 1996).

In addition to varying with depth, AVS can vary seasonally. For example, in systems where overlying water contains appreciable oxygen during cold-weather months, AVS tends to decrease, presumably because of a constant rate of oxidation of the AVS linked to a decrease in its generation by sulfate-reducing bacteria (Herlihy and Mills, 1985; Howard and Evans, 1993; Leonard et al., 1993). Because of potential temporal and spatial variability of AVS, it appears that the way to avoid possible underestimation of metal bioavailability is to sample the biologically "active" zone of sediments at times when AVS might be expected to be present at low concentrations. It is recommended that, at a minimum, AVS and SEM measurements be made using samples of the surficial (0 to 2.0 cm) sediments during the period from November to early May. Minimum AVS concentrations may not always occur during cool-weather seasons; for example, systems that become anaerobic during the winter can maintain relatively large sediment AVS concentrations (Liber et al., 1996). Therefore, AVS, SEM, and interstitial metal concentrations may need to be determined seasonally. Importantly, the biologically active zones of some benthic communities may be within only the surficial first few millimeters of the sediment, whereas other communities may be biologically active at depths up to a meter. In order to determine the potential for exposure to metals, sediment and interstitial water samples from multiple sediment horizons may be required.

The somewhat subjective aspects of these sampling recommendations have been of concern. Multiple sediment samples are necessary because of the dynamic nature of the metal-binding phases in sediments. Depending on the depth of bioturbation, the possible oxidation rates of specific metal sulfides, and the extent of possible metal concentrations, the horizontal and vertical resolution of the needed monitoring is likely to be site specific. Even if neither

of the sediment benchmarks is violated in extensive monitoring programs, metals concentrations on a dry weight basis may be high and widely distributed. This may be a good reason to conduct monitoring studies to determine the extent of metal bioaccumulation in benthic food chains. Furthermore, if the ultimate fate of the sediments is unknown, risk assessments to evaluate future risks caused by dynamic processes may be desirable.

Research suggests that the transient nature of AVS may be overstated relative to predicting the fate of all metal-sulfide complexes in aquatic sediments. Observations from the Duluth EPA laboratory made in the early 1990s indicate that AVS concentrations in sediments contaminated by metals such as cadmium and zinc tended to be elevated over concentrations typically expected in freshwater systems (G.T. Ankley, U.S. EPA, Duluth, MN, personal communication). The probable underlying basis for these observations did not become apparent, however, until a recent series of spiking and metal-sulfide stability experiments. The field colonization study of Liber et al. (1996) demonstrated a strong positive correlation between the amount of zinc added to test sediments and the resultant concentration of AVS in the samples. In fact, the initial design of their study attempted to produce test sediments with as much as five times more SEM_{Zn} (nominal) than AVS; however, the highest measured SEM_{Zn}/AVS ratio achieved was only slightly larger than 1. Moreover, the expected surficial depletion and seasonal variations in AVS were unexpectedly low in the zinc-spiked sediments. These observations suggested that zinc sulfide, which composed the bulk of AVS in the spiked sediments, was more stable than the iron sulfide present in the control sediments. The apparent stability of other metal sulfides versus iron sulfide also has been noted in laboratory spiking experiments with freshwater and saltwater sediments (Leonard et al., 1995; DeWitt et al., 1996; Hansen et al., 1996b; Peterson et al., 1996; Sibley et al., 1996; Boothman et al., 2001).

In support of these observations, metal-sulfide oxidation experiments conducted by Di Toro et al. (1996b) have confirmed that cadmium and zinc form more stable sulfide solid phases than iron. If this is also true for sulfide complexes of copper, nickel, silver, and lead, the issue of seasonal/spatial variations in AVS becomes of less concern because most of the studies evaluating variations in AVS have focused on iron sulfide (i.e., uncontaminated sediments). Thus, further research concerning the differential stability of metal sulfides, from both temporal and spatial perspectives, is definitely warranted.

5.2.1 *Sediments*

At a minimum, sampling of the surficial 2.0 cm of sediment between November and early May is recommended. A sample depth of 2.0 cm is appropriate for monitoring. However, for instances such as dredging or in risk assessments where depths greater than 2 cm are important, sample depths should be planned based on particular study needs. Sediments can be sampled using dredges, grabs, or coring, but mixing of aerobic and anaerobic sediments must be avoided because the trace metal speciation in the sediments will be altered (see Bufflap and Allen, 1995, for detailed recommendations to limit sampling artifacts). Coring is generally less disruptive, facilitates sampling of sediment horizons, and limits potential metal contamination and oxidation if sealed PVC core liners are used.

Sediments not immediately analyzed for AVS and SEM must be placed in sealed airtight glass jars and refrigerated or frozen. Generally, enough sediment should be added to almost fill the jar. If sediments are stored this way, there will be little oxidation of AVS even after several weeks. Sampling of the stored sediment from the middle of the jar will further limit potential effects of oxidation on AVS. Sediments experiencing oxidation of AVS during storage will become less black or grey if oxidized. Because the rate of metal-sulfide oxidation is markedly less than that of iron sulfide, release of metal during storage is unlikely.

5.2.2 *Interstitial Water*

Several procedures are available to sample interstitial water in situ or ex situ. Carignan et al. (1985) compared metals concentrations in interstitial water obtained by ex situ centrifugation at 11,000 rpm followed by filtration (0.45 μm and 0.2 or 0.03 μm) and in situ diffusion samplers with 0.2 μm polysulfone membranes. For the metals of concern in this benchmark document, concentrations of nickel and cadmium were equivalent using both methods, and concentrations of copper and zinc were higher and more variable using centrifugation. They recommended using in situ dialysis for studying trace constituents in sediments because of its inherent simplicity and the avoidance of artifacts that can occur with the handling of sediments in the laboratory.

More recently, Bufflap and Allen (1995) reviewed four procedures for collection of interstitial water for trace metals analysis. These included ex situ squeezing, centrifugation, in situ dialysis, and suction filtration. These authors observed that each method has its own advantages and disadvantages. Importantly, interstitial water must be extracted by centrifugation or squeezing in an inert atmosphere until acidified, because oxidation will alter metal speciation. Artifacts may be caused by temperature changes in ex situ methods that may be overcome by maintaining temperatures similar to those in in situ methods. Contamination of interstitial water by fine particles is important in all methods, because differentiation of particulate and dissolved metal is a function of the pore size of the filter or diffusion sampler membrane. The use of 0.45 μm filtration, although an often accepted definition of "dissolved" metals, may result in differences from laboratory to laboratory. Use of suction filtration devices is limited to coarser sediments, and they do not offer depth resolution.

Use of diffusion samplers is hampered by the time required for equilibrium (7 to 14 days) and the need for diver placement and retrieval in deep waters. Acidification of interstitial water obtained by diffusion or from suction filtration must occur immediately to limit oxidation. Bufflap and Allen (1995) conclude that in situ techniques have less potential for producing sampling artifacts than ex situ procedures. They concluded that, of the in situ procedures, suction filtration has the best potential for producing artifact-free interstitial water samples directly from the environment. Of the ex situ procedures, they concluded that centrifugation under a nitrogen atmosphere followed immediately by filtration and acidification was the simplest technique likely to result in an unbiased estimate of metal concentrations in interstitial water. At present, it is recommended filtration of the surface water through 0.40 to 0.45 μm polycarbonate filters to better define that fraction of aqueous metal associated with toxicity (Prothro, 1993). This guidance applies to interstitial water. Thurman (1985) equates the organic carbon retained on a 0.45 μm glass-fiber filter to suspended organic carbon, so that this filtration procedure under nitrogen atmosphere followed immediately by acidification is acceptable for interstitial waters. However, in studies comparing collection and processing methods for trace metals, sorption to filter membranes or the filtering apparatus does occur (Schults et al., 1992). These authors later presented a method combining longer centrifugation times with a unique single-step interstitial water withdrawal procedure that has potential for minimizing metal losses by eliminating the need for filtration (Ozretich and Schults, 1998).

Use of dialysis samplers to obtain samples of interstitial water is recommended for comparison of measured concentrations of dissolved metals with WQC. This is primarily because diffusion samplers obtain interstitial water with the proper in situ geochemistry, thus limiting artifacts of ex situ sampling. Furthermore, in shallow waters, where contamination of sediments is most likely, placement of diffusion samplers is easily accomplished and extended equilibration times are not a problem. Second, use of centrifugation under nitrogen and 0.45 μm filtration using polycarbonate filters for obtaining interstitial water from sediments in deeper aquatic systems. Care must be taken to ensure that filters or the filter apparatus do not remove metal from or add metal to the interstitial water sample to be analyzed. Perhaps most importantly, the extremely large database comparing interstitial metals concentrations with organism responses from spiked- and field-sediment experiments in the laboratory has demonstrated that, where the IWTU concept predicted that metals concentrations in interstitial water should not be toxic, toxicity was not observed when either dialysis samplers or centrifugation were used (Berry et al., 1996; Hansen et al., 1996a). Therefore, it is likely that when either methodology is used to obtain interstitial water for comparison with WQC, if metals concentrations are below 1.0 IWBU, sediments should be acceptable for protection of benthic organisms. The exception is for some silver-spiked freshwater and saltwater sediments that were toxic in spite of the absence of interstitial silver. It is for this reason that IWBUs are not used as $ESB_{AVS:WQC}$s for silver (see Sections 4.2.1 and 4.2.2).

5.3 Analytical Measurements

An important aspect to deriving ESB values is that the methods necessary to implement the approach must be reasonably standardized or have been demonstrated to produce results comparable to those of standard methodologies. From the standpoint of the $ESB_{AVS:WQC}$s, a significant amount of research has gone into defining methodologies to obtain interstitial water and sediments (see Section 5.2 above), to extract SEM and AVS from sediments, and to quantify AVS, SEM, and the metals in interstitial water.

5.3.1 *Acid Volatile Sulfide*

The SEM/AVS extraction method suggested is that of Allen et al. (1993). In terms of AVS quantification, a number of techniques have been successfully utilized, including gravimetric (Di Toro et al., 1990; Leonard et al., 1993), colorimetric (Cornwell and Morse, 1987), gas chromatography– photoionization detection (Casas and Crecelius, 1994; Slotton and Reuter, 1995), and specific ion electrodes (Boothman and Helmstetter, 1992; Brouwer and Murphy, 1994; Brumbaugh et al., 1994; Leonard et al., 1996b). Allen et al. (1993) report a detection limit for 50% accuracy of 0.01 μmol/g for a 10 g sediment sample using the colorimetric method. Based on several studies, Boothman and Helmstetter (1992) report a detection limit of 1 μmol AVS, which translates to 0.1 μmol/g dry weight for a 10 g sediment sample using the ion specific electrode method.

5.3.2 *Simultaneously Extracted Metals*

SEMs are operationally defined as metals extracted from sediment into solution by the AVS extraction procedure. The dissolved metals in this solution are also operationally defined as the metal species that pass through filter material used to remove the residual sediment. Common convention defines "dissolved" as metal species <0.45 μm in size. SEM concentrations measured in sediments are not significantly different, however, using Whatman #1 filter paper alone (<11 μm nominal interstitial size) or in combination with a 0.45 μm filter (W. Boothman, U.S. EPA, Narragansett, RI, personal communication). SEM solutions generated by the AVS procedure can be analyzed for metals, commonly including cadmium, copper, lead, nickel, silver, and zinc, by routine atomic spectrochemical techniques appropriate for environmental waters (e.g., inductively coupled plasma atomic emission or graphite furnace atomic absorption spectrophotometry [GFAA]) (U.S. EPA, 1994b). Because of the need to determine metals at relatively low concentrations, additional consideration must be given to preclude contamination during collection, transport, and analysis (U.S. EPA, 1995d,e,f).

5.3.3 *Total Organic Carbon*

Several methods for measuring organic carbon exist and are reviewed by Nelson and Sommers (1996). U.S. EPA (2001) summarizes the minimum requirements of acceptable methods for quantifying total organic carbon in sediments.

5.3.4 *Interstitial Water Metal*

Interstitial water can be analyzed for the metals cadmium, copper, lead, nickel, silver, and zinc by routine atomic spectrochemical techniques appropriate for environmental waters (e.g., inductively coupled plasma atomic emission or GFAA) (U.S. EPA, 1994b). Because of the need to determine metals at concentrations at or below the threshold of biological effects (i.e., WQC concentrations), additional consideration must be given to preclude contamination during collection, transport and analysis (U.S. EPA, 1995d,e,f; also see guidance on clean chemistry techniques in U.S. EPA, 1994c). Generally, detection limits should be at $\leq$0.1 IWBU because the contributions of each of the metals must be summed.

Section 6

Sediment Benchmark Values: Application and Interpretation

The procedures described in this document indicate that, except possibly where a locally, commercially, or recreationally important species is very sensitive, benthic organisms should be acceptably protected in freshwater and saltwater sediments if at least one of the following two conditions are satisfied: the sum of the molar concentrations of SEM cadmium, copper, lead, nickel, silver, and zinc is less than or equal to the molar concentration of AVS (Section 6.1), or the sum of the dissolved interstitial water concentration of cadmium, copper, lead, nickel, and zinc divided by their respective WQC FCV is less than or equal to 1.0 (Section 6.2). The AVS benchmark is intended to apply to sediments having ≥0.1 μmol AVS/g. The two conditions for deriving $ESB_{AVS:WQC}$ are detailed in Section 4.2 and are repeated below.

Consistent with the recommendations of EPA's Science Advisory Board, publication of these documents does not imply the use of ESBs as stand-alone, pass-fail criteria for all applications; rather, exceedances of ESBs could trigger collection of additional assessment data.

As discussed in Section 3.4, a more accurate prediction of toxicity can be derived if the presence of organic carbon is considered along with AVS. For the multiple metals cadmium, copper, lead, nickel, silver and zinc, the following assumptions are useful in deriving a benchmark:

1) Any sediment in which (SEM - AVS)/f_{OC} < 130 μmols/g_{OC} should pose low risk of adverse biological effects due to cadmium, copper, lead, nickel and zinc.

2) Any sediment in which 130μmols/g_{OC} < (SEM - AVS)/f_{OC} < 3000 μmols/g_{OC} may have adverse biological effects due to cadmium, copper, lead, nickel or zinc.

3) In any sediment in which (SEM - AVS)/f_{OC} > 3000 μmols/g_{OC} adverse biological effects due to cadmium, copper, lead, nickel or zinc may be expected.

4) Any sediment with AVS > 0.0 will not cause adverse biological effects due to silver.

6.1 AVS ESB

$$\Sigma_i[SEM_i] \le [AVS]$$

where

$$\Sigma_i[SEM_i] = [SEM_{Cd}] + [SEM_{Cu}] + [SEM_{Pb}] + [SEM_{Ni}] + [SEM_{Zn}] + 1/2[SEM_{Ag}]$$

6.2 Interstitial Water ESB

$$\Sigma_i \frac{[M_{i,d}]}{FCV_{i,d}} \le 1.0$$

where

$$\Sigma_i \frac{[M_{i,d}]}{[FCV_{i,d}]} = \frac{[M_{Cd,d}]}{[FCV_{Cd,d}]} + \frac{[M_{Cu,d}]}{[FCV_{Cu,d}]} + \frac{[M_{Pb,d}]}{[FCV_{Pb,d}]} + \frac{[M_{Ni,d}]}{[FCV_{Ni,d}]} + \frac{[M_{Zn,d}]}{[FCV_{Zn,d}]}$$

It is repeated here that the interstitial water benchmark applies only to the five metals: cadmium, copper, lead, nickel, and zinc. Silver is not included in this benchmark because the FCV for silver is not available.

Arguably, the most important additional data needed for assessing contaminated sediments along with ESBs are the results of toxicity tests. Sediment toxicity tests provide an important complement to ESBs in interpreting overall risk from contaminated sediments. Toxicity tests have different strengths and weaknesses compared to chemical-specific guidelines,

and the most powerful inferences can be drawn when both are used together (see U.S. EPA 2003c,d for further discussion of using toxicity testing with ESBs to assess contaminated sediments).

The ESB approaches are intended to protect benthic organisms from direct toxicity associated with exposure to metal-contaminated sediments. They are not designed to protect aquatic systems from metals release associated, for example, with sediment suspension, or the transport of metals into the food web from either sediment ingestion or ingestion of contaminated benthos. Furthermore, the ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with metal mixtures or the potential for bioaccumulation and trophic transfer of metal mixtures to aquatic life, wildlife or humans.

Appendix C

Quality Assurance Summary for the ESB Document: Procedures for the derivation of equilibrium partitioning sediment benchmarks (ESBs) for the protection of benthic organisms: Metal Mixtures (Cadmium, Copper, Lead, Nickel, Silver, and Zinc)

All data were obtained either from the WQC document for the metals cadmium, copper, lead, nickel, silver, and zinc (USEPA, 1980, 1985b, c, d, 1986, 1987) or from a comprehensive literature search completed in 1999 and updated in 2004. Data for the chromium appendix was obtained from a comprehensive literature search completed in 2004.

All data used in the example benchmark calculations were evaluated for acceptability using the procedures outlined in the Stephan et al. (1985): *Guidelines for deriving numerical national water quality criteria for the protection of aquatic organisms and their uses*. Data not meeting the criteria were rejected. The approach for deriving the values in this document were also reviewed by the U.S. EPA SAB (U.S. EPA, 1994a; 1995a; 1999). All calculations were made using the procedures in Stephan et al. (1985). This document was reviewed for scientific quality assurance by U.S. EPA Office of Water and Office of Research and Development scientists.

Hard copies of all literature cited in this document reside at ORD/NHEERL Atlantic Ecology Division - Narragansett, Rhode Island.

Appendix D

Procedures for the Derivation of Equilibrium Partitioning Sediment Benchmark (ESBs) for the Protection of Benthic Organisms: Chromium

Executive Summary

Chromium exists in sediments primarily in two oxidation states: Cr(III), which is relatively insoluble and nontoxic, and Cr(VI), which is much more soluble and toxic. Cr(VI) is thermodynamically unstable in anoxic sediments and AVS is formed only in anoxic sediments; therefore sediments with measurable AVS concentrations should not contain toxic Cr(VI). If this "chromium hypothesis" holds true, measuring AVS could form the basis for an ESB for chromium in sediments.

A review of the literature and recently performed experiments with both freshwater and saltwater sediments support the chromium hypothesis.

In saltwater:

1) Survival of amphipods was decreased by waterborne Cr(VI), with a 10-day median lethal concentration (LC50) of 1850 µg/L Cr(VI).
2) Survival of amphipods was not decreased by waterborne Cr(III) at concentrations well above saturation.
3) In both laboratory-spiked sediments with Cr(III) and Cr(VI) and field-contaminated sediments, in sediments where detectable AVS was present, chromium concentrations in interstitial water were very low (<100 µg/L) and no significant lethality to *A. abdita* was observed. In sediments in which AVS was not significantly greater than zero, chromium concentrations in interstitial waters increased significantly, with greater than 90% of the chromium present as Cr(VI), and the mortality of *A. abdita* was elevated.

In freshwater:

1) Survival of amphipods was decreased by waterborne Cr(VI), with a 42-day LC50 of 40 µg/L.
2) Cr(VI) spiked into test sediments with differing levels of AVS resulted in graded decreases in AVS.
3) Sediments with low AVS concentrations (<1 µmol/g) after spiking with Cr(VI) caused 100% mortality of amphipods, but no toxic effects were observed in Cr(VI)-spiked sediments that maintained higher AVS concentrations.
4) Waterborne Cr(III) levels near solubility limits caused decreased survival of amphipods at pH 7 and pH 8, but not at pH 6.
5) Sediments spiked with high levels of Cr(III) had no effect on amphipod survival, but caused significant decreases in reproduction and/or growth.
6) Interstitial waters of some Cr(III)-spiked sediments contained measurable concentrations of Cr(VI), but observed toxic effects did not correspond closely to concentrations of aqueous Cr species.

Thus, although both Cr(VI) and Cr(III) could be toxic to *H. azteca* in water and sediment, risks of Cr toxicity were low in sediments containing substantial concentrations of AVS. Results presented in this appendix suggest that measurements of AVS and interstitial water chromium can be useful in predicting the absence of acute effects from chromium contamination in both freshwater and saltwater sediments. In sediments with substantial AVS, risks of chromium toxicity should be low, because the chromium will be present in the form of Cr (III). This should apply to any sediment with SEM-AVS < 0.0. Sediments with SEM-AVS > 0.0, but which have substantial AVS present may be toxic due to copper, cadmium, lead nickel, or zinc, but should not be toxic due to chromium or silver. The relationship, (SEM-AVS)/f_{OC}, should be used with caution (with regard to chromium toxicity) in sediments with little or no AVS, because a sediment with no appreciable AVS or SEM and substantial chromium might be toxic due to chromium, even though no toxicity due to the other metals would be expected. These findings form the basis for a chromium ESB.

Section 1

Introduction

Chromium is often found in contaminated sediments (Pawlitz et al., 1977). Elevated chromium concentrations in sediments are usually associated with tanneries, smelters, and plating facilities. However, without a good understanding of the adverse biological effects of chromium in sediments, it is difficult to know what concentration of chromium in sediment may present ecological risk to benthos.

Although there have been several studies on the bioaccumulation of chromium from laboratory-spiked sediments (Wang et al., 1997; Griscom et al., 2000; Fan and Wang., 2001), there are few published studies on biological effects of chromium in laboratory-spiked sediments other than uptake of chromium. There are also very few reports on effects of chromium in field sediments. Leslie et al. (1999) found that a tributary below a chromium salt processing plant was incapable of supporting benthic macrofauna, presumably because of chromium leaching from stock piles along the banks of the tributary, but concluded that much of the chromium might be coming from the water rather than the sediment. In a study of sediments associated with a tannery, some toxicity was observed in ten-day static toxicity tests with several sediments with chromium in excess of 4000 μg/g; the same sediments, however, exhibited no toxicity in 28-day flow-through tests, suggesting that the toxicity observed in the 10-day static test was related to test conditions and duration and not sediment chromium (HydroQual, 1994). Several other studies have found elevated chromium concentrations in the tissues of benthos from sediments contaminated with high levels of chromium from mining activities (Bervoets et al., 1998) or tannery wastes (Catsiki et al., 1994), but these tissue concentrations were not linked to biological effects.

Part of the difficulty in understanding the biological effects of chromium in sediment is that chromium exists in sediments in two oxidation states, Cr(III) and Cr(VI), each with very different geochemical properties and toxicological effects. Cr(VI) is highly oxidized and unstable in reducing and even moderately oxidizing environments (DeLaune et al., 1998, Masscheleyn et al., 1992). Cr(VI) is also very soluble and highly toxic, while Cr(III) has very low solubility at environmentally relevant pH (DeLaune et al., 1998; Barnhart., 1997) and is generally thought to have relatively low toxicity (Wang et al., 1997; Thompson et al., 2002). For example, Leslie et al. (1999) assumed that the effects they saw due to chromium must have been caused by Cr(VI). However, they did not measure the chromium speciation.

This appendix provides the technical basis for the derivation of an ESB for chromium analogous to the ESB for the cationic metals cadmium, copper, lead, nickel, silver, and zinc discussed earlier. Determining the relationship between AVS and chromium in sediments would extend the utility of AVS measurements as a part of sediment assessments. Chromium should not necessarily be included among the SEM metals because its interaction with AVS is not via formation of an insoluble sulfide, but rather oxidation of sulfide and concomitant reduction of chromium. However, the geochemical relationship between AVS and chromium and the toxicological differences between oxidation states of chromium might be used to develop a theoretically-derived benchmark through what is called the "chromium hypothesis." The hypothesis is based on the concepts that Cr(III) is much less soluble and toxic than Cr(VI) and that Cr(VI) is not stable in reducing environments such as anoxic sediments in which AVS is formed. Thus, in a sediment where AVS is present, chromium will exist solely as Cr(III), and therefore the interstitial water should contain little chromium and the sediment should not be toxic due to chromium.

Although there is literature discussing chromium toxicity and geochemistry, no studies were available which had tested the "chromium hypothesis" directly. To this end, recently,

experiments have been carried out with both freshwater (Besser et al., *in press*) and saltwater sediments (Berry et al., *in press*) to verify the chromium hypothesis. In the saltwater test series ten-day water-only and ten-day spiked sediment toxicity tests with the amphipod *Ampelisca abdita* were performed with Cr(VI) and Cr(III). Ten-day sediment tests with saltwater sediments collected from a site contaminated with high concentrations of chromium were also performed. In freshwater sediments, chronic (28- to 42-d) water-only and spiked sediment toxicity tests with the amphipod *Hyalella azteca* were performed with Cr(VI) and Cr(III).

Section 2

Chemistry of Chromium in Sediment

2.1 Valence States of Chromium in Sediments

Studies by many researchers have provided a generalized model of the cycling of chromium between redox states in various aquatic soils/ sediments and their interstitial and overlying waters (Masscheleyn et al., 1992; Kozuh et al., 2000; Hassan and Garrison., 1996; Mattuck and Nikolaidis., 1996). This model is characterized by the relative stability of Cr(VI) in oxygenated overlying waters, particularly in marine waters, and rapid removal of Cr(III) through precipitation of the insoluble hydroxide and adsorption onto particulate matter. In freshwater systems with elevated dissolved organic carbon concentrations, such as in wetland soils and waters, a considerable amount of Cr(III) may be organically complexed, which slows the rate of removal to the particulate matter. In some circumstances, Cr(III) may be oxidized to Cr(VI) by Fe/Mn-rich films on the air-water interface where reduced Mn(II) and Fe(II) diffuses from sediments into oxic overlying water (Masscheleyn et al., 1992).

In sediments and soils, the reactivities of Cr(III) and Cr(VI) are somewhat reversed. Cr(III) may be oxidized to Cr(VI) in soils or sediments with high concentrations of MnO_2 and low organic content apparently by oxidation at MnO_2 surfaces (Hassan and Garrison., 1996). Similar oxidation by resuspended sediments rich in manganese oxides has also been postulated as the cause for relatively higher concentrations of Cr(VI) in deep ocean seawater relative to seawater overlying reduced coastal sediments (Nakayama et al., 1981). If organic content is elevated, however, Cr(III) is not oxidized, even in highly oxidizing sediments (Masscheleyn et al., 1992; Kozuh et al., 2000). On the other hand, Cr(VI) is reduced to Cr(III) and almost completely removed from solution in even moderately oxidizing sediments (redox potential E_h < 300 mV). In more reducing sediments (E_h < 200 mV), reduction is significantly more rapid due to reaction with ferrous ionic Fe(II). In such reduced sediments, very high partitioning constants indicate that almost all chromium is bound to the sediment, presumably as Cr(III), with very little mobile in interstitial waters (Mattuck and Nikolaidis., 1996). In wetland sediments, much of the dissolved chromium may be organically complexed Cr(III) (Icopini and Long, 2002). Once the reductive capacity of soils or sediments is exceeded, concentrations of dissolved Cr(VI) increase sharply and remain stable. Although the reductive capacity of sediments is generally proportional to organic content, the primary reductant is more likely Fe(II) or, in sulfidic sediments, sulfide.

2.2 Geochemical Distribution of Chromium in Toxicological Exposures

The geochemical distributions found in the recent experiments with marine sediments (Berry et al., *in press*) amended with Cr(VI) and Cr(III) reflected the behavior described in the previous section. Although the sediments had differing characteristics such as silt/clay and organic contents, they were both reducing sediments, as evidenced by the presence of AVS. Cr(III) added to these sediments in massive quantities was essentially inert to redox transformation: no Cr(VI) was evident in sediments, interstitial waters or overlying waters throughout the experiment, as was the case with organic-rich peat soils and wetland sediments. Cr(VI) added to the sediments was reduced completely and rapidly (<1 day), regardless of the amount added, up to the reductive capacity of the sediments. No significant amount of chromium was evident in either interstitial or overlying waters, indicating that Cr(III) complexed by dissolved organic carbon was not important in these sediments. Once the capacity of the sediments were exceeded, very high concentrations of chromium, almost entirely Cr(VI), were evident in interstitial

waters (Figure D-1). Concentrations of chromium in overlying waters decreased throughout the experiment and remained primarily as Cr(VI). These geochemical controls on the concentrations and redox speciation of chromium in sediments constrain exposure and consequent biological effects of the chromium on benthic organisms, such as the amphipods used in the saltwater tests.

In a recent study, spiking of freshwater sediments (Besser et al., *in press*) with several levels of Cr(VI) resulted in graded decreases in AVS concentrations and changes in POC concentrations in sediment and interstitial water. For example, mean AVS concentrations decreased by up to 97% in study sediments on day 0 of the test. Sediment TOC also decreased slightly in Cr(VI)-spiked sediments. Cr(VI) spikes were associated with increased DOC, increased alkalinity, and decreased hardness in interstitial waters.

Overlying and interstitial water Cr(VI) concentrations reflected differences in AVS concentrations among treatments. Initial concentrations of Cr(VI) in interstitial water samples were greater than 10,000 µg/L in treatments with the lowest AVS concentrations while interstitial water Cr(VI) concentrations remained low (≤20 µg/L) in treatments with higher AVS concentrations. In all three treatments with quantifiable Cr(VI) in interstitial water, concentrations decreased during the test. Cr(VI) concentrations in overlying water were much lower than those in interstitial water, but followed similar trends among treatments and over time. Decreases in Cr(VI) concentrations during the course of the study may have resulted from reactions with AVS and POC and from dilution due to replacement of overlying water. The smallest proportional decrease of Cr(VI) in interstitial and overlying water occurred in the treatment which had no AVS and low POC.

These results are consistent with the hypothesis that Cr(VI) concentrations remain low in sediments containing substantial concentrations of AVS. Berry et al. (*in press*), in studies with Cr(VI)-spiked marine sediments, did not detect Cr(VI) in interstitial waters of sediments spiked with Cr(VI) at Cr:AVS ratios of 2.2 or less. In contrast, substantial Cr(VI) concentrations were measured in sediments spiked at 3:1 Cr:AVS ratios (Besser et al., *in press*). AVS may have persisted in these treatments due to regeneration of AVS during the test, at least in some treatments. However, the data also suggested that some added Cr(VI) reacted with sediment POC, as has been reported in several previous studies (Wittbrodt and Palmer., 1995; Elovitz and Fish., 1995; U.S.EPA., 2002; Poleo., 1995). The relationship between Cr(VI) spikes and AVS depletion in one freshwater sediment was similar to the 2:1 ratio reported by Berry et al. (*in press*). However, AVS concentrations in a high-POC sediment decreased in a proportion of about one mole of AVS per eight moles of added Cr(VI). Reaction of Cr(VI) spikes with sediment POC is also suggested by decreases in organic carbon in several sediments and increases in interstitial water DOC in all three sediments. These results suggest that sediment POC also provides protection against Cr(VI) lethality in benthic environments, although Cr(VI) lethality occurred in some of the spiked sediments despite high levels of OM.

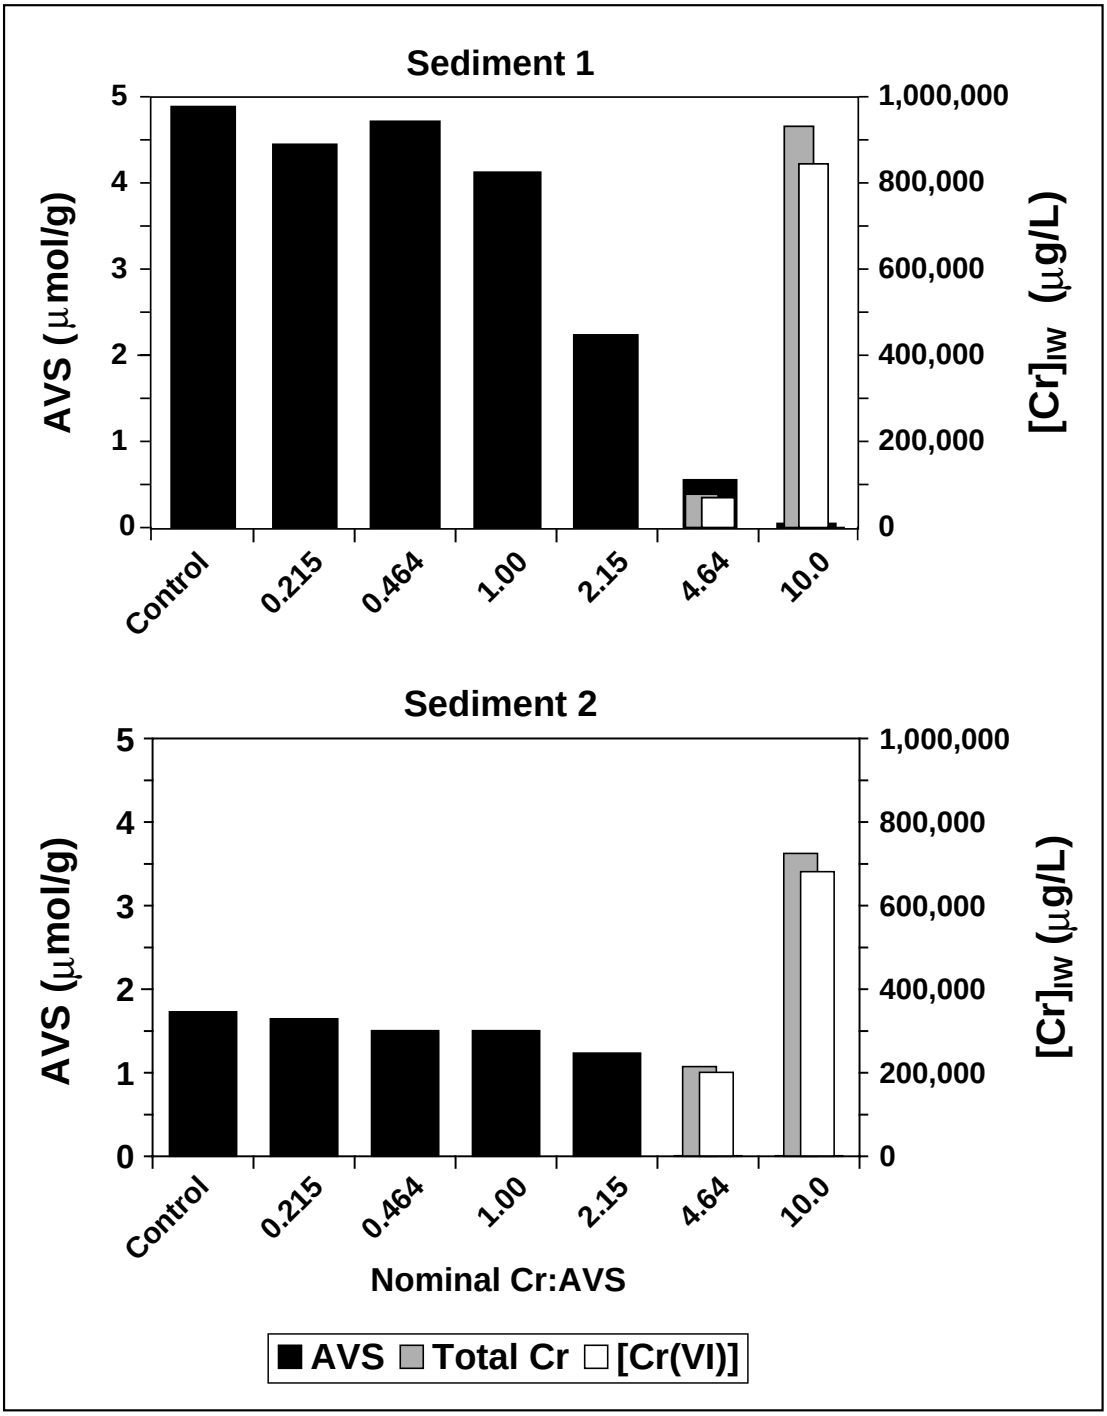

Figure D-1. Concentrations of AVS in sediment, and total Cr and Cr(VI) in interstitial waters of two saltwater sediments spiked with Cr (VI).

Section 3

Chromium Toxicity in Water and Sediment

3.1 Chromium Toxicity in Water-only Tests

Water-only tests were performed to complement the sediment toxicity tests conducted by Berry et al. (*in press*) and Besser et al. (*in press*). Survival of amphipods was decreased by Cr(VI) in water-only tests in saltwater, calculated 10-day LC50s were 1980 and 1854 µg Cr/L based on dissolved and hexavalent concentrations, respectively (Berry et al., *in press*). Survival of amphipods was not decreased by Cr(III) in water-only tests in saltwater at concentrations well above saturation.

Exposure to water-only Cr(VI) in freshwater caused decreased survival of *H. azteca* (Besser et al., *in press*) (Table D-1). Identical LC50s (40 µg/L) were determined for the 28- and 42-d exposure periods suggesting that lethal effects of Cr(VI) occurred early in the exposure. Evidence of sublethal effects of Cr(VI) on amphipods was less conclusive. Amphipod growth was not significantly decreased at any Cr(VI) exposure level, but reproduction in all Cr(VI) treatments was at least one-third less than controls. These results indicate that *H. azteca* is highly sensitive to chronic toxicity of Cr(VI). Excluding the reproduction data, the threshold for chronic Cr(VI) toxicity to *H. azteca* was 15 µg/L (geometric mean of Cr concentrations bracketing the lowest significant toxic effect) slightly greater than the current U.S.EPA water quality criterion for Cr(VI) of 10 µg/L (Richard and Bourg., 1991, U.S.EPA., 1995). Previous studies have reported chronic values for Cr(VI) between 6 µg/L and 40 µg/L for crustacean zooplankton and between 264 µg/L and 1987µg/L for fish (U.S.EPA, 1986).

Toxicity of Cr(III) in freshwater water-only tests was measured at 3 pHs: 6,7, and 8 (Besser et al., *in press*). Cr concentrations in the Cr(III) water-only test were less than the nominal concentration of 100 µg/L, indicating that Cr(III) concentrations were limited by solubility (Table D-2). Filterable Cr concentrations were highest at

Table D-1. Results of a toxicity test with the amphipod *H. azteca* exposed to Cr(VI) in water. Means with standard error in parentheses. Asterisks indicate significant difference between treatment and control (p<0.05; ANOVA and Dunnett's test with log-transformed data). From Besser et al. (*in press*).

Cr (ug/L) (n=4)	Survival (%) Day 28 (n=12)	Survival (%) Day 42 (n=8)	Length (mm) Day 42 (n=8)	Reproduction (young per female) (n=8)
<2.0	100 (0)	100 (0)	4.87 (0.11)	8.4 (2.4)
2.0 (0.3)	90 (7)	90 (7)	4.90 (0.07)	2.3 (1.1)*
4.7 (1.1)	95 (3)	95 (5)	4.84 (0.09)	2.9 (1.1)
10 (1.0)	98 (3)	95 (3)	5.27 (0.08)	5.4 (1.5)
18 (6)	88 (5)*	80 (4)*	5.05 (0.07)	3.3 (1.0)
48 (2)	38 (5)*	40 (9)*	5.22 (0.17)	1.6 (1.0)*

pH 6 and lowest at pH 8. Amphipod survival was high (≥90%) in controls at all three pH levels, but control growth and reproduction were significantly lower in pH 6 and pH 8 as compared to pH 7. Poor performance of amphipods in the pH 6 controls may indicate that this is near the lower limit of pH tolerance for this species, but growth and reproduction were also significantly decreased at pH 8, relative to the pH 7 control.

3.2 Spiked Sediments: Saltwater

Mortality of amphipods exposed to Cr(VI) in saltwater sediments increased with increasing chromium concentration, but the response was sediment dependent (Figure D-2a) (Berry et al., *in press*). In sediments where detectable AVS was present, chromium concentrations in interstitial water were very low (<100 μg/L). No significant lethality to *A. abdita* was observed in sediments with less than 0.5 interstitial water toxic units (IWTU) (Figure D-2b). In sediments in which AVS was not significantly greater than zero, chromium concentrations in interstitial waters increased significantly, with greater than 90% of the chromium present as Cr(VI), and *A. abdita* mortality was elevated (Figure D-2c). In a single treatment spiked with a high concentration of Cr(III) there was no chromium in the interstitial water, and the sediment was not toxic (Figures D-2a and D-2b). The results in these tests are consistent with the chromium hypothesis, and are similar to those for the other metals discussed in the main document.

3.3 Field Sediments: Saltwater

Berry et al. (*in press*) exposed amphipods for ten days to field sediments collected from Shipyard Creek, a tidal creek adjacent to a former ferrichromium alloy production facility in Charleston, SC, USA (Breedlove et al., 2002). The relationship between geochemical fractions and amphipod mortality in the field sediments was similar to that found with spiked sediments. AVS was measured at concentrations well above detection limits in all sediments, and despite some exceptionally high concentrations of total chromium (> 3000 μg Cr/g), only traces of Cr(VI) were detected (<4 μg/g) in sediments, and these concentrations were likely artifacts of the Cr(III)/

Table D-2. Results of toxicity test with the amphipod *H. azteca* exposed to Cr(III) in water at three pHs. Means with range (for pH) or standard error in parentheses. Within a pH level, asterisks indicate significant decreases in test endpoints in the Cr(III) treatment, relative to the control. For control sediments, means followed by the same letter are not significantly different (p≤0.05; ANOVA and Fisher's LSD test with log-transformed data). From Besser et al. *(In press*).

			Survival (%)		Length (mm)		Reproduction
Treatment	Chromium (μg/L)	pH	Day 28 (n=12)	Day 42 (n=8)	Day 28 (n=4)	Day 42 (n=8)	(young/female) (n=8)
Control - pH 6	<2	6.44 (6.00-7.12)	94 (1) ab	93 (2)	3.8 (0.1) b	3.3 (0.03) c	0 (0) c
Cr(III) - pH 6	76 (63-90)	6.41 (6.00-7.00)	98 (2)	95 (3)	4.3 (0.4)	4.3 (0.4)	1.0 (0.3)
Control - pH 7	<2	7.11 (6.90-7.34)	90 (2) b	93 (3)	4.4 (0.1) a	3.9 (0.04) a	1.4 (0.2) a

Cr(III) - pH 8	29 (23-35)	7.94 (7.81-8.12)	63 (4) *	53 (5) *	3.9 (0.1)	3.9 (0.1)	2.0 (0.6)

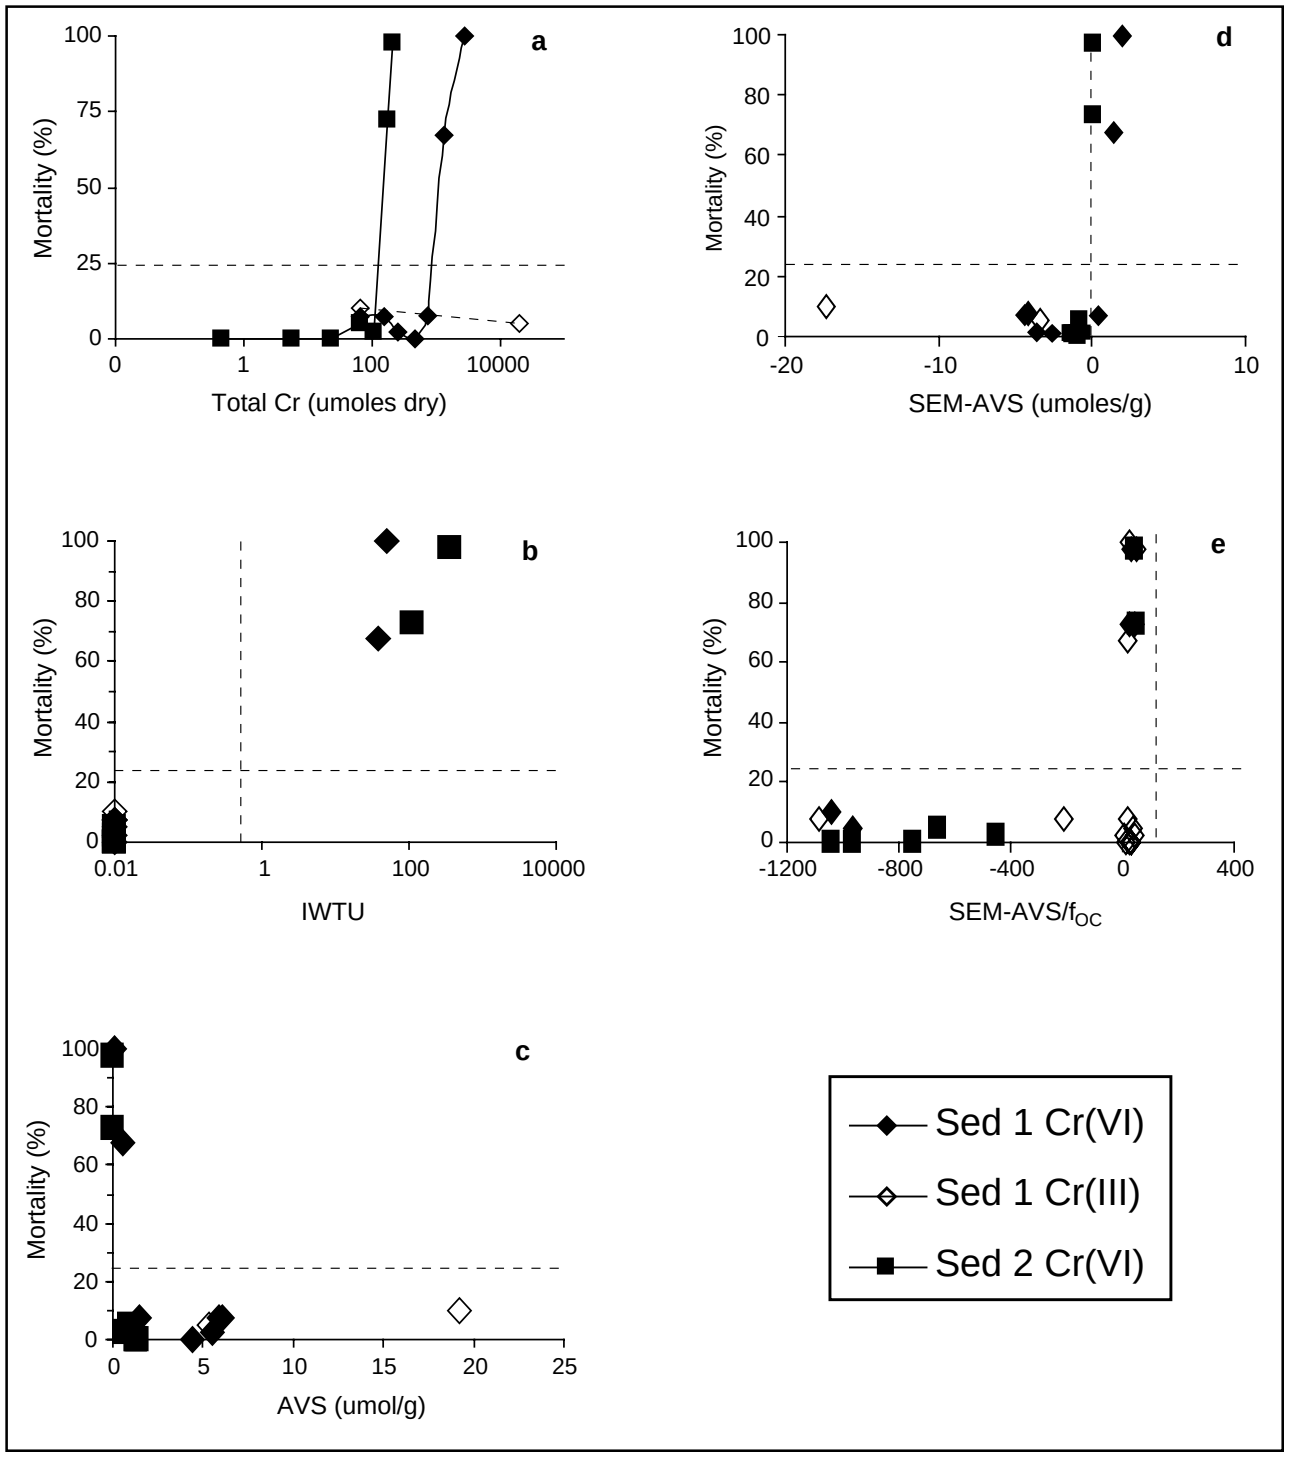

Figure D-2. Mortality in chromium-spiked saltwater sediment experiments (Berry et al., *in press*) vs. total chromium (a), IWTU (b), AVS (c), SEM – AVS (d), and SEM –AVS/f_{OC} (e). Where IWTU = interstitial water toxic units, AVS = acid volatile sulfide, SEM = simultaneously extracted metal, and f_{OC} = fraction of organic carbon. For illustrative purposes, sediments which caused greater than 24% mortality were classified as toxic (horizontal line), (Mearns et al., 1986). Vertical lines are drawn at 0.5 IWTU (b), 0.0 SEM-AVS (d), and 130 (SEM-AVS)/f_{OC} (e).

Cr(VI) separation technique (Berry et al., *in press*). No metals, including Cr(VI), were detected in interstitial waters of any of the sediments, which was expected given the large excess of AVS over SEM measured in all of the sediments. Despite concentrations of chromium exceeding 1700 to 3000 µg/g in some Shipyard Creek sediments, amphipod mortality in those sediments (5-25%) was no greater than in sediments from reference sites (5-20%) or a control sediment performed in conjunction with them (5-15%) (Berry et al., *in press*). These results are also consistent with the chromium hypothesis.

3.4 Spiked Sediments: Freshwater

The 28 and 42-day mortality results from the freshwater Cr(VI)-spiked sediment tests from Besser et al. (*in press*) were very similar to those from the 10-day saltwater Cr(VI) and Cr(III)-spiked sediment tests described by Berry et al. (*in press*). Mortality of amphipods exposed to Cr(VI) in freshwater sediments increased with increasing chromium concentration, but the response was sediment dependent (Figure D-3a) (Besser et al., *in press*). In sediments where detectable AVS was present, chromium concentrations in interstitial water were generally very low (Besser et al., *in press*). No significant toxicity to *H. azteca* was observed in sediments with less than 0.5 interstitial water toxic units (IWTU) (Figure D-3b). In sediments in which AVS was not significantly greater than zero, chromium concentrations in interstitial waters increased significantly (Besser et al., *in press*), with greater than 90% of the chromium present as Cr(VI), and mortality of *H. azteca* was elevated (Figure D-3c). Growth and reproduction were not significantly affected in any Cr(VI) -spiked treatment that did not show significant effects on survival (Besser et al., *in press*) (Figures D-3a ,D-3b, and D-3c)

The 28 and 42-day mortality results from the freshwater spiked sediment tests from Besser et al. (*in press*) with Cr(III) were also similar to those from the 10-day saltwater spiked sediment tests described by Berry et al. (*in press*) in that there was no increased mortality, even at high concentrations of Cr(III). However, the chemistry and sublethal results from the freshwater spiked sediment tests were different from the 10-day saltwater spiked sediment tests and the exposures with Cr(VI)-spiked freshwater sediment in several important respects. First, there was measurable chromium in the interstitial water of all three sediments spiked with a high concentration of Cr(III) (Figure D-3b). Also, there was significantly reduced growth in three of these sediments (Figures D-4a, D-4b, and D-4c) and reduced reproduction in one (Figures D-5a, D-5b, and D-5c). Finally, the reduced growth and reproduction was seen in some sediments which had less than 0.5 IWTU and/or significant amounts of AVS.

Besser et al. (*in press*) concluded that it was difficult to ascribe growth and reproductive effects in the Cr(III) - spiked sediments to chromium toxicity, because t he measured effects did not correspond with dissolved chromium concentrations, or with amphipod mortality. They hypothesized that the effects may have been a result of the physical effect of large amounts of chromium (presumably hydroxide) precipitate which forms when the Cr(III) solutions are pH-neutralized, prior to spiking (Besser et al., *in press*).

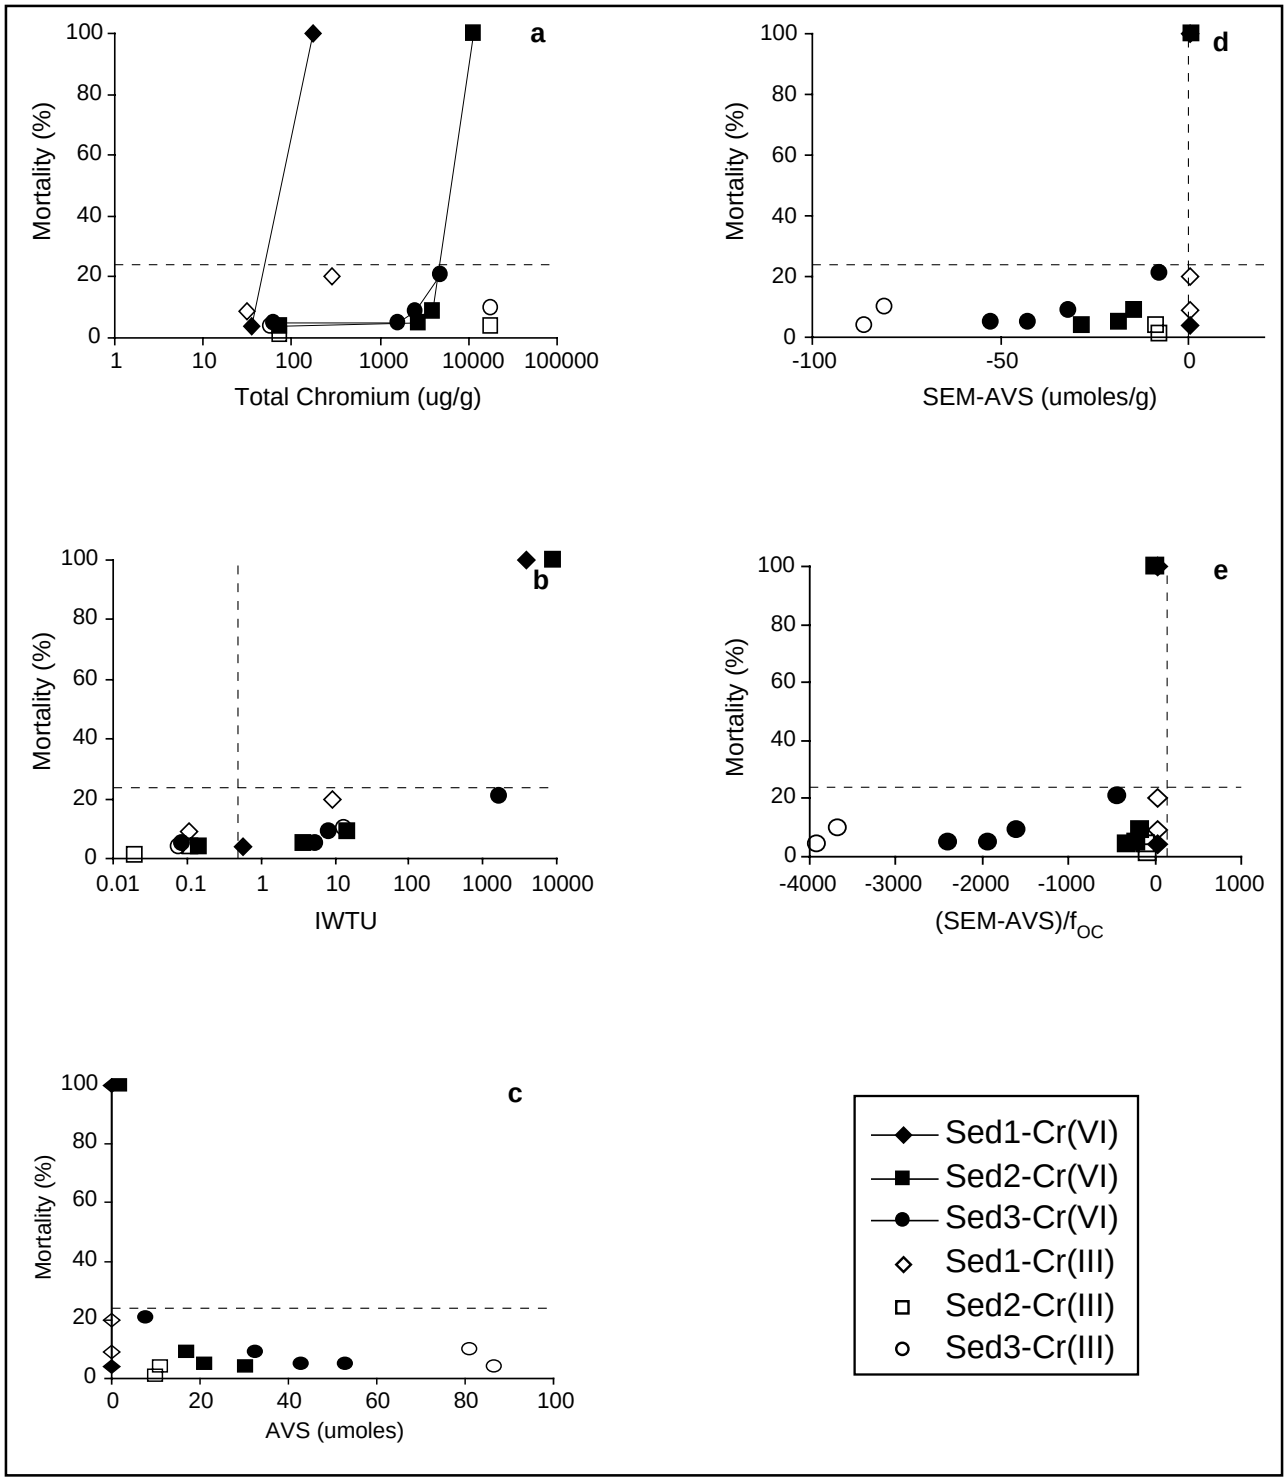

Figure D-3. Mortality in chromium-spiked freshwater sediment experiments (Besser et al., *in press*) vs. total chromium (a), IWTU (b), AVS (c), SEM – AVS (d), and SEM –AVS/f_{OC} (e). Where IWTU = interstitial water toxic units, AVS = acid volatile sulfide, SEM = simultaneously extracted metal, and f_{OC} = fraction of organic carbon. For illustrative purposes, sediments which caused greater than 24% mortality were classified as toxic (horizontal line) (Mearns et al., 1986). Vertical lines are drawn at 0.5 IWTU (b), 0.0 SEM-AVS (d), and 130 (SEM-AVS)/f_{OC} (e).

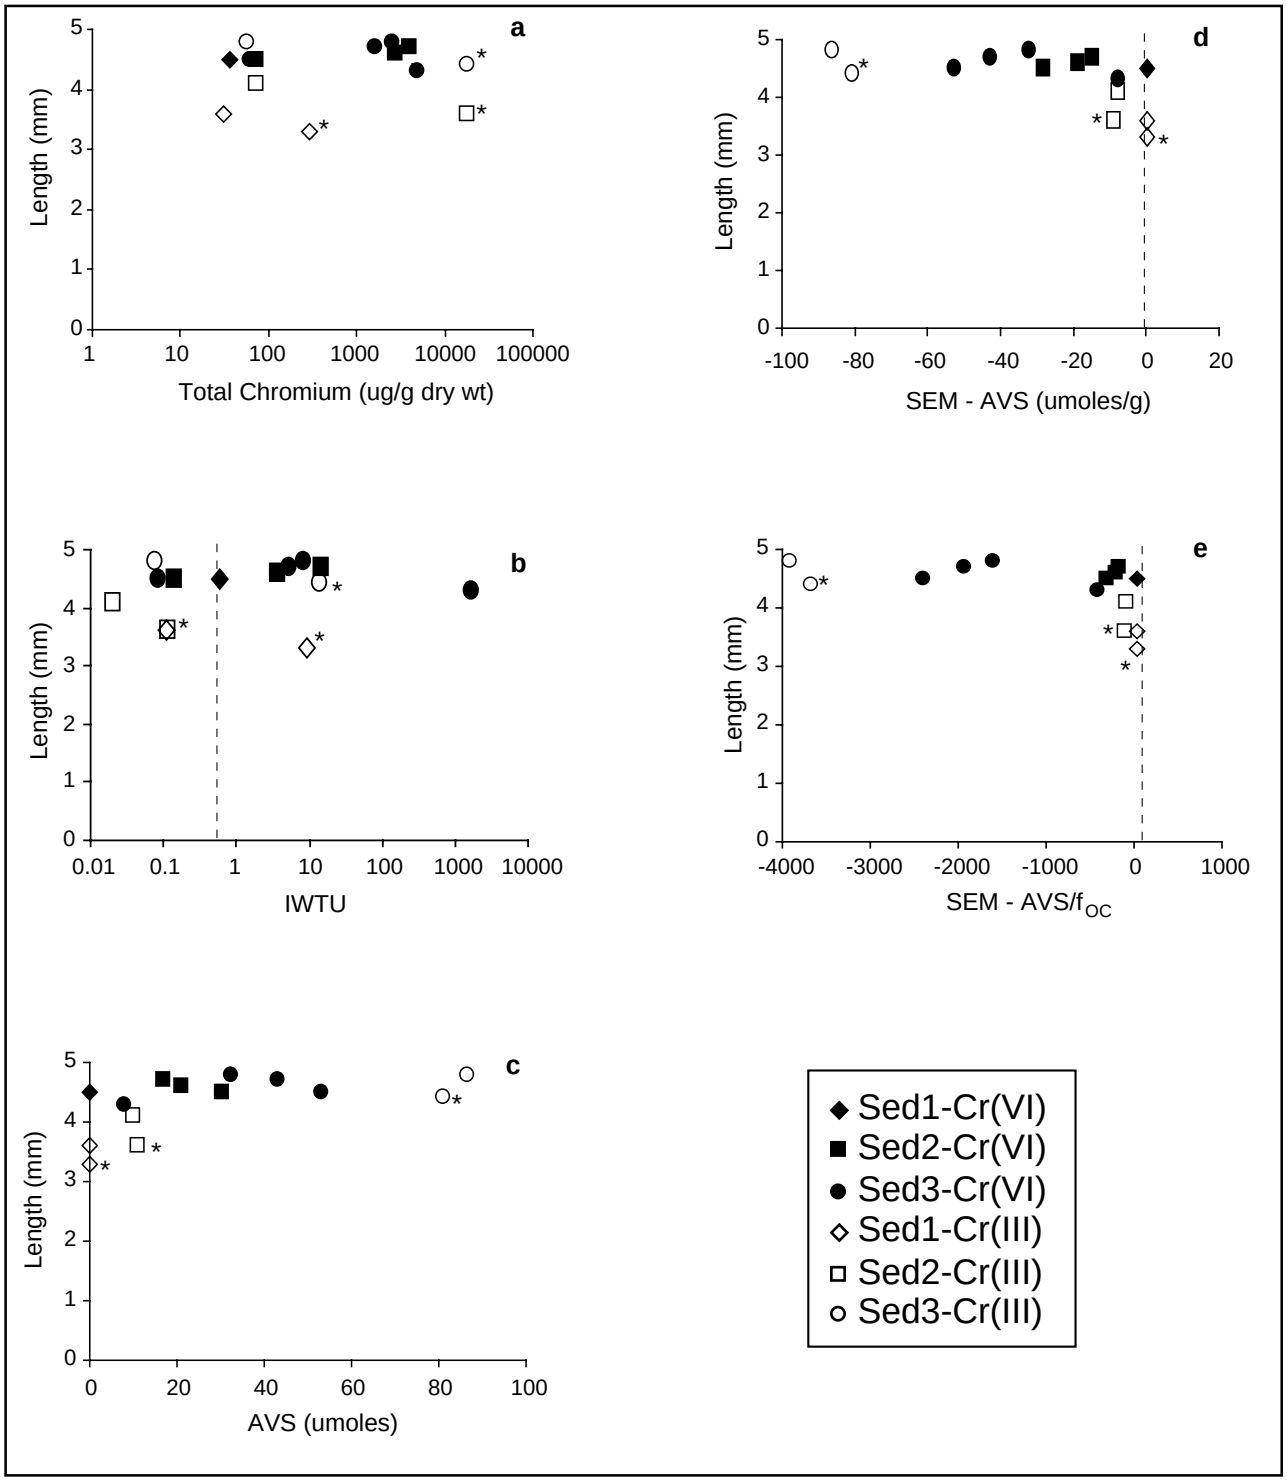

Figure D-4 Growth (length in mm) in chromium-spiked freshwater sediment experiments (Besser et al., *in press*) vs. total chromium (a), IWTU (b), AVS (c), SEM – AVS (d), and SEM –AVS/f_{OC} (e). Where IWTU = interstitial water toxic units, AVS = acid volatile sulfide, SEM = simultaneously extracted metal, and f_{OC} = fraction of organic carbon. Treatments significantly different from control are indicated with an asterisk. Vertical lines are drawn at 0.5 IWTU (b), 0.0 SEM-AVS (d), and 130 (SEM-AVS)/f_{OC} (e).

Where IWTU = interstitial water toxic units, AVS = acid volatile sulfide, SEM = simultaneously extracted metal, and f_{OC} = fraction of organic carbon. Treatments significantly different from control are indicated with an asterisk. Vertical lines are drawn at 0.5 IWTU (b), 0.0 SEM-AVS (d), and 130 (SEM-AVS)/f_{OC} (e).

Section 4

Derivation of ESB for Chromium

4.1. General Information

Mortality results of the toxicity tests conducted in both fresh and saltwater, with both spiked and field sediments, were generally consistent with the chromium hypothesis. They indicated that sediments with measurable amounts of AVS will not have acute toxicologically significant concentrations of chromium in the interstitial water, and that the sediments will not be acutely toxic due to chromium. Therefore, if measured sediment chemistry is being used as part of a sediment assessment, the presence of measurable AVS could be used to rule out chromium as the cause of observed acute toxicity. The chromium hypothesis can also serve as a foundation for a theoretically-derived sediment ESB for chromium.

The growth and reproduction results of the chronic tests conducted in freshwater with Cr(VI) were also consistent with the chromium hypothesis. The growth and reproduction results of the chronic tests conducted in freshwater with Cr(III) were more ambiguous. It is possible that these effects were observed as a result of the unrealistic conditions in the Cr(III)-spiked sediments, but more testing may have to be performed before the presence of growth and reproductive effects in sediments with large amounts of Cr(III) present can be ruled out.

4.2 Limitations of the chromium hypothesis

For the chromium hypothesis to work, and a Cr ESB to be useful, Cr(III) must not be toxic in interstitial water; however, many studies have reported on the toxic effects of Cr(III). Both the U.S. and Canada have water quality criteria (WQC) for Cr(III), although the criteria for Cr(III) are much higher than those for Cr(VI) (Pawlitz et al., 1997; U.S.EPA., 1985). Confounding factors in many of the tests used to develop these criteria, such as pH values outside of the tolerance range of test organisms (Dorfman., 1997) or reported LC50s orders of magnitude above limits of solubility for Cr(III) (Calabrese et al., 1973), make interpretation of the results of these tests difficult. Nonetheless, some of the tests used to develop the criteria demonstrate biological effects of Cr(III) at environmentally reasonable pH values and within limits of solubility (e.g., Stevens and Chapman (1984) showed chronic effects of Cr(III) on salmonid larvae).

Several recent studies have also shown biological effects due to Cr(III), including DNA damage and other sublethal effects associated with exposure to sediments from some of the same field sites from which Berry et al., (*in press*) collected sediments (Breedlovee et al., 2002), reduced growth of cyanobacteria (Thompson et al., 2002) and reduction in population growth rate of polychaetes (Mauri et al., 2002). Lastly, Besser et al. (2002) report reduced survival of the amphipod *Hyalella azteca* after 28 days in water-only exposures to Cr(III) at concentrations below solubility limits at a range of environmentally reasonable pHs. All of these reported effects are either sublethal or occurred after 10 days, so none of them would be expected to occur in the acute assays of Berry et al., (*in press*).

Another important fact to consider when deriving an ESB for chromium is that benthic animals, particularly tube and burrow dwellers such as *A. abdita*, modify the sediment around them by irrigation of their tubes and burrows, leading to changes in the sediment environment, and particularly in the redox condition of sediments near the animal (Wang et al., 2001). Thus, bulk sediment might have measurable AVS, while Cr(VI) might be present in oxic microenvironments within the sediment. The geochemistry of chromium argues against this,

however, because direct oxidation of Cr(III) to Cr(VI) by dissolved oxygen is slow (DeLaune et al., 1998), significant oxidation of Cr(III) to Cr(VI) occurs only in soils and sediments with elevated concentrations of manganese oxides and low organic content, conditions under which AVS would not be formed (Masscheleyn et al., 1992, Kozuh et al., 2000), and Cr(III) is very slow to react even in environments where it is thermodynamically unstable (Barnhart, 1997).

4.3 Incorporation into Multiple Metals Benchmark

In sediments where chromium is the only major metal of concern the AVS and interstitial water ESBs may be used as listed below. However, in many cases chromium will be present along with other metals, and will need to be evaluated along with them. One of the major objectives of this appendix is to expand the utility of the AVS methodology used with cadmium, copper, lead, nickel, silver, and zinc to include chromium. See sections 4 and 6 of the metals ESB for more detail on the benchmarks for cadmium, copper, lead, nickel, silver and zinc, and exact definitions of the AVS and interstitial water benchmarks.

Any sediment in which SEM -AVS < 0.0 should have low risk of adverse biological effects due to chromium, because measurable AVS must be present for this to be true (Figures D-2d, D-3d, D-4d, and D-5d). It should also have low risk of adverse biological effects due to cadmium, copper, lead, nickel, and zinc. Any sediment in which SEM - AVS > 0.0, but AVS > 0.0 should have low risk of adverse biological effects due to chromium or silver, but may have adverse biological effects due to cadmium, copper, lead, nickel or zinc. Sediments with SEM - AVS > 0.0 in which AVS does not exceed 0.0 may have adverse biological effects due to cadmium, copper, lead, nickel, silver, zinc and chromium.

The use of the (SEM - AVS)/f_{OC} benchmark in sediments contaminated with chromium is complicated slightly by the fact that a sediment with a slight excess of SEM - AVS may have AVS = 0.0, and thus be at risk to adverse biological effects of chromium, while at the same time not posing a risk due to cadmium, copper, lead, nickel, or zinc because of organic carbon binding. However, with an understanding of the chemistry of AVS, organic carbon, and metals it is possible to use the benchmark in sediment containing a mixture of metals including chromium. The interpretation of the benchmark with respect to cadmium, copper, lead, nickel, silver, zinc, and chromium is driven by four assumptions:

1) Any sediment with AVS > 0.0 will not cause adverse biological effects due to chromium or silver.
2) Any sediment in which (SEM -AVS)/f_{OC} < 130 μmols/g_{OC} should pose low risk of adverse biological effects due to cadmium, copper, lead, nickel and zinc.
3) Any sediment in which 130 μmols/g_{OC} < (SEM - AVS)/f_{OC} < 3,000 μmols/g_{OC} may have adverse biological effects due to cadmium, copper, lead, nickel or zinc.
4) In any sediment in which (SEM - AVS)/f_{OC} > 3,000 μmols/g_{OC} adverse biological effects due to cadmium, copper, lead, nickel or zinc may be expected.

Section 5

Sampling and Analytical Chemistry

5.1 General Information

All of the issues regarding proper sampling and analytical methods described for other metals (e.g., sampling biologically active zone, seasonal variation) are equally pertinent when chromium is an analyte of interest. Therefore, the guidance given on these topics earlier in this document are similarly appropriate. However, the differing physical and chemical characteristics of chromium in various oxidation states create additional concerns, both in sampling and analysis. For example, samples need to be collected and stored to preserve and minimize disturbance of existing redox conditions and thereby retain the distribution of solid and aqueous phase Cr(III) and Cr(VI) as much as possible. These chromium specific concerns are discussed below.

5.2 Sampling Sediment and IW

Normal procedures used to collect and preserve sediments for analysis of AVS and SEM are sufficient to preserve chromium speciation as well. Potential artifacts of sample handling and storage might include reduction of Cr(VI) or oxidation of Cr(III). The former should be addressed by keeping a sample cold, or even frozen, to inhibit *in situ* microbial reduction, while isolating a sediment sample from air, as well as chilling and freezing the sample, should eliminate the likelihood of oxidation of Cr(III) to Cr(VI) in sediments. Preservation of redox conditions in water samples, however; is significantly more problematic, and requires greater diligence.

As with sediment sampling, the guidance provided earlier in this document regarding collection of interstitial water is appropriate for samples in which chromium is an analyte of interest. Because of the potential of reduction of Cr (VI) to insoluble Cr(III) species within the sampler during the course of the experiment (Berry et al., *in press*), interstitial water samples should be filtered immediately after removal from the sampler, whether collected using centrifugation or *in situ* diffusion samplers (Berry et al., 1996). If centrifugation is used to isolate interstitial water, temperature should be kept low and the overlying atmosphere rendered inert to prevent possible oxidation of Cr(III) to Cr(VI) by Fe/Mn-rich films at the air-water interface (Masscheleyn et al., 1992).

Techniques that separate Cr species of different redox states should be applied to water samples as soon after collection as possible; if such separation cannot be obtained rapidly, samples should be frozen to preserve chemical speciation until such time as separation is practical. For example, Cr(III) and Cr(VI) species in overlying and interstitial water samples can be separated using a modified Fe(OH)3 coprecipitation technique (Berry et al., *in press*, Cranston and Murray, 1978) within hours of collection. Treatment with ion exchange resins to isolate Cr species has also been used (Besser et al., *in press*).

5.3 Chemical Analyses

5.3.1 Sediment Analysis

Techniques recommended for analysis of AVS in sediment samples are appropriate when chromium is a concern, with only slight modification of techniques for analyzing simultaneously extracted metals (SEM). As with water samples, if Cr(VI) is to be measured in the SEM solution, separation of redox species should be conducted as soon after filtration of the extract as possible. If Cr(VI) is expected to be a problem, it should be determined in an aliquot of the SEM extracts by using a modified $Fe(OH)_3$ coprecipitation technique to remove Cr(III) (Wang et al., 1997, Berry et al., *in press*) and analyzing Cr in the

supernatent by atomic spectrochemical means (e.g., inductively coupled plasma atomic emission spectrometry (ICP-AES) and graphite furnace atomic absorption spectrophotometry (GFAAS)).

5.3.2 Water analysis

Interstitial waters and overlying seawater from sediment tests may be analyzed for total and dissolved chromium and Cr(VI); however, analysis of chromium in saline waters at low concentrations can be problematic, so separation of redox species should only be conducted when evidence suggests the presence of Cr(VI) (i.e., AVS concentrations are near or below detection limits). Aliquots of water samples to be analyzed for dissolved metals should be filtered through a 0.4-micron polycarbonate membrane and then acidified with concentrated nitric acid (1% v/v), with Cr(VI) determined in subsamples of the dissolved sample using a modified $Fe(OH)_3$ coprecipitation technique (Cranston and Murray, 1978) as appropriate. Analysis of the various fractions may be conducted by GFAAS.

Section 6

Benchmark Sediment Values: Application and Interpretation

6.1 AVS Benchmark

The AVS benchmark for chromium is different from the SEM-AVS used for cadmium, copper, lead, nickel, silver and zinc because chromium does not form an insoluble sulfide. However, an AVS measurement is still useful in predicting the toxicity of chromium in a sediment, because sediments which have measurable AVS should be reducing in nature; therefore, most chromium should be present in the form of Cr(III), and the risk from acute toxicity due to chromium exposure should be low.

6.2 Interstitial Water Benchmark

The interstitial water benchmark is similar to that for cadmium, copper, lead, nickel, silver and zinc. If the interstitial water concentration of chromium does not exceed the chronic WQC FCV for Cr(VI) (10 µg/L in freshwater and 50 µg/L in saltwater (U.S.EPA., 1995)), the risk from chromium exposure should be low. The Cr(VI) WQC is used because most of the dissolved chromium in sediments should be in the form of Cr(VI), the freshwater benchmark for Cr(VI) is lower than that for Cr(III), and there is no chronic benchmark for Cr(III) in saltwater.

6.3 Incorporation into Multiple Metals Benchmark

The metals benchmark with respect to cadmium, copper, lead, nickel, silver, zinc and chromium is driven by four assumptions:

1) Any sediment with AVS > 0.0 will not cause adverse biological effects due to chromium or silver.
2) Any sediment in which (SEM -AVS)/f_{OC} < 130 µmols/g_{OC} should pose low risk of adverse biological effects due to cadmium, copper, lead, nickel and zinc.
3) Any sediment in which 130 µmols/g_{OC} < (SEM - AVS)/f_{OC} < 3,000 µmols/g_{OC} may have adverse biological effects due to cadmium, copper, lead, nickel or zinc.
4) In any sediment in which (SEM - AVS)/f_{OC} > 3,000 µmols/g_{OC} adverse biological effects due to cadmium, copper, lead, nickel or zinc may be expected.

These four assumptions should prove useful in the application of the chromium ESB in sediment assessments. However, the relationship (SEM - AVS)/f_{OC} should be used with caution (with regard to chromium toxicity) in sediments with little or no AVS. This is because a sediment with no appreciable AVS or SEM and substantial chromium might be toxic due to chromium, even though no toxicity due to other metals would be expected. Other potential limitations to the use of the chromium ESB are outlined in Section 4 of this appendix.

Use of an AVS based benchmark for assessing and predicting mortality in sediments due to chromium was successful in both freshwater and saltwater. Assessing and predicting sublethal toxicity in freshwater sediments was hindered by the observation of significant growth and reproductive effects in treatments where such effects were not expected. Causes of these effects remain ambiguous and may reflect sublethal chromium toxicity or experimental artifacts. Further study is needed to resolve these questions. Consequently, consistent with the recommendations of EPA's Science Advisory Board, publication of this document does not

imply the use of ESBs as stand-alone, pass-fail criteria for all applications; rather, exceedances of ESBs could trigger collection of additional assessment data.

Arguably, the most important additional data needed for assessing contaminated sediments along with ESBs are the results of toxicity tests. Sediment toxicity tests provide an important complement to ESBs in interpreting overall risk from contaminated sediments. Toxicity tests have different strengths and weaknesses compared to chemical-specific guidelines, and the most powerful inferences can be drawn when both are used together (see U.S. EPA 2003a,b for further discussion of using toxicity testing with ESBs to assess contaminated sediments).

The ESB approaches are intended to protect benthic organisms from direct toxicity associated with exposure to metal-contaminated sediments. They are not designed to protect aquatic systems from metals release associated, for example, with sediment suspension, or the transport of metals into the food web from either sediment ingestion or ingestion of contaminated benthos. Furthermore, the ESBs do not consider the antagonistic, additive or synergistic effects of other sediment contaminants in combination with metal mixtures or the potential for bioaccumulation and trophic transfer of metal mixtures to aquatic life, wildlife or humans.

Predicting Bioavailability of Sediment Polycyclic Aromatic Hydrocarbons to *Hyalella azteca* using Equilibrium Partitioning, Supercritical Fluid Extraction, and Pore Water Concentrations

STEVEN B. HAWTHORNE,*,† NICHOLAS A. AZZOLINA,‡ EDWARD F. NEUHAUSER,§ AND JOSEPH P. KREITINGER‡

Energy and Environmental Research Center, University of North Dakota, Grand Forks, North Dakota 58201, The RETEC Group, Incorporated, 1001 West Seneca Street, Suite 204, Ithaca, New York 14850, and National Grid, 300 Erie Boulevard West, Syracuse, New York 13202

Polycyclic aromatic hydrocarbon (PAH) bioavailability to *Hyalella azteca* was determined in 97 sediments from six former manufactured-gas plants and two aluminum smelter sites. Measurements of Soxhlet extractable, rapidly released based on mild supercritical fluid extraction, and pore water dissolved concentrations of 18 parent and 16 groups of alkyl PAHs (PAH_{34}) were used to predict 28 day survival based on equilibrium partitioning and hydrocarbon narcosis models. Total PAH concentrations had little relationship to toxicity. Amphipods survived in sediments with PAH_{34} concentrations as high as 2990 μg/g, while sediments as low as 2.4 μg/g of PAH_{34} resulted in significant mortality. Equilibrium partitioning using either total extractable or rapidly released concentrations significantly improved predictions. However, pore water PAH_{34} concentrations were best for predicting amphipod survival and correctly classified toxic and nontoxic sediment samples with an overall model efficiency of 90%. Alkyl PAHs accounted for 80% of the toxicity, demonstrating that careful measurement of the 16 alkyl clusters in pore water is required. Regression analysis of the pore water PAH_{34} data from 97 field sediments against amphipod survival resulted in a mean 50% lethal residue value of 33 μmol/g of lipid, consistent with 32 μmol/g of lipid for fluoranthene determined by others in controlled laboratory conditions, thus demonstrating the applicability of EPA's hydrocarbon narcosis model when using pore water PAH_{34} concentrations.

Introduction

Industries that historically produced or utilized coal tars have been a major source of polycyclic aromatic hydrocarbons (PAHs) to the environment. Many such industries were (or are) located on waterways, with the result that PAH-contaminated sediments are often associated with these sites. In addition, sediments that have not been impacted by these industries contain background levels of PAHs from other sources such as atmospheric deposition of combustion particulates and background levels of PAHs that typically exceed baseline regulatory concentrations. For example, the regulatory based probable effects concentration (PEC, the total concentration of 13 parent PAHs above which toxicity is expected to be likely) and the threshold effects concentration (TEC, below which toxicity is considered unlikely) are 22.8 and 1.6 μg/g, respectively (*1*), but few urban sediments have PAH concentrations below either criteria. In a recent study of 114 field-collected sediments (both background and impacted), only 27 had PAH_{13} concentrations below the PEC, and only four sediments were below the TEC (*2*).

Efforts to improve predictive methods for the risks posed by sediments contaminated with PAHs have used equilibrium partitioning models to predict the partitioning of PAHs from sediments to water based on natural organic carbon–water partitioning coefficients (K_{OC}) (*3–6*). However, historically contaminated sediments often have much lower pore water concentrations of PAHs than predicted using literature K_{OC} values (*2, 7*), supposedly because of a greatly reduced availability of PAHs as sequestration processes occur. Measured K_{OC} values for historically contaminated sediments from manufactured-gas plant (MGP) sites have been reported to be as much as 3 orders of magnitude higher than literature K_{OC} values used in equilibrium partitioning models (*2, 7*). There are also an increasing number of reports demonstrating that many different carbon types (such as coal, combustion soots, charcoal, and coal tar pitch) are present in many sediments that bind PAHs much more tightly (and result in much less partitioning to water) than predicted by equilibrium partitioning models using K_{OC} values based on natural organic carbon (*2, 7–12*).

Recently, there has been an increasing amount of evidence that the bioavailability of PAHs can also be overestimated using equilibrium partitioning models based on K_{OC} values that are normally used to describe partitioning with natural organic carbon. Several investigators have reported the lack of observable toxicity to aquatic organisms, despite high sediment concentrations of PAHs (*13–16*), and PAH uptake in *Lumbriculus variegatus* was found to be as much as 1000-fold less than predicted by sediment PAH concentrations and equilibrium partitioning models (*17*). In a recent report, the toxicity of PAHs in sediments from MGP sites to *Hyalella azteca* was found to be much lower than predicted by the equilibrium partitioning model but was more accurately predicted when either pore water PAH concentrations or the rapidly released PAH concentrations measured by mild supercritical fluid extraction (SFE) were used rather than sediment concentrations (*18*). The use of mild SFE to obtain rapidly released PAH concentrations has also previously been reported to correlate with water desorption of PAHs from soils (*19, 20*) and to improve the prediction of earthworm uptake of PAHs from soil (*21*).

In the present study, we compare three approaches to predict the availability of PAHs to *H. azteca* based on a 28 day chronic toxicity test. Ninety-seven background and industrially impacted sediments were studied from six different MGP sites and from two aluminum smelting operations. Both 18 parents and 16 groups of alkyl PAHs (PAH_{34}) suggested by the U.S. EPA (*5*) were measured in the sediment, the pore water, and the rapidly released or available fraction based on mild SFE (*19–21*). Predictions of the internal

PAH concentrations expressed on a lipid basis (and thus, toxicity to the organism) were based on the U.S. EPA's PAH equilibrium partitioning/hydrocarbon narcosis model (*3*–*6*), which uses generally accepted K_{OC} values to predict pore water PAH concentrations from sediment concentrations, followed by the use of octanol–water coefficients (K_{OW}) to predict the organism lipid PAH concentrations. Biota lipid PAH concentrations were also predicted using the rapidly released sediment PAH_{34} concentrations and the measured pore water PAH_{34} concentrations as input data to the equilibrium partitioning model proposed by the U.S. EPA (*3*–*6*).

Experimental Procedures

Sediment Collection and Characterization. Sediment collection procedures and analytical methods have been described in detail in earlier reports (*2*, *22*, *23*). In brief, approximately 150 sediments were collected using a Ponar grab sampler or, in a few cases, with a shovel. Approximately 15 L of the sediment–water slurry was transferred to a clean bucket, sieved through a 2 mm screen, briefly mixed, transferred to new glass jars with Teflon-lined lids, and immediately placed on ice. This procedure resulted in sediment–water slurries with approximately 40–70% water content. Samples were shipped by overnight air to the analytical and toxicology laboratories and stored at ca. 4 °C until use. All analytical tests were completed, and all biological tests were begun within 28 days of sample collection. All sediments were initially screened for PAH concentrations and total organic carbon (TOC) to select 97 sediments that best represented the range of PAH concentrations, organic carbon contents, and sediment textures existing at each site, as well as to spatially represent the site. Field reference sediments were also selected from each site that were not contaminated by the MGP or aluminum smelter activities (based on their PAH concentrations).

TOC and BC (black or soot carbon) were determined by elemental analysis (C,H,N) after acidification with HCl to remove inorganic carbonates. Samples for BC were prepared by oxidation under air at 375 °C for 24 h in a gas chromatographic oven (*24*). Pore water dissolved organic carbon (DOC) was determined after alum flocculation using the U.S. EPA method 415.1.

The 34 PAHs (18 parent and 16 groups of alkyl PAHs) listed for the sediment PAH narcosis model by the U.S. EPA (*5*) were determined in all sediment Soxhlet extracts, SFE extracts, and pore water samples. Each method used several 2- to 6-ring perdeuterated PAHs as analytical internal standards to aid in quantitation (*22*, *23*). Pore water PAH concentrations were obtained in quadruplicate by briefly centrifuging the sediment–water slurry, flocculating with alum twice to remove colloids, adding the perdeuterated internal standards, and quantitative analysis of the dissolved pore water PAH concentrations with solid-phase microextraction (SPME) and GC-MS with selected ion monitoring (*22*). SFE available and total extractable sediment PAH concentrations were based on extractions of quadruplicate 2 g samples of the sediment, after the pore water fraction was removed by centrifugation, and the sediments were mixed with 4 g of sodium sulfate (*23*). SFE was performed for 40 min with pure carbon dioxide at 200 bar, 50 °C, and a flow rate of 1.0 mL/min (*19*, *20*). Soxhlet extraction was performed for 18 h with 150 mL of acetone–methylene chloride (1:1).

Toxicity Testing. Toxicity to *H. azteca* was determined using EPA method 100.4 for a 28 day exposure period as previously described (*18*).

Data Analysis. Statistical analysis of amphipod survival data was performed to estimate the dose response for each of the three chemical measurements of PAHs. A Probit regression model was run in SAS (SAS Institute, Cary, NC) using the Probit procedure to estimate the mean amphipod survival. The statistical fits (χ^2 test of significance) of the Probit regression models were evaluated for significance ($\alpha = 0.05$), and the mean dose and probability were presented as the Probit regression line. The 85% survival dose was determined by the lower 95% confidence interval for a probability of 85% survival, and the 15% survival dose was represented by the upper 95% confidence interval for a probability of 15% survival. The modeled dose response for each of the three chemical measurements of PAHs was evaluated for statistical fit using a binary logistic regression model and the Goodman–Kruskal γ (*25*). The Goodman–Kruskal γ is a rank-order correlation statistic used as a measure of association for the ability of a predictor variable (e.g., pore water concentrations) to explain the response variable (the binary variable toxic or nontoxic). The γ value ranges from −1.0 (no predictive ability) to 1.0 (perfect predictor).

TABLE 1. Summary of Sediment and Pore Water Characteristics

	units	minimum	maximum	median
Bulk Sediment[a]				
total PAH_{34}	μg/g	1.31	17 600	277
total PAH_{16}	μg/g	0.22	8580	128
TOC	wt %	0.3	42.4	3.3
BC	wt %	0.1	39.7	0.8
Fraction (BC/TOC)	%	5.3	100	33.4
% alkylated PAHs[b]	%	25	94	53
2- and 3-ring PAHs/ total PAH_{34}[c]	%	6	96	38
Sediment Pore Water				
total PAH_{34}	ng/mL	0.02	10 900	17.4
total PAH_{16}	ng/mL	0.02	9250	5.84
DOC	mg/L	1.4	114	4.35

[a] Sediment PAH concentrations are on a dry weight basis. [b] Total concentration of alkyl PAHs divided by total PAH_{34} concentration. [c] Sum concentration of all 2- and 3-ring PAHs divided by total PAH_{34} concentration.

Results and Discussion

Sediment Characteristics and PAH Concentrations. Sediment textures ranged from coarse sand to fine-grained silts and clays. The TOC ranged from 0.3 to 42 wt %, and BC ranged from 0.1 to 40 wt %, indicating both low and high impact from industrial carbon residues. The fraction of BC as compared to TOC ranged from 5% (indicating no significant contribution of BC) to 100% (indicating that all organic carbon in that sediment was present as BC).

PAH concentrations for the 97 test sediments are summarized in Table 1 and Table S1. PAH concentrations ranged from very low background concentrations (<μg/g) to sediments contaminated as high as 1.8 wt % (17 600 μg/g) total PAH_{34}. The fraction of low molecular weight PAHs (sum of 2- and 3-ring PAHs) as compared to the total EPA_{34} PAHs (2–6-ring) ranged from 6% (indicating highly weathered PAHs from coal tar or coal tar pitch) to 96% (indicating unweathered coal tar PAHs) (Table 1). Pore water concentrations also ranged over several orders of magnitude, from a lowest detected concentration of 0.02 ng/mL to a highest detected concentration of 10 900 ng/mL (PAH_{34}). A more complete description of the individual 34 PAH concentrations for sediment, the SFE rapidly released fractions, and the pore water concentrations is given in Table S1.

Approximately 10 impacted sediments showed significant heterogeneity in the quadruplicate Soxhlet extracts and in the SFE extracts. For these sediments, the relative standard deviations (RSDs) for individual and total PAH_{34} concentrations in the quadruplicate extracts sometimes exceeded 50

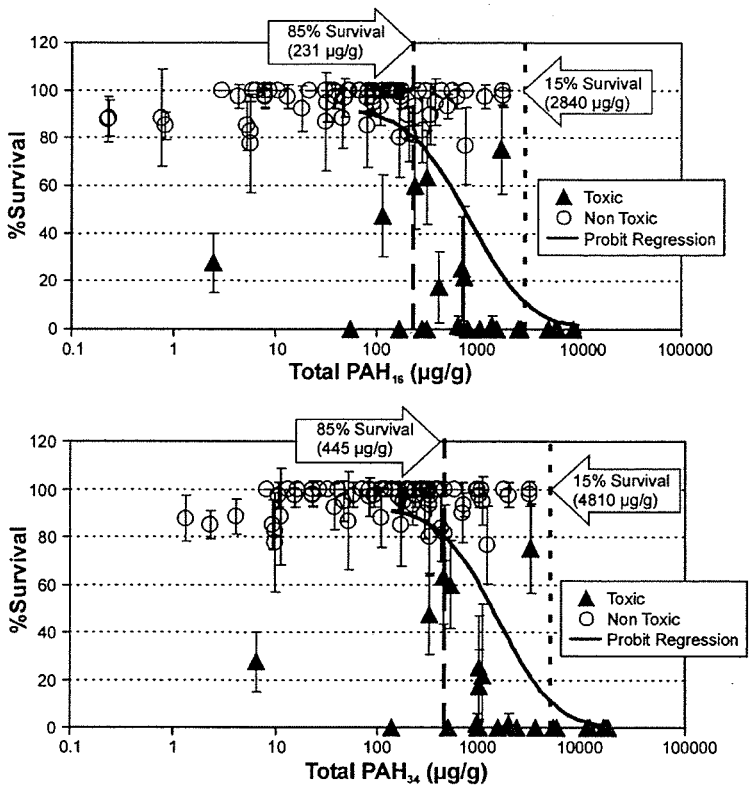

FIGURE 1. ***H. azteca*** **survival as compared to total extractable PAH_{16} and PAH_{34} sediment concentrations.**

or 100%, and for such sediments, the replicate extracts usually ranged from light yellow to dark brown. When this occurred, a second set of quadruplicate samples was extracted and analyzed, and in all cases, the sediment PAH heterogeneity was confirmed, demonstrating that the sediments contained blebs of nonaqueous-phase coal tars, pieces of coal tar pitch, or pieces of other material that were highly contaminated with PAHs. In many cases, visual observation under a low-power microscope confirmed the presence of pitch particles and/or tar droplets. In contrast, the quadruplicate pore water samples from each sediment showed good reproducibility, with % RSDs typically less than 10% for low- and mid-molecular weight PAHs and typically less than 15% for higher molecular weight PAHs.

Survival Predictions Based on Sediment Total Extractable PAH Concentrations. Out of the 97 sediments used to compare toxicity predictions, 25 were found to result in reduced survival to *H. azteca* following 28 day exposures. Both MGP and aluminum smelter sites had toxic sediments, with 17 out of the 73 MGP sediments causing reduced survival and eight of the 24 aluminum smelter sediments causing reduced survival.

The poor relationship between total PAH concentrations expressed as micrograms per gram (whether EPA_{16} or EPA_{34}) and *H. azteca* survival is shown in Figure 1. When compared to the probable effects concentration (PEC) of 22.8 µg/g (PAH_{13}) (*1*), 73 of the sediments have total PAH_{13} concentrations that exceed the PEC, yet 67% of those that exceed the PEC value are nontoxic. Similarly, the total extractable PAH_{34} concentration shows little relationship to *H. azteca* survival (Figure 1). Except for sediments with very low or very high PAH concentrations, total PAH concentrations have little or no ability to predict toxicity. (Note that the plot for total PAH_{13} versus toxicity is essentially identical to that shown in Figure 1 for total PAH_{16} since PAH_{13} concentrations are only a few percent lower than the PAH_{16} values for all of these sediments.)

The use of equilibrium partitioning models as developed by DiToro and others and proposed as a regulatory sediment guidance approach by the U.S. EPA (*3*–*6*) to improve toxicity predictions is explored in Figure 2. This model first predicts pore water concentrations from sediment concentrations using literature and modeled K_{OC} values. The resultant pore water PAH concentrations are then used to predict biota lipid concentrations using K_{OW} values for each of the 34 parent and groups of alkyl PAHs (*3*–*6*). Thus, proper prediction of the final lipid total molar PAH concentration depends heavily on the assumption that K_{OC} values used for each individual PAH (and each group of alkyl clusters) are correct and that each PAH has a single K_{OC} value that applies to all sediments.

As shown in Figure 2 (top), the use of total extractable PAH_{34} sediment concentrations and the equilibrium partitioning model (*5*, *6*) significantly improves the ability to predict survival to *H. azteca* over the simple use of total extractable (PAH_{34} or PAH_{16}) concentrations shown in Figure 1. The overall model efficiency (% of correct predictions) improves from 48 to 80% (Table 2). However, substantial overlap between toxic and nontoxic sediments still exists, and 26 of the 97 sediment samples lie within the region of 85–15% survival where it is difficult to make statistically strong predictions of toxicity (Table 2). The scatter in predicted versus actual survival shown in the top of Figure 2 might be expected based on a recent report where the K_{OC} values for each individual PAH from a similar set of sediments (including most of the sediments reported here) varied by nearly 3 orders of magnitude for the same PAH from different sediments. For example, while a log K_{OC} value for pyrene of 4.84 is used for all sediments in the model (*5*), measured values of log K_{OC} in 114 sediments ranged from 4.17 to 7.40, and the median log K_{OC} was 5.81, nearly one log unit higher

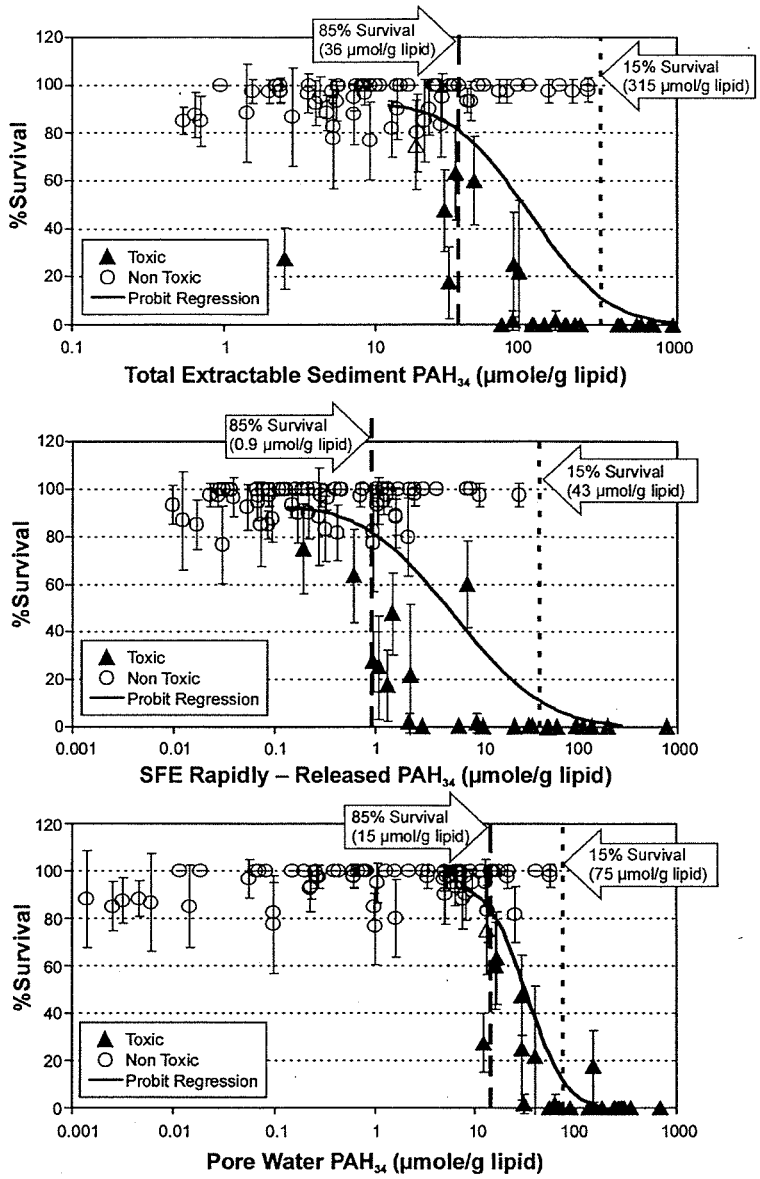

FIGURE 2. ***H. azteca*** **survival (28 day) as compared to predicted micromol per gram of lipid for 97 sediments based on total extractable sediment, SFE rapidly released, and pore water PAH_{34} concentrations.**

than the value used in the model (*2*, *5*). Thus, the essential assumption in the equilibrium partitioning model that K_{OC} values for a single PAH are constant for all sediments is not supported by experimental data on field sediments (*2*, *7*).

Survival Predictions Based on SFE Rapidly Released PAH Concentrations. The next approach we investigated was to replace the total Soxhlet extractable concentrations for each PAH by the concentration that was measured to be rapidly released by mild SFE, then predicting the lipid PAH concentrations in the same manner as that used for the total extractable concentrations using equilibrium partitioning modeling based on literature K_{OC} and K_{OW} values (*3*–*6*). As shown in Figure 2 (middle), replacing the total extractable PAH concentrations with rapidly available PAH concentrations does not appear to significantly differentiate toxic and nontoxic sediment samples. The Goodman–Kruskal γ increases modestly from 0.78 to 0.80, and the model sensitivity (correctly identifying toxic samples) increases from 80 to 92%. However, in gaining sensitivity, the model specificity (correctly identifying nontoxic samples) decreased significantly to 64%, with an even greater number of samples (forty) within the uncertain region of 85–15% survival, forcing the overall model efficiency to 71% (Table 2).

Survival Predictions Based on Pore Water PAH Concentrations. Finally, the predicted biota lipid PAH concentrations were determined based on measured pore water concentrations for PAH_{34}. The pore water approach has the obvious advantage that only K_{OW} values for each PAH need to be accurate (and apply to all water samples) (*3*–*6*), which is certainly more valid than the assumption that K_{OC} values are correct and apply to all sediment samples (*2*, *7*–*12*). As shown in Figure 2 (bottom), the use of pore water concentrations and lipid–water partitioning coefficients based on K_{OW} values significantly improves the prediction of toxic and nontoxic sediments over the other two approaches discussed previously. The Goodman–Kruskal γ improves dramatically, to 0.95. In addition, the model sensitivity (correctly predicted toxicity) reaches 92%, and the specificity (correctly predicted

[a] Lower 95% confidence interval for 85% survival and upper 95% confidence interval for 15% survival. [b] Sensitivity is the extent to which a test correctly classifies a toxic sample as toxic and is therefore protective of the environment. [c] Specificity is defined as the rate at which a test correctly classifies a nontoxic sample as nontoxic. [d] Overall efficiency is the fraction of correct predictions for all samples. [e] TEC is the sum of 13 parent PAH concentrations below which toxicity is considered unlikely (*1*). [f] PEC is the sum of 13 parent PAH concentrations above which toxicity is considered likely (*1*).

nontoxic) reaches 89%, yielding an overall model efficiency of 90% (Table 2).

Since the data presented in Figure 2 come from sediments from eight different MGP and aluminum smelter sites, and since they encompass such a large range of carbon concentrations and types (as well as PAH concentrations), it would seem likely that specific sites or sediment characteristics may strongly relate to the toxicity and/or ability of the models to predict toxicity. However, there is no apparent relationship between toxicity and model behavior among the different sites or between MGP and aluminum sites (Supporting Information Figure S1). In addition, there appears to be no relationship between total TOC (Supporting Information Figure S2), BC (Supporting Information Figure S3), the fraction of BC as compared to TOC (Supporting Information Figure S4), or sediment texture (not shown) on the predictive abilities of the models based on total extractable PAH, SFE available PAH, or porewater PAH concentrations.

As shown in Table 2 and Figure 2, Probit regression analysis shows that the number of sediment samples within the 95% confidence interval for 15–85% survival was significantly fewer for the pore water predictions than for either SFE rapidly released or total extractable concentrations. With the pore water data, only two toxic sediments were incorrectly predicted to have less than 85% survival (i.e., had a predicted μmol/g of lipid PAH concentration below the 85% survivability line). However, it should be noted that the toxicity for the sediment with ca. 30% survival (Figure 2, bottom) is unlikely to be caused by PAHs since the total sediment concentrations were only 2.4 μg/g (PAH_{16}) and 6.4 μg/g (PAH_{34}). In fact, only three sediments out of the 97 shown in Figure 2 had lower total extractable PAH concentrations. This sediment also had only 0.2 wt % natural organic carbon (0.8 wt % TOC minus 0.6 wt % SOC) and was composed primarily of sand. Recent studies with uncontaminated sandy sediments show that the lack of essential nutrients may cause mortality, even with the addition of food as per EPA method 100.4 (Francis Doherty, personal communication). Unidentified toxic agents may have also been present. However, none could be found by full-scan GC-MS analysis of the pore water and sediment extracts. The other sample defined as toxic (by failing the 85% survival criteria) but predicted as nontoxic had a survival of 75 ± 19% (Figure 2, bottom), which is very close to the conservative 85% survival value used in our study as the cutoff for nontoxic sediments.

Ideally, any method used to predict biological effects of pollutants would be conservative (i.e., tend to overpredict rather than underpredict toxicity). The pore water predictions of toxicity had a sensitivity of 92%, classifying only two sediments (just discussed previously) out of 25 toxic sediment samples as nontoxic (Table 2). The pore water predictions also had fewer sediments in the uncertain region between 85 and 15% survival as compared to the rapidly released and total extractable PAH_{34} approaches (Table 2). These results from Probit regressions show that (to a 95% confidence level) sediments falling outside the 85–15% survival range would not need to be tested during field surveys but could be directly classified as toxic or nontoxic based on pore water PAH concentrations. The sediments falling between the predicted 85 and 15% survival range would then require toxicity testing. Thus, for the 97 sediments, 26 sediments would require biological testing based on total extractable sediment PAH_{34} concentrations, 40 sediments for rapidly available sediment concentrations, while only 17 sediments would need biological testing for the predictions based on pore water concentrations (Table 2).

The relatively poor ability of rapidly released PAH concentrations to predict toxicity was a surprise since our initial report comparing pore water and SFE predictions showed both methods to improve toxicity predictions over using total extractable concentrations and the equilibrium partitioning model (*18*). All of the sediments studied in the initial report were from MGP sites, while the present study includes sites near aluminum smelters that had higher relative proportions of high molecular weight PAHs (likely associated with coal tar pitch used for anode production) than the MGP sites (likely contaminated with MGP tars having a lower molecular weight distribution). There are no apparent differences in toxicity (or the ability to predict toxicity) between MGP and aluminum sites as shown in Figure S1.

The poorer predictive ability of mild SFE is likely a result of the types of available PAH molecules measured by the two techniques. Pore water PAH measurements determine the equilibrium (or near equilibrium) pore water PAH concentrations found in the sediment–water slurry. In contrast, SFE measures the capacity of the sediment to rapidly release PAHs to water (*19*). Since *H. azteca* presumably absorbs solvated PAHs from the water phase, it would seem logical that pore water concentrations may more closely reflect exposure in the toxicity tests. It should also be noted that sediment heterogeneity (discussed previously) also likely reduces the predictive abilities of both total extractable and rapidly released PAH concentrations, as compared to the good homogeneity shown by pore water PAH concentrations. In any case, the results in Figure 2 and Table 2 clearly demonstrate that pore water concentrations are superior to either total extractable PAH_{34} or SFE rapidly available PAH_{34} concentrations in predicting *H. azteca* mortality.

Since the two methods measure different phenomena (capacity to rapidly release PAHs vs equilibrium pore water concentrations), it was hoped that a combination of the two approaches would further increase the ability to predict

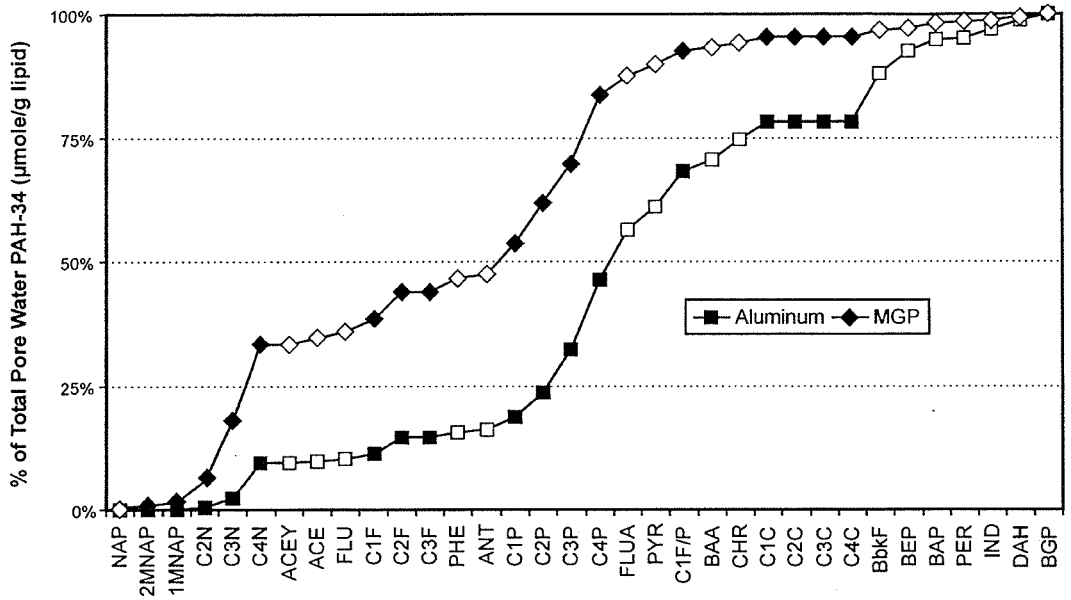

FIGURE 3. Cumulative average relative contribution to lipid PAH burden of each of the 34 PAHs in MGP and aluminum smelter sediment pore water samples. Alkyl PAHs are designated with a solid symbol and parent PAHs with an open symbol.

toxicity. As would be expected, the molar PAH lipid concentrations predicted by SFE and pore water measurement concentrations are correlated, but not strongly, and a linear regression of the log SFE µmol/g of lipid versus log pore water µmol/g of lipid only has an r^2 value of 0.55. A binary logistic regression model using the molar PAH lipid concentrations predicted by pore water as the predictor and toxic/nontoxic as the response was statistically significant ($p < 0.0001$) and explained approximately 95% of the variance in toxicity (Goodman–Kruskal $\gamma = 0.95$). Unfortunately, adding the molar PAH lipid concentrations predicted by SFE as an additional predictor was not statistically significant ($p = 0.657$), nor did it change the Goodman–Kruskal γ, indicating that adding SFE to the pore water measurements did not improve the predictions of toxicity. Thus, based on the results from the 97 sediments, there was no added value in obtaining the SFE rapidly released PAH_{34} concentrations for the prediction of *H. azteca* toxicity in freshwater sediments.

Effect of Nonaqueous-Phase Hydrocarbon Liquids (NAPL). As might be expected for sediments collected in industrial waterways, approximately one-third of the samples had a sheen or NAPL phase observed during sample collection, which was later confirmed by independent observation at the analytical laboratory. Any significant amount of a NAPL hydrocarbon phase (whether PAHs or other hydrocarbons such as petroleum alkanes) could change the mechanism from sediment–water partitioning to liquid–liquid partitioning. Since the equilibrium partitioning model assumes that PAH partitioning occurs between natural organic carbon on the sediment and pore water, the presence of the NAPL phase in one-third of our test sediments may contribute to the model's inability to predict pore water concentrations and thus reduce its ability to predict toxicity.

Surprisingly, the presence or absence of NAPL did not have a significant relationship to toxicity or on the predicted µmol/g of lipid PAH concentrations, as shown in Supporting Information Figure S5. Out of the 97 sediments tested, 27 had NAPL phases, of which 17 were toxic and 10 were nontoxic. Note also that removing the NAPL containing sediments from the sample set did not improve the prediction of toxicity based on the total Soxhlet extractable PAH_{34} concentrations or the rapidly available PAH_{34} concentrations.

Field versus Laboratory Determination of Threshold Toxicity Concentration. As shown in Figure 2, the sediment samples used in this study had a fairly broad distribution of nontoxic, moderately toxic, and toxic samples that allows a lethal residue (LR_{50}) to be calculated using Probit regression modeling. For the field sediments used in this study, the LR_{50} lipid concentration (total PAH_{34} molar concentration) was 33.0 µmol/g of lipid (31–35 µmol/g of lipid, 95% CI). This value is in good agreement with a laboratory-determined value recently reported by Schuler et al. (*26*) for fluoranthene with 28 day exposures to *H. azteca* of 32 µmol/g of lipid (26–40 µmol/g of lipid, 95% CI). This good agreement from controlled laboratory exposure and from 97 field sediments validates the EPA's narcosis model with pore water concentrations for describing PAH toxicity to sensitive benthic organisms such as *H. azteca*.

Relative Contributions of Alkyl and Parent PAHs to Toxicity Predictions. Historically, only 16 (or 13) parent PAHs determined by EPA method 8270 are considered in regulatory processes, as well as in the majority of scientific studies reported in the literature. This is potentially misleading since the majority of PAHs found in the environment are likely to be alkylated rather than parent PAHs. For example, a recent report showed that ca. 99% of the PAHs in a petroleum crude oil was alkylated and that ca. 60–70% of the PAHs in MGP coal tars was alkylated (*23*). In recognition of the potential importance of alkylated PAHs, the EPA's PAH hydrocarbon narcosis model suggests that a total of 18 prominent parent PAHs and 16 groups of alkyl PAHs be measured as was done in the present study (*5*). (Note that, with the exception of the two methylnaphthalene isomers, each group of alkyl PAHs can contain a few to nearly 100 isomers, so that this list of 16 groups of alkyl PAHs represents several hundreds of PAHs (*23*).) The potential impact of the alkyl PAHs on the predicted toxicity is potentially quite large since their modeled K_{OW} values are significantly larger than the related PAH (*3–5*), and therefore, the concentration of a particular group of alkyl PAHs can be much lower to account for one predicted toxic unit than the concentration required for the related

parent PAH. For example, the pore water concentrations required for one toxic unit in the EPA model (equivalent to a concentration of 2.24 μmol/g of lipid) for naphthalene, and its C1, C2, C3, and C4 isomers, were 194, 82, 30, 11, and 4 ng/mL, respectively (*5*, *22*). Therefore, C4 naphthalenes contribute nearly 50-fold higher toxic units than the same concentration of naphthalene in pore water. In contrast, the concentrations of sediment PAHs that account for one toxic unit only vary by a factor of 2, essentially since the partitioning coefficients (K_{OC} and K_{OW}) used in the model tend to cancel each other's effect on the predicted lipid concentration (*5*).

Figure 3 shows the average relative contributions of the different PAHs and groups of alkyl PAHs in pore water to predicted bioaccumulation and related PAH narcosis for all non-background sediments (i.e., sediments that had the majority of PAHs as nondetected are not included). Two features are important to note in these data. First, an average of 96% (MGP) and 78% (aluminum) of the predicted toxicity is contributed by 2–4 four-ring PAHs (e.g., naphthalene through chrysene), and the measurement of 5- and 6-ring PAHs in pore water does little to change the predicted lipid molar PAH concentration. This is fortunate since the measurement of 5- and 6-ring PAHs at the required picogram per milliliter detection limits is difficult (*22*). The results in Figure 3 also show that, since only the higher molecular weight PAHs have significant partitioning into dissolved organic matter (DOM) (*22*), there is no significant difference in the predicted lipid PAH concentrations (or the EPA toxic units (*5*)), whether freely dissolved (PAHs associated only with the pore water phase) or total dissolved (freely dissolved PAHs and PAHs associated with DOM). For the 97 sediments used in the present study, predicting the lipid PAH concentrations using freely dissolved or total dissolved PAH concentrations did not yield significantly different results in model interpretations. Therefore, the distinction of freely dissolved and total dissolved PAH concentrations for predicting PAH toxicity does not appear to be important as long as PAHs associated with colloids are removed by flocculation prior to analysis of the pore water (*22*).

The second observation from Figure 3 is that alkyl PAHs contribute an average of 81% (MGP) and 55% (aluminum) of the total predicted lipid molar PAH concentrations (and therefore 81 and 55% of the predicted toxicity, respectively). For the combined sites, 69% of the total toxicity was caused by the C1 to C4 alkyl naphthalene and phenanthrene/anthracene isomers. The importance of the alkyl PAHs to toxicity clearly demonstrates the need to apply methods capable of measuring both parent and alkyl PAHs (*22*, *23*) rather than relying on methods that only determine parent PAHs.

The results of this study involving 97 field sediments clearly demonstrate that the measurement of pore water PAHs is superior to the use of total extractable or SFE rapidly available PAH_{34} concentrations to accurately predict the bioavailability and toxicity of PAHs from background and impacted sediments using the EPA's hydrocarbon narcosis model. Considering sediment matrix characteristics such as TOC, BC, texture, and presence of NAPL did not appear to improve predictions based on total sediment PAH concentrations. In addition, it is clear that the common practice of measuring only the parent PAHs is not sufficient to describe environmental effects and that the high contribution of alkyl PAHs to the predicted sediment toxicity emphasizes the need for consistent and accurate methods to calibrate for, and quantitate, the complex clusters of isomers that make up most alkylated groups on the PAH_{34} list.

This study was conducted to examine the application of Equilibrium Partitioning Sediment Benchmarks (ESBs) for assessing the toxicity of polycyclic aromatic hydrocarbons (PAHs) in sediments at former manufactured gas plant (MGP) and coke sites. Samples of freshwater sediment from four MGP and coke sites in the U.S. Northeast and Midwest were analyzed for 34 individual PAHs, total organic carbon, "black" carbon (potentially composed of pitch, soot, and other forms of pyrogenic carbon), and sediment toxicity (28-day Hyalella azteca *toxicity test). The sum of the Toxic Units in each sample was calculated from a one-phase model that accounts for sorption of PAHs to total sediment organic carbon, and a two-phase model that accounts for sorption to black carbon as well as to natural organic carbon. Although both the one-phase and two-phase models accurately predicted concentrations of PAHs that were not toxic to aquatic invertebrates, the two-phase model was more often in agreement with results of sediment toxicity tests. While the bioavailability and toxicity of PAHs may vary at other sites, the two-phase model correctly predicted that sediments from these sites with concentrations of total PAHs as high as 52 mg/kg were not toxic to invertebrates.*

Keywords Black carbon, equilibrium partitioning, MGP, PAHs, sediment

1. Introduction

A manufactured gas plant (MGP) is an industrial facility at which gas for lighting and other purposes was produced from coal, oil, and other feedstock. Sometimes, coke was the primary product, and the gas was a by-product, and the facility was called a coke plant. From the early 1800s, manufactured gas plants (MGPs) produced byproducts that included commodities such as coal tars containing high concentrations of polycyclic aromatic hydrocarbons (PAHs) (Hayes et al., 1996). Because MGPs were often located close to water bodies, contamination of sediment with PAHs is common at these sites. The distribution of PAHs in the aquatic environment is of concern because of their toxicity, carcinogenicity, and persistence (Neff, 1979). Many state regulatory authorities use empirical Sediment Quality Guidelines (SQGs), such as the Effects Range Low and Median (Long and Morgan, 1990; Long et al., 1995), Ontario Lowest and Severe Effect Levels (Persaud et al., 1993),

Address correspondence to Susan B. Kane Driscoll, Exponent, Inc., 3 Clock Tower Place, Suite 205, Maynard, MA 01754, USA. E-mail: sdriscoll@exponent.com

and Consensus Threshold and Probable Effect Concentrations (MacDonald et al., 2000), for predicting toxicity or as remediation goals for sediments. However, one of the greatest sources of uncertainty associated with use of empirical SQGs is that they do not take into account site-specific bioavailability of sediment-associated contaminants. The National Research Council states that sediment cleanup goals should be based on site-specific risk considerations (NRC, 2001), and information on the bioavailability of PAHs is an important site-specific consideration that can be used to guide remedial strategies and focus clean-up actions at MGP sites.

U.S. EPA recently published Equilibrium Partitioning Sediment Benchmarks (ESBs) for PAH mixtures (U.S. EPA, 2003) and is developing a site-specific procedure (U.S. EPA, 2000) that can be used to estimate the bioavailability and toxicity of sediment-associated PAHs to benthic (bottom-dwelling) aquatic organisms. To develop the ESBs, U.S. EPA used a narcosis mode of action model incorporating water-only acute toxicity test data to estimate a lipid-normalized final chronic value (FCV) of 2.24 μmol PAH/g lipid, which is expected to be protective of 95% of the species tested (U.S. EPA, 2003; Di Toro and McGrath, 2000; Di Toro et al., 2000). Under the assumptions of equilibrium partitioning (EqP), the FCV is used to estimate the corresponding critical concentrations of individual PAHs in other phases (e.g., sediment organic carbon and pore water). The ESB approach calculates a Toxic Unit for each PAH as either:

$$\mathrm{TU} = \frac{C_{\mathrm{oci}}}{\mathrm{FCV_i}}$$

or

$$\mathrm{TU} = \frac{\mathrm{C_{pw}}}{\mathrm{FCV_i}}$$

where:

$\mathrm{C_{oci}}$ = the concentration of a specific PAH in sediment (ug/kg organic carbon)

$\mathrm{C_{pw}}$ = the concentration of a specific PAH in pore water (ug/L pore water)

$\mathrm{FCV_i}$ = the PAH-specific final chronic value (expressed either as ug/kg organic carbon or ug/L pore water).

If the sum of the Toxic Units for "total PAHs" in the sediment or pore water is less than or equal to 1.0, the concentration of the mixture of PAHs in the sediment is acceptable for the protection of benthic organisms from chronic effects. Previous studies have demonstrated that ESBs are useful in identifying concentrations of PAHs in sediment samples that are not likely to be toxic to invertebrates (Kane Driscoll et al., 2004; Kreitinger et al., 2007).

U.S. EPA (U.S. EPA, 2003) defines "total PAHs" as comprising, at a minimum, the 34 parent and alkylated PAHs that were measured in the U.S. EPA Environmental Monitoring and Assessment Program (U.S. EPA, 1996). This definition is used because few databases are available that have measured a greater number of PAHs, and because the use of fewer PAHs could underestimate the total toxicity of the PAH mixture. However, U.S. EPA recognizes most historical data consist of either the 13 PAHs identified by U.S. EPA as among the priority pollutants, or the 23 PAHs typically monitored by the National Oceanic and Atmospheric Administration (NOAA) for the Status and Trends Program. If data on only 13 PAHs are available, U.S. EPA (2003) states that an uncertainty factor (UF) can be applied to the sum of Toxic Units for 13 PAHs to estimate the sum of Toxic Units for 34 PAHs. U.S. EPA used a data set of 488 sediment samples to calculate a UF of 2.75 (the 50th percentile of the data set) or 11.5 (the 95th percentile of the data set) to account for the presence of the unmeasured PAHs. The data used by U.S. EPA to derive the UF

were primarily from sites contaminated with pyrogenic PAHs although a subset of samples contained more petrogenic PAHs (USEPA, 2003). Pyrogenic PAHs, which are formed under high temperatures and elevated concentrations of oxygen, are dominated by parent non-alkylated molecules. Conversely, petrogenic PAHs, which are formed under relatively low temperature and low oxygen conditions over thousands of years, are typically highly alkylated. Uncertainty Factors calculated for sites affected by petrogenic sources will tend to be larger than sites affected primarily by pyrogenic PAHs. Because of the fundamental differences between petrogenic PAHs and pyrogenic PAHs, using the uncertainty factors from the ESB (USEPA, 2003) for every site is not advisable, and the development of a source-specific UF is recommended.

U.S. EPA recognizes that a comparison of the EqP-based concentration of PAHs in bulk sediment (or pore water) to FCVs, as described above, may be overprotective at some sites if the characteristics of the sediment or of the PAHs reduce the partitioning of PAHs into pore water, thereby reducing their bioavailability and toxicity. For example, numerous studies have demonstrated that partitioning of PAHs cannot always be explained by standard models of equilibrium partitioning to sediment organic carbon (McGroddy and Farrington, 1995; Maruya et al., 1996; Ghosh et al., 2000). Additional studies suggest PAHs occlude in or adsorb to forms of pyrogenic carbon partition differently than in natural sediment organic carbon (Gustafsson et al., 1997; Buchelli and Gustafsson, 2000; Accardi-Dey and Gschwend, 2002). The presence of pyrogenic carbonaceous particles in sediment (collectively termed "black carbon") have been shown to reduce the bioavailability and bioaccumulation of PAHs in sediment by benthic invertebrates (Vinturella et al., 2004; Rust et al., 2004), which is expected to result in reduced toxicity. The draft U.S. EPA site specific procedure (2000) assumes that the bioavailable concentration in sediment can be reasonably measured or estimated from the "freely dissolved" chemical in pore water. An approach that is based on concentrations of bioavailable PAHs in pore water has the potential to help MGP site managers negotiate cleanup values that are appropriately based on actual bioavailability and toxicity. We use data from several MGP sites to examine the ability of the ESB site-specific procedure to assess the bioavailability and predict the chronic toxicity of sediment-associated PAHs.

The primary goal of this study is to examine whether the ESB approach can be used as a conservative predictor of toxicity (or lack of toxicity) of sediment-associated PAHs at MGP sites. A second goal is to examine whether a one-phase model that accounts for sorption of PAHs to total natural sediment organic carbon, or a two-phase model that accounts for sorption to black carbon as well as to natural organic carbon, is a better predictor of the bioavailability and toxicity of PAHs in sediments from MGP or coke sites. A third goal is to calculate an MGP-specific UF that can be used to predict toxicity associated with the specific suite of PAHs likely to be present at MGP sites if data are available for only a subset of PAHs.

2. Materials and Methods

2.1. Field Collection

Freshwater sites used in this study include a former coking plant in New Jersey, two MGP sites in central New York, and an MGP site in northern Indiana, USA. Samples of sediment were collected from 22 locations across these sites with concentrations of PAHs ranging from approximately 10 mg/kg to several thousand mg/kg total PAHs. Composite surficial

sediment samples (0–15 cm) were made from approximately six individual grab samples at each sample location. The composite sample was mixed in a large stainless-steel bowl, and subsamples taken for analysis of sediment chemistry, sediment characteristics, and toxicity. Field duplicates for sediment chemistry were collected as aliquots of the composite.

2.2. Sediment Analyses

Sediment samples collected at the New York and New Jersey sites (SD-1 to SD-4, K-1, P-1 to P-5) were analyzed for 34 PAHs using U.S. EPA SW846 Method 8270C, with the modification of the GC/MS in the selected ion monitoring (SIM) mode of operation. The sediment samples from the Indiana site (identified as SMR-1 to –12) were analyzed for 34 PAHs (parent and alkylated) by GC/FID using U.S. EPA Method 8100M, GC/MS using U.S. EPA Method 8270M, and GC/IRMS (U.S. EPA, 1986). All samples were analyzed for total organic carbon (TOC) using U.S. EPA SW846 Method 9060 (U.S. EPA, 1986). Samples were also analyzed for "black carbon," which is procedurally defined as carbon remaining after high-temperature combustion (375°C) and acid treatment of sediments to remove other forms of carbon (Gustaffson et al., 1997; Accardi-Dey and Gschwend, 2003). Total organic carbon and black carbon were also analyzed in a standard reference material, SRM-1944 (NIST 1999), which is an urban marine sediment.

2.3. Sediment Toxicity Tests

A 28-day sediment toxicity test with the freshwater amphipod, *Hyalella azteca,* was conducted on each sediment sample. Endpoints examined included survival and growth. This test was selected because its results are reported to be less variable than those obtained with other standard tests (Ingersoll et al., 2000). If the data met assumptions of normality and homogeneity of variance, then a parametric two-sample, equal-variance t-test was used to compare the sample response to the laboratory control response. If the assumptions of normality or homogeneity were not met, the non-parametric Wilcoxon Rank Sum test was used. Results for the site samples were compared to results for a laboratory control sediment, as well as to results for sediments collected from local reference sites.

2.4. Calculation of Toxic Units

As described in the Introduction, toxic units for individual PAHs were calculated as the concentration of bioavailable PAH in pore water divided by the corresponding FCV for that PAH. The one-phase model estimates the pore-water concentration from the sediment concentration of PAHs and the fraction of total organic carbon (f_{TOC}) in sediment, using an organic carbon normalized partition coefficient (Koc) that describes the partitioning from sediment organic carbon in sediment to pore water (US EPA, 2003). The two-phase model uses an additional term to account for the partitioning of PAHs from black carbon in sediment to pore water.

2.4.1. One-phase model for calculating the sum of toxic units. The one-phase model is used to estimate the freely dissolved concentration of each PAH in pore water using the following relationship:

$$C_{SED}/C_W = f_{TOC} * Koc$$

where:

C_{SED} = the concentration of each PAH in sediment(μg/kg dry wt)

C_W = the concentration of truly dissolved PAH in pore water(μg/L)

f_{TOC} is the weight fraction of total organic carbon in sediment (kg organic carbon/ kg dry wt)
K_{OC} is the organic carbon-water partition coefficient for a specific PAH (L/kg-OC)
The equation is rearranged and used to solve for C_W. C_W for each PAH is divided by its corresponding FCV to calculate Toxic Units. If the sum of the Toxic Units for 34 PAHs is less than or equal to 1.0, the concentration of the mixture of PAHs in sediment is predicted to be acceptable for the protection of benthic organisms from chronic effects.

2.4.2. Two-phase model for calculating the sum of toxic units. The two-phase model is used to estimate the freely dissolved concentration of each PAH in pore water using the following relationship:

$$C_{SED}/C_W = f_{NPOC} * K_{OC} + f_{BC} * K_{BC} C_W^{n-1}$$

where:

f_{NPOC} = the weight fraction of non-pyrogenic organic carbon in sediment (kg non-pyrogenic organic carbon/kg dry wt, calculated from the difference between total organic carbon and black carbon)

f_{BC} = the weight fraction of black carbon in sediment (kg black carbon/kg dry wt)

K_{BC} = the black-carbon-to-pore-water partition coefficient for each PAH (L/kg-BC)

n = the Freundlich exponent, which accounts for nonlinear sorption behavior of black carbon (n=0.6) (Accardi-Dey and Gschwend 2002)

We use an iterative approach to solve for C_W. C_W for each PAH is divided by its corresponding FCV to calculate a Toxic Unit.

Black carbon distribution coefficients, K_{BC}, were not available for all 34 PAHs; therefore, a regression relationship was used to estimate these values for the other PAHs based on data presented in Table 1. The regression relationship between K_{BC} values and K_{ow} for 17 PAHs that were determined experimentally (Accardi-Dey and Gschwend, 2003) is presented in Figure 1, and the estimated K_{BC} values are presented in Table 1. While this is an approximation, our study is designed to determine whether this relatively simple approach can be used to reduce the uncertainty associated with predictions of the potential toxicity of mixtures of PAHs in sediment.

2.5. Calculation of an MGP-Specific Uncertainty Factor

Data collected for this study are used to develop an MGP-specific UF that is likely to be a more accurate predictor of chronic toxicity to benthic invertebrates than the U.S. EPA UF (U.S. EPA, 2003). The ratio of the sum of Toxic Units for 34 PAHs to that of the sum of Toxic Units for 13 PAHs was calculated for each of the 22 sediment samples collected for this study.

3. Results and Discussion

3.1. Sediment Chemistry

Concentrations of total PAHs in sediments ranged from 9 mg/kg to greater than 5,000 mg/kg (Table 2). Concentrations of total organic carbon ranged from 0.7 to 6.8% of sediment dry weight. Concentrations of black carbon ranged from 0.06% to 2.8% of sediment dry weight, and from 3% to 81% as a percent of TOC. Results reported for the standard reference material, SRM-1944 (0.0059 g black C/g dry wt) agree reasonably well with values reported by other researchers for this reference material: 0.0066 and 0.0088 g black C/g dry wt, (Gustaffson et al., 2001).

3.2. Sediment Toxicity

Four sediment samples, with total PAH concentrations of 60, 1,730, 3,363, and 5,160 mg/kg showed significantly reduced survival of *H. azteca* in comparison to 91% survival observed in laboratory controls, while samples with concentrations as high as 325 mg/kg were not significantly toxic in comparison to controls (Table 2). None of the other samples had significantly reduced survival, and none of the samples had significantly reduced growth (Table 2).

The concentration of PAHs in one toxic sample (60 mg/kg, 9% survival) was considerably lower than in other toxic samples that exhibited reduced survival (1,730 to 5,160 mg/kg). Field notes state that sheens were observed when this sample was collected. A review of the analytical data for this sample showed elevated levels of benzene, toluene, ethylbenzene, and xylenes (BTEX) in comparison to other samples, which may have contributed to the observed toxicity (data not shown).

3.3. Results of the One-Phase Model

The one-phase model correctly predicted a lack of toxicity for three samples with concentrations of total PAHs ranging from 9 to 21 mg/kg and a sum of Toxic Units <1.0, but incorrectly predicted (with one exception) that 16 samples with concentrations of total PAHs ranging from 18 to 325 mg/kg (Table 2, Figure 2) and a sum of Toxic Units >1.0 would be toxic. The one-phase model correctly predicted that three samples with

Table 2

Concentrations of PAHs, fraction total organic carbon (f_{TOC}), fraction black carbon (f_{BC}), corresponding Sum-Toxic Units and sediment toxicity. Results for f_{OC} and f_{BC} represent mean and standard deviation (n=2), except for samples for which a single analysis was conducted. Asterix denotes significant difference from laboratory control.

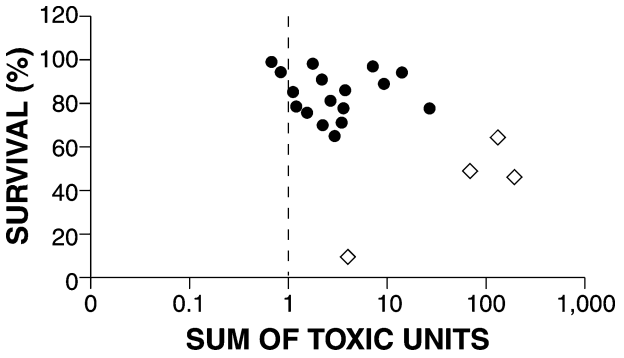

Figure 2. Sum of Toxic Units estimated using 1-phase model versus survival in sediment toxicity tests. Samples shown as diamonds had significantly reduced survival in comparison to laboratory controls.

high concentrations of PAHs in sediment (1,730 to 5,160 mg/kg) would be toxic (Table 2, Fig. 2).

3.4. Results of the Two-Phase Model

Predictions of the two-phase model were in closest agreement with the results of the sediment toxicity tests. The two-phase model correctly predicted (with one exception) that 15 samples with a sum of Toxic Units <1.0 and concentrations of PAHs in sediment ranging from 9 to 60 mg/kg (Table 2, Figure 3) would not be toxic, but incorrectly predicted that four samples with concentrations of PAHs ranging from 93 to 325 mg/kg and a sum of Toxic Units >1.0 would be toxic. The two-phase model also correctly predicted that three samples with high concentrations of PAHs in sediment (1,730 to 5,160 mg/kg) would be toxic (Table 2, Figure 3).

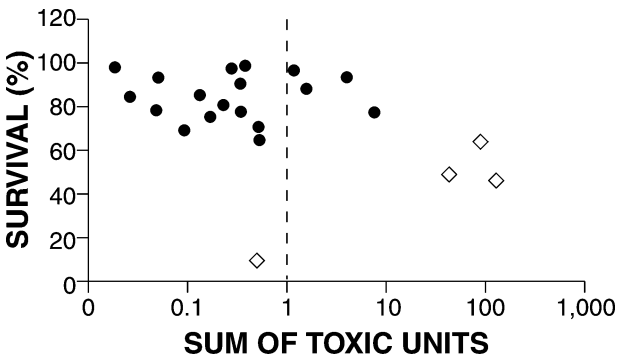

Figure 3. Sum of Toxic Units estimated using 2-phase model versus survival in sediment toxicity tests. Samples shown as diamonds had significantly reduced survival in comparison to laboratory controls.

3.5. Uncertainty Factor

We used the Excel^{TM} percentile function to calculate source-specific UF values of 1.98 (the 50th percentile of our data set) and 2.71 (the 95th percentile of our data set). The UF calculations indicate that source-specific UF for coke and MGP sites are lower than those recommended by U.S. EPA for use when source-specific data are lacking and sources are not known. The 50th percentile UF of 1.59, previously reported for four MGP site samples (Kane Driscoll et al., 2003), and the mean UF of 2.9 and 95th percentile UF of 4.2 that were calculated for 45 MGP-affected sediments from six sites (Hawthorne et al., 2006) are also lower than the U.S. EPA UF. Collectively, these studies demonstrate that application of the U.S. EPA UF is likely to overestimate the sum of Toxic Units for sediments affected by MGP and coke sites.

4. Conclusions

The present study demonstrates that, although both the one-phase and two-phase models can be used to predict concentrations of PAHs that are not toxic to aquatic invertebrates, the two-phase model is a better predictor of toxicity at these sites. Specifically, the two-phase model, which takes into account the influence of black carbon on the bioavailability of PAHs, demonstrated that sediments from these sites with concentrations of total PAHs as high as 52 mg/kg and less than 1.0 Toxic Unit are not toxic to benthic invertebrates. Results further demonstrate that the two-phase model is a conservative predictor of toxicity, because sediments estimated to have a sum of Toxic Units as high as 10 were not toxic, a result that has also been observed for other studies on MGP-affected sediments (Kreitinger et al., 2007). Thus, this study demonstrates that both models can accurately identify concentrations of PAHs in sediment at MGP sites that are not toxic, but the two-phase model is less conservative and provides more accurate predictions.

Although we recognize that estimates of black carbon include a heterogeneous mixture of materials, such as coal, coke, and coal tar pitch (Khalil et al., 2006), this study demonstrates that the simple measurement of black carbon can be used to reduce uncertainty and make conservative predictions of toxicity. This work also demonstrates that measurements of the full suite of 34 PAHs will reduce the uncertainty associated with the characterization of the source-specific suite of PAHs that are likely to be present at MGP or coke sites. In particular, the use of overly conservative UF in the calculation of the sum of Toxic Units should be avoided at MGP sites, because this and other studies demonstrate that the application of an overly conservative UF can result in the overestimation the concentration of alkylated PAHs in these sediments and their contribution to toxicity (Kreitinger et al., 2007).

Although the use of the two-phase model showed improved predictive ability in comparison to the one-phase model at these sites, uncertainties associated with the use of the two-phase model must be considered for future applications. For example, levels of black carbon were quite high in these samples (up to 81% of the total organic carbon) in comparison to "normal" sediment with black carbon levels that range from 1 to 10% of total organic carbon (Gustafsson and Gschwend, 1998). In particular, the K_{BC} values (Fig. 1) and the non-linear isotherm exponent are additional sources of uncertainty that may vary as the nature of the sediments and types of black carbon varies among sites (Jonker and Koelmans, 2001a; Ghosh et al., 2000; Cornelissen and Gustafsson, 2004; Hawthorne et al., 2007a). In addition, the potential for the presence of lighter aromatic hydrocarbons (e.g.,

BTEX) and other contaminants to confound results will need to be considered at other sites as well as sites discussed in the study.

Additional research that collects synoptic measurements of bioavailability and toxicity using various analytical techniques will most effectively demonstrate the factors controlling bioavailability of PAHs at MGP and other sites. For example, low-density polyethylene device samplers (Vinturella et al., 2004), polyoxymethylene extraction (Jonker and Koelmans, 2001b), and desorption to XAD resin (Lamoreaux and Brownawell, 1999) have been used to measure the bioavailable fraction of PAHs in sediments, and supercritical fluid extraction and solid phase microextraction (Kreitinger et al., 2007; Hawthorne et al., 2007b) have been used to demonstrate the relationship between bioavailable PAHs in sediments and toxicity to benthic invertebrates. Concordance among various lines of evidence, including bioaccumulation and toxicity tests with additional test organisms, along with validation and standardization of analytical techniques for measuring freely dissolved concentrations in pore water and black carbon in sediment, will increase confidence in the reliability of the two-phase model for use in environmental risk assessments and in the development of remedial strategies at MGP sites and other PAH-contaminated sites.

ABSTRACT

An ecological risk-based approach was used to define the extent of remediation in a brook adjacent to a former manufacturing and assembly plant. Sediment contained concentrations of metals, polycyclic aromatic hydrocarbons (PAHs), phthalates, polychlorinated biphenyls (PCBs), and pesticides above sediment quality benchmarks. Samples of sediment were analyzed for metals, 34 individual PAHs, phthalates, PCBs, pesticides, total organic carbon, black carbon, and sediment toxicity using the 42-day *Hyalella azteca* toxicity test. In addition, freely dissolved concentrations of PAHs in pore water from a subset of samples were determined using a solid phase microextraction (SPME) technique. Concentrations of freely dissolved PAHs in pore water and bioavailable PAHs in sediment were below levels of concern for aquatic organisms. Further evaluations indicated that lead was the contaminant most closely associated with sediment toxicity. A site-specific sediment cleanup level for lead in sediment was developed to define areas for sediment removal in the brook. Using the site-specific sediment cleanup level for lead resulted in a substantially smaller remediation footprint in the brook (24,434 ft^2; 2,270 m^2) than that originally proposed (64,799 ft^2; 6,020 m^2) based on exceedance of sediment quality benchmarks.

Key words: lead, polycyclic aromatic hydrocarbons, ecotoxicity, sediment cleanup level

1. INTRODUCTION

An investigation was conducted to determine the extent of remediation in a brook (the Brook), located along the western property line of a former manufacturing and assembly facility (the facility) in eastern Massachusetts. The work described here is a part of the comprehensive response actions that were conducted in compliance with the Massachusetts Contingency Plan. Other components of the response actions included a comprehensive site assessment, human health risk assessment, ecological risk assessment, remedial feasibility study, and remedial action plan. The focus of this paper is on ecological risks, which need to be reduced through remediation of sediment in portions of the Brook.

The facility and the Brook are located in an urban setting with mixed industrial, commercial, and residential uses. The headwaters are surrounded by undeveloped wooded and emergent wetlands in an area immediately upstream of the facility. Approximately 3.5 miles downstream of the facility, the Brook discharges into a pond, which is located in a municipality. Historically, four sources of discharges entered the Brook within the study area: an outfall from the wetlands that discharges to the upstream reaches of the Brook near the facility, a roof drain from facility buildings, an outfall from a settling lagoon that was used to treat process and non-process wastewater, and a storm water drainage outfall from paved areas of the facility.

Habitat quality in the Brook reflects the influence of stressors that are typical in an urban setting, such as high peak flows caused by the preponderance of impervious surfaces in the drainage area, encroachment of development and subsequent riparian habitat loss, and water quality degradation resulting from urban storm water discharges. The Brook is shallow and, under normal flow conditions, ranges from 0.5 to 2.5 ft (2 ft average) in depth and from 15 to 28 ft (20 ft average) in width. These physical and hydrologic conditions are generally adequate to support benthic macroinvertebrates and seasonal populations of fish and semi-aquatic organisms, such as reptiles and amphibians. In addition, habitat features that support aquatic life, such as submerged or emergent aquatic vegetation, leaf litter, and submerged terrestrial vegetation (deadfall) are also present in the Brook at various locations.

Previous site studies indicated that sediment in the Brook contained elevated concentrations of metals, PAHs, phthalates, PCBs, and pesticides that exceeded sediment quality benchmarks (SQBs) (MacDonald et al., 2000; Long and Morgan, 1990; Jones et al., 1997). Toxicity testing conducted in November 1998 revealed that some sediment samples from the Brook were toxic to test organisms in 10-day toxicity tests using the amphipod, *Hyalella azteca,* and the midge, *Chironomous tentans* (USEPA, 2000; ASTM, 2005). No station exhibited lethal toxicity in the chironomid test, while 4 of the 12 stations displayed lethal toxicity in the amphipod test. Two stations downstream of the lagoon exhibited sublethal toxicity (reduced growth) for the chironomid test, and one of these stations also exhibited sublethal toxicity (reduced biomass) for the amphipod

test. Sublethal toxicity was not observed in the furthest downstream reach. The lack of observed toxicity in sediments from the furthest downstream station suggested that toxic effects are confined to the areas of the Brook adjacent and just downstream of the lagoon. Because state agencies currently recommend the use of long-term toxicity tests, the current study re-evaluated toxicity of the Brook sediment using a 42-day toxicity test with *H. azteca* (USEPA, 2000), with survival, growth, and reproduction endpoints.

The Sediment Quality Triad is commonly used to evaluate risk to benthic organisms from sediment-associated contaminants. This approach uses three types of measurements: concentrations of contaminants in bulk sediment, laboratory toxicity tests, and characterization of the benthic community, to reach conclusion regarding risk. Although the utility of the Sediment Quality Triad approach has been clearly demonstrated (Chapman, 1996; Krantzberg et al., 2000; Borgmann et al., 2001; Grapentine et al., 2002; Reynoldson et al., 2002a, b; Chapman, 2002), at some contaminated sites, the presence of non-contaminant factors such as nutrient enrichment, changes in dissolved oxygen or water temperature, or streambed sedimentation may mask the contaminant-related impacts on the benthic invertebrate community. In such cases, more reliance may be placed on the other two types of measurements, the bulk sediment chemistry and laboratory toxicity tests, and the benthic invertebrate community field study may not be considered. A benthic invertebrate community field study was not conducted as part of the current investigation; it was determined that this kind of investigation would not yield meaningful results because the high spatial and temporal variability associated with non-contaminant stressors discussed above are likely impacting the habitat quality of the Brook study site.

The main objective of the current study was to define the extent to which facility-related chemicals pose a risk to benthic invertebrates exposed to sediment in the Brook. Benthic invertebrates were selected as the potential receptor community in the Brook, because they are relatively immobile and would be highly exposed to contaminants in the sediment of the Brook. No fish were observed in the Brook during the Site visits and sediment sampling, probably because of low flow conditions. In addition, aquatic habitat characteristics of the Brook are not conducive to the establishment and maintenance of a permanent fish community. Because the Brook does not contain abundant prey items for wildlife, such as freshwater mussels and fish, wildlife also were not selected as receptors for this assessment. The results of the study were used to determine whether remedial actions are necessary to protect benthic invertebrates, and to assist in developing a remedial design plan that is appropriate for the Brook.

2. MATERIALS AND METHODS

2.1 Study Design

Sediment was collected from 25 stations along the length of the Brook. Sampling locations included an upstream reference location (i.e., outside of the influence of the facility); several locations immediately downstream from outfalls, which once released process and non-process wastewater but currently release runoff from parking lots adjacent to the Brook or are sealed; and six locations in the Brook but downstream of the property boundary (Figure 1). Using existing data on sediment chemistry, stations were selected to represent a broad range of concentrations of potentially facility-related chemicals.

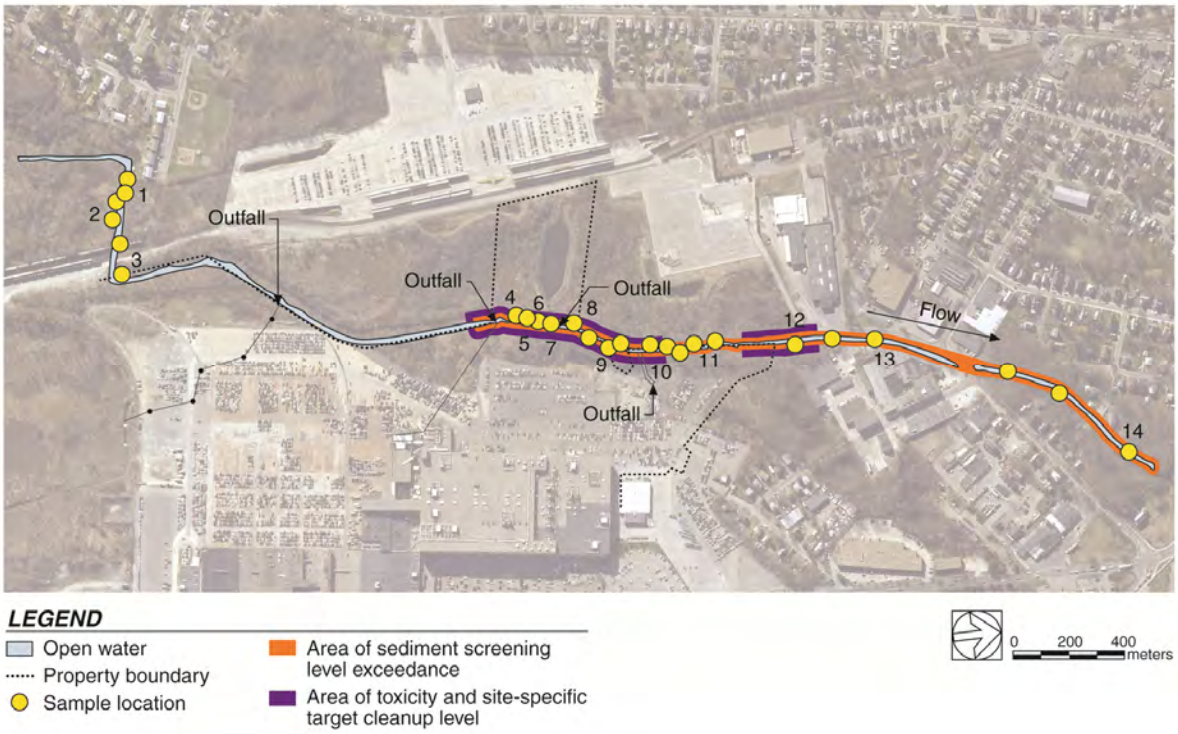

Figure 1. Sampling locations in a brook along a former manufacturing and assembly facility in eastern Massachusetts (USA). Numbered locations were submitted for the full suite of chemical analysis and sediment toxicity testing. Also shown are the two excavation footprints based on exceedance of sediment quality benchmarks and observed toxicity and exceedance of site-specific target cleanup level.

Expedited analyses of metals and semi-volatile compounds (SVOCs) were conducted to identify a subset of samples for toxicity testing and additional chemical testing. A total of 14 sediment samples, with a wide range of contaminant concentrations, were

submitted for toxicity testing. The goal was to bracket the upper and lower effects concentrations for potentially facility-related chemicals and establish quantitative relationships between exposure and effects. Samples included: three samples from the upstream reference area (sample locations 1, 2 and 3), six samples from the reach adjacent to the facility (sample locations 4, 5, 6, 7, 8 and 9), two samples from the reach downstream of the facility but within property boundaries (sample locations 10 and 11), and three samples (sample locations 12, 13, and 14) from downstream of the property boundaries (Figure 1). The selected subset of sediment samples were analyzed for target analyte list (TAL) metals, target compound list (TCL) SVOCs, TCL pesticides, PCB Aroclors®, TOC, black carbon, and sediment grain size.

A subset of five samples (sample locations 5, 6, 7, 11 and 13) was selected for analysis of the bioavailable fraction of PAHs using a laboratory-based solid-phase microextraction technique. The selected sediment samples represented typical physical sediment conditions (e.g., grain size, presence of organic material, texture, and color) and were not associated with any anomalous field observations, such as presence of a sheen or petroleum odor that might confound data interpretation.

2.2 Sediment Collection and Processing

Sediment at the 25 stations was sampled between July 23 and 25, 2007. Samples of sediment were collected using a 0.023-m^2 Eckman grab sampler (Wildlife Supply Company, Buffalo, NY, USA) or 0.0071-m^2 hand-auger sampler (Ben Meadows Company, Janesville, Wisconsin, USA). The top 15 cm of sediment, where most benthic organisms live in this freshwater system, were sampled at each station. Five to seven grabs from each station were collected and homogenized to obtain sufficient sample size for all analyses and sediment toxicity tests. Sediment samples were collected in a downstream-to-upstream fashion, to avoid disturbing the sediment prior to sampling. Samples for SPME analysis were sieved in the field through 2-mm mesh to remove debris. Sediment sample containers for chemical analysis, SPME analysis, and toxicity testing were placed on ice immediately after collection and maintained at about 4°C in coolers during transport to the receiving laboratories.

2.3 Sediment Chemical Analysis

Sediment samples from all 25 stations were analyzed within one week from the date of collection for TAL metals by EPA Methods 6020 and 7471A, and TCL SVOCs by EPA Method 8270C (http://www.epa.gov/osw/hazard/testmethods/sw846/ online/index.htm). Prior to metals analysis, two extractions were used. EPA Method 3050 without the addition of hydrochloric acid (HCl) was used for all metals, except silver and antimony. A separate extraction, EPA Method 3050 with HCl, was used for analysis of silver and antimony.

Following review of metals and SVOC data, 14 stations were selected for further chemical analysis and toxicity testing. Sediment from these 14 stations was analyzed by Alpha Analytical, Inc. (Mansfield, MA) for 34 PAHs by EPA Method 8270C (mass spectrometry in the selected ion-monitoring mode), TCL pesticides by EPA Method 8081A, PCB Aroclors® by EPA Method 8082, TOC by EPA Method 9060, black carbon by the Arccardi-Dey and Gschwend (2002) method, and grain size by Method D 422-63 (ASTM, 2007a).

2.4 Sediment Toxicity Testing

Standard sediment toxicity tests were conducted using the 42-day test with *H. azteca* (USEPA, 2000; ASTM, 2005) by Springborn-Smithers Laboratories (Wareham, MA). *H. azteca* was selected as the test organism because previous short-term toxicity testing conducted on Brook sediments suggested that *H. azteca* was more sensitive than *C. tentans* to site chemicals. Prior to test initiation, the toxicity laboratory sieved the samples through 0.5-mm mesh to remove larger indigenous organisms that could prey on the test organisms, a problem that was previously encountered in toxicity tests of sediments from this site. The tests were initiated 23 to 25 days after sample collection, within the recommended holding time of 2–8 weeks (USEPA, 2000; ASTM, 2005). The 42-day toxicity test with *H. azteca* measures the number of surviving amphipods and dry weight in milligrams after 28 days, and the number of progeny per female amphipod at day 42. Twelve replicates were evaluated for each tested sediment, with 10 amphipods in each replicate. Twelve replicates were used for the survival endpoint, four replicates were used for the growth endpoint, and eight replicates were used for the reproduction endpoint. Overlying water was renewed at a rate of two volume replacements per day. An artificial sediment prepared according to OECD Guideline NO. 219 (OECD, 2001) was used as a negative control. Potassium chloride was used as a positive control.

Overlying water quality characteristics were measured in accordance with guidance in USEPA (2000). Total hardness, alkalinity, conductivity, dissolved oxygen, pH, and total ammonia-N were measured in the overlying water from each test chamber on days 0, 28, 29, and 42 of the test. Conductivity was monitored weekly from a composite sample. Dissolved oxygen and pH were monitored three times per week in one alternating replicate throughout the course of the study. Temperature was monitored daily in one alternating replicate throughout the course of the study.

2.5 Solid Phase Microextraction and Analysis of 34 PAHs

For PAHs, various methods have been developed to estimate or measure the bioavailable fraction of PAHs in sediment, including the USEPA bioavailability procedure for measuring the bioavailable concentration in pore water (USEPA, 2003), equilibrium partitioning (EqP) methods that estimate the bioavailable fraction in pore water by accounting for association to non-pyrogenic and pyrogenic organic carbon in sediment

(Accardi-Dey and Gschwend, 2003; Gustafsson et al., 1997), supercritical fluid extraction (Hawthorne et al., 2007), and SPME (Hawthorne et al., 2005; Hawthorne et al., 2007; Kreitinger et al., 2007). Recent work has demonstrated that freely dissolved concentrations of PAHs in pore water as determined by SPME is a good predictor of sediment toxicity for PAH-contaminated sediments (Hawthorne et al., 2007; Kreitinger et al., 2007).

The SPME measurement of 34 parent and alkylated PAHs (18 parent and 16 groups of alkyl PAHs listed for EPA's equilibrium partitioning sediment benchmark (ESB) model [2003]) in pore water of sediment samples was conducted by TestAmerica (Knoxville, TN) using the ASTM Method D 7363 (ASTM, 2007b). The SPME analysis began within 28 days of sample collection. Briefly, sediment samples were centrifuged at 1,000 g for 30 min to collect pore water. Pore water samples were re-centrifuged after addition of alum to precipitate colloids. PAHs were extracted using SPME with fibers coated with poly(dimethylsiloxane). SPME sorption was performed for 30 minutes, after which the fiber was desorbed directly into the gas chromatography/mass spectrometer injection port.

2.6 Estimating Sum-TU

Recent EPA guidance (USEPA, 2003) establishes ESBs to protect benthic organisms from the narcotic effects of PAHs. To more accurately reflect the potential exposure of biota in the environment, the guidelines are applied to PAH mixtures, as opposed to individual PAHs. This guidance established final chronic values (FCVs) for individual PAHs that are expected to be protective of aquatic species. A toxic unit (TU) is the quotient of an individual PAH concentration in sediment or pore water (predicted or measured) divided by its corresponding FCV. If the sum of the TUs for 34 individual PAHs (Sum-TU) is ≤ 1.0, it can be concluded that the concentrations of PAHs in the bulk sediment sample are below the toxicity threshold for benthic organisms. Because of the environmentally conservative nature of the FCVs, a Sum-TU > 1.0 does not necessarily mean that bulk sediment PAHs will result in adverse effects to benthic organisms.

Three methods were used to calculate the Sum-TUs in the present study. The first method is referred to as a one-phase model, which estimates concentrations of PAHs in pore water from the concentrations of PAHs in bulk sediment and TOC. The second method, referred to as a two-phase model, estimates concentrations of PAHs in pore water from the concentrations of PAHs in bulk sediment, TOC, and black carbon (an additional phase that can also adsorb PAHs). The third method is the SPME method, which directly measures freely dissolved concentrations of PAHs in pore water.

The one-phase model is used to estimate the freely dissolved concentration of each PAH in pore water using the following relationship:

$$C_{SED}/C_W = f_{OC} * K_{OC} \quad \text{(Equation 1)}$$

where:

C_{SED} = the concentration of each PAH in sediment (μg/kg dry weight)

C_W = the concentration of freely dissolved PAH in pore water (μg/L)

f_{OC} = the weight fraction of total organic carbon in sediment (kg organic carbon/kg dry weight)

K_{OC} = the organic carbon-water partition coefficient for a specific PAH (L/kg organic carbon)

The equation is rearranged and used to solve for C_W. C_W for each PAH is divided by its corresponding FCV to calculate TUs.

The two-phase model is used to estimate the freely dissolved concentration of each PAH in pore water using the following relationship:

$$C_{SED}/C_W = f_{NPOC} * K_{OC} + f_{BC} * K_{BC} C_W^{n-1} \quad \text{(Equation 2; Accardi-Dey and Gschwend, 2002)}$$

where:

f_{NPOC} = the weight fraction of non-pyrogenic organic carbon in sediment (kg non-pyrogenic organic carbon/kg dry weight, calculated from the difference between total organic carbon and black carbon)

f_{BC} = the weight fraction of black carbon in sediment (kg black carbon/kg dry weight)

K_{BC} = the black carbon-pore water partition coefficient for each PAH (L/kg black carbon)

n = the Freundlich exponent, which accounts for nonlinear sorption behavior of black carbon (n=0.6) (Accardi-Dey and Gschwend, 2002)

We use an iterative approach to solve for C_W. C_W for each PAH is divided by its corresponding FCV to calculate a TU. Black carbon-pore water partition coefficients, K_{BC}, for 17 PAHs were taken from Accardi-Dey and Gschwend (2003). Because K_{BC} values were not available for all 34 PAHs, a regression relationship was used to estimate these values for the other PAHs (Kane Driscoll et al., 2009).

In order to calculate the sum of ESB TUs for the SPME method, the measured concentration of each PAH was divided by its corresponding ESB FCV (USEPA, 2003). The TUs for the individual PAH were summed in accordance with Hawthorne et al. (2007); if a peak was not detected above the method-specified signal-to-noise threshold, a zero was used in the TU calculation.

2.6 Statistical Data Analysis

Analysis of variance (ANOVA) followed by Dunnett's multiple comparison test and the Wilcoxon non-parametric test were used to detect significant differences among the toxicity test sample results. ANOVA followed by Dunnett's test is the most powerful analytical method for detecting statistical differences among multiple samples and a single control or reference group, but the data should meet the underlying assumptions of the method (equal variance and normality). Multiple residual and probability plots were used to test these assumptions. A non-parametric comparison was also conducted using an overall Kruskal-Wallis test followed by Wilcoxon pair-wise tests with an adjusted significance level to account for multiple tests. Additionally, an outlier evaluation using Dixon's test with a 0.05 significance level was completed to identify any samples that may be highly influencing the statistical comparison results. Statistical comparisons were conducted with and without these outlier samples. A sample was considered significantly lower than the upstream background samples or laboratory control sample if either statistical method indicated significance. An overall significance level of 0.05 was used, except for the non-parametric comparisons, which used adjusted significance levels.

Spearman correlation was used to evaluate the strength of relationships between each of the toxicity endpoints and the chemical (e.g., contaminant concentration, Sum-TU) and physical characteristics (e.g., TOC) of the sediment samples. Additionally, correlations among chemical and physical characteristics were used to examine the covariance among chemical contaminants in Brook sediments.

3. RESULTS AND DISCUSSION

3.1 Sediment Chemical Analyses

The 14 sediment samples contained a mixture of sands and fine-grained material (e.g., silt and clay). None of the samples contained any gravel or cobble. TOC content of sediments ranged from 0.6 to 3.2 percent (Table 1). Because *H. azteca* is tolerant to sediment grain size ranging from silt to predominantly sand, and TOC ranging from 0.3 to 9.6 percent (USEPA, 2000), grain size and TOC in these sediment samples probably did not adversely affect the results of the sediment toxicity tests.

Table 1. Physical characteristics of sediments.

Station	Total Organic Carbon (%)	Black Carbon (%)	Silt/Clay (%)
1	0.62	0.01	9.6
2	1.4	0.01	18
3	2.6	0.065	52
4	2.2	0.27	21
5	2.3	0.055	78
6	2.0	0.03	55
7	2.7	0.12	56
8	1.7	0.14	60
9	3.2	0.075	63
10	1.9	0.01	71
11	1.9	0.01	52
12	2.0	0.04	47
13	1.4	0.24	31
14	2.0	0.045	56

Sediments sampled near the facility had elevated concentrations of metals, PAHs, phthalates, and other organic chemicals (results of key chemical analyses are shown in Table 2). Concentrations of lead in sediment adjacent to and downstream of the facility ranged from 240 to 6,400 mg/kg dry, and upstream samples ranged from 7.9 to 52 mg/kg dry. Other metals, including antimony, cadmium, and zinc, were also elevated in sediment adjacent to and downstream of the facility relative to the upstream stations. Concentrations of total (34) PAHs in sediment adjacent to and downstream of the facility ranged from 48,000 to 890,000 μg/kg dry, and concentrations in upstream sediment samples ranged from 2,000 to 11,000 μg/kg dry. Similarly, concentrations of butyl

benzylphthalate in sediment adjacent to and downstream of the facility ranged from 32,000 to 1,000,000 μg/kg dry, and concentrations in upstream sediment samples were below detection limits (<440 μg/kg dry). In addition, total PCB Aroclors® up to 1,032 μg/kg dry and total DDT up to 90 μg/kg dry were detected in sediments near and downstream of the facility (Table 2).

Concentrations of metals, total PAHs, total PCB Aroclors®, and total DDT in sediment samples were compared to probable effect concentrations (PECs) and threshold effect concentrations (TECs) (MacDonald et al., 2000) to judge whether adverse biological effects to benthic macroinvertebrates could be occurring. Such comparisons alone do not indicate that adverse effects are occurring. The TECs for metals and the PECs for organic compounds have been adopted as the Massachusetts SQBs (http://www.mass.gov/dep/water/laws/ecoturss.pdf). Concentrations of metals, total PAHs, total PCB Aroclors®, and total DDT in upstream stations were below the PECs, and most of these chemicals were also below the TECs (Table 2). However, concentrations of lead and total PAHs in the sediment samples near and downstream of the facility were up to 50 and 40 times the PEC for lead and total PAHs, respectively. Concentrations of cadmium also exceeded the PEC at many locations near and downstream of the facility. Concentrations of zinc and total PCB Aroclors® occasionally exceeded their PECs near and downstream of the facility. Concentrations of total DDT in sediments exceeded the TEC at every location, but never exceeded the PEC. Although PECs were unavailable for butyl benzylphthalate and dibenzofuran, concentrations of these two chemicals were elevated in downstream sediment samples as compared to upstream sediment samples.

Concentrations of many of the chemicals co-vary in the Brook sediment (Table 3). In fact, all of the metals are significantly correlated with each other, as well as with total PCB Aroclors®, total PAHs, and butyl benzylphthalate (Spearman rank, $p<0.05$). Black carbon is also significantly correlated with all of the metals, total PCB Aroclors®, total PAHs, and butyl benzylphthalate. However, TOC is only significantly correlated with total DDT. The Sum-TUs did not significantly correlate with any of the metals or organic chemicals.

Table 2. Results of key chemical analyses and sediment toxicity tests for the Brook study site.

3.2 Sediment Toxicity Tests

In general, there were no unacceptable water quality deviations during the 42-day *H. azteca* test, and test results met the test acceptability criteria. The negative control had mean survival at 28 days of 93 percent, growth at day 28 of 0.37 mg per amphipod, and 5.93 offspring per female amphipod at day 42. The performance of the positive control suggested that the test organisms were suitably sensitive for testing.

Mean survival of *H. azteca* ranged from 2 percent at Station 9, which was downstream of the facility, to 96 percent at Station 1, which was upstream of the facility. Mean number of offspring per *H. azteca* female ranged from 0 at Station 9 to 8.18 at Station 1. No significant reductions in growth, which ranged from 0.24 to 0.50 mg dry weight per amphipod, were observed in any of the downstream samples in comparison to the upstream background samples (Table 2). Survival and reproduction were significantly reduced in five of the six sediment samples (Stations 4, 6, 7, 8, and 9) from areas adjacent to the facility and in one of the samples from downstream of the facility (Station 12) in comparison to the upstream background samples. Reproduction was also significantly reduced at Station 14 in comparison to the upstream background samples, although survival was not depressed at Station 14.

3.3 SPME for 34 PAHs

The SPME method was used on a subset of five sediment samples (Stations 5, 6, 7, 11, and 13) to measure concentrations of freely dissolved PAHs in pore water. Most of the 34 PAHs were detected in at least one of the five sediment samples by the SPME analysis, with the exception of benzo[a]pyrene, indeno[1,2,3-cd]pyrene, dibenz[a,h]anthracene, C3–fluorenes, C4–phenanthrenes + anthracene, C1–chrysene + benz[a]anthracene, C2–chrysene + benz[a]anthracene, C3–chrysene + benz[a]anthracene and C4–chrysene + benz[a]anthracene. According to the approach adopted by Hawthorne et al. (2005), the Sum-TU for the SPME samples was calculated using zero as the concentration for PAHs below the practical quantitation limits for this method.

3.4 Prediction of PAH Toxicity

The Sum-TUs estimated from the one-phase model, which accounts for association of PAHs with TOC, were greater than 1.0 for the entire set of sediment samples including those from the upstream stations, ranging from 1.2 to 39 Sum-TU (Table 4). Sum-TUs estimated from the two-phase model, which accounts for association of PAHs with TOC and black carbon, were greater than 1.0 for all sediment samples, except for one upstream sample, ranging from 0.8 to 30. Although the results of the one- and two-phase models predict that concentrations of PAHs in the 14 sediment samples are not acceptable for the protection of benthic organisms, the toxicity results for 7 of the 14 samples (Stations 1, 2,

3, 5, 10, 11, and 13) were not significantly different from the laboratory control sample. In contrast, the Sum-TUs calculated from the results of the SPME for 5 samples were all less than 1.0, ranging from 0.22 to 0.56, a result that suggests that concentrations of freely dissolved PAHs in these samples are below a concentration that would be expected to result in adverse effects to benthic invertebrates. However, toxicity test results for two of the five samples (Stations 6 and 7) analyzed by SPME were significantly different from the laboratory control and upstream samples. Thus, none of the three Sum-TU models could adequately explain the observed toxicity in all samples. In addition, results of these three models were not significantly correlated with survival and reproduction of *H. azteca* (Table 5). Growth of *H. azteca* was negatively correlated with Sum-TU SPME results, but growth was not significantly different among the stations.

Measured concentrations of PAHs in pore water by SPME and corresponding Sum-TUs were much lower than predicted from the one-phase or two-phase model. The

differences between measured and modeled concentrations of PAHs in pore water may relate to the partitioning coefficients used in the two-phase model. The K_{BC} values in the two-phase model were taken from Accardi-Dey and Gschwend (2003), which calculated K_{BC} values for 17 PAHs. Kane Driscoll et al. (2009) estimated the K_{BC} values for the other 17 PAHs using a regression relationship between the existing K_{BC} and K_{OW} values. However, K_{BC} values for individual PAHs in sediments can range nearly three orders of magnitude (Hawthorne et al., 2007). Rearranging Equation 2 to solve for K_{BC}, we calculated the K_{BC} values for individual PAHs in the Brook sediment samples using the pore water concentrations determined by SPME in five samples run in duplicate analysis (i.e., 10 results). The site-specific K_{BC} values for individual PAHs were compared to those found by Hawthorne et al. (2007) and those used in the two-phase model (Kane Driscoll et al., 2009) (Figure 2). The site-specific K_{BC} values for individual PAHs fell within the range observed by Hawthorne et al. (2007), but the site-specific K_{BC} values for several PAHs were greater than those used in the two-phase model. These comparisons suggest a greater than expected adsorption of PAHs to black carbon in Brook sediments. It is also possible that other sorbent phases were present in the sediment samples that were not accounted for in the black carbon and TOC analyses.

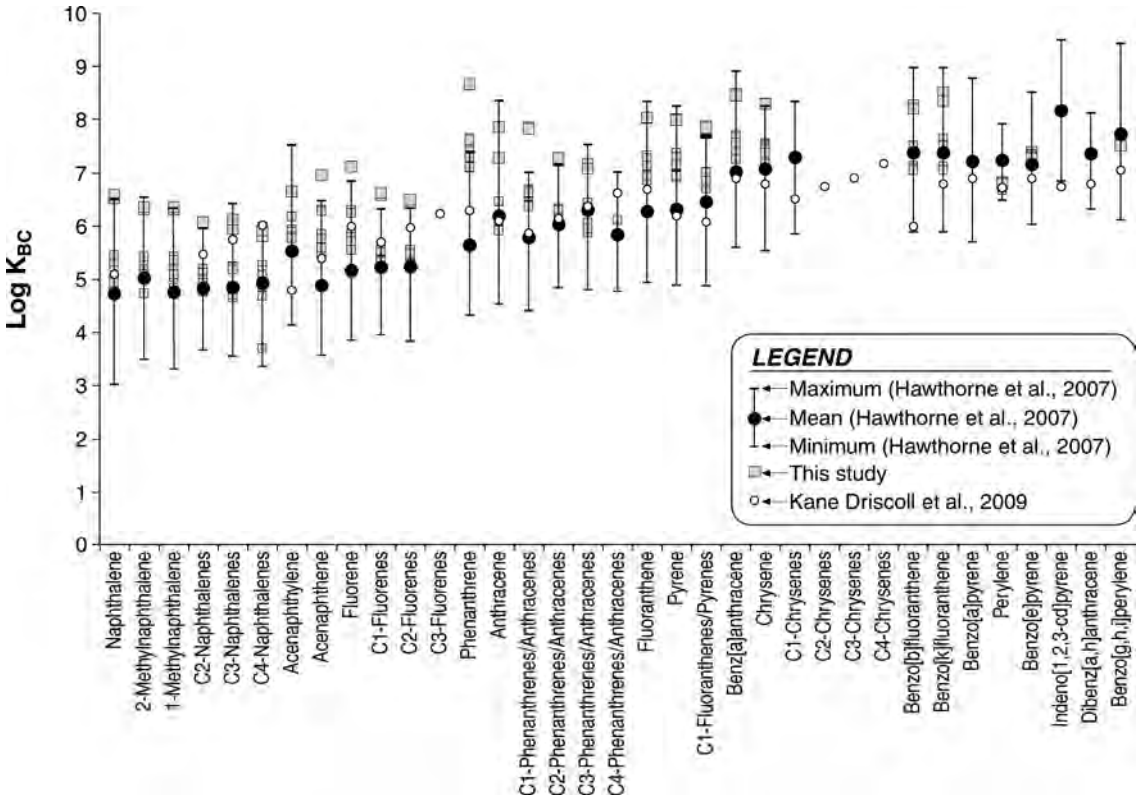

Figure 2. Black carbon-pore water partition coefficient (K_{BC}) values for parent and alkyl PAHs from 114 background and historically contaminated sediments (Hawthorne et al. 2007), Boston Harbor sediments (Kane-Driscoll et al. 2009), and Brook sediments (the present study).

3.5 Correlation Evaluation

The potential contribution of co-occurring metals and other organic sediment contaminants to toxicity was further evaluated. Spearman correlation was used to evaluate the strength of relationships between concentrations of chemicals and each of the toxicity endpoints. Chemicals included in the correlation analysis were those metals with sediment concentrations that were consistently greater than the PECs (cadmium, lead, and zinc) and organic compounds with sediment concentrations consistently greater than the TECs (total PCBs, total DDT, and the 34 PAH compounds). Antimony, butyl benzylphthalate, dibenzofuran, and the Sum-TUs calculated from the one- or two-phase models or SPME were also included in the correlation analysis because they were elevated relative to upstream samples. In addition, TOC and black carbon were included in the correlation analysis to determine whether these constituents were related to the observed toxicity. Correlations between concentrations of organic contaminants and the toxicity test endpoints were analyzed on both a dry-weight basis and an organic carbon-normalized basis.

Both survival and reproduction had significant negative correlations with concentrations of metals, black carbon, and the total PAHs on a dry-weight and organic-carbon basis (Table 5). Additionally, these endpoints were also correlated with organic-carbon normalized concentrations of DDT. Total PCBs and butyl benzylphthalate were also significantly correlated to survival and reproduction. Additional chemicals had significant correlations with only one of the toxicity endpoints (Table 5). Growth was significantly and negatively correlated with the Sum-TU for the SPME method, but growth was not significantly different among the stations. PAHs were ruled out as chemicals contributing to observed toxicity, because the Sum-TU SPME analysis indicated that concentrations of PAHs in these sediments would not result in toxicity to benthic organisms, and the Sum-TU determined by any method (one-phase, two-phase, or SPME) did not correlate strongly with survival and reproduction.

To further assess which chemical(s) may be contributing to the observed toxicity in the chronic sediment toxicity tests, the concentrations of antimony, cadmium, lead, zinc, total PCBs, total DDT, butyl benzylphthalate, and dibenzofuran in sediment samples were compared to the PECs, or other sources of sediment concentrations associated with effects if PECs were unavailable for a particular chemical. For example, the secondary chronic value (SCV) from Jones et al. (1997) was used for dibenzofuran after being corrected for 2% TOC. Studies on phthalate exposures to benthic organisms are limited; although the available data suggest that sediment effect concentrations for phthalates are in the range of >1,000 to >30,000 mg/kg dry weight for sediments with medium organic carbon content (approximately 5 percent TOC) (Staples et al., 1997). The low end of this range (1,000 mg/kg dry weight) was used as the SQB for butyl benzylphthalate after being corrected for 2% TOC.

Zinc, PCBs, DDT, butyl benzylphthalate, and dibenzofuran were eliminated as primary contributors to observed toxicity because concentrations did not exceed or only slightly exceeded sediment effect concentrations (Table 6). Toxicity appears to be most closely correlated with metals, especially lead (Figure 3). Other metals correlate well with toxicity, but have much lower PEC quotients than lead, and therefore are considered less likely than lead to contribute to toxicity. Because PEC quotients for lead, which range from 2 to 50, are much more consistent and much higher than PEC quotients for other metals, and because the severity of the effects on survival and reproduction increased with lead concentration, lead was considered to be the major contributor to observed sediment toxicity.

3.6 Cleanup Strategy for the Brook

A remedial feasibility study was conducted using the information from this investigation and other technical engineering investigations to develop a remedy for the Brook. Based on those studies, sediment removal is the planned remedial approach for the Brook. Sediment down to native material (i.e., pre-facility stream sediment) will be removed in areas where sediment toxicity was observed in the chronic sediment toxicity tests, and where that toxicity is strongly related to the presence of lead. These areas include Stations 4 through 9, which are adjacent and immediately downstream of the facility, and Station 12, which is a downstream hot spot. There was no toxicity observed at Stations 10 and 11. In certain areas (e.g., Station 12) that are not bounded by the presence of a sample with significant toxicity, the extent of contamination was delineated by the concentration of lead.

A target cleanup level for lead in sediment was developed by determining the concentration of lead at or below which no adverse effects are observed, referred to as the apparent effects threshold (AET). This approach used only "matched" chemical and biological effects data. Sediment samples were labeled "impacted" if survival, growth, or reproduction in facility samples was significantly lower than in the upstream samples. Note that survival, growth, and reproduction in the upstream background samples were not statistically different from the laboratory control. Using only the nonimpacted samples, the site-specific AET was set as the highest concentration that did not exhibit statistically significant effects on survival, growth, or reproduction. The AET for lead in these sediment samples was 1,100 mg/kg dry weight. The lowest concentration of lead at which significant effects were observed was 1,200 mg/kg dry weight. The putative toxicity threshold for lead in sediment is between 1,100 and 1,200 mg/kg dry weight, and the target cleanup level was set equal to the geometric mean of these values or 1,150 mg/kg dry weight.

Table 6. Comparison of sediment concentrations to sediment quality benchmarks.

	Sediment Concentrations				Sediment Quality Benchmark			Sediment Quality Benchmark Quotient			
Chemical	Range						Source	Mean	Range		
Antimony	4.9	–	210	mg/kg	25	mg/kg	ERM	1.9	0.2	–	8.4
Cadmium	3.1	–	24	mg/kg	4.98	mg/kg	PEC	1.7	0.6	–	4.8
Lead	240	–	6,400	mg/kg	128	mg/kg	PEC	14	2	–	50
Zinc	200	–	920	mg/kg	459	mg/kg	PEC	0.96	0.4	–	2.0

Butyl benzylphthalate	32,000	–	1,000,000	µg/kg	500,000	µg/kg	Staples et al. 1997	0.56	0.1	–	2.0
Dibenzofuran	150	–	4,600	µg/kg	840	µg/kg	SCV	1.2	0.18	–	5.5

Note: ERM - effects range Median (Long and Morgan 1990),

PEC - probable effect concentration (MacDonald et al. 2000),

SCV - secondary chronic value (Jones et al. 1997).

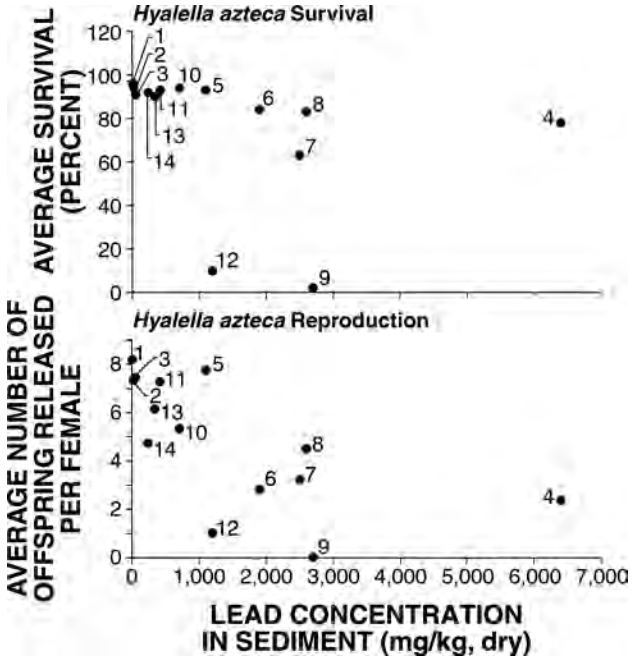

Figure 3. Relationship between lead concentrations in Brook sediments and *Hyalella azteca* survival (top) and reproduction (bottom).

While several samples were taken from the Brook to assess risk to benthic invertebrates, additional data were needed to delineate the removal area at Station 12, the one downstream station where toxicity was observed. The strategy for delineating the removal area at Station 12 was developed to protect benthic invertebrates from hazardous exposure to facility-related chemicals. First, the initial limits of sediment removal at Station 12 were defined as 50 ft upstream and 50 ft downstream of Station 12 (2,000 ft^2). One composite sediment sample was collected and submitted for analysis to confirm the presence of lead in excess of 1,150 mg/kg dry weight. Additional composite sediment samples were collected over 1,000-ft^2 sections of the Brook bed, starting with the closest 1,000-ft^2 sections upstream and downstream of the initial removal area, and extending to up to 3,000-ft^2 upstream and downstream of the initial limits of sediment removal at Station 12. Each sediment sample was composited from seven field-collected samples on a randomized basis and analyzed for lead. The area of approximately 1,000 ft^2 was selected to further define the limits of remediation around Station 12 because Massachusetts has set a regulatory precedent for evaluating exposure of benthic invertebrates to chemical concentrations in sediments over an area no greater than 1,000 ft^2. Analysis of the composite sediment sample from the initial limits of sediment removal at Station 12 showed a concentration of 1,980 mg/kg dry weight, confirming the presence of elevated lead concentrations in sediments at Station 12. The limit of excavation downstream of Station 12 was extended 50 ft from Station 12 to include an additional 1,000 ft^2 segment because the sediment sample from that segment contained a lead concentration of 1,310 mg/kg dry weight. Samples further downstream contained lead concentrations less than the site-specific target level for lead and will remain in place

(Figure 4). The sediment sample from the most distant upstream segment contained a lead concentration higher than the site-specific target cleanup level for lead. To address this area upstream of Station 12 and potentially contaminated areas just upstream of this segment, the excavation limit was extended 230 ft from Station 12, which is the midway point between Stations 12 and 11 (the nearest nontoxic station) (Figure 4).

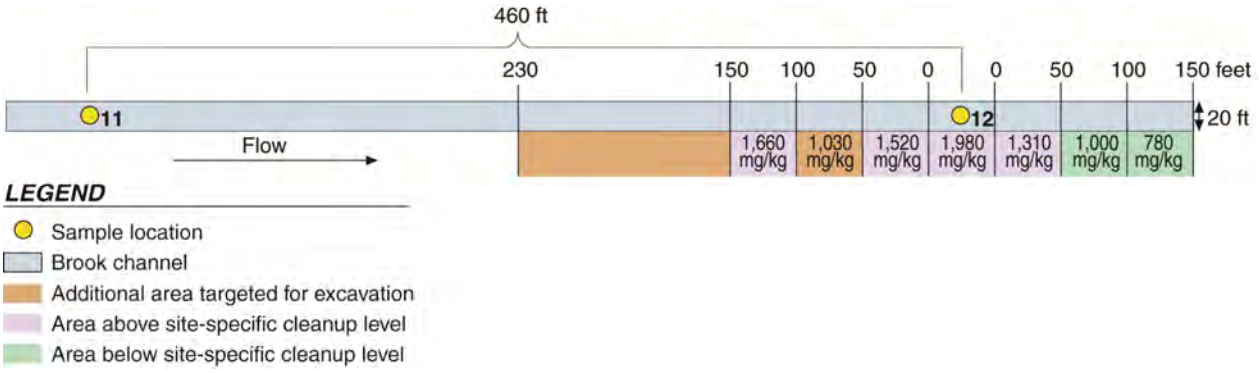

Figure 4. Delineation of sediment removal area at Station 12. Concentrations of lead in composite samples from 1,000 ft^2 segments are shown. Areas designated for sediment removal based on comparison of lead concentrations to the site-specific target cleanup level (1,150 mg/kg) are shown.

The sediment excavation limits at Station 12 will be limited to 6,600 ft^2 in total (1,000 ft^2 downstream and 4,600 ft^2 upstream of the center point at Station 12). However, confirmatory sampling and other verification activities will be conducted to demonstrate that cleanup objectives were met in that area.

4. CONCLUSIONS

The results of this study identified areas where sediment in the Brook exhibited significant toxicity and contained potentially facility-related contaminants at concentrations that were closely associated with observed toxicity. Use of SPME analysis of PAHs in sediment pore water provided evidence that the observed toxicity to *H. azteca* was not primarily caused by PAHs. In the SPME analysis, bulk sediment concentrations of total PAHs ranging from 48,000 to 890,000 μg/kg dry weight were predicted not to be toxic to benthic invertebrates. Freely dissolved concentrations of PAHs in pore water were much lower than predicted based on bulk sediment PAH concentrations. Further analysis of the co-located toxicity and sediment chemistry data indicated that lead was the primary contributor to the observed toxicity to *H. azteca*. Use of the site-specific target cleanup level (1,150 mg lead/kg sediment dry weight) resulted in a substantially smaller remediation footprint in the Brook (24,434 ft^2; 2,270 m^2) than that originally proposed (64,799 ft^2; 6,020 m^2) based on exceedance of SQBs (Figure 1).

5. ACKNOWLEDGEMENTS

The authors thank Ben Amos for technical assistance in the one- and two-phase ESB models, Melanie Edwards for technical assistance in statistical analyses, Ramón Pierce for GIS support, Patti Warden for technical editing, as well as Betty Dowd and Jason Pope for improving the graphical presentation of the data.

Designation: D 7363 – 07

Standard Test Method for Determination of Parent and Alkyl Polycyclic Aromatics in Sediment Pore Water Using Solid-Phase Microextraction and Gas Chromatography/Mass Spectrometry in Selected Ion Monitoring Mode[1, 2]

This standard is issued under the fixed designation D 7363; the number immediately following the designation indicates the year of original adoption or, in the case of revision, the year of last revision. A number in parentheses indicates the year of last reapproval. A superscript epsilon (ε) indicates an editorial change since the last revision or reapproval.

1. Scope

1.1 The U.S. Environmental Protection Agency (USEPA) narcosis model for benthic organisms in sediments contaminated with polycyclic aromatic hydrocarbons (PAHs) is based on the concentrations of dissolved PAHs in the interstitial water or "pore water" in sediment. This test method covers the separation of pore water from PAH-impacted sediment samples, the removal of colloids, and the subsequent measurement of dissolved concentrations of the required 10 parent PAHs and 14 groups of alkylated daughter PAHs in the pore water samples. The "24 PAHs" are determined using solid-phase microextraction (SPME) followed by Gas Chromatography/Mass Spectrometry (GC/MS) analysis in selected ion monitoring (SIM) mode. Isotopically labeled analogs of the target compounds are introduced prior to the extraction, and are used as quantification references.

1.2 Lower molecular weight PAHs are more water soluble than higher molecular weight PAHs. Therefore, USEPA-regulated PAH concentrations in pore water samples vary widely due to differing saturation water solubilities that range from 0.2 µg/L for indeno[1,2,3-cd]pyrene to 31 000 µg/L for naphthalene. This method can accommodate the measurement of milligram per litre concentrations for low molecular weight PAHs and nanogram per litre concentrations for high molecular weight PAHs.

1.3 The USEPA narcosis model predicts toxicity to benthic organisms if the sum of the toxic units (ΣTU_c) calculated for all "34 PAHs" measured in a pore water sample is greater than or equal to 1. For this reason, the performance limit required for the individual PAH measurements were defined as the concentration of an individual PAH that would yield 1/34 of a toxic unit (TU). However, the focus of this method is the 10 parent PAHs and 14 groups of alkylated PAHs (Table 1) that contribute 95 % of the toxic units based on the analysis of 120 background and impacted sediment pore water samples.[3] The primary reasons for eliminating the rest of the 5-6 ring parent PAHs are: *(1)* these PAHs contribute insignificantly to the pore water TU, and *(2)* these PAHs exhibit extremely low saturation solubilities that will make the detection of these compounds difficult in pore water. This method can achieve the required detection limits, which range from approximately 0.01 µg/L, for high molecular weight PAHs, to approximately 3 µg/L for high molecular weight PAHs.

1.4 The test method may also be applied to the determination of additional PAH compounds (for example, 5- and 6-ring PAHs as described in Hawthorne et al).[4] However, it is the responsibility of the user of this standard to establish the validity of the test method for the determination of PAHs other than those referenced in 1.1 and Table 1.

1.5 *This standard does not purport to address all of the safety concerns, if any, associated with its use. It is the responsibility of the user of this standard to establish appropriate safety and health practices and determine the applicability of regulatory limitations prior to use.* For specific hazard statements, refer to Section 9.

P., "Solid Phase Microextraction Measurement of Parent and Alkyl Polycyclic Aromatic Hydrocarbons in Milliliter Sediment Pore Water Samples and Determination of K_{DOC} Values," *Environmental Science Technology*, 39, 2005, pp. 2795-2803.

[B] All relative response factors are based on the SPME-GC/MS peak area per ng of the alkyl PAH in a water standard compared to that of its parent PAH as determined by SPME followed by GC/MS.When several isomers were available, (for example, C2-naphthalenes), the mean relative response factor is reported. The relative response factors of alkyl PAHs for which no standards were available were estimated based on the closest analogous alkyl PAH as described in reference 2.1.

[C] Performance limits were determined as 3 times the background concentrations from the SPME fiber based on the analysis of water blanks ("B"), the lowest calibration standard which consistently yielded a signal to noise ratio of at least 3:1 ("C"), or (for when no calibration standard was available) for the lowest concentrations consistently found in pore water samples with a signal to noise ratio of at least 3:1 ("S"). Detection limits for alkyl PAHs are based on a single isomer.

[D] Alkyl PAHs used to determine the SPME-GC/MS relative response factors including alkyl naphthalenes (1-methyl-, 2-methyl-, 1,2-dimethyl-, 1,3-dimethyl-1,8-dimethyl-, 2,7-dimethyl-, 1-ethyl, 2-ethyl, 1,4,5-trimethyl-, 2,3,5-trimethyl-, and 2-isopropyl-), 1-methylfluorene, 2-methyl- and 9-methylanthracene, 1-methyl-, 2-methyl-, and 3-methylphenanthrene, 9,10-dimethylanthracene, 2-ethylanthracene, 2-tertbutylanthracene, 1-methyl-7-isopropylphenanthrene, 1-methylpyrene, 7-methylbenz[a]anthracene, and 7,12-dimethylbenz[a]anthracene.

3. Terminology

3.1 *Definitions:*

3.1.1 *calibration standard*—a solution prepared from a secondary standard, stock solution, or both, and used to calibrate the response of the instrument with respect to analyte concentration.

[6] Withdrawn.

3.1.2 *calibration verification standard (VER)*—the mid-point calibration standard (CS3) that is analyzed daily to verify the initial calibration.

3.1.3 *CS1, CS2, CS3, CS4*—shorthand notation for calibration standards.

3.1.4 *data acquisition parameters*—parameters affecting the scanning operation and conversion of the analytical signal to digitized data files. These include the configuration of the ADC circuitry, the ion dwell time, the MID cycle time, and acquisition modes set up for the method. Examples of acquisition modes for the HP5973 include SIM mode, and Low Mass Resolution Mode.

3.1.5 *performance limit*—performance limit for individual PAH is defined as the concentration of an individual PAH that would yield 1/34 of a toxic unit. For performance limit of individual PAH, refer to Table 2 (see 4.6).

3.1.6 *deuterated PAH (d-PAH)*—polycyclic aromatic hydrocarbons in which deuterium atoms are substituted for all hydrogens (that is, perdeuterated). In this method, d-PAHs are used as internal standards.

3.1.7 *GC*—gas chromatograph or gas chromatography.

3.1.8 *HRGC*—high resolution GC.

3.1.9 *LRMS*—low resolution MS.

3.1.10 *internal standards*—isotopically labeled analogs (d-PAHs) of the target analytes that are added to every sample, blank, quality control spike sample, and calibration solution. They are added to the water samples immediately after completing the flocculation step and transferring the water aliquot to the autosampler vial, and immediately after adding the calibration PAH solution to water calibration standards, but before SPME extraction. The internal standards are used to calculate the concentration of the target analytes or estimated detection limits.

3.1.11 *laboratory blank*—see *method blank*.

3.1.12 *method blank*—an aliquot of reagent water that is extracted and analyzed along with the samples to monitor for laboratory contamination. Blanks should consistently meet concentrations at or less than one-third of the performance limits for individual PAHs stated in Table 2. Alternatively, if the PAH concentrations calculated from the water blank immediately preceding the test samples are <20 % of the test sample concentrations, the blank is acceptable.

3.1.13 *low calibration level (LCL)*—the level at which the entire analytical system must give a recognizable signal and acceptable calibration point for the analyte. It is equivalent to the concentration of the lowest calibration standard assuming that all method-specified sample weights, volumes, and cleanup procedures have been employed.

3.1.14 *high or upper calibration level (UCL)*—the concentration or mass of analyte in the sample that corresponds to the highest calibration level in the initial calibration. It is equivalent to the concentration of the highest calibration standard, assuming that all method-specified sample weights, volumes, and cleanup procedures have been employed.

3.1.15 *MS*—mass spectrometer or mass spectrometry.

3.1.16 *PAH*—polycyclic aromatic hydrocarbon, or alternately, polynuclear aromatic hydrocarbon.

TABLE 2 Toxic Unit Factors and Performance Limits[A]

Analyte	Added d-PAH Internal Standard	d-PAH Internal Std. for Calculation	SPME-GC/MS RRF versus Parent	Conc. for One Toxic Unit, C_{tu}, (ng/mL)	Performance Limit (ng/mL)
Naphthalene	A	A	1.00	193.47	5.69
2-Methylnaphthalene		B	1.00	81.69	2.40
1-Methylnaphthalene	B	B	1.00	81.69	2.40
C2-Naphthalenes		A	1.44	30.24	0.89
C3-Naphthalenes		A	0.88	11.10	0.33
C4-Naphthalenes		A	0.71	4.05	0.12
Acenaphthylene		C	1.00	306.85	9.03
Acenaphthene	C	C	1.00	55.85	1.64
Fluorene	D	D	1.00	39.30	1.16
C1-Fluorenes		D	0.73	13.99	0.41
C2-Fluorenes		D	0.59	5.30	0.16
C3-Fluorenes		D	0.35	1.92	0.06
Phenanthrene	E	E	1.00	19.13	0.56
Anthracene		E	1.00	20.72	0.61
C1-Phenanthrenes/Anthracenes		E	0.57	7.44	0.22
C2-Phenanthrenes/Anthracenes		E	0.32	3.20	0.09
C3-Phenanthrenes/Anthracenes		E	0.29	1.26	0.04
C4-Phenanthrenes/Anthracenes		E	0.12	0.56	0.02
Fluoranthene	F	F	1.00	7.11	0.21
Pyrene	G	G	1.00	10.11	0.30
C1-Fluoranthenes/Pyrenes		G	0.51	4.89	0.14
Benz[a]anthracene		H	1.00	2.23	0.066
Chrysene	H	H	1.00	2.04	0.060
C1-Chrysenes/Benz[a]anthracenes		H	0.62	0.86	0.025

[A] From Hawthorne, S. B., Grabanski, C.B., Miller, D .J., and Kreitinger, J. P., "Solid Phase Microextraction Measurement of Parent and Alkyl Polycyclic Aromatic Hydrocarbons in Milliliter Sediment Pore Water Samples and Determination of K_{DOC} Values," *Environmental Science Technology*, 39, 2005, pp. 2795-2803.

3.1.17 *percent difference (%D)*—the difference between the analyzed concentration and expected concentration, expressed as a percentage of the expected concentration.

3.1.18 *relative response factor (RRF)*—the empirically determined ratio between the area ratio (analyte to internal standard) and the unit mass of analyte in the calibration standard (area ratio/ng) for available alkyl PAHs in a given homolog and their parent PAH.

3.1.19 *selected ion monitoring (SIM)*—a mode of operation for the mass spectrometer in which specific ions are monitored. This mode of operation differs from the full scan mode, in which the MS acquires all ions within a range. Because the spectrometer is monitoring fewer ions in the SIM mode, more acquisition (dwell) time is possible for each ion. This results in greater instrument sensitivity for the selected ions. Spectral scanning and library searching, used for tentatively identified compounds, are not supported in this mode.

3.1.20 *signal-to-noise ratio*—the ratio of the mass spectrometer response of a GC peak to the background noise signal.

4. Summary of Test Method

4.1 Either the use of an autosampler, or a manual approach can be used to perform the SPME extraction and the subsequent injection of collected analytes into the GC/MS. An autosampler (Leap Technologies Compi-Pal or equivalent) is much preferred over the manual method because: *(1)* the autosampler yields lower and more reproducible blanks, *(2)* the manual method requires the use of a stir bar that can cause sample cross-contamination, *(3)* the manual method is highly labor-intensive and requires multiple timed manipulations per analysis leading to operator fatigue and resultant errors, and *(4)* the autosampler reduces the technician time required to prepare samples for a 24-h run sequence to approximately 3 h, while the manual method requires 24-h operator attendance. Therefore, the method procedures are written assuming the use of an autosampler, with modifications to the autosampler procedures listed for the manual method.

AUTOSAMPLER METHOD

4.2 *Pore Water Separation and Preparation*—The pore water is separated from wet sediment samples by centrifugation and supernatant collection. Colloids are removed from the separated pore water samples by flocculation with aluminum potassium sulfate (alum) and sodium hydroxide as described in Hawthorne et al.[4] A second flocculation and centrifugation, followed by supernatant collection completes the colloid removal. The prepared pore water samples are then split into the required number of replicate aliquots (1.5 mL each) and placed into silanized glass autosampler vials. The 8 perdeuterated PAH internal standards (d-PAHs) are then added immediately. All of the water preparation steps beginning with the centrifugation and ending with the addition of d-PAH internal standards should be conducted continuously and in the minimum amount of time possible.

4.2.1 The SPME fiber should be cleaned at the beginning of each sampling set (and after very contaminated samples) for 1 h by placing in the cleaning chamber under helium flow at 320°C. This can conveniently be performed while the pore waters are being prepared.

4.3 *Solid-Phase Microextraction*—The SPME extraction of the pore water samples is performed using a commercially available (available from Sigma-Aldrich, formerly Supleco, or equivalent) 7 µm film thickness polydimethylsiloxane (PDMS)-coated fused silica fiber for 30 min while the water sample is mixed by the precession of the autosampler mixing chamber at a rate of 250 revolutions per minute. The target

PAHs and d-PAH internal standards adsorb to the nonpolar PDMS phase at equivalent rates. The use of the d-PAHs (that is, isotopic dilution) to quantitate the target PAHs compensates for variations in equilibrium partitioning and kinetics.

4.4 *GC/MS SIM Analysis*—Following the sorption period, the SPME fiber is immediately desorbed to a GC/MS injection port in the splitless mode at 320°C for 5 min. The GC/MS system specified uses a 60 m narrow-bore (250 µm ID) HP5-MS or equivalent capillary column to achieve high resolution for PAHs. Following the 5 min desorption period, the SPME fiber is inserted into the cleaning port and additionally cleaned for 15 min under helium flow at 320°C. At the end of the cleaning period, sorption of the next water sample is begun.

MANUAL METHOD

4.5 *Alternate Procedures for Manual Method*—Samples are prepared as for the autosampler method, except that a small Teflon-coated stir bar is placed in the silanized autosampler vial prior to adding the water and d-PAH internal standard solution. A new stir bar should be used for each sample, calibration standard, and blank to avoid cross-contamination caused by carryover on the stir bar. To perform the SPME step, the vial is set on a stir plate and the stirring rate adjusted so that no large vortex is formed. The SPME fiber should be inserted into the water so that the entire 1-cm active length is exposed to the water sample, but not so low that the fiber comes into contact with the stir bar or that the metal needle sheath contacts the water. All time sequences should be the same as specified for the autosampler method. A spare GC split/splitless injection port at 320°C and under helium flow can be used for the 15-min cleaning step between samples as well as for the initial 1-h cleaning step at the beginning of each experimental day.

4.6 The mass spectrometer is operated in the SIM mode for the molecular ions of the target PAHs and d-PAHs to achieve low limits of detection. Analyte concentrations are quantified by three methods:

4.6.1 PAHs for which an exact deuterated analog is included in the internal standard mix are quantified by isotope dilution.

4.6.2 Parent PAHs (that is, unsubstituted PAHs) for which an exact deuterated analog is not included in the internal standard mix are quantified by reference to a deuterated analog of a PAH with the same number of rings as the analyte.

4.6.3 Alkyl PAHs are quantified using the experimentally and empirically-determined relative response factors from Hawthorne et al.[4] and as shown in Table 1. The laboratory may use updated response factors, if additional alkyl PAH standards become commercially available. However, the laboratory must correct for purities of less than 98 %.

4.7 *Conversion of Quantified Concentration to Toxic Units*—The USEPA narcosis model predicts toxicity to benthic organisms if the sum of the toxic units calculated for all "34 PAHs" measured in a pore water sample is greater than or equal to 1. For this reason, the performance limits required for the individual PAH measurements were defined as the concentration of an individual PAH that would yield 1/34 of a toxic unit. See Table 2. This distribution reflects the relative concentrations of PAHs expected to be found in pore water because the lower molecular weight PAHs are more soluble and have lower organic carbon partition coefficients (Koc), and reflects the lower partitioning of lower molecular weight PAHs to the receptor organism since they have smaller octanol/water coefficients (Kow). The performance limits are essentially benchmarks to ensure that the adequate sensitivity is achieved to predict toxicity.

5. Significance and Use

5.1 This method directly determines the concentrations of dissolved PAH concentrations in environmental sediment pore water samples. The method is important from an environmental regulatory perspective because it can achieve the analytical sensitivities to meet the goals of the USEPA narcosis model for protecting benthic organisms in PAH contaminated sediments. Regulatory methods using solvent extraction have not achieved the wide calibration ranges from nanograms to milligrams per litre and the required levels of detection in the nanogram-per-litre range. In addition, conventional solvent extraction methods require large aliquot volumes (litre or larger), use of large volumes of organic solvents, and filtration to generate the pore water. This approach entails the storage and processing of large volumes of sediment samples and loss of low molecular weight PAHs in the filtration and solvent evaporation steps.

5.2 This method can be used to determine nanogram to milligram per litre PAH concentrations in pore water. Small volumes of pore water are required for SPME extraction, only 1.5 mL per determination and virtually no solvent extraction waste is generated.

6. Interferences

6.1 Non-target hydrocarbons can cause peaks on selected ion current profiles (SICPs) intended for other PAHs. Pattern recognition must be employed for identifying interfering peaks, and peak series that should not be considered for the homolog or target PAH under consideration. Analysts should be intimately familiar with both parent and alkyl PAH analyses in complex environmental samples. Representative samples having higher PAH concentrations should periodically be analyzed by full scan GC/MS so that pattern recognition of alkyl PAHs (and interfering species) can be verified by their full mass spectra. This procedure is particularly important for newer operators.

6.2 Solvents, reagents, glassware and other sample processing hardware may yield discrete artifacts or elevated baselines that may cause misinterpretation of the chromatographic data. All of these materials must be demonstrated to be free from interferences under the conditions of analysis by performing laboratory method blanks. Analysts should avoid using PVC gloves, powdered gloves, or gloves with measurable levels of phthalates.

NOTE 1—The use of high purity reagents and solvents helps minimize interference problems.

7. Apparatus

7.1 *Centrifuge*, capable of sustaining 1000 g with cups for securing 40 mL and 20 mL vials.

7.2 *SPME Fiber Holder*, compatible with 7-µm SPME fiber and compatible with either the autosampler or the manual method.

TABLE 3 Primary Material Hazards

Material	Hazards	Exposure Limit[A]	Signs and Symptoms of Exposure
Alum (Aluminum Potassium Sulfate)	Irritant	2 mg/M^3 TWA	May cause skin irritation, especially under repeated or prolonged contact, or when moisture is present. May irritate or burn the eyes. Dust or mist inhalation at levels above the TLV may cause irritation to the respiratory tract. May irritate the gastrointestional tract.
Acetone	Flammable	1000 ppm-TWA	Inhalation of vapors irritates the respiratory tract. May cause coughing, dizziness, dullness, and headache.
Dichloromethane (DCM)	Carcinogen, Irritant	25 ppm-TWA, 125 ppm-STEL	Causes irritation to respiratory tract. Has a strong narcotic effect with symptoms of mental confusion, light-headedness, fatigue, nausea, vomiting and headache. Causes irritation, redness and pain to the skin and eyes. Prolonged contact can cause burns. Liquid degreases the skin. May be absorbed through skin.
Sodium Hydroxide	Corrosive	2 mg/M^3 TWA	Causes skin irritation, chemical burns, permanent injury or scarring, and blindness. Vinegar is a mild acid that will neutralize lye if it were to make contact with the skin. Harmful if inhaled or ingested. Causes Sore throat, cough labored breathing, shortness of breath, and abdominal pain. Symptoms may be delayed.

[A] Exposure limit refers to the OSHA regulatory exposure limit.

7.3 *SPME Fibers*, 7-µm diameter, coated with polydimethylsiloxane (PDMS).

7.4 *PTFE Coated Stir Bars (Stir Fleas)*, of a size effective for stirring 1.5 mL water without vortexing (for manual method only).

7.5 *Magnetic Stir Plate (for manual method only)*.

7.6 *SPME Holder Stand (for manual method only) or GC/MS Autosampler*, capable of SPME extraction and injection.

7.7 *Cleaning Port*, capable of purging SPME fibers in a helium-swept atmosphere at 320°C.

7.8 *GC/MS Analysis*:

7.8.1 *Gas Chromatograph* shall have split/splitless injection port for capillary column, temperature program with isothermal hold.

7.8.2 *GC Column*, 60 mm × 0.25 mm ID × 25 µm film thickness HP5-MS or equivalent.

7.8.3 *Inlet Liner*, 2 mm ID silanized glass.

7.8.4 *GC Inlet*, 320°C, splitless mode.

7.8.5 *Oven Program*—Isothermal 5 min hold at 40°C. Ramp at 50°C/min to 110°C, followed by a temperature ramp of 12°C/min to 320°C (hold for 10 min).

7.8.6 *Mass Spectrometer*—Electron impact ionization with the ionization energy optimized for best instrument sensitivity (typically 70 eV), stability and signal to noise ratio. Shall be capable of repetitively selectively monitoring at least 12 m/z during a period of approximately 1 s and shall meet all manufacturers' specifications.

7.8.7 *GC/MS Interface*—The mass spectrometer (MS) shall be interfaced to the GC such that the end of the capillary column terminates within 1 cm of the ion source but does not intercept the electron or ion beam.

7.8.8 *Data System*, capable of collecting, recording, and storing MS data.

8. Reagents and Materials

8.1 *Purity of Reagents*—Reagent grade chemicals must be used in all tests. Unless otherwise indicated, it is intended that all reagents shall conform to the specifications of the Committee on Analytical Reagents of the American Chemical Society, where such specifications are available.[7]

8.2 *Purity of Water*—Unless otherwise indicated, references to water shall be understood to mean reagent water that meets the purity specifications of Type I or Type II water, presented in Specification D 1193.

8.3 *40 mL Vials*, with Teflon-lined caps.

8.4 *20 mL Vials*, with Teflon-lined caps.

8.5 *Silanized 2.0 mL Autosampler Vials*.

8.6 *Internal Standard Stock Solution*—A dichloromethane solution of d-PAH internal standards used for preparing spiking solutions by dilution into acetone (see 12.2).

8.7 *Internal Standard Spiking Solution*—A dilution of the internal standard stock solution in acetone used to spike d-PAH internal standards into all sample, calibration, and blank water vials.

8.8 *Calibration Stock Solution*—A dichloromethane solution of PAHs used for preparing calibration standards (see 12.2).

8.9 *Calibration Spiking Solutions*—A series of solutions prepared by diluting the calibration stock solution with acetone (see 12.2).

8.10 *Calibration Standards*—Prepared by adding internal standard and calibration spiking solutions in reagent water (see 12.2).

8.11 *Acetone*.

8.12 *Dichloromethane* (DCM).

8.13 *Sodium Hydroxide* (NaOH).

8.14 *Aluminum Potassium Sulfate Dodecahydrate* ($AlK(SO_4)_2 \cdot 12H_2O$).

8.15 *Alum Solution*—Add 20 g ($AlK(SO_4)_2 \cdot 12H_2O$) to 80 mL reagent water.

9. Hazards

9.1 The effluents of sample splitters for the gas chromatograph and roughing pumps on the mass spectrometer must be

[7] *Reagent Chemicals, American Chemical Society Specifications*, American Chemical Society, Washington, DC. For suggestions on the testing of reagents not listed by the American Chemical Society, see *Analar Standards for Laboratory Chemicals,* BDH Ltd., Poole, Dorset, U.K., and the *United States Pharmacopeia and National Formulary,* U.S. Pharmacopeial Convention, Inc. (USPC), Rockville, MD.

vented to the laboratory hood exhaust system or must pass through an activated charcoal filter.

9.2 *Primary Materials Used*—The table contains a summary of the primary hazards listed in the MSDS. A complete list of materials used in the method can be found in the reagents and materials section. Practitioners must review the information in the MSDS for each material before using it for the first time or when there are major changes to the MSDS.

10. Sampling and Sample Preservation

10.1 Collect the sediment sample in accordance with Practices D 3370 and Specification D 1192, as applicable.

10.2 Prior to shipment, the samples should be mixed well. Sieve the slurry of sediment and site water through a 2-mm screen to remove debris. If the sieved slurry is to be stored or shipped before use, store in 250 mL to 1 L jars with PTFE-lined lids. Great care must be taken to clean the lid of the jar before capping with the lid to avoid leakage of the water during shipment.

10.3 Ship in an ice chest with adequate ice to maintain 0 to 6°C. Store at the laboratory in the dark at 0 to 6°C.

11. Preparation of Apparatus

11.1 Set up the GC system using the following parameters.

11.1.1 GC Column Agilent HP-5MS column (0.25 µm film thickness, 0.25 mm ID) or equivalent.

11.1.2 Inlet liner 2-mm ID silanized glass.

11.1.3 GC Inlet 320°C, splitless mode.

11.1.4 *Oven Program*—Isothermal 5 min hold at 40°C. Ramp at 50°C/min to 110°C, followed by a temperature ramp of 12°C/min to 320°C. (Hold for 10 min.)

MS Quad Temperature	150°C, maximum 200°C
MS Source Temperature	230°C, maximum 250°C

11.1.5 Set up SIM Groups to monitor the quantitation and internal standard ions shown in Table 4. Each ion dwell time should be set at 25 ms. Twelve ions are monitored in each group.

NOTE 2—Some ions (for example, m/z 184.1 for C4 naphthalenes) are included in two ion groups to ensure that the target peaks are adequately monitored. Table 4 should be used with the chromatograms in Appendix X1 to aid the analyst in setting proper retention time windows and recognition of target and contaminant peaks, especially for the alkyl clusters.

12. Calibration

12.1 Determine the absolute and relative retention times of the first and last characteristic peak in each homolog with the aid of the examples in Appendix X1.

12.1.1 Set up a SIM program with the necessary ions to acquire all the alkyl-PAH homologs using the ion groups shown in Table 4 and 25 ms dwell time per ion.

12.1.2 Update the expected retention times in the method section of the quantitation software using the d-PAH internal standards of previous runs as relative retention time markers and the representative chromatograms in Appendix X1. Assure that the SIM windows for the homologs are set to at least 8 s before the first, and 30 s after the last characteristic peaks to assure coverage of the elution range.

12.2 *Analyze Initial Calibration*:

TABLE 4 SIM Ion Groups and Retention Time Windows

NOTE—Retention times must be verified by the user.

Analyte	SIM Ion Group	Target m/z	Retention Time (min)	
			Start	Stop
Naphthalene	1	128.1	7	17

Chrysene-d12	3	240.2	21	30

12.2.1 Prepare stock solutions of PAHs and internal standard stock solutions of d-PAHs at approximately the concentrations shown in Table 5. These concentrations were based on the PAH distributions previously determined in 120 sediment pore water samples. Stocks are prepared in DCM. Spiking solutions are prepared by dilution of intermediate stocks in acetone. For calibration solutions, spiking solutions are added to reagent water.

12.2.1.1 Prepare calibration standard spiking solutions. These are prepared by adding acetone to the stock to give the calibration solution concentrations (CS1–CS4), as described below:

(1) For CS1, take 5 µL stock to 100 mL in acetone.

(2) For CS2 take 50 µL to 100 mL in acetone.

(3) For CS3, take 25 µL to 10 mL in acetone.

(4) For CS4, take 100 µL to 10 mL in acetone.

12.2.1.2 Spike 4 µL of each calibration solution into 1.5 mL of reagent water to give a calibration series with the low calibration limits (LCLs) and upper calibration limits (UCLs) shown in Table 5. Spike 10 µL of internal standard spiking solution at the concentrations shown in Table 5 into each vial.

12.2.1.3 Extract and analyze the calibration series.

(1) Extract and analyze two water blank solutions.

(2) Extract and analyze the water calibration solutions, as described in 13.4 and 13.5. Begin with the CS1-spiked sample,

TABLE 5 Initial Calibration Standard Series

Analyte	DCM Stock Conc. mg/mL	LCL			UCL
		CS1	CS2	CS3	CS4
		ng/1.5 mL	ng/1.5 mL	ng/1.5 mL	ng/1.5 mL
Naphthalene	41.5	8.3	83	415	1660

Chrysene-d12	0.033	0.33	0.33	0.33	0.33

followed by sequentially more concentrated calibration standards. Follow by two water blanks.

12.2.1.4 Calculate the performance parameters for the calibration.

(1) Generate ion chromatograms for the masses listed in Table 4 that encompass the expected retention windows of the target analytes. Integrate the selected ion current profiles of the quantitation ions shown in the table. Integration of alkyl clusters should be as the total area of the cluster integrated from the baseline before the first peak in the cluster to the baseline after the last peak in the cluster peaks. Cluster peaks should never be integrated using the valley-to-valley method. The peak areas of non-target peaks (see Appendix X1) must be removed from the alkyl cluster peak area before any calculation.

(2) Calculate the area ratio (analyte peak area divided by internal standard peak area) per unit mass of analyte, using the area of the appropriate internal standard listed in Table 1. Quantitative calculations are based on a comparison of the area ratio per ng from the calibration and sample waters. The area ratio per ng is calculated for calibration runs by dividing the calibration peak area by the peak area of its most closely associate d-PAH internal standard (the deuterated parent PAH, in most cases), and dividing this result by the ng of the calibration PAH present in the vial (that is, its mass in the vial, not its concentration). Calibration standards are given in Table 5.

$$area\ ratio\ per\ ng\ (ar\ rat/ng) = \frac{[(peak\ area\ cal.\ std)/(peak\ area\ d{-}PAH)]}{(mass\ of\ std\ in\ cal\ vial)} \quad (1)$$

(3) Calculate the mean ar rat/ng. The mean relative response factor for these duplicate daily calibration standards should agree with those from the 4-point (or 3-point) standard curve within 20 % for the two and three-ring PAHs, and within 25 % for the four-ring PAHs. No sample data will be reported if these calibration criteria are not met. Calculate the mean area ratio/ng and the standard deviation of the relative response factors for each calibration standard solution using the following equations:

$$\overline{ar\ rat/ng} = \frac{1}{n}\sum_{i=1}^{n}(ar\ rat/ng)_i \quad (2)$$

where:

$(ar\ rat/ng)_i$ = ar rat/ng calculated for calibration solution "i" using the equation in 12.2.1.4*(2)*, and

n = number of calibration points in the curve.

(4) Calculate the percent relative standard deviation:

$$\%RSD = \frac{SD}{\overline{ar\ rat/ng}} \times 100 \quad (3)$$

where:

$\overline{ar\ rat/ng}$ = mean ar rat/ng calculated above, and

SD = sample standard deviation of the replicate area rat/ng values used to calculate the mean ar rat/ng.

12.3 *Criteria for Acceptable Initial Calibration*—Prior to analyzing any samples, the standard curves are prepared using the identical analysis procedures as used for sample waters. To be acceptable, the linearity of each PAH standard curve should be $r^2 > 0.99$, and the relative response factor per ng for each concentration should show a relative standard deviation of <25 % for two- to three-ring PAHs, and <30 % for four-ring PAHs. See Section 16. If acceptable initial calibration is not achieved, identify the root cause, perform corrective action, and repeat the initial calibration. If the root cause can be traced to an abnormal disruption of an individual acquisition (for example, injector malfunction) repeat the individual analysis and recalculate the percent relative standard deviation. If the

calibration is acceptable, document the problem and proceed; otherwise repeat the initial calibration.

12.3.1 Because of the large range of calibration concentrations required, the wide range of water solubilities of the individual PAHs, and the desire to require only one stock calibration solution, some PAHs may only have a three point linear calibration curve that meets the above criteria. This is most likely to occur for the higher molecular weight PAHs, because the dilution of lowest calibration standard is likely to be below detection limits for many labs (and is also below the required detection limits needed for the method, so it does not negatively impact the analyses). In such cases, the lowest calibration standard is ignored, and the "J" level adjusted appropriately. Less frequently, the highest concentrations of the lowest molecular weight PAHs may exceed the linear dynamic range of the GC/MS response. In such cases the laboratory should investigate lowering the MS multiplier voltage to autotune voltage or slightly below and rerun the calibration curve. If the highest calibration standard still exceeds the detector linearity, it is acceptable to reject the highest concentration for those specific PAHs (and adjust the "E" value accordingly), as long as a minimum of a three-point standard curve is generated for each PAH.

12.3.1.1 It is recommended that a 4-point (or 3-point) initial calibration be established every two weeks, when continuing calibration criteria are not met, or when service is performed on the GC/MS instrument system.

12.3.2 The signal to noise ratio (S/N) for the GC signals present in every selected ion current profile (SICP) must be ≥10:1 for the labeled internal standards and unlabeled calibration compounds.

12.4 *Calibration Verification*—Continuing calibration is performed daily at the beginning of a 24-h period. The injection of the first continuing calibration begins the 24-h window, within which all pore water samples must be injected. Duplicate daily standards are analyzed.

12.4.1 Into 1.5 mL of reagent water, add 4 µL of the CS3 spiking solution and 10 µL of the d-PAH internal standards.

12.4.2 Analyze duplicate vials of the Calibration Standard Solution CS3. Use the same data acquisition parameters as those used during the initial calibration. Check for GC resolution and peak shape. If peak shape or retention times are unacceptable, perform column and injector maintenance. If this fails to correct the problem, the column must be replaced and the calibration repeated.

12.4.3 *Criteria for Acceptable Daily Calibration Check*—The criteria listed below for acceptable calibration must be met at the beginning of each 24-h period that samples are analyzed. The mean relative response factor for these duplicate daily calibration standards should agree with those from the 4-point (or 3-point) standard curve within 20 % for the two- and three-ring PAHs, and within 25 % for the four-ring PAHs. No sample data will be reported if these calibration criteria are not met. If the continuing calibration criteria are not met, identify the root cause, perform corrective action and repeat the continuing calibration. If the second consecutive continuing calibration does not meet acceptance criteria, additional corrective action must be performed.

12.4.4 The signal to noise ratio (S/N) for the GC signals present in every selected ion current profile (SICP) must be ≥10:1 for the labeled internal standards and unlabeled calibration compounds.

12.5 *Method Blanks*—Method blanks are prepared and analyzed daily in duplicate following the continuing calibration and between analysis of replicate sets of the same pore water sample. See 12.5.2.2.

12.5.1 For each method blank, add 10 µL of the d-PAH internal standards solution into 1.5 mL of reagent water.

12.5.2 Two types of sources of background PAHs must be considered. For the higher molecular weight PAHs, typical GC/MS criteria for signal to noise are appropriate, since their detection limits are normally controlled by GC/MS sensitivity. However, for lower molecular weight PAHs, atmospheric contaminants can cause significant background peaks, especially for low MW alkyl PAHs. This problem is most likely to be significant in urban areas impacted by atmospheric PAHs (for example, from diesel exhaust), and with laboratories using manual techniques, rather than the SPME autosampler.

12.5.2.1 *Background PAHs from Ambient Air*—Concentrations of each PAH in the water blanks should be calculated in the same manner as a sample. Should the blank prior to the subsequent pore water sample have detectable background concentrations more than ⅓ of the target detection limit given in Table 3, the analyses should not continue until the fiber is sufficiently cleaned as demonstrated by a clean water blank. The mean of the calculated concentrations of the PAHs in the blanks analyzed immediately before and immediately after sample pore waters should be subtracted from the sample pore water concentrations.

12.5.2.2 *Carryover from Highly Contaminated Samples*—Carryover blanks are analyzed between each new pore water sample (not including replicates). Significant carryover can occur if the previous sample was highly contaminated. Should the blank prior to the subsequent pore water sample have detectable background concentrations more than ⅓ of the target detection limit, the analyses should not continue until the fiber is sufficiently cleaned as demonstrated by a clean water blank. Alternatively, if the concentrations determined in the blanks are less than 20 % of those found in the related sample, the data can be accepted.

13. Procedure

13.1 At the laboratory, store samples and extracts in the dark at 0 to 6°C.

13.2 *Holding Times*:

13.2.1 Pore waters must be generated within 28 days of sediment sample collection.

13.2.2 Pore waters must be generated and flocculated as quickly as possible, and then immediately spiked with 10 µL of d-PAH solution.

13.2.3 Solid phase micro-extraction must be completed within 24 h of flocculation.

13.3 *Generation of Pore Water*:

13.3.1 Stir the slurry and transfer approximately 40 mL (containing a solids and liquids in proportion to the slurry provided) to a clean 40 mL vial. Cap the vial with a PTFE-lined cap. Place the vials in a centrifuge. Spin for 30 min at 1000 g.

TABLE 6 Example of a 24-h Analytical Sequence[A]

Example Analytical Sequence					
Run Type	Minutes	Cumulative Minutes to Start	Cumulative Minutes to End	Cumulative Hours to Start[A]	Cumulative Hours to End
Standard	50	0	50	0.0	0.8
Standard	50	50	100	0.8	1.7
Blank	50	100	150	1.7	2.5
Blank	50	150	200	2.5	3.3
Sample	50	200	250	3.3	4.2
Sample	50	250	300	4.2	5.0
Blank	50	300	350	5.0	5.8
Blank	50	350	400	5.8	6.7
Sample	50	400	450	6.7	7.5
Sample	50	450	500	7.5	8.3
Blank	50	500	550	8.3	9.2
Blank	50	550	600	9.2	10.0

Blank	50	900	950	15.0	15.8
Blank	50	950	1000	15.8	16.7
Sample	50	1000	1050	16.7	17.5
Sample	50	1050	1100	17.5	18.3
Blank	50	1100	1150	18.3	19.2

[A] The last pore water sample must be injected within 24 h of the flocculation step (that is, the value for cumulative hours to start must be ≤24).

Using a new, graduated serological pipette, transfer 10 mL of the supernatant to a new 20 mL vial.

13.3.2 *Flocculation of Pore Water*—Flocculation must be performed no more than 24 h prior to extraction.

13.3.2.1 If a flocculation blank is to be analyzed, create the blank by placing 10 mL of reagent water in clean a 40 mL vial. Process this blank along with pore water samples.

13.3.2.2 Add the working alum solution (see Section 9) to each vial of pore water (and QC samples). The volume of the alum solution should be 1/40th of the sample volume. After the addition, swirl the vial for several rotations to incorporate the solution.

13.3.2.3 Add 3 to 5 drops of NaOH working solution (see Section 9) to each vial. Swirl to incorporate the NaOH.

13.3.2.4 Shake the vial for 15 s.

13.3.2.5 Centrifuge for 30 min at 1000 g.

13.3.2.6 Collect the supernatant into a clean 20 mL vial.

13.3.2.7 Repeat 13.3.2.2 through 13.3.2.6 once.

13.3.2.8 Immediately transfer 1.5 mL aliquots to new silanized autosampler vials and immediately add the internal standard solution as described below. Vials are weighed before and after adding the water sample to determine the exact sample water mass.

13.4 *Extraction and Analysis of Flocculated Pore Water*:

13.4.1 Split the prepared pore water samples into the required number of replicate samples, placing 1.5 mL aliquots of each into a new silanized glass autosampler vial. For QC samples, add 1.5 mL of reagent water.

NOTE 3—The SPME fiber should be cleaned at the beginning of each sampling set (and after very contaminated samples) for 1 h by placing in the cleaning chamber under helium flow at 320°C. This can conveniently be performed while the pore waters are being prepared.

13.4.2 Immediately add 10 µL of the d-PAH solution to each sample and QC sample.

NOTE 4—All of the water preparation steps beginning with the centrifugation and ending with the addition of d-PAH internal standards should be conducted continuously and in the minimum amount of time possible.

13.4.3 Load the autosampler following the recommended analytical sequence in Table 6. Verify the sequence against documented sequence following the loading process.

13.5 The recommended analytical sequence described in Table 6 is based on a 24-h "clock."

13.5.1 Two calibration verification standards are analyzed (122 min). The sequence begins with analysis of the first continuing calibration standard.

13.5.2 Analyze two method blanks (61 min each).

13.5.3 Analyze pore water samples (in duplicate at a minimum) (61 min each).

14. Data Analysis and Calculations

14.1 Generate ion chromatograms for the masses listed in Table 4 that encompass the expected retention windows of the target analytes (see Appendix X1). Integrate the selected ion current profiles of the quantitation ions shown in the table.

14.1.1 *Qualitative Identification Criteria for Individual Analytes*—For a gas chromatographic peak to be identified as a target analyte, it must meet all of the following criteria:

14.1.1.1 The quantitation ion must be present, with a signal-to-noise ratio of at least 3:1 for environmental samples.

14.1.1.2 The relative retention time (RRT) of the parent PAHs (and the 2 and 1-methylnaphthalene compounds) compared to the RRT for the labeled-standards must be within ±3 s of the relative retention times obtained from the continuing calibration (or initial calibration if this applies). Alkyl clusters must be identified based on their relative retention times to the parent PAHs and related d-PAHs, and also by observation of their characteristic fingerprints by an experienced analyst.

14.1.2 *Qualitative Identification Criteria for Total Homolog Groups* (for example, total C2 or C3 alkylnaphthalenes)—Integration of the alkyl PAHs requires hands-on labor from a highly experienced analyst. Retention time windows, like those used for the parent PAHs are inadequate for identifying alkyl clusters (that can be minutes wide). Proper identification of alkyl clusters is critical, as is the proper identification of non-target species that occur at the same nominal mass. Mental pattern recognition must be used to avoid including non-target species that may occur at the same mass and retention time window as the target alkyl PAHs. All alkyl clusters should be integrated baseline to baseline to sum the total area of the cluster (adjusting the baseline for detector drift), but not valley to valley. Manual control of the integration is required for alkyl clusters.

14.1.2.1 Representative selected ion chromatograms from coal tar contaminated sediment pore water for all target species are shown in Appendix X1. The top chromatogram on each page is the d-PAH internal standard used for the parent and alkyl PAHs associated with that parent. For example, the first page shows d8-naphthalene (m/z 136) followed by naphthalene (m/z 128), the two methylnaphthalene isomers (m/z 142), the C2 naphthalene cluster (m/z 156), the C3-naphthalene cluster (m/z 170), and the C4 naphthalene cluster (m/z 184). The chromatogram also shows a typical interference that occurs in sediments for the C4-naphthalene cluster, that is, the dibenzothiophene isomers that occur in the same selected ion chromatogram as the C4-naphthalene cluster. These interfering dibenzothiopenes are crossed out, and the correct cluster for integration (based on full scan analyses of several different contaminated sediment pore waters) are indicated by brackets. Similar designations are used to indicate common interfering peaks and the correct target species in the subsequent chromatograms.

14.1.3 The retention time (RT) of the analyte must be no more than 5 s before the expected RT of the first isomer in the homolog, based on the continuing windowing solution analysis.

14.1.4 The retention time (RT) of the analyte must be no more than 5 s after the expected RT of the last isomer in the homolog, based on the continuing windowing solution analysis.

14.2 *Quantitation for Target Analytes*:

14.2.1 Sample water concentrations are calculated by dividing the peak area of the sample peak by the peak area of its d-PAH internal standard, and then dividing the result by the calibration area ratio per ng, and dividing that result by the sample water weight.

$$Concentration\ (ng/mL) = \frac{(area\ sample\ peak)/(area\ d-PAH\ peak)}{(area\ ratio\ per\ ng\ cal.\ std) \times (sample\ weight)} \quad (4)$$

14.2.2 The mean calibration area ratio per ng values from the daily calibration runs is used for sample concentration calculations (assuming QA/QC checks with the full calibration curve meet criteria).

14.2.3 The concentrations of alkyl PAH clusters are based on the calibration response of their parent PAH as adjusted for the relative response factor (rrf) for that cluster of species (including SPME and GC/MS responses) taken from Table 1. Thus, the concentrations of alkyl clusters are calculated by:

$$Concentration\ (ng/mL) = \frac{(area\ sample\ cluster)/(area\ d-PAH\ peak)}{(area\ ratio\ per\ ng\ parent\ cal\ std) \times (sample\ weight)} \quad (5)$$

NOTE 5—The two methylnaphthalene isomers are individual alkyl peaks (not clusters as in all other alkyl cases) and are treated as parent PAHs in the calculations.

14.2.4 If no peaks are present at a signal to noise value ≥3 to 1 in the region of the ion chromatogram where the compounds of interest are expected to elute, report the result as "Not Detected" (that is, ND) at the reporting limit.

14.2.5 Depending on project objectives, the results may be reported to TDLs or estimated detection limits (EDLs).

14.2.5.1 If project-specific guidance requires analysis-specific EDLs, calculate the detection limit for that compound according to the following equation:

$$Estimated\ Detection\ Limit = \frac{N \times 2.5}{His \times (ar\ rat/ng)} \quad (6)$$

where:

N = height of peak to peak noise of quantitation ion signal in the region of the ion chromatogram where the compound of interest is expected to elute,

His = peak height of quantitation ion for appropriate internal standard, and

ar rat/ng = mean ar rat/ng of compound obtained during daily calibration.

14.2.5.2 If project-specific guidance requires total toxic units (TTU) to be reported, calculate the detection limit for that compound according to the following equations:

$$TU_c = Ctu \times result(ng/mL)^{-1} \quad (7)$$

$$Total\ Toxic\ Units\ (TTU) = \sum_{1}^{34} TU_c \quad (8)$$

where:

TU_c = toxic unit concentration for each individual compound or homolog (ng/mL),

Ctu = concentration for one toxic unit (ng/mL), see Table 2,

result = individual pore water result for a compound or homolog (ng/mL), and

TTU = total toxic units for all 34 compounds and homologs.

14.2.6 Flag all compound results in the sample which were estimated below the lowest calibration level with a "J" qualifier.

14.2.7 Flag all compound results in the sample which were estimated above the upper calibration level with an "E" qualifier.

15. Precision and Bias

15.1 *Single Analyst Precision Statement*:

15.1.1 The recommendations of the ASTM task group members were followed in performing the single-laboratory study. Three environmental sediment samples were selected from archived sediments to represent low, medium, and high

[A] ND: Analyte not detected in the associated sample.

concentrations of pore water PAHs. Efforts were made to ensure that sediments were chosen that had a full distribution of target PAH ring sizes, a range of PAH concentrations found in environmental sediment samples, and a representative range in total organic carbon concentration and texture.

15.1.2 The quantitations were based on three- or four-point calibration curves as verified by daily analysis of duplicate calibration verification standards at the medium-high concentration level. Prior to sample analysis, the initial calibration curves must have a coefficient of determination greater than 0.990, and the relative response factors must have a relative standard deviation of less than 25 % for two to three-ring PAHs, and less than 30 % for four-ring PAHs. The calibration verification mean relative response factor must agree with those of the initial calibration curve within 20 % for two to three-ring PAHs, and less than 25 % for four-ring PAHs. No sample data were reported if these criteria were not met. All method blanks met the requirement that the concentrations be at or less than 20 % of the Performance Limits for individual PAHs.

15.1.3 As directed in section 10.3 of Practice D 2777, the data were evaluated for outliers. The data were evaluated using the one-sided t-test at the upper 5 % significance level as described in Practice E 178, Section 6. Two outlying observations were found for high-level sample HP-4. One C3-naphthalenes result and one acenaphthylene result for sample HP-4 were outliers. The mean and single operator standard deviation were recalculated for sample HP-4 C3-naphthalenes and acenaphthylene without the outlying observations (that is, n = 6).

15.1.4 The precision statements for each analyte are shown on Table 7. For this single-laboratory study, it was assumed that the calculated standard deviation is equivalent to the single operator standard deviation (S_o). Replicate determinations of sample PAH concentrations typically had relative standard deviations (RSDs) less than 10 %, with somewhat higher RSDs for higher molecular weight compounds. The only unusually high RSDs occurred for the highest molecular weight PAHs from high-level sample HP 4. The reason for this is that the saturation limits may have been reached for the high molecular weight PAHs (that is, C1-phenanthrenes/anthracenes through C1-chrysenes).

15.1.5 Finally, the variation of individual PAH determinations had no significant effect on the repeatability of the total toxic unit determinations. See Table 7. This was demonstrated even though the statistical outliers found in sample HP-4 were not omitted in the calculation of total toxic units. The RSDs for the total toxic unit results ranged from 5 to 7 %.

15.2 *Single Analyst Bias Statement*:

15.2.1 A single laboratory study was performed using the perdeuterated PAHs d12-benz(a)anthracene and d10-2-methylnaphthalene spiked at low, medium, and high levels into environmental sediment samples. The quality control statements for each analyte level sample, obtained from the perdeuterated spike study, are shown in Tables 8-10. The quality control statements can also be considered precision and bias statements because the true spiking levels of the perdeuterated PAHs were known. The graphs and regression equations show the relationship between single-operator standard deviation and concentration, and mean measured value and

TABLE 8 HP-24 Low Concentration Quality Control

TABLE 10 HP-4 High Concentration Quality Control

Analyte	True Spiked Value (ng/mL)	Number of Retained Values	Mean Recovery (ng/mL)	Mean Recovery (%)	Single Standard Deviation (So)	Relative Standard Deviation (%)
2-Methylnaphthalene-d10	283.9	7	230.7	81.3	11.0	4.8
Benz[a]anthracene-d12	2.61	7	2.13	81.7	0.13	5.9

concentration for both perdeuterated PAHs (see Figs. 1-4). The figures show the linearity of precision and accuracy with increasing concentration. The d12-benz(a)anthracene recoveries were consistently around 80 %. This may possibly indicate the consistent suppression of the mass spectral signal by a near-eluting compound. The recoveries for d10-2-methylnaphthalene ranged from 81 to 112 %. The repeatability for the known spike recoveries was consistent; the known spike RSDs ranged from 3 to 9 %. PAH concentration had no significant effect on the repeatability of the technique.

16. Quality Control Criteria

16.1 *Initial Calibration*:

16.1.1 The following acceptance criteria will be used for initial calibration: *(1)* The signal to noise (S/N) ratio for the GC signals present in every selected ion current profile (SICP) must be ≥10:1 for the labeled internal standards and calibration compounds; *(2)* The percent relative standard deviation (RSD) for the mean area ratio/ng for labeled internal standards and the calibration compounds must be less than 30 % for high molecular weight PAHs and less than 25 % for low molecular weight PAHs, and the $r^2 > 0.99$. The calibration curve must not be forced through the origin; *(3)* The number of calibration standards may be reduced from four to three based on the criteria in 12.3 of this test method.

16.1.2 The following corrective action will be adopted for initial calibration: *(1)* Initial calibration must be re-established if the RSD(s) exceed the limit(s); *(2)* The calibration will not be re-established in response to a nonconforming RSD if the sample results are less than the PQL.

16.2 *Daily Duplicate Calibration Verifications*:

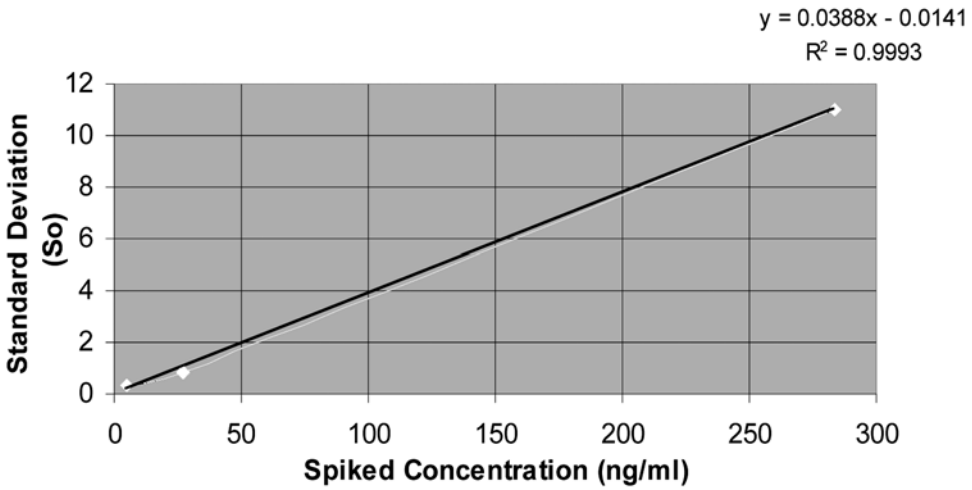

FIG. 1 2-Methylnaphthalene-d10 Single Standard Deviation versus Spiked Concentration

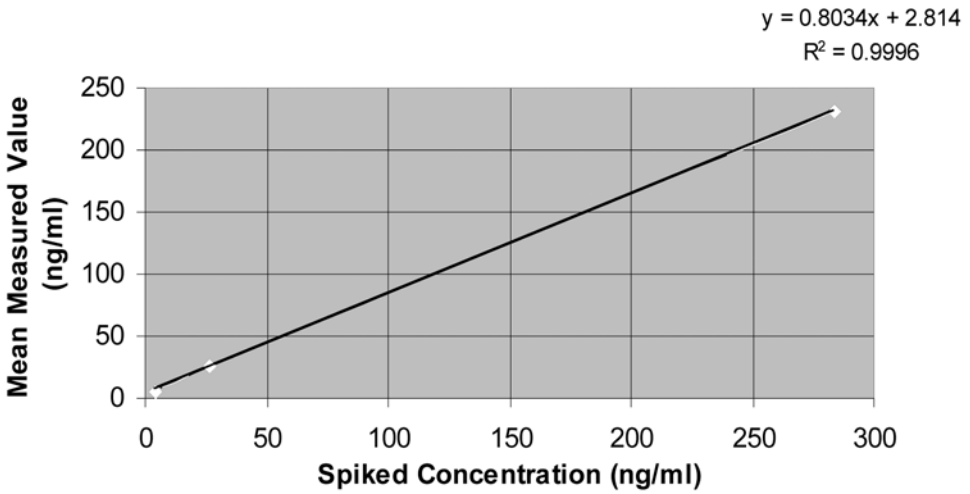

FIG. 2 Methylnaphthalene-d10 Mean Measured Value versus Spiked Concentration

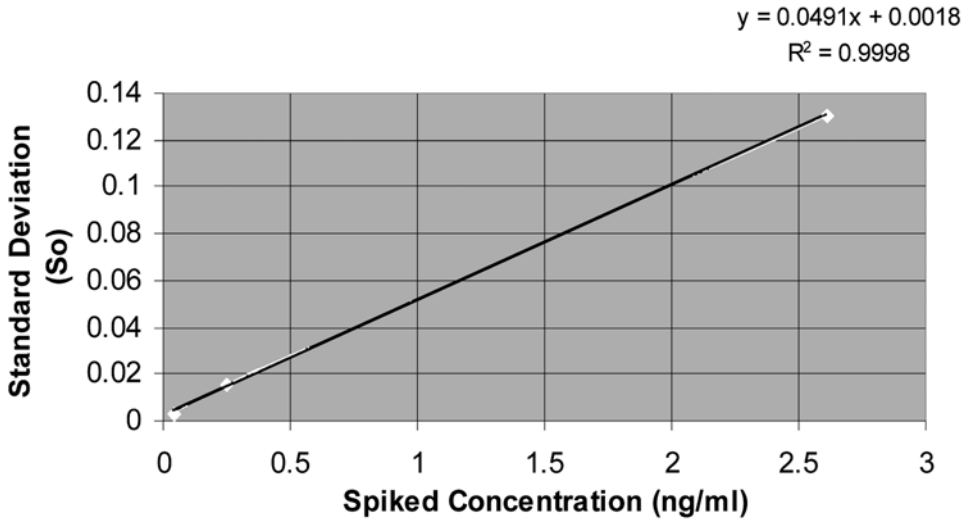

FIG. 3 Benz[a]anthracene-d12 Single Standard Deviation versus Spiked Concentration

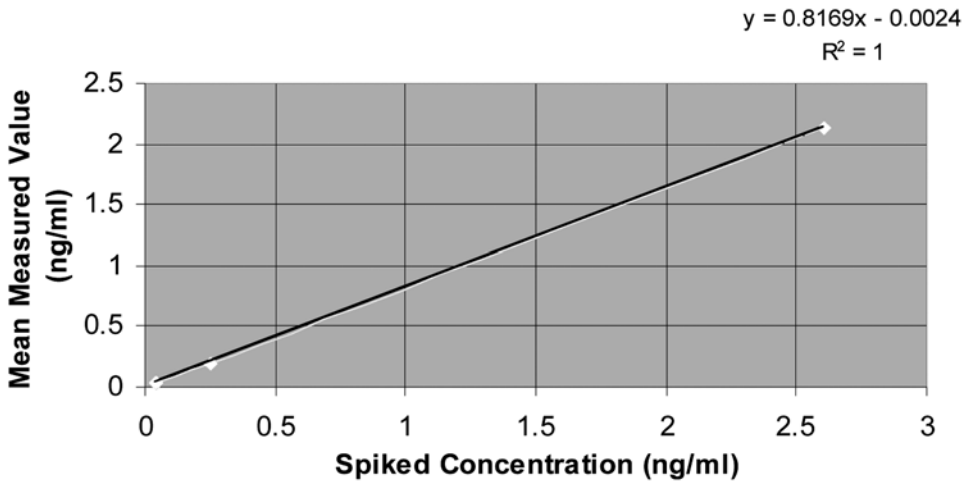

FIG. 4 Benz[a]anthracene-d12 Mean Measured Value versus Spiked Concentration

16.2.1 The following acceptance criteria will be used for daily duplicate calibration verifications: *(1)* The S/N ratio for the GC signals present in every SICP must be ≥10:1 for the labeled internal standards and the calibration compounds; *(2)*

The percent differences for the measured area ratio/ng of all analytes must be within ±25 % for high molecular weight PAHs and less than ±20 % for low molecular weight PAHs of the mean values established during the initial calibration.

16.2.2 The following corrective action will be adopted for daily duplicate calibration verifications if the first acceptance criterion is not satisfied: a new initial calibration curve must be established before sample extracts can be analyzed.

16.3 *Flocculation Blanks*:

16.3.1 The following acceptance criterion will be used for flocculation blanks: Prepared as needed to assess contamination from flocculation reagents and handling. Target analytes must not be detected above ⅓ of the target detection limits or >20 % of the associated sample result(s).

16.3.2 The following corrective action will be adopted for flocculation blanks: Locate the source of the contamination; correct the problem. Re-extract and reanalyze associated samples that are less than ten times the level of the contaminants present in the method blank.

16.4 *Extraction and Analytical Blanks*:

16.4.1 The following acceptance criterion will be used for extraction and analytical blanks: Analyzed between every sample to monitor the baseline. Target analytes must not be detected above ⅓ of the target detection limits or >20 % of the associated sample result(s).

16.4.2 The following corrective action will be adopted for extraction and analytical blanks: Locate the source of the contamination; correct the problem. Re-extract and reanalyze associated samples that are less than ten times the level of the contaminants present in the method blank.

16.5 *Signal to Noise Ration*:

16.5.1 The following acceptance criterion will be used for signal to noise ratio: The signal to noise (S/N) ratio for the GC signals present in every selected ion current profile (SICP) must be ≥3:1 for target compounds in environmental samples and ≥10:1 for the labeled internal standards.

16.5.2 The following corrective action will be adopted for signal to noise ratio: Reanalyze the sample unless obvious matrix interference is present.

MARINE CHEMISTRY

Black carbon in marine sediments

Jack J. Middelburg *, Joop Nieuwenhuize, Peter van Breugel

Netherlands Institute of Ecology, Centre for Estuarine and Coastal Ecology, P.O. Box 140, 4400 AC Yerseke, Netherlands

Received 9 September 1998; accepted 16 December 1998

Abstract

Concentrations of black carbon were determined for a number of marine sediments. A comparison of black carbon based on thermal oxidation and hot concentrated nitric acid pretreatments revealed that the latter significantly overestimates combustion derived carbon phases. Black carbon accounts for about 15 to 30% of total organic carbon and therefore reduces the fraction of unidentified sedimentary organic carbon. Examination of a relict oxidation front in a Madeira Abyssal Plain turbidite provided the first evidence for significant black-carbon degradation (about 64%) in marine sediments given time (10–20 kyr) and oxygen exposure.

Keywords: black carbon; soot carbon; organic carbon; sediments; degradation; Black Sea; turbidite; North Sea; Scheldt Estuary; Eastern Mediterranean

1. Introduction

Black carbon is usually defined as the highly condensed carbonaceous residue from incomplete combustion processes. It has been found omnipresent in the atmosphere, ice, soils and sediments due to its widespread production and its supposed chemical and microbiological inertness in the environment (Goldberg, 1985). Its distribution in the atmosphere has been investigated in detail because of its strong absorbance of solar radiation, its catalytic effects on chemical reactions and its importance to the global carbon cycle (Seiler and Crutzen, 1980; Kulbusch and Crutzen, 1995). Black carbon could represent a significant sink for carbon dioxide because vegetation fires and wood fuel combustion transfer carbon from the relatively fast biological-atmosphere carbon cycle to the long-term geological carbon cycle.

Estimates of global black carbon formation (0.05–0.270 Gt yr^{-1}; Kulbusch and Crutzen, 1995) are of the same order as those of riverine input of particulate organic carbon to the ocean (0.17 Gt yr^{-1}; Ludwig et al., 1996) and burial of organic carbon in marine sediments (0.13–0.6 Gt yr^{-1}; Berner, 1982; Middelburg et al., 1997). If these flux estimates are correct, black carbon should contribute considerably to the organic matter being buried in marine sediments.

The sedimentary record of black carbon has been used as a record of forest fires and fossil fuel emissions (Smith et al., 1973; Bird and Cali, 1998), and past atmospheric oxygen content, because the presence of charcoals provides a lower limit to atmospheric oxygen levels (Cope and Chaloner, 1980). Verardo and Ruddiman (1996) proposed that the

black carbon record may improve estimates of marine organic carbon burial and may contain paleo-environmental information. The distribution of black carbon in surface sediments may significantly affect the distribution, speciation and bioavailability of polycyclic aromatic hydrocarbons (Gustafsson et al., 1997; Gustafsson and Gschwend, 1998).

Here we compare two recently developed techniques for black carbon determinations in sediments (Gustafsson et al., 1997; Verardo, 1997) and apply them to surface sediments from the North Atlantic Ocean, the North Sea, the Eastern Mediterranean, the Black Sea, and an intertidal flat in the Scheldt estuary (The Netherlands). The contribution of black carbon to total organic carbon will be discussed. We will also present results from the oxidised and reduced sediment zones from a relict turbidite in the Madeira abyssal Plain which indicate that black carbon was degraded significantly within 10–20 kyr.

2. Materials and methods

There is no unique definition of black carbon (Goldberg, 1985; Kulbusch, 1995) and many terms are in use (e.g. soot, black carbon, elemental carbon and charcoal). The definition chosen usually reflects the operational technique applied or the processes studied. The former three terms are usually applied to the combustion products formed at higher temperatures than charcoal (Lim and Cachier, 1996). Following a review of the literature we selected two methods: (1) a thermal oxidation method for soot carbon (Gustafsson et al., 1997) and (2) the HNO_3 method for charcoal (Verardo, 1997). Both methods have specifically been developed for determination of low quantities of black carbon in complex sedimentary matrices containing refractory macromolecular organic matter and large amounts of carbonate minerals. They both rely on in situ acidification to remove inorganic carbonate and carbon analysis of the residue by an elemental analyser, but they differ in the pretreatment procedure to remove non-black-carbon organic matter.

Samples were thoroughly ground in an agate mortar mill and very well homogenised to reduce variability between replicates and to reduce any potential charring during thermal treatments. Organic carbon (OC) was determined according to Nieuwenhuize et al. (1994) and involves the determination of total carbon using an automatic elemental analyser (Carlo Erba type NA-1500) following the partitioning of inorganic and organic carbon phases by acidification with 25% HCl in situ within precleaned silver cups (12 mm × 5 mm; Van Loenen Instruments, D2010). The soot carbon method of Gustafsson et al. (1997) follows that for organic carbon, except that there is a pretreatment in which the samples are thermally oxidised at 375°C for 14 h in the presence of oxygen at atmospheric partial pressure. The carbon remaining after thermal oxidation and HCl acidification is considered to be soot (SC1). Gustafsson et al. (1997) have extensively tested their method with synthetic samples and observed no interference but for corn pollen which were partly recovered as soot. The average blank value for OC and SC1 is 4.1 μg C, which mainly originates from the Ag containers used.

The charcoal method of Verardo (1997) is also similar to the organic carbon method, except that aluminium containers are used, instead of HCl, 10 times 30 μl of concentrated nitric acid (50°C) is added, and that the chromatographic column was kept at 35°C instead of 80°C to better separate the nitrogen (derived from nitric acid) and carbon dioxide peaks. Recovery and interference tests indicated that refractory carbon in coal, humic acids and *Lycopodium* spore tablets were removed by the hot nitric acid treatment and that natural charcoal and elemental carbon were quantitatively recovered as charcoal (Verardo, 1997). For reasons given below, we will refer to this fraction as nitric acid resistant carbon (NARC) and not charcoal. Samples were also subjected to hot nitric acid treatment after thermal oxidation (SC2). The average blank value for NARC and SC2 is 5.1 μg C, which mainly originates from the nitric acid. Reproducibility of carbon measurements is better than 5% at concentrations above 0.1 wt.%, but is on the order of 20% at concentrations less than 0.05 wt.%.

Sediment samples were obtained from various locations covering a range of environments (Table 1). Sediments from the Molenplaat (MOL1–5), an intertidal flat in the Scheldt estuary, are sandy and dynamic. Sediments from the Iberian Margin (OMEX1–5) are carbonate-rich and cover a range of water depths and grain sizes. Black Sea sediments

OC: organic carbon concentration; SC1: carbon after thermal oxidation/HCl treatment; SC2: carbon after thermal oxidation/hot nitric acid treatment; NARC: hot nitric acid resistant carbon: SC/OC: contribution of soot carbon (average of SC1 and SC2) to organic carbon.

are from the north western shelf area including the mouths of the Danube (BS5), Dniestr (BS13) and Dnieper (BS15) and a transect from the Danube delta to the anaerobic, sulphide-containing deep basin (BS9, BS10, BS24, BS22, BS21). The samples from the North Sea, a continental shelf, have been investigated in detail for their biochemical composition and cover a range of degradation states and grain sizes

(Dauwe and Middelburg, 1998). Samples from the Madeira abyssal plain *f* turbidite (MAPox–red) have been studied in detail by Cowie et al. (1995) and Prahl et al. (1997) and will be used to estimate the extent of post-depositional oxidation of black carbon. Sediments from the Eastern Mediterranean comprise hemipelagic (MED1–2) muds and an organic-carbon rich sapropel (MED3; De Lange et al., 1994).

3. Results and discussion

3.1. Soot, charcoal and organic carbon contents

Soot concentrations determined with the thermal oxidation/HCl method (SC1) and thermal oxidation/HNO_3 method (SC2) are very well correlated ($r^2 = 0.96$; $n = 33$) with a slope (1.02 ± 0.04) and intercept (0.00 ± 0.04) not significantly different from 1 and 0, respectively (Fig. 1). This indicates that the fraction of carbon resistant to thermal oxidation (soot) is not removed by hot nitric acid. Although some pollen may survive thermal oxidation (Gustafsson et al., 1997), they are most likely degraded during acidification with hot concentrated nitric acid (Verardo, 1997).

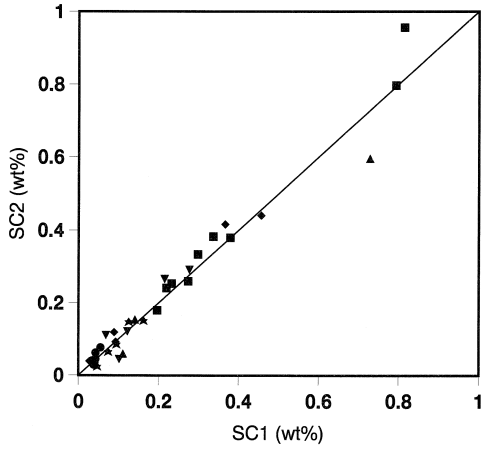

Fig. 1. Agreement between soot carbon results based on thermal oxidation/HCl treatment (SC1) and those based on thermal oxidation/hot nitric acid treatment (SC2). The solid line represents the best fit ($r^2 = 0.96$, $n = 33$): $SC2 = (1.02 \pm 0.04)SC1 + (0.00 \pm 0.04)$. Sample identification: dots: Molenplaat; stars: Iberian Margin; squares: Black Sea; rhombi: North Sea; inverted triangle: Madeira Abyssal Plain turbidite; triangle: Mediterranean.

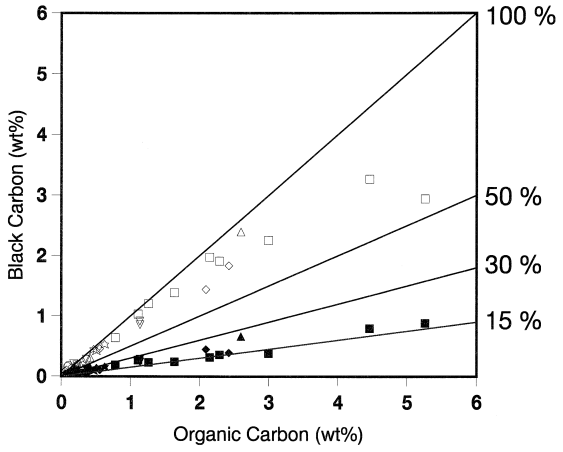

Fig. 2. Relation between organic carbon (OC), soot carbon (solid symbols, average of SC1 and SC2) and charcoal (NARC, open symbols). Lines representing 15, 30, 50 and 100% black carbon contributions to organic carbon are shown as well. Sample identification as in Fig. 1.

Soot contents range from 0.03 to 0.9 wt.% C (Table 1) and correlate with organic carbon contents (Fig. 2). Soot carbon contributes about 15 to 30% to total organic carbon with a tendency for deep-sea samples and other organic-carbon poor samples to contain a larger proportion of soot carbon (Fig. 3), perhaps an artefact of accumulated errors. Literature

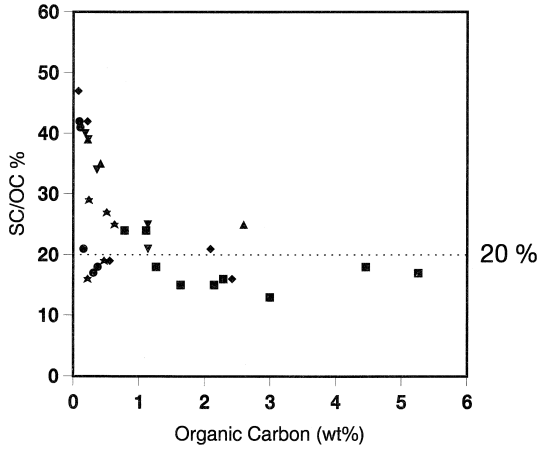

Fig. 3. Relation between organic carbon (OC) and the contribution of soot carbon (average of SC1 and SC2) to organic carbon (SC/OC). A line representing 20% black carbon contributions to organic carbon is shown as well. Sample identification as in Fig. 1.

data for the soot-to-organic carbon contribution range from 5 to 38% in Western Mediterranean sediments (Lim and Cachier, 1996) and 3 to 13% in North American shelf sediments (Gustafsson and Gschwend, 1998). The correlation between soot and organic carbon is probably due to their common dependence on grain size and hydrodynamic sorting during deposition.

Charcoal concentrations (NARC) based on the hot nitric acid digestion technique range from 0.08 to 3.2 wt.% and always account for more than 50% of the organic carbon (Fig. 2). Based on the same technique, Verardo and Ruddiman (1996) have reported that NARC was the dominant ($>50\%$) component of the organic carbon preserved in tropical Atlantic deep-sea sediments. If the NARC fraction indeed corresponds to charcoal, a product of terrestrial biomass burning, this would imply that the majority of organic carbon in marine sediments is terrestrial (charcoal and non-charcoal terrestrial carbon). This is clearly at odds with isotopic, elemental, NMR and molecular compositional constraints (Hedges and Oades, 1997; Bird and Cali, 1998). For instance, North Sea sediments contain at least 70% NARC and have $\delta^{13}C$ values ranging from -21.5 to -22.2‰ (Dauwe and Middelburg, 1998). If all NARC would be charcoal with a $\delta^{13}C$ of -27 to -26‰, this would imply that the marine organic carbon end-member should have $\delta^{13}C$ values heavier than -11‰. It is therefore more likely that hot nitric acid resistant carbon comprises not only charcoal (and soot), but also non-hydrolysable macromolecules from marine sources (De Leeuw and Largeau, 1993; Bird and Cali, 1998).

3.2. Black carbon and the unidentified fraction of sedimentary organic carbon

Despite significant improvements in analytical techniques and considerable efforts to characterise sedimentary organic carbon, a large fraction of it remains biochemically uncharacterised (Hedges and Oades, 1997). This unidentified fraction varies from about 40% in coastal sediments to more than 80% in deep-sea sediments. (e.g., Cowie et al., 1995; Wakeham et al., 1997; Dauwe and Middelburg, 1998). The major groups identified are amino acids, carbohydrates, lipids, and hexosamines (Cowie et al., 1995; Hedges and Oades, 1997). For a number of our samples there is additional information on the biochemical composition and the contributions of various biochemicals and soot carbon to total organic matter are shown in Fig. 4. The relative contributions of biochemical groups are remarkably similar: carbohydrates (8–19%), amino acids (8–19%) and hexosamines ($<2.2\%$). The total contribution of these hydrolysable fractions (17–41%) is similar to that of soot (16–42%), but smaller than the non-soot fraction (39–66%) that remains after hot nitric acid treatment ([NARC − SC]/OC). It therefore appears

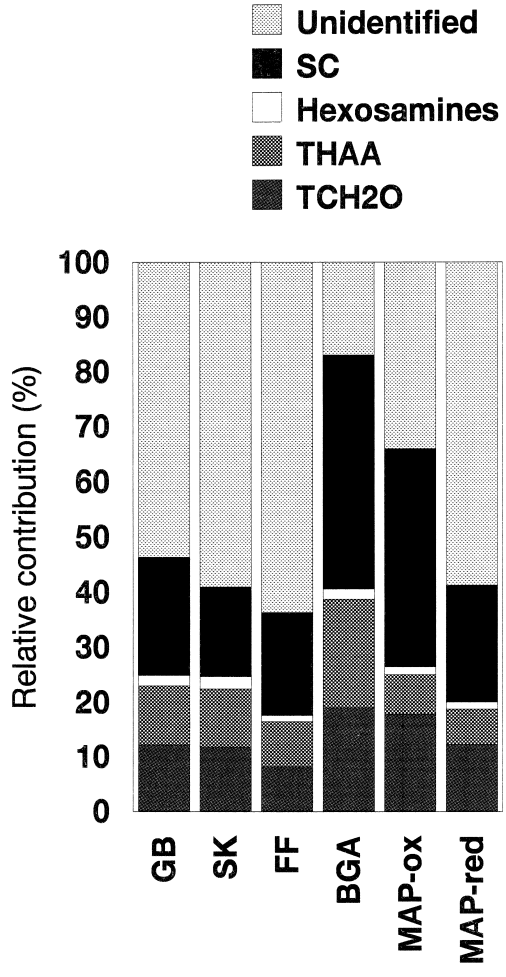

Fig. 4. Cumulative contribution of carbohydrates, total hydrolysable amino acids, hexosamines and soot carbon (SC) to total organic carbon. TCH_2O, THAA and hexosamine results for GB, SK, FF and BGA from Dauwe and Middelburg (1998) and for MAPox and MAPred from Cowie et al. (1995) and our own unpublished data.

that inclusion of black carbon in comprehensive analyses of sedimentary organic matter will significantly reduce the unidentified fraction.

3.3. Black carbon degradation

Black carbon is usually assumed to be chemically and biologically inert in the marine environment because (1) it has been identified in sediments of 65 Ma (Herring, 1985), (2) there is no down-core trend in size distribution of black carbon particles (Herring, 1985) and (3) it reacts very slowly towards chemical oxidation (Wolbach and Anders, 1989). Although microbiological breakdown during laboratory experiments has been reported (Potter, 1908; Shneour, 1966), there is as yet no information on degradation in marine sediments. The natural oxidation experiments provided by the Madeira Abyssal Plain *f* turbidite (Middelburg and De Lange, 1988; Prahl et al., 1989, 1997; Keil et al., 1994; Cowie et al., 1995) can be used to test the assumption of black carbon inertness. This distal turbidite originates from the northwestern African margin and was introduced to the Madeira Abyssal Plain about 140 kyr ago as a 4–4.5 m thick ungraded, uniform mud deposit (Middelburg and De Lange, 1988). The emplacement of this turbidite caused the exposure of labile and reduced components to oxic pelagic conditions. The post-depositional exposure to oxygen (and nitrate) under pelagic conditions during 10–20 kyr resulted in carbon removal in the uppermost section due to a downward progressing oxidation front (Wilson et al., 1985). A comparison between the organic matter concentrations and composition of the oxidised upper and reduced, unreacted lowermost section provides a unique opportunity to establish the extent of black carbon degradation.

Post-depositional oxidation of the upper section resulted in a decrease in total organic carbon from 1.14 to 0.25 wt.% and soot carbon from 0.27 to 0.10 wt.% (Fig. 5). Post-depositional oxidation removed about 77% of the organic carbon, but only about 64% of the soot carbon. Selective preservation of soot carbon increased its contribution to organic carbon from about 23 to 40% (Fig. 5) and is consistent with the preferential removal of marine organic matter and the selective preservation of terrestrial organic matter in these sediments (Prahl et al., 1997).

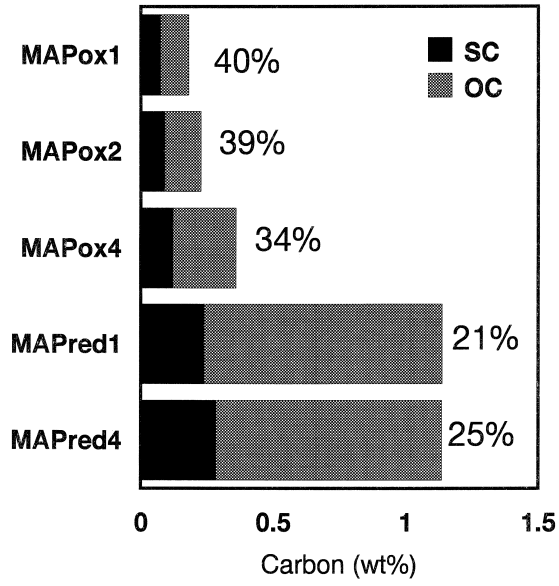

Fig. 5. Organic carbon (OC) and soot carbon (average of SC1 and SC2) in oxidised and reduced sections from the MAP *f* turbidite. MAPox1,2,4 have been subjected to extensive post-depositional oxidation, whereas MAPred1,4 have experienced little alteration since deposition. The relative contribution of soot carbon to organic carbon is also indicated.

These data definitely indicate that black carbon is degraded in marine sediments when exposed to oxygen (and nitrate), although the microbiological or chemical mechanisms involved remain unknown and require further study. Degradation of black carbon in marine sediments complicates the use of its sedimentary record to trace biomass burning (Herring, 1985; Verardo and Ruddiman, 1996; Bird and Cali, 1998) and to constrain past atmospheric oxygen levels (Cope and Chaloner, 1980). Our data also provide support for the oxygen exposure time impact on carbon preservation (Hartnett et al., 1998). It has been proposed that black carbon formation may represent a significant sink of atmospheric carbon dioxide and a minor source of oxygen (Kulbusch and Crutzen, 1995). This is based on the premise that black carbon is not degraded in the bio- and geosphere after formation. The observed degradation of black carbon in marine sediments during prolonged exposure to oxygen provides a small negative feedback between oxygen in the atmosphere (and ocean) and black carbon burial.

Acknowledgements

We thank Els Flach, Jeroen Wijsman, Peter Herman, Birgit Dauwe, Gert de Lange and Ralf Haese for providing samples and Carlo Heip, Birgit Dauwe and Eric Boschker for reading the manuscript. (*Received* 5 *March* 2007; *Accepted* 14 *May* 2007)

Abstract—Pesticide formulators formerly operating at Lauritzen Channel, a portion of San Francisco Bay near Richmond (CA, USA), caused contamination of sediment with dichlorodiphenyltrichloroethane (DDT). The present study evaluated the distribution of residual DDT in channel sediment six years following extensive remedial dredging. High DDT concentrations (up to 252 mg/kg) were found in Young Bay Mud sampled across the channel. Particle analyses showed most of the contamination is contained in the clay/silt sediment fraction, and desorption tests showed that availability is greater for DDT metabolites than parent DDT. The present study examined the feasibility of using activated carbon amendment to sequester DDT from sediment, including an evaluation of reactivated carbon as a less costly alternative to virgin activated carbons. Treatment success of activated carbon amendment to sediment collected from Lauritzen Channel was measured by reductions in aqueous equilibrium concentrations and uptake in semipermeable membrane devices (SPMDs). Four different activated carbons were tested and, after one month of treatment with 3.2 weight % carbon, DDT aqueous equilibrium concentrations were reduced up to 83% and SPMD uptake was reduced up to 91%. Reactivated carbon was comparable with virgin carbons in all tests. Reduction in SPMD uptake of DDT by treatment with 3.2% reactivated carbon increased to 99% after 26 months of treatment. The effectiveness of activated carbon was dependent on the type, size, dose, and contact time. The results show the potential usefulness of activated carbon amendment as a follow-up remedial technology for management of residuals after dredging contaminated sediment.

Keywords—DDT Sediment treatment Activated carbon amendment Dredging residuals Hydrophobic organic chemicals

INTRODUCTION

Dredging is the most prevalent ex situ approach for sediment remediation. However, problems with this approach include destruction of benthic habitat, incomplete removal of contaminated sediments, and resuspension of contaminated fines that may migrate to surrounding waters. Such limitations of dredging for management of contaminated sediments materialized at Lauritzen Channel, an active marine shipping terminal and industrial waterway connected to San Francisco Bay in Richmond, California, USA (Fig. 1). Several chemical processors conducted operations in this area from 1947 to 1966, including the pesticide formulator United Heckathorn. Chemical releases from processing and equipment washing caused DDT and dieldrin contamination in the embankment soil, sediment, and water of Lauritzen Channel [1]. The U.S. Environmental Protection Agency (U.S. EPA) added the United Heckathorn site to its National Priority List of Federal Superfund sites in March 1990, and a site history and description of embankment soil remedial actions can be found in Weston et al. [2]. The selected sediment remediation remedy was dredging and dewatering of all soft bay mud material with offsite disposal and placement of a clean material (sand) cap to enhance habitat value [3]. Remedial dredging was completed in 1997. Six years of postdredging marine monitoring of water and fauna by Pacific Northwest National Laboratory (PNNL) found residual DDT contamination levels exceeding the remediation goals of 0.59 ng/L and 0.59 mg/kg in water and sediment, respectively [4,5]. The highest sediment concentrations, greater than 1,000 mg/kg, were found under the eastern dock. Because the docks were not removed during dredging, contaminated sediment remained in this location. Total water DDT concentrations at the north end of the channel have remained consistently near 100 ng/L from 1991 to 2003 [5,6]. Several biological studies found remaining sediment toxicity to amphipods and DDT bioaccumulation in mussels [5,7]. After completion of remedial activities, Weston et al. [2] also found body burdens as great as or greater than before dredging.

The present study revisits the residual sediment contamination at Lauritzen Channel and proposes an in situ treatment strategy to sequester DDT and its metabolites. Sediment was collected at various locations in Lauritzen Channel to quantify the remaining DDT contamination residing at the sediment-water interface and at depth. Particle analysis and desorption kinetic testing further characterized the distribution of residual DDT and its metabolites in the sediment.

These results show the remedial action of environmental dredging proved ineffective for completely managing the DDT contamination at Lauritzen Channel. The remaining residual contamination continues to pose a risk to biota and human health more than six years after environmental dredging. The present study therefore investigates the in situ stabilization of residual DDT in sediment with activated carbon and tests the utility of reactivated carbon as a less costly alternative to virgin activated carbons. The efficacy of activated carbon amendment to sediment collected from Lauritzen Channel was measured using DDT aqueous equilibrium and uptake in semipermeable membrane devices (SPMDs) over two years of treatment in

laboratory studies. These investigations derive from work showing that, compared to other types of sediment particles, polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons accumulate to a much greater extent in black carbonaceous particles and become more strongly bound and less bioavailable [8–10]. Black carbonaceous particles comprise a portion of the total organic carbon in sediments that strongly affects the partitioning of hydrophobic organic chemicals, via nonlinear, extensive, and competitive adsorption [11]. Zimmerman et al. [12] proposed that, by mixing activated carbon into the biologically active upper layer of sediment, PCBs would repartition and be sequestered in the carbon, thus reducing PCB bioavailability and release to water. Physicochemical [12,13] and 28- and 56-d benthic organism uptake studies [14–16] found high effectiveness in reducing polycyclic aromatic hydrocarbon and PCB availability after mixing sediment with activated carbon. These experiments and modeling [17] show activated carbon amendment effectiveness is dependent on size, dose, and contact time of activated carbon.

EXPERIMENTAL METHODS

Sediment characterization

Vibracore sampling and analysis. Sediment was collected at various locations in Lauritzen Channel to study the remaining DDT contamination within the sediment down to historic Old Bay Mud. In May 2003, six years after dredging of the channel, PNNL conducted vibracore sampling. The composition of strata in each core was identified and described by PNNL. We sampled distinct strata of three different cores collected near the hotspot at the north end of Levin Pier. The cores sampled included Heck 03-01, Heck 03-03, and Heck 03-05, at locations shown in Figure 1. After collection, all samples were placed in cold storage (4°C). Before analysis, deionized water containing 1 g/L sodium azide was added to each jar to inhibit microbial growth. The jars then were homogenized by rolling (2 rpm) for one week. The sediment samples were dried at room temperature and powdered with a clean mortar and pestle.

Dried sediment samples (2 g) were mixed with anhydrous sodium sulfate to form a free-flowing powder. Sediment DDT was extracted three times with an acetone:hexane mixture (1:1), following U.S. EPA Ultrasonic Extraction Method 3550B (http://www.epa.gov/sw-846/pdfs/3550b.pdf). Pesticide-grade solvents were used in all extractions and cleanups. Extracts were exposed to activated copper to remove sulfur and concentrated under nitrogen.

A variation of U.S. EPA Method 3620B (http://www.epa.gov/sw-846/pdfs/3620b.pdf) was followed for cleanup of extracts. A 1-cm diameter chromatographic column was packed with activated Florisil PR (3 g; Fluka, Buchs, Switzerland) and anhydrous sodium sulfate (1 cm). The column was preeluted with 40 ml of hexane. Sample extract was transferred into the column and eluted with 30 ml of 20% dichloromethane in hexane. The eluents were solvent switched to hexane and concentrated under nitrogen. Dibromooctafluorobiphenyl was added as an internal standard to correct for volume differences.

Concentration analyses were performed with an Agilent 6890N (Santa Clara, CA, USA) gas chromatograph with an electron capture detector and a fused silica capillary column (HP-5, 60 m × 0.25 mm i.d., 0.25-μm film thickness). Quantification of six desired peaks including *p,p′*-DDT, *o,p′*-DDT, *p,p′*-dichlorodiphenyldichloroethane (*p,p′*-DDD), *o,p′*-DDD, *p,p′*-dichlorodiphenyldichloroethylene (*p,p′*-DDE), and *p,p′*-dichlorodiphenylmonochloroethylene (*p,p′*-DDMU) was achieved using standard solutions prepared from solid standards (UltraSci, N. Kingstown, RI, USA). Standard curves were checked against a chlorinated pesticides standard (TCL) Mix (Supelco, Bellafonte, PA, USA). The breakdown of DDT on the gas chromatograph was monitored using a *p,p′*-DDT standard, and no samples were quantified unless breakdown was below 15%. In reporting data, ΣDDT represents the sum of the six identified compounds.

Surface sediment sampling. In February 2003, a surface-sediment sample was collected at the north end of Lauritzen Channel using an Eckman dredge (Fig. 1). The collected sediment was sieved through a 0.5-cm mesh to remove large objects (gravel, shells, worms) and stored in a cold room (4°C) until further analysis and use. The total organic carbon of the sediment was measured at 2.8 weight % by an elemental carbon analyzer after acid treatment to remove carbonates (Huffman Laboratories, Golden, CO, USA).

Particle analysis. Surface sediments were separated into size fractions by wet sieving. A saturated solution of cesium chloride was used to produce two density fractions termed light and heavy, as described elsewhere [18]. The light fraction contained coal- and wood-derived particles, and sand, silt, and clays comprised the heavy mineral fraction. Light microscopy identified the particle types within the fractions, and tweezers were used to remove individual types particle greater than 0.25 mm for analysis. Identified particles included heavy density particles of shell and mineral, and light density particles were comprised of black carbon, plant materials, and charred and uncharred wood. Particles then were ground in 3 g of clean sand (Fluka) and extracted using described methods. Petrographic analysis (R&D Carbon Petrography, Monroeville, CA, USA), used historically to identify different coal particles [19], also was used to identify the amount of coal-derived particles and wood and plant material in the various fractions.

Desorption kinetics. Following previously described meth-

Table 1. Properties of activated carbons used in amendment studies. Surface area data provided by manufacturer

Carbon	Manufacturer	Type	Specific surface area (m^2/g)	Sizes tested (mm)
TOG®	Calgon Carbon (Pittsburgh, PA, USA)	Virgin	935	0.074–0.177 0.074–0.297
Filtrasorb® 400 (F400)	Calgon Carbon	Virgin	1,100	0.074–0.177 0.5–1
Aquacarb® 830 (AC830)	Westates Carbon (Santa Fe Springs, CA, USA)	Virgin	900	0.074–0.177 0.595–2.38
Aquacarb RS (ACRS)	Westates Carbon	Reactivated	900	0.074–0.177 0.595–2.38

ods [8,18,20], untreated sediment from a control bottle of the series 1 contact experiment was used in desorption studies lasting for 55 d to determine the mass of readily desorbing DDT and metabolites.

Activated carbon amendment tests

Activated carbon. As in previous studies [12,16], contact experiments were set up to measure activated carbon amendment effectiveness. In this study, three virgin activated carbons, including Filtrasorb® 400 (Calgon Carbon, Pittsburgh, PA, USA), TOG® (Calgon Carbon), and Aquacarb® 830 (Westates Carbon, Santa Fe Springs, CA, USA), were tested at differing sizes and doses. Aquacarb RS (Westates Carbon), a reactivated carbon, also was tested. Carbon properties and sizes tested are shown in Table 1. Before use, the activated carbons were boiled for 5 min to remove air pockets from pores.

Sediment-activated carbon contact: Series 1 comparing types and size of carbons. In the first series of tests, the four different activated carbons were used both in the as-received size provided by the manufacturer and as a common size achieved by grinding to 0.074 to 0.177 mm. Grinding the activated carbons does not result in an appreciable change in surface area. Large glass bottles were filled with surface-sediment collected in February 2003 (90 g dry sediment/L) followed by the addition of 3.2 weight % activated carbon, on a dry mass basis. This dose corresponds to about 1.1 times the existing total organic carbon in the sediment. Untreated sediment controls were set up without addition of activated carbon. The bottles were rolled at 2 to 3 rpm for 31 d, and then the sediment was used for SPMD and aqueous equilibrium tests.

Sediment-activated carbon contact: Series 2 comparing dose of reactivated carbon. Aquasorb RS (ACRS) reactivated carbon was tested further at the as-received size and at a smaller size at three different doses each, for a total of six treatments plus an untreated control. Glass bottles were filled with surface-sediment collected in February 2003 (170 g dry/L) followed by the addition of either as-received sized (0.595–2.38 mm) at 3.2, 6.4, and 9.6 weight % or ground reactivated carbon (0.074–0.177 mm) at 0.8, 1.6, and 3.2 weight %, on a dry mass basis. The bottles were rolled at 2 to 3 rpm for over two years, with aliquots for SPMD tests removed after 1, 6, and 26 months.

Aqueous equilibrium concentration. The glass bottles from series 1 containing treated or untreated sediment were filled with deionized water and 1 g/L sodium azide. The bottles were rotated at 2 to 3 rpm for 14 d, after which the sediment/water mixture was allowed to settle. Duplicate water samples then were taken from the bottles, and colloids were removed using a flocculation technique described previously [21]. The aqueous phase was extracted with hexane following U.S. EPA method 3510C (http://www.epa.gov/sw-846/pdfs/3510c.pdf) for liquid-liquid extraction. All extracts were cleaned and analyzed for ΣDDT using the described method.

Semipermeable membrane devices. The SPMDs are biomimetic devices used for assessing the passive uptake of DDT in water [22]. Custom-made SPMDs 5-cm long and filled with 0.05 g triolein (EST Labs, St. Joseph, MO, USA) were used. Approximately 20 g of activated carbon treated or untreated sediment from series 1 and 2 experiments was added to a 40-ml clear glass vial. The vial was filled with deionized water and 1 g/L sodium azide and rotated for 14 d. Cleanup and dialysis of SPMDs followed previously described procedures [12]. All extracts were cleaned and analyzed for ΣDDT using the described method.

Quality assurance and control. Validation of procedures was completed prior to sample analysis. Spiked clean sediment matrices achieved ΣDDT recovery of 76 to 91% across six replicates. Blank sediment matrix and method replicates reported no ΣDDT. Liquid-liquid extraction achieved 93 to 100% recovery of ΣDDT across three replicates. The calculated method limit of detection was 0.1 μg/L in all final extracts. However, procedurally, sufficient sample was used to achieve levels above 1 μg/L for all metabolites in final extracts, which corresponds to 0.5 ng DDT/g dry sediment.

RESULTS AND DISCUSSION

Characterizing contamination in sediment

Vibracores. The vibracore sampling was used to quantify DDT concentration in soft, Young Bay Mud that overlies historic, hard Old Bay Mud. The vibracores also were used to assess whether the nominal 12-inch (30.5 cm) sand layer [23] applied after dredging was intact six years later. A typical vibracore collected by PNNL in May 2003 contained Young Bay Mud, which is indicated by softer consistency, fine grain size, and a dark gray to black color near the sediment-water interface [5]. Table 2 describes the consistency and measured DDT concentrations in the strata of the three sampled vibracores. Core Heck 03-01, located across the channel from the hotspot delineated by PNNL, contained 1 foot (30.5 cm) of Young Bay Mud with the highest concentration in all the samples (252 mg/kg ΣDDT) with tan Old Bay Mud below. No sand was noted between the Young Bay Mud and Old Bay Mud layers. The core taken from the middle of the channel, Heck 03-03, contained highly contaminated Young Bay Mud (12.7–62.1 mg/kg ΣDDT) overlying Old Bay Mud containing ΣDDT at levels less than the 0.59 mg/kg ΣDDT remediation goal (0.1–0.4 mg/kg ΣDDT). Again, no distinct sand layer was noted in the core. In the core Heck 03-05, located closest to

Table 2. Sediment descriptions and sum DDT (ΣDDT) concentrations in vibracores containing Young Bay Mud (YBM) and Old Bay Mud (OBM). Concentrations are an average of three replicates with a standard deviation (SD) or two replicates with the relative percent difference (RPD) reported

Core Heck 03-01		
Depth interval (cm)	Description	ΣDDT (mg/kg)
0–12 inches (0–30.5)	Black YBM, fine silt and clay	252 (SD: 1%)
12–27 inches (30.5–69)	Tan OBM with sand	
27–40 inches (69–102)	Tan OBM more clay, stiffer, denser	
Core Heck 03-03		
Depth interval (cm)	Description	ΣDDT (mg/kg)
0–10 inches (0–25)	YBM, silty clay, smooth, black	12.7 (SD: 25%)
10–16 inches (25–41)	YBM, black clay, some sandy texture	62.1 (SD: 9%)
16–20.5 inches (41–52)	OBM, gray clay	
20.5–24.5 inches (52–62)	OBM, brown	3.2 (RPD: 11%)
24.5–30 inches (62–76)	Sand mixed with clay, reddish brown	0.4 (RPD: 11%)
30–34 inches (76–86)	OBM, brown stiff smooth clay	0.1 (RPD: 4%)
34–36 inches (86–91)	Sandy clay, brown	
Core Heck 03-05		
Depth interval (cm)	Description	ΣDDT (mg/kg)
0–1 inches (0–2.5)	Black YBM, clay, soft	7.5 (SD: 4%)
1–24 inches (2.5–61)	Black YBM, clay, soft	14.7 (SD: 9%)
24–27 inches (61–69)	Olive green sand	15.4 (SD: 10%)
27–34 inches (69–86)	YBM, black	151 (SD: 7%)
34–48 inches (86–122)	OBM, gray clay, dry crumbly	0.9 (SD: 29%)

the hotspot, Young Bay Mud was found both above and below a 3-inch (7.6 cm) sand layer. In this location, a highly contaminated Young Bay Mud layer (151 mg/kg ΣDDT) lay between the sand layer and Old Bay Mud containing levels of ΣDDT slightly above the remediation goal.

These three cores show highly contaminated Young Bay Mud exists across the channel and up to 2 feet (61 cm) in depth. At the water-sediment interface, the Young Bay Mud contains DDT at levels ranging from 4 to 428 times the remediation goal. These high levels act as a DDT source to the water column and to the benthic biota in the area. A distinct sand layer was noted in only one of the three cores reported here, and in a total of only three of 16 vibracores collected throughout the channel by PNNL in 2003 [5]. Therefore, the sand layer applied after dredging with an expected depth of 12 inches (30.5 cm) [23] either was not applied evenly or has since washed away. Also, because highly contaminated sediment was found below the sand layer in core Heck 03-05, this sample suggests not all Young Bay Mud was removed during dredging prior to sand layer application.

Particle analysis

Sediment characterization quantified the amount of ΣDDT in different size fractions and types of particles. Analysis of sieved grain sizes in a mixed sample of surface sediment from Lauritzen Channel shows the sediment clay/silt (<63 μm) fraction comprises 82% of the sediment mass and contains 77% of the ΣDDT (in Supplemental Data; http://dx.doi.org/10.1897/07-179.S1). The light density sediment fraction comprises 6% of the total mass and contains 37% of ΣDDT. Investigations by Ghosh et al. [9] with Hunters Point sediment from South Basin, San Francisco Bay, found 5 to 7% of the total sediment mass resided in the light fraction but accounted for 68% of the PCBs. For Lauritzen Channel sediment, light particles certainly contain a greater absolute amount of DDT by mass, but not to nearly to the extent seen in other harbor sediments. Petrographic analysis of Lauritzen Channel sediment identified very little black carbon particles such as coal, coke, or byproduct-related materials (0.6% by volume). In contrast to the dominance of charcoal and coal in the Hunters Point light-density sediment fraction, the Lauritzen Channel light-density sediment fraction mostly consists of wood or humic plant material.

Extraction of different classes of particles from Lauritzen Channel sediment found that black and wood particles had the highest ΣDDT concentrations; minerals and shell had statistically lower concentrations by about one order of magnitude (in Supplemental Data; http://dx.doi.org/10.1897/07-179.S1). The light density particles therefore have significantly (t-test, $p = 0.05$) higher DDT concentrations, likely due to the higher sorptive capacity of plant-derived organic and black carbon particles. However, as Lauritzen Channel sediment lacks many black carbonaceous particles and mostly is comprised of fine-grained, inorganic minerals, 94% as revealed by both petrography and density separation, the majority of ΣDDT (61%) resides in the fine, heavy density mineral fraction. Because of these Lauritzen Channel sediment characteristics, adding small amounts of highly sorptive activated carbon to the sediment likely would have a significant effect on the partitioning and availability of DDT.

Desorption from sediment

Figure 2 shows the measured desorption of *p,p′*-DDT and its metabolites into the water over 55 d. At the end of the test period, the extent of desorption of DDT metabolites exceeded 57% of the total mass. In contrast, the *p,p′*-DDT desorbed to a much lesser extent (20%) in the same time interval. The same phenomenon of more rapid release and uptake of DDT metabolites compared to *p,p′*-DDT was noted in aqueous equilibrium concentration tests and SPMD uptake data, as sub-

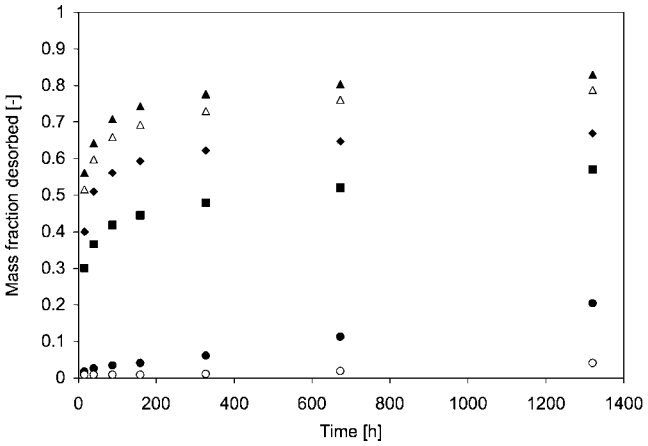

Fig. 2. Mass fraction of DDT and its metabolites desorbed from Lauritzen Channel (Richmond, CA, USA) untreated sediment over 55 d. Each point is an average of two replicates. Data are shown for *p,p′*-DDT (●), *o,p′*-DDT (○), *p,p′*-dichlorodiphenyldichloroethane (DDD) (▲), *o,p′*-DDD (△), *p,p′*-dichlorodiphenyldichloroethylene (DDE) (■), and *p,p′*-dichlorodiphenylmonochloroethylene (DDMU) (◆).

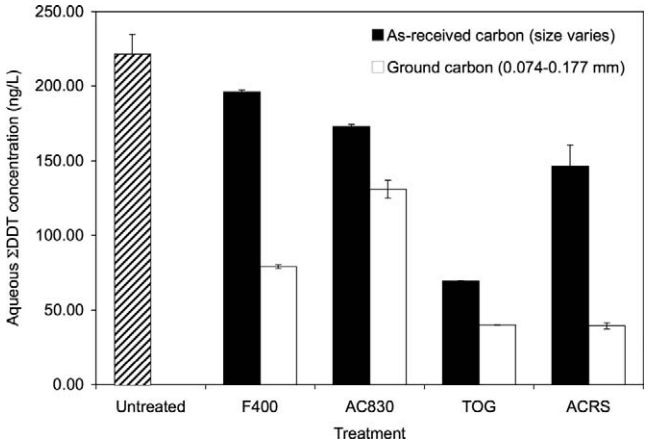

Fig. 3. Aqueous sum DDT (ΣDDT) concentrations for Lauritzen Channel sediment (Richmond, CA, USA) amended with 3.2 weight % of four types of activated carbon (F400, AC830, TOG, ACRS) for one month, comparing the as-received manufacturer size and a smaller size. The average and range of two or three replicates are represented.

sequently discussed. Desorption did not reach an equilibrium plateau during the 55-d test period as shown in Figure 2. These results show *p,p′*-DDT is desorbed less readily from Lauritzen Channel sediment in the time frame of the activated carbon tests. Jafvert et al. [24] noted a similar extreme desorption resistance for DDT from sediment over 46 d of gas-purged–induced desorption with DDT, DDD, and DDE averaging of 22, 58, and 75% of release, respectively. These data show DDT metabolites exhibit faster release and thus probably greater bioavailability than parent DDT.

With such widespread residual contamination and continued bioavailability of ΣDDT to the water column, the use of an alternative means for sediment remediation is appealing. Thus, activated carbon amendment was evaluated in feasibility tests with Lauritzen Channel sediment as a possible method to sequester residual DDT.

Activated carbon amendment

Series 1 comparing types and size of carbons. The results of this study show that both activated carbon type and size affect the extent of reduction in SPMD uptake or aqueous equilibrium concentration after sediment treatment. Figure 3 shows the aqueous equilibrium concentrations for the four different types of carbon at two different sizes. Untreated sediment has an aqueous equilibrium concentration of 222 ng/L ΣDDT. The as-received sized virgin coal carbons F400 and AC830 produce modest (15 and 19%, respectively) reduction in aqueous phase ΣDDT as compared to the average untreated control. In these short-term tests, the effect of grinding the activated carbon was significant, resulting in 66 and 43% reduction, respectively. Higher effectiveness was noted for type TOG carbon, which has been used in previous studies with PCBs [12], as well as ACRS, a reactivated carbon. Virgin type TOG activated carbon in its as-received and ground sizes showed 67 and 83% reduction in aqueous phase ΣDDT concentration. The ground, reactivated ACRS carbon showed a similar reduction in aqueous phase ΣDDT (83%), proving it as an alternative to more expensive virgin carbons for sediment treatment. If the 83% reduction noted in aqueous equilibrium studies was achieved for dissolved ΣDDT concentrations measured in the field at the north end of Lauritzen Channel in 2002 and 2003 [5], the remediation goal of 0.59 ng/L would be nearly met in 2002 (4.51 ng/L reduces to 0.77 ng/L ΣDDT), and water quality would have been much improved in 2003 (22 ng/L reduces to 3.7 ng/L ΣDDT). The overall reductions noted in ΣDDT concentrations are similar to the 87% reduction obtained for aqueous PCB concentration after one month of treatment of Hunters Point sediment with 3.4 weight % virgin carbon [12].

The same trends of reduced DDT availability in activated carbon–amended sediment were apparent in the SPMD uptake data. The results from batch experiments are presented as reduction in SPMD uptake compared to untreated sediment in Figure 4. The highest reduction in SPMD uptake was seen for the type TOG (80%) and ACRS (91%) ground carbons. The data in Figures 2 through 5 indicate the system is limited kinetically, because differing sizes of the same carbon do not perform alike. Longer treatment times, therefore, would increase effectiveness, as observed in the series 2 experiments

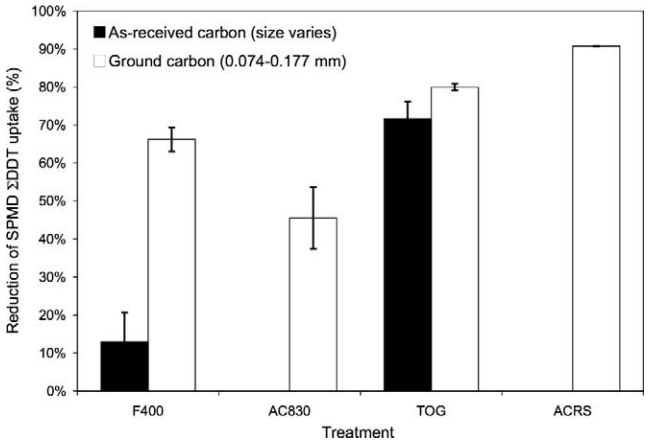

Fig. 4. Reduction in sum DDT (ΣDDT) uptake in semipermeable membrane device (SPMD) for Lauritzen Channel (Richmond, CA, USA) sediment after amendment with 3.2 weight % of activated carbon for one month using the as-received manufacturer size and a ground size. The average and standard deviation of three replicates are represented for four different activated carbons (F400, AC830, TOG, ACRS) and two particle sizes.

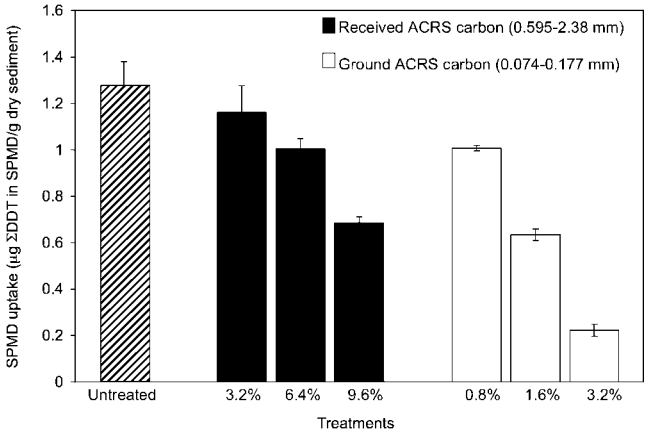

Fig. 5. Sum DDT (ΣDDT) semipermeable membrane device (SPMD) uptake for Lauritzen Channel (Richmond, CA, USA) sediment amended with different doses of Aquasorb® RS reactivated carbon (ACRS) for one month in the received manufacturer size and a grinded size. The average and standard deviation of three replicates are represented.

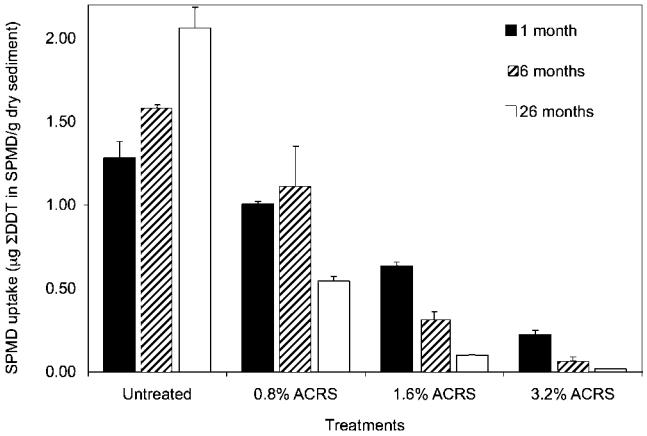

Fig. 6. Sum DDT (ΣDDT) uptake in semipermeable membrane device (SPMD) for Lauritzen Channel (Richmond, CA, USA) sediment amended with different doses of ground (0.074–0.177 mm) Aquasorb® RS reactivated carbon (ACRS) for one, six, and 26 months of contact time. The average and standard deviation of three replicates are represented.

described below (see *Series 2 comparing dose of reactivated carbon* section).

As shown in the desorption experiments, *p,p′*-DDT desorbs from Lauritzen Channel sediment to a much less extent than its metabolites. A similar trend was noted in the case of the mass of DDT partitioning into the SPMDs. A total of 24% of *p,p′*-DDD transferred from the untreated sediment to the SPMD over two weeks as compared to 1% of *p,p′*-DDT. Octanol-water partitioning coefficients (K_{OW}) and a linear free energy relationship, reported in Schwarzenbach et al. ([25], Eqn. 9–26a), were used to estimate organic carbon-normalized partition coefficients (K_{OC}) for the *p,p′* isomers of DDE, DDE, and DDT.

$$\log K_{OC}\ [\text{L/kg}] = 0.74 \cdot \log K_{OW} + 0.15$$

Apparent experimental K_{OC} values were calculated using

$$C_s/C_w = K_d = f_{OC} \cdot K_{OC}$$

where the distribution coefficient (K_d) is the quotient of the aqueous equilibrium concentration data for sediment (C_s) and water (C_w) for untreated Lauritzen Channel sediment. As reported in Table 3, apparent log K_{OC} values of 6.6, 6.3, and 8.3 for *p,p′*-DDE, DDD, and DDT, respectively, were calculated using the measured native organic carbon content (f_{OC} = 2.8%). The apparent K_{OC} values for *p,p′*-DDE and *p,p′*-DDD are two orders of magnitude greater than those estimated from literature [25]. The observed K_{OC} for *p,p′*-DDT is nearly four orders of magnitude greater than estimated values, again showing the low desorption potential of *p,p′*-DDT from Lauritzen Channel sediment.

Series 2 comparing dose of reactivated carbon. Because reactivated carbon was found highly effective in series 1 tests, complimentary tests examining different doses and treatment times with type ACRS reactivated carbon were completed. Figure 5 shows SPMD uptake results for dosing with 3.2, 6.4, and 9.6 weight % as-received ACRS carbon and 0.8, 1.6, and 3.2 weight % ground carbon in one-month treatment studies. For the larger carbon, as the dose was increased, SPMD uptake was reduced by 8, 20, and 46%. Doubling the dose corresponds to near doubling the effectiveness. For the ground ACRS carbon, an increase in SPMD uptake reduction with increasing dose also was noted (21, 50, 87%).

A numerical mass transfer model developed by Werner et al. [17] estimates reductions in aqueous and SPMD uptake upon addition of activated carbon. This model predicts that, at equilibrium, increasing the dose will increase proportionally the observed reduction in aqueous phase or SPMD PCB concentration. Experimental data from this study agrees with the trend suggested by the model's prediction of dose-effect.

Figure 6 shows ΣDDT uptake in a SPMD after 1, 6, or 26 months of treatment with increasing doses of ground (0.074–

Table 3. Apparent versus literature estimated partitioning coefficients of DDT compounds in untreated Lauritzen Channel (Richmond, CA, USA) sediment

[e] DDD = dichlorodiphenyldichloroethane.

0.177 mm) type ACRS reactivated carbon. As the treatment time increases, the uptake of ΣDDT in a SPMD was reduced significantly. The effectiveness of reactivated carbon for sequestering DDT was not diminished over 26 months of treatment, demonstrating that DDT was not rereleased from the activated carbon. For the 3.2 weight % dose, a reduction of 99% in SPMD uptake was noted after 26 months of contact with reactivated carbon. This data shows the positive effect of dose and that a lower dose (1.6%) can produce high reduction (95%) at long treatment time.

CONCLUSION

Results from this work show that, despite extensive environmental dredging, high levels of available ΣDDT remain in Lauritzen Channel sediment. DDT metabolites are less strongly sorbed to the sediment than parent DDT. Amendment of field-collected residual sediments with activated carbon resulted in large reductions in aqueous equilibrium concentration and SPMD uptake. Aqueous phase concentration was reduced up to 83% with one month of treatment, and SPMD uptake reduced from 91 to 99% during 1 to 26 month treatment with 3.2 weight % reactivated carbon. Effectiveness of treatment increases with contact time and decreasing activated carbon particle size, and varies for different activated carbons with similar surface areas. Reactivated carbon was found to be as effective as virgin carbon in sequestering ΣDDT. Reactivated carbon is significantly less costly than virgin carbons, and thus it has a cost-advantage in field-scale treatment.

In total, the present study supports the use of activated carbon amendment to manage residual DDT contamination that may remain after environmental dredging. These results show the effectiveness of activated carbon amendment to reduce the availability of DDT in field sediments, as found previously for PCBs and polycyclic aromatic hydrocarbons. Hence, activated carbon amendment might be especially useful at sites with a mixture of legacy hydrophobic pollutant contamination to achieve the ideals of high containment effectiveness, limited taxing of the ecosystem, and low costs.

(*Received* 1 *July* 2003; *Accepted* 30 *April* 2004)

Abstract—The sorption of polycyclic aromatic hydrocarbons (PAHs) to soot carbon in marine sediments has been hypothesized to reduce PAH bioavailability. This hypothesis was tested for eight species of marine benthic invertebrates (four polychaete worms, *Clymenella torquata*, *Nereis virens*, *Cirriformia grandis*, and *Pectinaria gouldii*, and four bivalve mollusks, *Macoma balthica*, *Mulinia lateralis*, *Yoldia limatula*, and *Mya arenaria*) that span a wide range of feeding behavior, ability to metabolize PAHs, and gut chemistry. Organisms were exposed for 20 d to two PAH-spiked sediments, one with soot and one without soot. The soot treatment generally resulted in lower bioaccumulation than the no soot treatment, though the differences between treatments were not significant for all species. All but one species accumulated significant PAH concentrations in their tissues from the soot treatment, indicating that soot-bound PAH cannot be dismissed as unavailable to infaunal benthic biota. Bioaccumulation factors were correlated negatively to both the organisms' ability to metabolize PAHs and the gut fluid contact angle, supporting the hypotheses that high PAH metabolism results in lower bioaccumulation factors and bioavailability of PAHs may be limited partially by PAH solubilization in the gut lumen. The variability in bioaccumulation due to the soot treatment was much less than the variability between species and between PAH analytes. Comparatively low bioaccumulation was observed in *Nereis virens*, a species commonly used in bioaccumulation tests. These results suggest that more effort is needed in understanding the salient characteristics of species present in a threatened environment, rather than focusing solely on the sediment geochemistry (e.g., soot and organic carbon content) and contaminant characteristics when predicting ecological risk of PAH-contaminated sediments.

Keywords—Polycyclic aromatic hydrocarbon Bioavailability Soot Gut fluid Metabolism

INTRODUCTION

Soot carbon, also referred to as black carbon, can be described as a carbonaceous residue resulting from the incomplete combustion of organic matter [1]. The term soot carbon has been used to describe many types of carbon residues resulting from high temperature alteration of organic carbon, including charcoal, fly ash, carbon black, and elemental carbon, which hereafter will be referred to as soot. Soot particles have a high degree of aromatic structure and contain reactive oxygenated surface functional groups (e.g., carbonyls, carboxyls, and ethers) [2]. Recent studies have suggested that the affinity of polycyclic aromatic hydrocarbons (PAHs) for soot carbon is linked to their planar aromatic structure and it is hypothesized that the two interact by establishing pi–pi bond interactions [3].

The presence of soot carbon in marine sediments has been proposed to explain observed PAH organic carbon normalized distribution coefficients (K_{oc}) that are much higher than predicted based on equilibrium partitioning to sedimentary organic carbon [4–6]. Research also has shown that a very high proportion of PAHs in sediment likely are associated with soot-like particles and that partitioning to the soot-carbon fraction of the sedimentary organic carbon can dominate equilibrium partitioning processes [7,8]. Soot is ubiquitous in marine sediments, with U.S. coastal waters containing from 0.11 to 6.6 mg/g dry sediment of black carbon (3–14% of the total organic carbon) [9,10]. Gustafsson et al. [4] have proposed that sediment quality criteria for PAHs should be revised to reflect the important role of soot carbon on PAH partitioning. This is accomplished through an extension of equilibrium partitioning to account for the strong sorption of PAHs to soot carbon using a soot carbon partition coefficient (K_{sc}). The model of Gustafsson et al. [4] has been further refined by Accardi-Dey and Gschwend [7] to include nonlinearity of PAH sorption to soot carbon:

$$K_d = f_{oc} \cdot K_{oc} + f_{sc} \cdot K_{sc} \cdot C_w^{n-1} \quad (1)$$

where K_d is the sediment–water partition coefficient, f_{oc} and f_{sc} are the fraction organic and soot carbon in the sediment, respectively, C_w is the truly dissolved PAH concentration in sediment pore waters, and n is the Freundlich exponent of the PAH-soot carbon relationship being investigated.

Little research has been conducted to directly evaluate the effect of soot carbon in sediments on PAH bioavailability to infaunal biota. Elevated petrogenic (e.g., characterized by a signature of high alkylated/parent PAH ratios) relative to pyrogenic PAH in organism tissues suggest that the combustion-derived pyrogenic PAH are less bioavailable [11]. However, the composition of PAHs in organism tissues also may be affected by differences in metabolism/depuration rates rather than differences in bioavailability [12,13]. The few studies that have endeavored to investigate directly the effect of soot carbon on PAH bioavailability suggest that the presence of soot

Presented at the 23rd Annual Meeting, Society of Environmental Toxicology and Chemistry, Salt Lake City, Utah, USA, November 16–20, 2002.

does result in reduced bioavailability [2,14]. Lamoureux and Brownawell [15] found reduced PAH desorption and bioavailability to a deposit-feeding polychaete, *Nereis succinea*, from soot-amended sediments. However, the difference in bioaccumulation between the soot/no soot treatments was not as pronounced as the difference in the rates of desorption in seawater measured using XAD (Sigma-Aldrich, Milwaukee, WI, USA) resin.

High surfactant levels in the gut fluids of deposit-feeding invertebrates are one reason that soot-bound PAHs still may be bioavailable to some species despite strong binding. Solubilization of sediment-bound PAHs by gut fluids of deposit-feeding benthic invertebrates has been shown to correlate well with assimilation efficiency and bioaccumulation [16–18]. Furthermore, contact angle, a simple estimation of the surfactant strength of gut fluids, has been shown to correlate well with the extent of PAH desorption by organism gut fluids across several different phyla [19]. Polycyclic aromatic hydrocarbon desorption from various soot-like matrices in the gut fluid of *Arenicola marina*, a deposit-feeding polychaete, has been shown to exceed predictions by soot-corrected equilibrium partitioning [20].

Benthic invertebrates also vary in other important characteristics that may affect PAH bioaccumulation and account for deviations from equilibrium partitioning predictions derived from bulk sediment properties. Such factors include feeding behavior (e.g., head-down vs surface deposit feeders, filter feeders, carnivores, etc.), size-selective particle ingestion (e.g., selection for or against organic carbon and contaminant-enriched size fractions), gut passage time, depletion of PAH concentrations in the local environment (e.g., enhanced degradation and contaminant flux across sediment/water interface in infaunal burrows) [21–26]. The ability of organisms to metabolize and excrete PAH also has been shown to be related to bioaccumulation, where species with limited metabolic ability tend to accumulate higher PAH concentrations in their tissue [27–29]. Present approaches to bioaccumulation modeling generally ignore species-specific biology (other than total lipid content and, in some cases, growth rates) that may affect the apparent steady state concentration of PAHs in organism tissues.

The nature of the particular PAH being examined also is important to consider. Field studies show that bioaccumulation of PAHs generally either decreases with increasing octanol–water partition coefficient (K_{ow}) or exhibits a maximum at midranged logK_{ow} values of 5 to 5.5 (possible reasons for reduced accumulation of lower K_{ow} compounds include faster depuration rates and/or depletion of microhabitat in the exposure sediments) [12,30–32].

This study was designed to examine the influence of soot on the bioavailability of PAHs to benthic organisms that vary in their gut fluid surfactant strength and metabolic abilities. This was accomplished by exposing eight infaunal marine species to two PAH-spiked sediments, one with and one without soot. Bioaccumulation factors ([BAFs], from sediment to organism) for a diverse mixture of PAHs were then calculated and interpreted in relation to the treatment effect as well as other physiological parameters thought to affect PAH bioaccumulation (e.g., PAH metabolism, feeding mode, and gut fluid surfactant strength). We hypothesized that soot would limit the bioavailability of PAHs, that sediment-sorbed PAHs would be accumulated to greater extent by deposit-feeding as compared to filter-feeding organisms, the soot treatment effect would be minimized in deposit-feeding organisms with higher levels of gut surfactancy, and organisms with greater ability to metabolize PAHs would accumulate them to a lesser extent that those with limited metabolic capability.

MATERIALS AND METHODS

Organisms

Organisms used in this experiment were collected in September 2000 from intertidal areas adjacent to Ponquogue Bridge, Hampton Bays, New York, USA (*Clymenella torquata*, *Nereis virens*, *Cirriformia grandis*) and from intertidal areas in Stony Brook Harbor, New York, USA (*Mya arenaria*) or obtained from the Marine Biological Laboratory, Woods Hole, Massachusetts, USA (*Macoma balthica*, *Pectinaria gouldii*, *Mulinia lateralis*, *Yoldia limatula*). Taxonomic groups and feeding types are found in Table 1. The average wet weight of individual organisms ranged between 0.1 and 0.5 g for all species except *M. arenaria* and *M. balthica*, which averaged 1.0 each. Juvenile *M. arenaria* and *M. balthica* were used, but all the other species were adults. All organisms were considered to be from environments with limited hydrocarbon sources that were verified by chemical analysis of organism tissues prior to the start of each experiment. To avoid using organisms compromised by collection or transit to the laboratory, individuals were acclimated to laboratory conditions for at least 48 h prior to starting the experiment.

Gut fluid

Gut fluid from each species was sampled within 24 h of collection from the field by dissecting each organism and inserting a glass capillary tube into the lumen of the midgut to withdraw the gut contents. For bivalves, gut fluid was collected from the vicinity of the crystalline style. Gut fluid samples from between one and twenty individuals were pooled in acid-washed centrifuge tubes to obtain at least 10 μl, sufficient volume for repeated 2 μl analyses, and samples were frozen at −80°C until the time of contact angle measurement. Surfactancy of gut fluids was measured by drop contact angle analysis on a Parafilm™ (Royal Purple, Humble, TX, USA) coated slide following the methods described in detail by Mayer et al. [33] and Ahrens et al. [16].

Chemicals

The following compounds were used to spike exposure sediments: 1-methylfluorene, phenanthrene, fluoranthene, benzo[*a*]anthracene, chrysene, benzo[*a*]pyrene, and 7-methylbenzo[*a*]pyrene (Sigma-Aldrich) and 1-methylphenanthrene and 3,6-dimethylphenanthrene (Ultra Scientific, North Kingstown, RI, USA). LogK_{ow} values for these compounds were obtained from the literature [34], except for 3,6-dimethylphenanthrene and 7-methylbenzo[*a*]pyrene, which were estimated using LeBas molar volume as outlined by Mackay et al. [35] (See Table 2). Surrogate standards added before the extraction of all samples were d10-phenanthrene, d12-benzo[*a*]anthracene, d12-chrysene, and d12-perylene (Supelco, Bellefonte, PA, USA).

Sediment spiking and soot treatment

Exposure sediment was collected from the top 5 cm of benthic grab samples from a reference site in central Long Island Sound (41°08.036′N, 72°52.730′W, 1.8% organic carbon, 92% silt- and clay-size particles). Sediment was sieved immediately to 0.5 mm and stored at 4°C. Seawater used

throughout the experiment was collected from Flax Pond (Old Field, NY, USA) (28 ppt, ~23°C).

Diesel soot used in the soot treatment was collected from the tailpipes of diesel buses on the campus of Stony Brook University (Stony Brook, NY, USA). Soot was sieved through a 63-μm mesh sieve, placed in a beaker with excess 20% dichloromethane in hexane, and sonicated in a sonic bath for 5 min. Soot was then collected on a glass fiber filter, rinsed with clean hexane, and dried in a drying oven overnight at 65°C. Solvent extraction was performed to remove the majority of PAHs and other hydrocarbon residues that had condensed on the soot deposited in the tailpipes. Removal of most of the native PAHs should have acted to promote sorption of spiked PAHs due to the nonlinearity of PAH soot sorption isotherms [7,36]. The intention was to create a sorbed PAH phase that would be less chemically available than PAHs sorbed to natural sediment organic matter. As described below, the total concentration of PAHs spiked was then within a broad range observed in urban harbor sediments [15]. The sediment for the no soot treatment was spiked by adding a PAH stock solution to an empty glass jar and allowing the excess solvent to evaporate. A 50/50 mixture of sediment and seawater was then added, the jars sealed, and rolled in the dark for one week to ensure a homogenous distribution of PAH in the sediment. The nominal spiking concentration was approximately 1 μg/g dry sediment of each PAH (for a total of 9 μg PAH/g dry sediment).

The soot treatment sediment was prepared in a similar manner by equilibrating a PAH stock solution with extracted diesel soot and seawater for 6 d, adding sediment, and rolling for an additional 24 h. The final exposure sediment for the soot treatment had a nominal soot dosage of 1.93% diesel soot by dry weight. Lamoureux and Brownawell [30] found that diesel soot from these same buses was 36% soot carbon when measured by the thermal oxidation method of Gustafsson et al. [4]. Thus, the soot-amended sediment was 0.69% soot carbon, assuming no soot carbon was present in the control sediment. This soot concentration is on the upper end of the broad range measured in coastal and urban harbor sediments [9,10,15]. The final soot treatment sediment contained 3 μg/g dry sediment (nominal) of each PAH. The soot treatment was dosed at a higher level in anticipation that there would be reduced bioavailability of PAH.

Spiked sediments were allowed to equilibrate and settle in the dark for 5 d after rolling. Overlying water was then removed and discarded. Exposure chambers (solvent-rinsed, 60-ml glass jars) were filled to within 5 mm of the rim with exposure sediment (~85 g wet sediment/jar). Three replicate jars were placed in a plastic bucket and filtered seawater was dripped continuously into the bucket to create a flow-through system. Each exposure jar contained three individuals of each organism, except *M. arenaria* exposure chambers, which contained one organism in each jar due to their larger size.

Tissue and sediment samples from all treatments were collected on days 0 and 20. Organisms from the same exposure jar were combined as one tissue sample and samples from each of the three replicate exposure jars were collected at each time point. Sediment samples were composites of sediment from each of the three jars that were replicate exposures. Tissue and sediment samples were stored in glass at −20°C until extraction.

To determine whether or not 20-d exposures were sufficient to approach steady state body burdens, samples were collected at additional time points for three species, *C. grandis*, *Y. limulata*, and *M. balthica*, at days 5, 10, and 28. No additional PAH bioaccumulation was observed between days 20 and 28, indicating that in this system, 20 d appears to be a sufficient exposure period for small, infaunal benthic organisms to reach a steady PAH body burden.

Sample extraction and quantification

Sediments were extracted using a sonication method. Approximately 1 g of wet sediment was ground to a fine powder in a mortar and pestle with 5 g of anhydrous sodium sulfate to remove water. The dried sediments were then extracted in Teflon® centrifuge tubes using 15 ml of 1:1 acetone:hexane and a sonic probe (Cole-Parmer Instrument, Chicago, IL, USA). A second extraction using dichloromethane (15 ml) was done and the combined extracts concentrated and transferred into hexane using a combination of Kuderna Danish concentrators and nitrogen gas blow-down. Extracts were then purified using a column of 5% deactivated silica.

Tissues were homogenized using a VerTishear tissue homogenizer (Vertis, Gardiner, NY, USA) and then extracted in acetone with a vortex mixer. The extract was separated by centrifugation and removed, and the tissue re-extracted with fresh acetone. Water and hexane were added to the combined extracts to concentrate PAHs into hexane. A subsample of the

hexane was taken for lipid analysis and the remainder cleaned up for gas chromatography/mass spectrometry analysis using a Sep-Pak® Plus silica cartridge (Waters, Milford, MA, USA). Lipid analysis was performed on each tissue sample by gravimetric analysis on a Cahn C-26 automatic electrobalance (Thermo Orion, Beverly, MA, USA).

The PAH concentrations in tissue and sediment samples were quantified on a Hewlett-Packard (Avondale, PA, USA) 5890 series II gas chromatograph equipped with a 7673a autosampler and a 5971a mass selective detector (Agilent Technologies, Wilmington, DE, USA) [37]. Polycyclic aromatic hydrocarbons were quantified relative to the response of the most closely eluting deuterated surrogate standard. Coefficients of variation on replicate analyses of composite sediment samples averaged 12%. For separate samples of tissue or XAD resins, coefficients of variation were higher, averaging 27% and 23% respectively. Recovery of standard additions to tissue and XAD samples averaged 107% and 101%, respectively, of the nominal amount spiked. Total organic carbon content of sediments was determined after removal of inorganic carbon using an excess of 10% HCl. Sediment samples were then rinsed well in distilled water, dried, homogenized, and analyzed on a Carlo Erba EA1108 CHN Analyzer (CE Institute, Milan, Italy).

Accumulation factors and statistics

In this study, two types of accumulation factors were calculated following the nomenclature outlined by Meador et al. [31]. Lipid- and organic carbon–normalized bioaccumulation factors (BAF_{loc}s, g OrgC/g lipid) were calculated using the day 20 lipid-normalized tissue PAH concentrations and the average of days 0 and 20 organic carbon–normalized sediment PAH concentrations. For comparison, BAFs also were calculated without lipid and organic carbon normalization (BAFs g dry sediment/g wet tissue).

All statistical analyses were performed using the SAS System® 8E for Windows (SAS Institute, Cary, NC, USA). Accumulation factors and tissue PAH concentrations were log transformed prior to analysis to better approximate a normal distribution of the data. Three factor analysis of variance and tests for significant differences (e.g., Tukey and Dunnett's) were performed using the general linear model (proc GLM). A p-value of < 0.05 was considered statistically significant. Linear regressions were performed using proc REG.

RESULTS AND DISCUSSION

Sediment PAH analysis

Procedural blanks contained undetectable levels of PAHs. Control sediments had readily detectable PAH levels ranging from 5.5 (1-methylfluorene in control sediment) to 265 (phenanthrene in soot-added control) ng/g, but levels in control sediments were a relatively small fraction (<10%) of the total analyte signal present in day 0 exposure sediments (Table 1). Measured concentrations of analytes from day 0 sediments averaged 116% of the nominal (spiked) concentration for the no soot treatment and 106% of nominal for the soot treatment.

In both treatments, analysis of day 20 sediments showed good retention of PAHs with logK_{ow}s of >5.5, and significant losses of the smaller PAHs (Table 1). The loss of smaller PAHs was less in the soot-amended treatments (15% on average) as compared to the no soot treatments (36% on average). No species-specific effects were observed in day 20 sediment PAH concentrations except for the *Y. limatula* no soot treatment (data not shown), where sediment PAH concentrations were significantly lower than all other no soot treatment sediments ($p < 0.05$, Tukey test). The decrease in sediment PAH concentrations in the *Y. limatula* no soot treatment was likely due to a preferential loss of fine sediment caused by feeding-induced resuspension. To better represent the integrated exposure to sediment PAH concentrations over the time course of the experiment, accumulation factors were calculated using an average of day 0 and day 20 sediment concentrations.

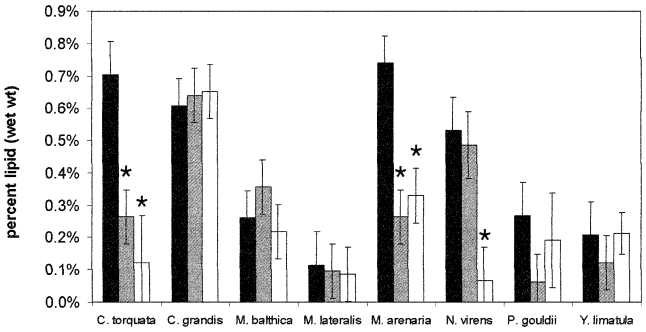

Fig. 1. Percent lipid in organism tissues. An asterisk (∗) over day 20 data indicates a significant change from day 0 ($p < 0.05$, Tukey test). Only *Nereis virens* showed a significant difference between treatments at day 20 ($p < 0.05$, Tukey test). Error bars represent 95% confidence intervals. *Clymenella torquata, Cirriformia grandis, Macoma balthica, Mulinia lateralis, Mya arenaria, N. virens, Pectinaria gouldii, Yoldia limatula.* ■, Day 0; ▨, day 20: no soot; □, day 20: soot.

Organism survival and lipid content

Survival of organisms at day 20 averaged 93 ± 8% (95% confidence interval—no soot) and 81 ± 16% (95% confidence interval—soot). In five of the eight species, lipid values did not vary significantly over time, and only in one species (*N. virens*) were lower values seen in the soot treatment (Fig. 1). Reduction in lipid content over time or with treatment may be an indication that organisms were not feeding/behaving normally during the exposure period (e.g., *C. torquata*, *M. arenaria*, and *N. virens*), which in turn may have affected bioaccumulation results.

Gut fluid analysis

Contact angle measurements indicate that gut fluid of the polychaetes generally is higher in surfactant strength (indicated by lower contact angle) than the bivalve mollusks, and that the surfactant strength of deposit feeders frequently is higher than that of filter feeders (Table 2). This is consistent with the trends observed in other crossphyletic studies of gut fluid characteristics [19,33]. The contact angle presented here for *N. virens* (47°) is very close to previously published results (44–42.5°) [33]. The values for *P. gouldii* (39°) and *M. balthica* (68°) also agree very well with previously reported results of 40° and approximately 67°, respectively [16,38]. The contact angle measured for *C. torquata* (38°), however, is very different from the result of 76° reported by Craig [39]. The methodology of Craig [39] generally was the same, both studies yielded internally consistent results, and the specimen collection site was the same for both studies. The source of this discrepancy, therefore, is unclear at this time.

PAH tissue concentrations

Tissue concentrations of PAH analytes are shown in Figure 2. Despite the variability of individual data points, a three-

[e] ND = not detected.

factor analysis of variance on the log-transformed tissue concentration data from each treatment revealed that, overall, PAH bioaccumulation increased significantly over the 20 d in both treatments for all species except *M. lateralis*. For individual PAHs, significant bioaccumulation was observed for PAHs with logK_{ow}s > 5.3. Absence of significant accumulation and high variability was most pronounced for the lower molecular weight PAHs, which also showed the greatest depletion in sediment concentrations over the 20-d experimental period (Table 1). In addition, bulk sediment concentrations of these more soluble compounds may overestimate exposure concentrations proximate to the organism due to local depletion caused by burrowing and feeding activities of the biota.

Filter feeders tend to bioaccumulate less from contaminated sediments than deposit-feeding species [40], as illustrated here by *M. lateralis*, which showed no significant PAH bioaccumulation from either treatment. However, *M. arenaria*, another filter feeder, did show significant uptake from both treatments. *Mulinia lateralis* has gut fluid and metabolic properties similar to those of *M. arenaria* (Table 2), suggesting that other species-specific factors may be responsible for the observed results. For example, it is known that *M. arenaria* uses post-ingestion particle selection, while *Mulinia edulis* has been shown to use pre-ingestion particle selection that may reduce contaminant exposure for organisms in this genus [41,42]. Exposure sediments also had extensive contact with soft tissues of *M. arenaria* due to the fact that its shell does not close fully and the siphons are very large. This may facilitate diffusive uptake from the sediment in *M. arenaria*, while *M. lateralis* has very little soft tissue in contact with exposure sediments.

Effect of K_{ow} on bioaccumulation

The BAF_{loc} values within a treatment often exhibit a maximum at log$K_{ow} = 5.4$ (3,6-dimethyl-phenanthrene) or show an inverse relationship with K_{ow} (Fig. 3). The notable exception is *M. lateralis*, which showed no obvious trend in BAF_{loc} when plotted against logK_{ow} (likely due to the fact that no significant bioaccumulation was observed in this species for any compound). The peak in BAF_{loc} and/or the inverse relationship between BAF_{loc} and K_{ow} also have been observed in other studies [13,30–32]. In exposures of PAH-contaminated sediments to benthic species, low K_{ow} compounds may show reduced BAF_{loc}s due to their shorter half-life in sediments (e.g., the exposure concentration drops over the course of the exposure), the depletion of the local environment due to burrow irrigation (e.g., diffusive loss from sediment immediately surrounding the organism, enhanced microbial activity near irrigated burrows, or loss from sediments due to bioaccumulation), and faster depuration rates of low K_{ow} compounds from organism tissues [22,23,31]. Reduced bioavailability of high K_{ow} PAHs also is observed consistently in literature reports and may be due to stronger sorption to the sediment and the tendency of organisms to more rapidly metabolize high K_{ow} PAHs [12,30]. The interaction of these many factors often results in lower BAF_{loc}s for low and high molecular weight PAHs and creates a peak in bioaccumulation of midsized compounds. For this study, BAF_{loc}s appear to be highest for compounds with a logK_{ow} between 5 and 5.5, with 3,6-dimethylphenanthrene typically having the highest BAF_{loc} (Fig. 3).

Effect of soot on bioaccumulation

Analysis of biota-sediment accumulation factors revealed that bioaccumulation of PAHs by benthic invertebrates is dependent on many interacting factors (Fig. 3). A three-factor analysis of variance of all the day 20 BAF_{loc}s, with species, compound, and soot treatment as explanatory variables, revealed that compound and species had a significant effect on BAF_{loc} results ($p < 0.0001$), while the soot treatment effect on BAF_{loc} generally was not significant ($p = 0.096$). Although treatment was not significant overall, the treatment interaction terms were all significant ($p < 0.05$ for species·treatment, compound·treatment, and compound·species·treatment). Bioaccumulation factors calculated without lipid and organic carbon normalization (BAFs) showed similar patterns except that the soot treatment variable became significant as well ($p < 0.0001$, $F = 59.6$ data not shown). The impact of lipid and organic carbon normalization on interpretation of BAF values is considered further below.

To examine the effect of soot on PAH bioaccumulation, we calculated the ratio of bioaccumulation factors between no soot and soot treatments for each species. Average ratios across all individual PAH analytes (*i*) between BAFs of no soot (NS) and soot (S) treatments (NS/S) are shown in Table 3 for each

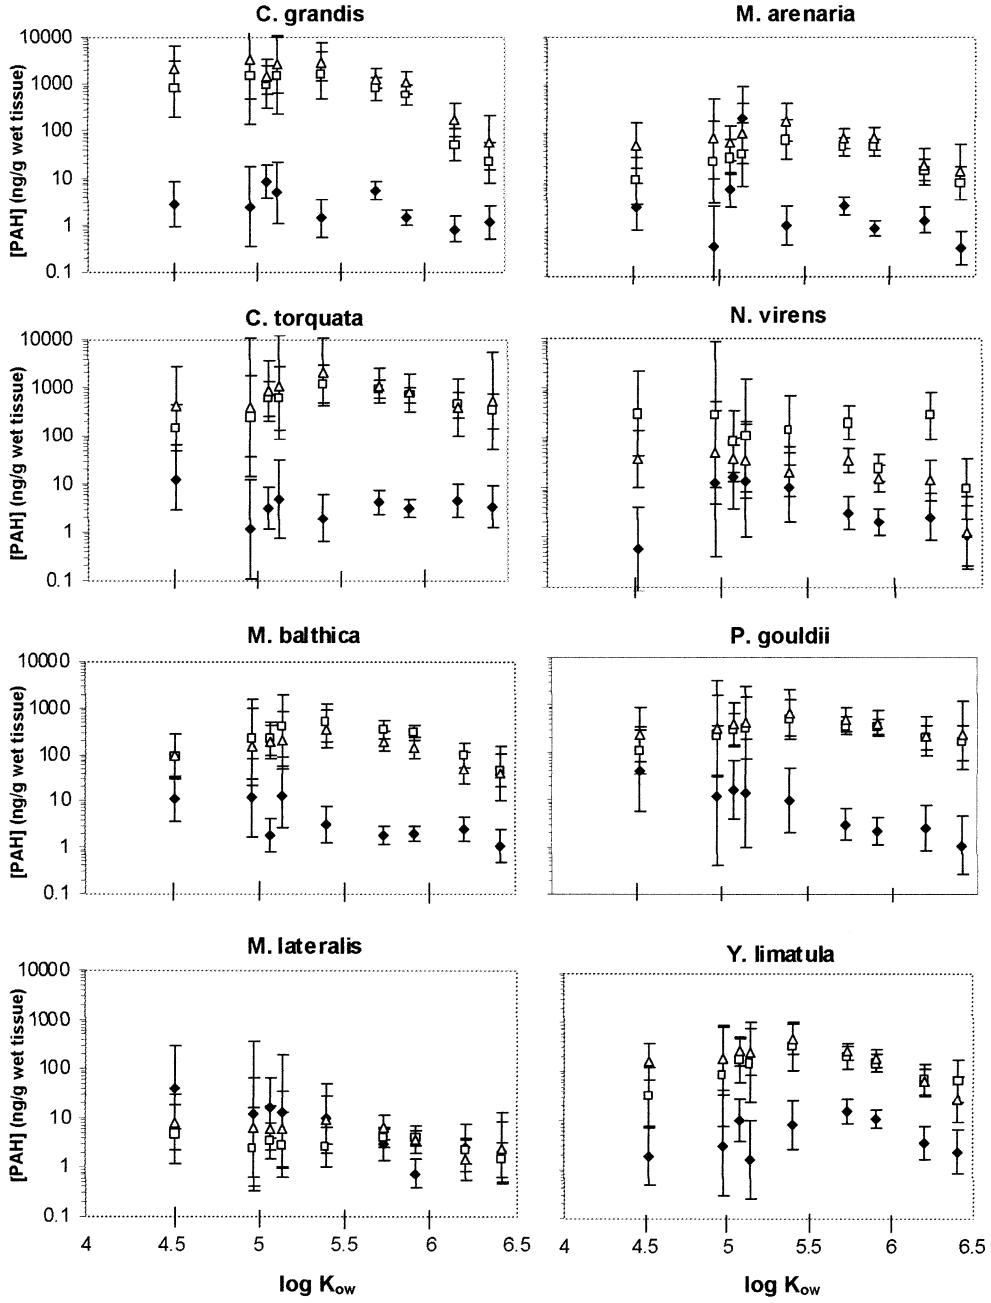

Fig. 2. Tissue concentrations of polycyclic aromatic hydrocarbons (PAHs) at days 0 and 20. All organisms except *Mulinia lateralis* showed significant uptake at day 20 in both treatments. Note that the same scale is used on all graphs and the *y*-axis is on a log scale. Error bars represent 95% confidence intervals. Refer to Figure 1 caption for names of species. ♦, Day 0; □, day 20: no soot; △, day 20: soot.

species and treatment (where n is the number of PAH analytes detected in both treatments)

$$\overline{\text{NS/S}} = \frac{\sum_{i=1}^{n} \frac{\text{BAFns}_i}{\text{BAFs}_i}}{n} \quad (2)$$

NS/S ratios calculated from BAF_{loc} data were greater than one for only five species and only two species (*Y. limatula* and *N. virens*) had a significant difference in BAF_{loc} between treatments. For both species, the NS/S values (2.7; 3.0) are interpreted as a reduction in PAH bioaccumulation in the presence of soot.

The apparent effect of soot is greater when the data are interpreted through analysis of the BAF values, those not normalized to lipid and organic carbon. When comparing BAF values, all species had NS/S ratios greater than one and the reduction in bioaccumulation from the soot treatment was significant for four species (Table 3). The differences between analyses using bioaccumulation factors normalized in different ways are caused in part by higher total organic carbon content (almost a factor of 2) in the soot treatments. Thus, the NS/S is lower when BAFs are normalized to organic carbon. In *N. virens*, decreased lipid in soot treatment organisms also leads to reducing the difference between NS/S when BAFs are lipid normalized. The reduction of soot treatment BAFs relative to the no soot treatment observed (for two species when using BAF_{loc} and for four species when using BAF) supports the results of previous studies that also have shown reduced as-

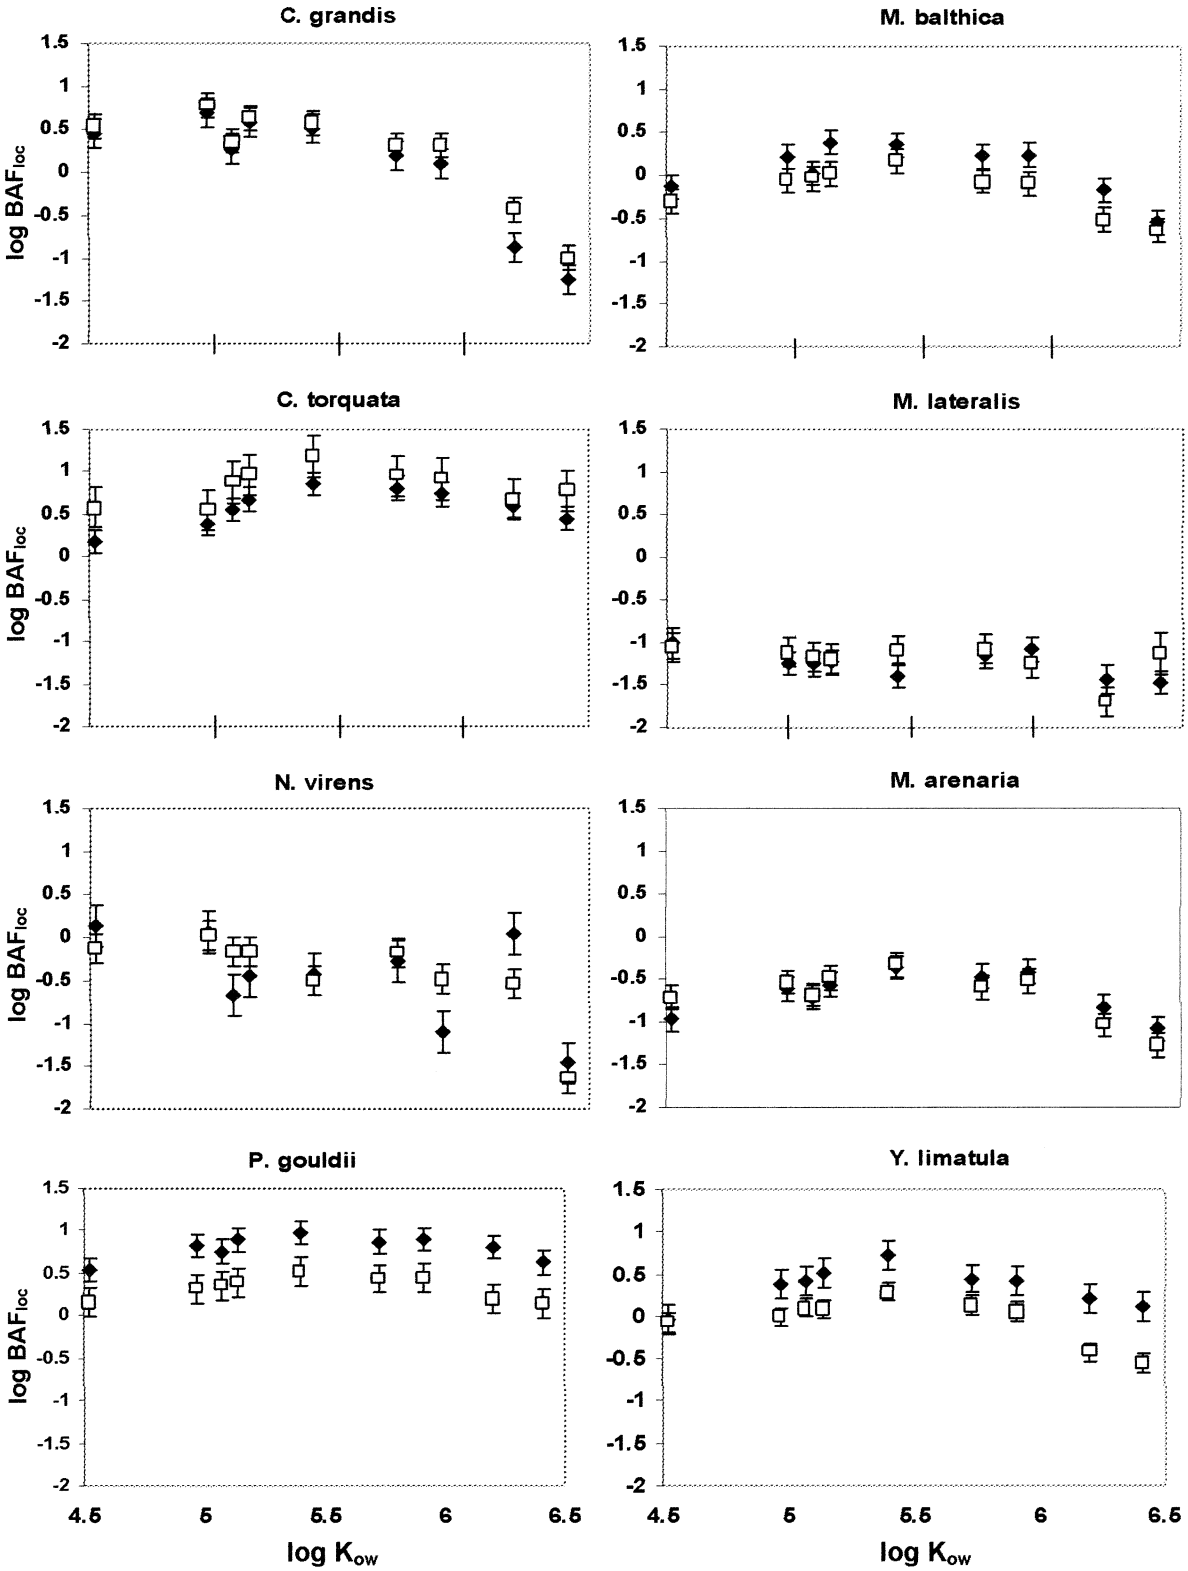

Fig. 3. Log BAF_{loc}s for day 20 data plotted against logK_{ow}, illustrating the difference between treatments for each analyte in each species. The BAF_{loc}s also tend to be highest for polycyclic aromatic hydrocarbons with midranged K_{ow} (e.g., 3,6-dimethylphenanthrene: K_{ow} = 5.4), though this pattern is not totally consistent. Error bars represent 95% confidence intervals. BAF = bioaccumulation factor. Refer to Figure 1 caption for names of species. ♦, No soot; □, soot.

similation efficiency or bioaccumulation of PAHs from soot-enriched sediments [2,15]. The fact that the effect of soot on bioaccumulation is relatively modest for all species is surprising in that it shows significant bioaccumulation of PAHs from sediments amended with high levels of soot (1.9% by weight). These data support the hypothesis of Voparil et al. [20] that digestive exposure to soot-bound PAHs may result in significant bioaccumulation. One cannot assume that soot-

Table 3. Statistical analysis of the effect of soot on bioaccumulation factor (BAF)

	BAF_{loc}			BAF		
Species	NS/S[a]	F[b]	p[b]	NS/S[a]	F[b]	p[b]
Cirriformia grandis	0.7 ± 0.2	1.25	0.27	1.3 ± 0.3	0.38	0.54
Clymenella torquata	0.6 ± 0.2	1.92	0.18	2 ± 0.5	2.6	0.12
Macoma balthica	1.8 ± 0.4	3.52	0.07	4.8 ± 1.2	29.41	<0.0001
Mulinia lateralis	1.0 ± 0.4	0.13	0.72	1.5 ± 0.7	1.01	0.33

[a] NS/S > 1 indicates higher bioaccumulation from the no soot (NS) treatment and NS/S < 1 indicates higher bioaccumulation from the soot (S) treatment (± standard deviation).

[b] Three-factor analysis of variation was used to determine whether the trend of elevated accumulation factors (BAF_{loc}s and BAFs) in the no soot treatment was significant. The F- and p-values are the results of slicing the species*treatment interaction term by species ($p < 0.05$ indicates there is a significant difference between treatments).

bound PAHs are not available to benthic species or that there is a uniform reduction in bioavailability for all benthic species. Further work is required to determine the extent to which these results can be generalized to other sources of soot carbon. It also should be noted that the soot-amended treatment differed not only in the amount of soot carbon present, but also in the amount of total sorbed PAHs (three times higher than the no soot treatment). It is not expected that this modest elevation in PAH concentration would appreciably change bioaccumulation from sediments.

Effects of biological properties on bioaccumulation

Approximately a two order of magnitude difference existed between species with the highest BAF_{loc}s, *C. torquata* and *P. gouldii*, and those with the lowest BAF_{loc}s, *M. lateralis* and *M. arenaria* (Fig. 3). This is consistent with expectations based on the contact angle, metabolic abilities [28], and feeding behavior for these species (Table 2). High surfactant strength, low metabolism, and exclusive deposit-feeding behavior in *C. torquata* and *P. gouldii* would be expected to result in high bioaccumulation of sediment-bound PAHs, while lower surfactant strength, intermediate metabolism, and filter feeding in *M. lateralis* and *M. arenaria* would be expected to result in very low bioaccumulation. As has been observed in other studies, these data illustrate that deposit feeders are at increased risk of accumulating PAHs from bedded sediment than are filter feeders [24,25,40]. The facultative deposit feeders (*M. balthica* and *N. virens*) and the possibly more selective deposit feeders (*C. grandis* and *Y. limatula*) show intermediate bioaccumulation (Fig. 3).

Bioaccumulation of PAHs by strict deposit feeders was influenced significantly by gut fluid surfactant strength. Contact angle is correlated negatively to the day 20 BAF_{loc}s and the slopes of linear regressions are significantly different from zero for both treatments ($p < 0.05$), indicating higher PAH bioaccumulation for species with stronger gut fluid surfactants (Fig. 4). These data are consistent with the findings of several studies that have shown that gut fluids and synthetic surfactants of increasing strength (lower contact angle) can solubilize more PAHs from sediments and that the amount solubilized is approximately equal to the amount assimilated [16–19]. Linear regressions yielded a similar correlation coefficient for the no soot (adjusted, $r^2 = 0.25$) and the soot (adjusted, $r^2 = 0.27$) treatments. Because the gut fluid of a deposit-feeding polychaete has been shown to solubilize more PAHs from soot and other black carbon matrices than predicted by soot-corrected equilibrium partitioning [20], we had hypothesized that the correlation of contact angle to BAF_{loc} results would be higher in the soot treatment due to surfactants playing a more important role. However, our data do not support this.

The extent of benzo[*a*]pyrene (B[*a*]P) metabolism, observed in vivo after 7-d exposures to radiolabeled sediments determined previously for these species [28], also is correlated negatively with BAF_{loc}. The slopes of the regressions are significantly different from zero for both treatments ($p < 0.05$ with adjusted r^2s being 0.49 for the soot and 0.27 for the no soot treatments; Fig. 4), consistent with previous work [27,29] and with results from a companion study evaluating short-term (7-d) bioaccumulation with many of the same species [28]. The more significant correlation between BAF_{loc} and B[*a*]P metabolism as compared to BAF_{loc} and contact angle, at least in the no soot treatments, suggests that metabolism may play a more important role than gut surfactancy in bioaccumulation, at least in some cases.

It is likely that other species-specific characteristics not taken into account by this study also are important in determining BAF_{loc}s. These may include particle selectivity, depletion of PAHs in the local environment (e.g., bioturbation/burrow irrigation), and differential metabolism of various PAHs. For example, Shull and Yasuda [21] found that *C. grandis* selects for particles in the 16- to 32-μm size range, and this is quite close to the size range of the soot particles used in this study (sieved to 63 μm). Self and Jumars [26] showed that *Yoldia scissurata* and *M. balthica* also selectively ingest particles of a certain size range. They hypothesize that most deposit feeders are highly selective for a similar size range of particles that carry the majority of bacteria and total organic carbon in the sediment (~3–17 μm). This additional variable may have an important effect on the BAF_{loc}s reported here, especially for the soot treatment. It also may explain why there are higher BAF_{loc}s in the soot treatment for *C. grandis* and *C. torquata*. Furthermore, the ability of an organism to metabolize PAHs can vary depending on the particular compound of interest [12,31]. The metabolic parameter used here, which is percent of B[*a*]P body burden represented as metabolites after 7-d sediment exposures, does not take into account variable rates of metabolism for different compounds and other factors influencing depuration rates. It also is known that bio-

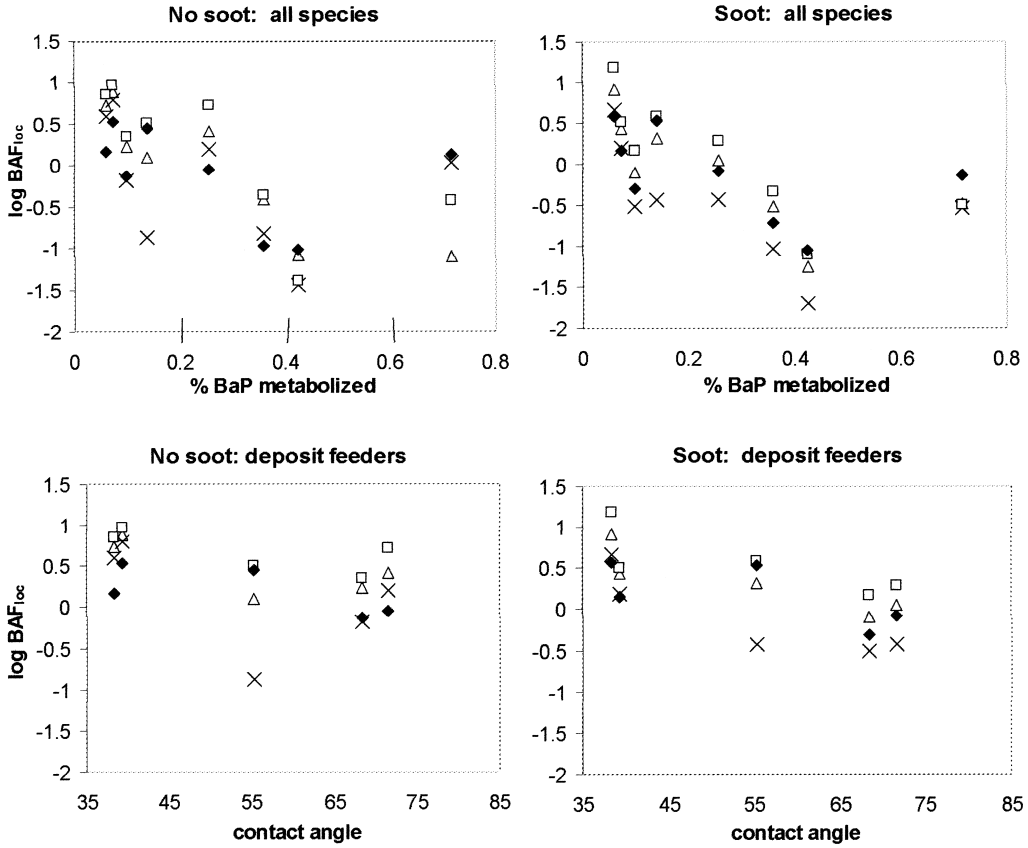

Fig. 4. The BAF_{loc}s of four representative polycyclic aromatic hydrocarbons plotted against contact angle and metabolism for each treatment. Contact angle plots exclude *Nereis virens*, *Mya arenaria*, and *Mulinia lateralis* because they are not primarily deposit feeders and contact angle is relevant only to species whose primary exposure pathway is through ingested sediment. Phen = phenthanthrene, diM phen = dimethylphenanthrene, BAA = benzo[*a*]pyrene, B[*a*]P = benzo[*a*]pyrene, BAF = bioaccumulation factor. ♦, Phen; □, diM phen; △, BAA; ×, B[*a*]P.

turbation and irrigation of bedded sediments caused by burrowing benthic organisms can enhance degradation and geochemical and contaminant fluxes across the sediment water interface [22,23]. Depending on the nature of the burrowing behavior for a particular species, this may mean that organisms actually are exposed to a microenvironment in an irrigated burrow that is depleted in contaminants relative to the bulk sediment, reducing their overall exposure to sediment contaminants.

Two of the test species *M. balthica* and *N. virens*, were chosen in part because they are recommended by the U.S. Environmental Protection Agency and commonly are used as model organisms to assess bioaccumulation of potentially toxic contaminants in site assessment, dredging management, or remediation studies [43]. This study suggests that, though *M. balthica* (intermediate metabolism and intermediate/low surfactant strength; among the higher BAF_{loc}s observed here for bivalves) may be a suitable monitoring species, *N. virens* (very high metabolism and intermediate/high surfactant strength; among the lowest BAF_{loc}s observed) clearly does not represent a sensitive indicator of PAH bioaccumulation among polychaetes (BAF_{loc}s for *C. torquata* and *P. gouldii* ~10× higher; Fig. 3). Effort should be focused on verifying the suitability of other current test species (as well as suitable replacement species) by measuring characteristics such as metabolic ability and contact angle.

UBIQUITOUS OBSERVATIONS OF ENHANCED SOLID AFFINITIES FOR AROMATIC ORGANOCHLORINES IN FIELD SITUATIONS: ARE IN SITU DISSOLVED EXPOSURES OVERESTIMATED BY EXISTING PARTITIONING MODELS?

THOMAS D. BUCHELI* and ÖRJAN GUSTAFSSON
Institute of Applied Environmental Research (ITM), Stockholm University, S-10691 Stockholm, Sweden

(*Received* 11 *July* 2000; *Accepted* 13 *November* 2000)

Abstract—This paper investigates the ability of the traditional organic matter partitioning (OMP) model to predict the solid–water distribution, and hence the dissolved exposures, of hydrophobic organic compounds (HOCs) in real field situations. Observed organic-carbon-normalized partitioning coefficients ($(K_{oc})_{obs}$) of polychlorinated biphenyls, polychlorinated benzenes, polychlorinated dibenzo-dioxins and -furans, and *p,p′*-dichlorodiphenyltrichlorethane (DDT) with metabolites were selected from the literature and compared with their respective OMP model estimates. For all compound classes and in a majority of the investigated cases, $(K_{oc})_{obs}$ values were significantly larger than predicted. This translated into factors of overestimated dissolved exposures ranging from 1 to 1,000. Various reasons are discussed for the discrepancies between predictions and actual observations, such as the effect of the diagenetic state and other properties of the particulate organic matter. The greater enhancement in $(K_{oc})_{obs}$ of planar over nonplanar compounds suggests in certain cases that efficient interactions with aromatic soot phases may be significant. For an improved predictability of $(K_{oc})_{obs}$ and dissolved exposures of HOCs in the real environment, the inclusion of soot and possibly other distinct subfractions of bulk organic carbon into an extended solid–water partitioning model may be considered.

Keywords—Organic matter partitioning model Hydrophobic organic compounds Soot Sediment quality criteria Dissolved exposures

INTRODUCTION

The partitioning of hydrophobic organic compounds between water and various solid phases is a key process strongly influencing their environmental transport, reactivity, and dissolved exposures. The magnitude of the solid–water distribution coefficient (K_d) has been assumed to be linear and to be predictable from easily obtainable physicochemical properties of both the solid sorbent and the contaminant hydrophobic organic compound (HOC) sorbate [1,2], that is, as

$$K_d = \frac{c_s}{c_w} = f_{oc} \cdot K_{oc} \quad (1)$$

where c_s is the concentration of a sorbate in the solid phase (mol/kg solid), c_w is the concentration in the aqueous phase (mol/L water), f_{oc} is the organic carbon fraction of the sorbent (kg organic carbon/kg total solid), and K_{oc} is the organic-carbon-normalized partition coefficient (L water/kg organic carbon). According to this model, the f_{oc} represents the portion of the solid that matters in HOC sorption; HOCs may dissolve into nonpolar environments of the natural organic matter. The compound-specific value of K_{oc} represents the relative affinity of a HOC for this natural organic matter relative to that of water. Given that f_{oc} is easily measurable and since K_{oc} is obtainable from linear free energy relationships with direct measures of solvophilicity such as aqueous solubility and octanol/water partition coefficients (K_{ow}), the organic matter partitioning model of Equation 1 is a potentially powerful tool to predict solid–water distributions. This model has been successful in explaining the sorption behavior of many HOCs with a wide range of soils and sediments in laboratory studies. It has consequently won broad recognition (cf., [3]) and even formed the basis for development of sediment quality criteria (SQC) [4,5].

While the organic matter partitioning (OMP) model may still provide a useful reference point, results over the past several years from longer term sorption experiments spanning over wider concentration ranges as well as observations of the actual distribution in the field are at odds with the simple partitioning view of the OMP model: Sorption isotherms exhibit nonlinearity (cf., [6,7]), and K_ds of PAHs in the field are far in excess of OMP model expectations (cf., [8,9]). Two reviews of mechanisms that may account for these observations have been presented [10,11].

The ultimate test of our understanding of the solid–water partitioning process is to compare the model predictions with the actual phase distributions in the field along with collection of the relevant system descriptors. With this approach, it was realized that observed K_{oc} numbers ($(K_{oc})_{obs}$) of polycyclic aromatic hydrocarbons (PAHs) were systematically much underestimated (often by several orders of magnitude) by the OMP model in real field measurements [9,12]. For PAHs, it has been hypothesized that these elevated $(K_{oc})_{obs}$ values were caused by additional and efficient sorption to soot, a highly condensed subfraction of the total organic-matter pool [9,12]. Indeed, soot has been found to be ubiquitously present in modern day soils and sediments, where it may make up as much as 30% of the total organic carbon [13–15]. Recent laboratory determinations of the soot–water partition coefficients (K_{sc}) of PAHs demonstrated that the interaction with condensed soot carbon was about a factor of 100 stronger than with natural organic carbon [16]. The adsorption was rapid and the surface-normalized K_{sc} values agreed well with the-

[a] PCB = polychlorinated biphenyl; PAH = polycyclic aromatic hydrocarbon; QSAR = quantitative structure–activity relationship.

oretical estimates of PAH adsorption to both soot [12] and activated carbon (cf., [17]).

Given that activated carbon is a more efficient adsorbent also for other HOCs than PAHs and that its natural analogue (i.e., soot) is ubiquitous in the environment, it behooves us to investigate whether enhanced sorption may be systematically observed in presumed soot-rich environments for HOCs in general. To this end, it can be hypothesized that especially the highly planar compounds such as non-*ortho*-substituted polychlorinated biphenyls (PCBs) or polychlorinated dibenzodioxins and -furans (PCDDs and PCDFs) might exhibit similarly elevated affinities to soot as observed for PAHs. Hence, the objective of the present paper is to test the hypothesis of enhanced solid affinity of rigid organochlorine compounds by evaluating available literature data on $(K_{oc})_{obs}$ of PCBs, PCDDs, PCDFs, polychlorinated benzenes, *p,p′*-DDT with metabolites (hereafter collectively referred to as DDXs). The intention of this investigation is not limited to testing the scope of the soot supersorbent hypothesis but is aimed at evaluating the general need for an improved characterization of the speciation of HOCs and the necessity of considering specific subfractions of the bulk particulate organic matter.

DATA SELECTION AND ANALYSIS

Compilation of $(K_{oc})_{obs}$ *data*

The reporting criteria set up for data selection from the literature were field observations, individual compound concentrations, organic carbon content of the solid phase, and transparency and reliability of the analytical methods. Hence, these criteria apply to peer-reviewed articles that either explicitly report $(K_{oc})_{obs}$ values or from which $(K_{oc})_{obs}$ values could be derived from supplied information on concentrations in both the dissolved and particulate phase as well as the particulate organic carbon content. Consequently, the selected data sets do not include any laboratory-derived data such as from batch sorption experiments with spiked analytes. A considerable amount of field-observed K_d values have been published without any information on corresponding organic matter contents. Unfortunately, such data are not comparable with other studies and were therefore excluded from this compilation. We only include $(K_{oc})_{obs}$ numbers given for single compounds/congeners and do not consider any work that reported any kind of pooled values such as for PCBs distinguished only by numbers of chlorine substitution. Finally, for reasons of uncertainty and credibility, we did not attempt to extract any data from published $(K_{oc})_{obs}$ versus K_{ow} figures.

Selection of K_{ow} *data*

Considerable variability exists in reported K_{ow} values for individual compounds. For the more hydrophobic compounds, i.e., log $K_{ow} > 6$, this variability easily ranges over one order of magnitude (cf., Mackay et al. [18] for a thorough compilation). Any comparison of model-predicted K_{oc} versus $(K_{oc})_{obs}$ therefore depends to a certain extent on the K_{ow} values selected. As will be shown below, this variation does not affect the general conclusions of the present study. Our attempt was to use well-established K_{ow} values, with emphasis on the consistence and comparability of the data for individual compound classes. Hence, K_{ow} numbers were taken from Hawker and Connell [19] for PCBs, Govers and Krop [20] for PCDDs and PCDFs, De Bruijn et al. [21] for polychlorinated benzenes, and from Chiou et al. [22] and Baum [23] for DDXs.

Selection of K_{oc}–K_{ow} *linear free energy relationships*

From the ample laboratory-derived or quantitative structure–activity relationships and modeled log-linear K_{oc}–K_{ow} relationships, the ones using a data set with predominantly or only chlorinated HOCs were used for comparison with the actual $(K_{oc})_{obs}$ values from real environments. Because other compound classes such as modern pesticides and PAHs may exhibit different abilities of interaction with organic matter, K_{oc}–K_{ow} relationships based on data sets of such compounds were not considered. Table 1 compiles the various K_{oc}–K_{ow} estimates applied. The minimum and maximum log K_{oc} predictions are indicated in all subsequent log $(K_{oc})_{obs}$ versus log K_{ow} plots.

DATA EVALUATION

Comparison of field-observed versus model-predicted phase distributions

This compilation of actual solid–water distributions of aromatic organochlorines demonstrates a solid affinity that is, in a majority of the cases, significantly larger than predictions based on the widely employed OMP model. Observations from a large variety of aquatic environments suggest that the OMP model is underestimating the solid–water distribution of PCBs (Fig. 1), polychlorinated benzenes (Fig. 2), PCDDs and PCDFs (Fig. 3), and DDX (Fig. 4) by up to three orders of magnitude. Obviously, this consistently enhanced solid affinity corresponds to a proportional lowering of the actual dissolved exposures relative to predictions. For the compound classes where the congeners span a wider range of physicochemical

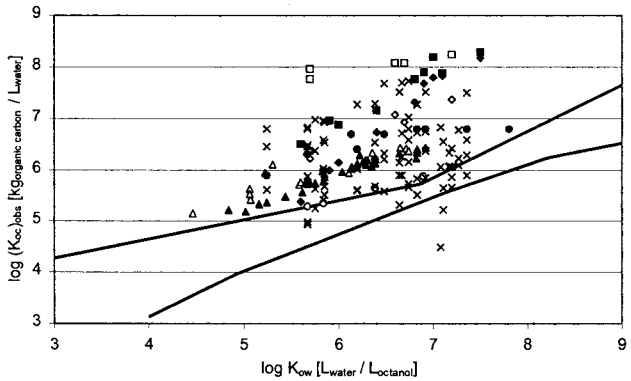

Fig. 1. Organic-carbon-normalized in situ partition coefficients (log $(K_{oc})_{obs}$) for PCBs, elevated relative to organic matter partitioning (OMP) model predictions (solid lines: upper and lower range of estimates given in Table 1), in different environmental compartments: planar (open squares) and nonplanar (filled squares) congeners in Ketelmeer surficial sediment [24], planar (open diamonds) and nonplanar (filled diamonds) congeners in deeper Ketelmeer sediment [24], St. Clair and Detroit suspended river sediment (filled circles; [25]), planar (open triangles) and nonplanar (filled triangles) congeners in Hudson River open water column [26], Lake Superior open water column (open circles; [27]), open North Atlantic Ocean waters (crosses; [33]).

properties (i.e., PCBs, polychlorinated benzenes, PCDDs, and PCDFs), there is a generally increasing trend in $(K_{oc})_{obs}$ with increasing K_{ow}. This suggests that the enhanced solid affinity is a result of active hydrophobicity-driven sorption to some supersorbent as opposed to a production-related permanent pollutant-to-particle association. The patterns and even magnitude of enhancements are reminiscent of the trends in previously reported compilations for PAHs (cf., [12]). The up to three orders of magnitude difference in reported values of $(K_{oc})_{obs}$ for a given compound may result from a combination of several factors, including a large variation in the abundance and availability of the postulated supersorbent media. Below, we attempt to discuss various factors that may contribute to the variations observed within the compiled data sets.

Effects of diagenetic state and properties of the particulate organic matter

For the PCBs (Fig. 1), the relative $(K_{oc})_{obs}$ enhancement is most pronounced in sediments [24], thereafter in suspended river sediments [25], but less so for pelagic water compartments [26,27]. This could be an indication that the origin and quality of particulate organic matter affects its overall sorptivity. Diagenetically younger organic matter (as observed in the pelagic water column) is richer in polysaccharides (cf., [28]), which is a poor sorbent matrix for HOCs [29]. The lipid fraction and the soot fraction are likely to be more resistant to degradation than bulk organic matter, and their relative importance for partitioning might thus increase with overall organic matter degradation increasing from the pelagic system to the sediment. Increasing values for individual PCB $(K_{oc})_{obs}$ with depth in a doubly stratified 400-m water column in the Baltic Sea was recently reported [30]. This is consistent with a dependency on the aging effect of the organic matter sorbent properties, as the increasing PCB $(K_{oc})_{obs}$ values were associated with increasing lipid fractions of the total particulate organic carbon. The notion of increased sorptivity of organic matter with aging is also supported by the polychlorinated benzenes data set (Fig. 2). For instance, the surface waters in

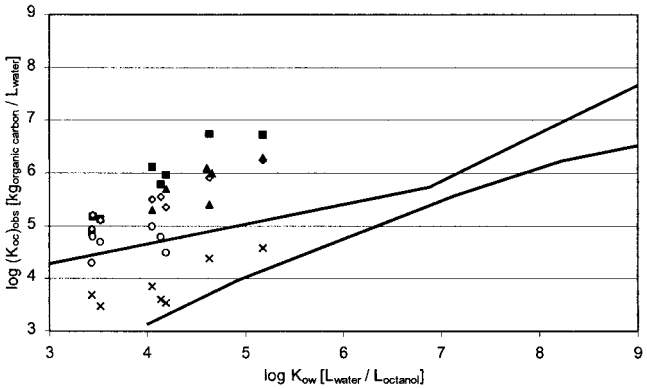

Fig. 2. Organic-carbon-normalized in situ partition coefficients (log $(K_{oc})_{obs}$) for polychlorinated benzenes, elevated relative to organic matter partitioning (OMP) model predictions (solid lines: upper and lower range of estimates given in Table 1) in different environmental compartments: surficial (filled squares) and deeper (open diamonds) Ketelmeer sediment [24], St. Clair and Detroit suspended river sediment (filled triangles; [25]), Ketelmeer sediment (open circles; [32]), Ise Bay (Japan) surface water (crosses; [31]).

the Ise Bay (Japan) exhibited considerably lower $(K_{oc})_{obs}$ values [31] than other studies with suspended river sediments or Ketelmeer sediments [24,32].

The open ocean PCB data set of Schulz-Bull et al. [33] is unique both in its abundance and in that it represents the only measurements of PCBs in both the dissolved and particulate phase from remote oceanic regimes far removed from anthro-

Santschi and Ö. Gustafsson, personal communication); *p,p′*-DDT, *p,p′*-DDD, and *p,p′*-DDE in St. Clair and Detroit suspended river sediment (filled triangles; [25]).

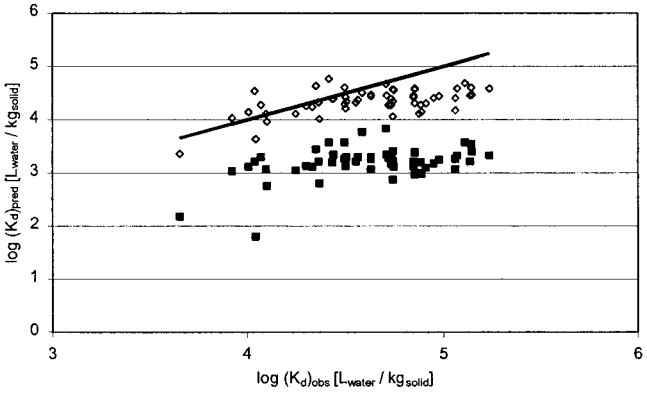

Fig. 5. Improved prediction of K_d values for pyrene in Humber Estuary sediments by application of the soot-inclusive organic matter partitioning (OMP) model. The solid line represents an ideal 1:1 line between $(K_d)_{obs}$ and $(K_d)_{pred}$. $(K_d)_{pred}$ from $f_{oc}K_{oc}$ (filled squares), $(K_d)_{pred}$ from $f_{oc}K_{oc} + f_{sc}K_{sc}$ (open diamonds). All $(K_d)_{obs}$ values from [46]. Numbers of the other parameters: $f_{oc} = 0.03 \pm 0.02$, $f_{sc} = 0.0022 \pm 0.0010$ (both from [46]), log $K_{oc} = 4.8$ [52], log $K_{sc} = 7.03$ [16].

pogenic sources. The North Atlantic has been proposed as a possibly dominant sink for PCBs (cf., [34]), and a correct understanding of their phase distribution in this regime is therefore warranted. Notably, in their study [33] with all samples collected on the same cruise using the same equipment and with analysis performed with identical procedures, there is a factor of >100 variability in individual congener $(K_{oc})_{obs}$ values between four different water masses investigated. While the data set in Figure 1 is not separated into these different water masses, somewhat contradictory to the above observed aging effect, there appeared to be a trend of increasing $(K_{oc})_{obs}$ values with younger halocarbon ages of the water masses [33,35].

In surface ocean systems, the particulate sorbents may be dominated by living cells, foremost phytoplankton, in which the organic matter is highly structured, contrasting to lyzed and diagenetically altered organic matter in settling particles and sediments. For instance, the lipid bilayer may be actively water decontaminated in living cells, making it a more ideal solvent for HOCs than water-contaminated octanol in binary octanol–water systems [11]. Further contributing to expectations of elevated K_{oc} values in living partitioning, one may expect a lower DOC contamination in the surrounding seawater than the octanol contamination in the water phase of the binary solvent system. Yet further complemented by salting out and freezing out effects (cf., [3]), this would lead to an increased fugacity in seawater relative to in the water compartment of the octanol–water system.

Effects of planarity and known presence of soot

The data of Jonker and Smedes [24] and Butcher et al. [26] are presented separately for ortho- and non–*ortho*-PCB congeners (Fig. 1). The preferentially elevated sorptivity for planar PCBs relative to their nonplanar counterparts observed in these two field studies cannot be rationalized with the sorbate hydrophobicity. Rather, it suggests interactions of these planar HOCs with specific adsorption sites. Elevated non–*ortho*-PCB binding with humic substances of a higher degree of aromaticity and polarizability was recently observed in laboratory studies [36]. A subfraction of the solid bulk organic matter that might offer adsorption sites preferentially favorable to planar HOCs is soot. The accessibility (e.g., by diffusion into narrow interplanar soot spaces) of and interaction (e.g., by efficient π-π overlap) with this highly condensed combustion residue might be enhanced for planar compounds due to steric advantages over the more bulky nonplanar compounds. Jonker and Smedes [24] in fact confirmed the presence of soot-like material in their sediment samples and brought up this finding as a plausible explanation for their observed elevated partition values. However, even the nonplanar PCBs regularly exhibit enhanced $(K_{oc})_{obs}$ values (Fig. 1), indicating that efficient sorption to soot seems not to be restricted to fully planar HOCs such as PAHs or non–*ortho*-substituted PCBs.

Interestingly, the PCDD/PCDF data (D. Broman, personal communication), with some of the largest ever observed log K_{oc} values of up to nine (Fig. 3), were obtained in the highly contaminated Frierfjord (recipient of releases from a magnesium smelter plant). The presence of soot-like solid phases in waters and sediments of smelter-affected fjords has previously been implicated to determine the speciation and distribution of PAHs [37,38]. Finally, soot partitioning was shown quantitatively to much better explain than the OMP model the sediment–porewater distribution of *p,p′*-DDT and its metabolites in Palos Verdes Shelf sediments (P.H. Santschi and Ö. Gustafsson, personal communication). At this soot-contaminated site [13], the more planar *p,p′*-(dichlorodiphenyl)dichloroethylene and *p,p′*-(dichlorodiphenyl)monochloroethylene exhibited higher $(K_{oc})_{obs}$ values than the more hydrophobic but nonplanar *p,p′*-DDT and *p,p′*-(dichlorodiphenyl)dichloroethane (Fig. 4; P.H. Santschi and Ö. Gustafsson, personal communication).

Due to the present absence of any K_{sc} values for aromatic organochlorines, it is not yet possible to test the potential for improved prediction of K_d by inclusion of a soot adsorption term into the OMP model, as recently performed for PAHs [9,12]. Figure 5 illustrates the beneficial application of the enhanced, soot-inclusive OMP model using the available K_{sc} values for PAHs [16]. Whereas the values of $(K_d)_{pred}$ for pyrene from the traditional OMP model are roughly two orders of magnitude lower than the observed ones, a much better agreement between predicted and observed K_d values is obtained when applying the enhanced, soot-inclusive model.

Other factors affecting the apparently dissolved fraction

Inclusion of a colloid-associated form in the operationally defined filter-passing dissolved fraction leads to an underestimation of K_d. This so-called particle-concentration effect (cf., [11,39]) is most pronounced for more hydrophobic compounds and in regimes where the colloid-to-large particle ratio is large. It can be expressed as

$$(K_{oc})_{obs} = \frac{K_{oc}}{1 + K_{coc} \cdot COC} \quad (2)$$

where the deviation in $(K_{oc})_{obs}$ from the true K_{oc} is a function of the product of the organic-carbon-normalized HOC partition coefficient with colloids (K_{coc}) and the abundance of colloidal organic matter (COC).

The phenomenon results in $(K_{oc})_{obs}$ versus K_{ow} plots with decreasing (i.e., nonlinear) slopes at higher K_{ow}, approaching in the limit apparently constant $(K_{oc})_{obs}$ values as the colloid partitioning overwhelms the truly dissolved form in the filtrate.

The potential presence of the particle concentration effect is indicated in several of the surveyed data sets in Figure 1, notably in Baker et al. [27], Lau et al. [25], and Butcher et al. [26]. Similarly, a decreasing $(K_{oc})_{obs}$ versus K_{ow} slope was observed for the highly hydrophobic PCDDs and PCDFs (Fig. 3a, and b; data from Broman et al. [40] and Götz et al. [41]) in the presumed colloid-rich waters of the Baltic Sea and the Elbe River. If the surveyed $(K_{oc})_{obs}$ data were corrected for this colloid effect, the true particle water distributions would be even more enhanced relative to OMP predictions than is currently depicted in Figures 1 through 4.

Extremely low log $(K_{oc})_{obs}$ values, on the order of only two to three, were reported for PCBs in organic-rich (total organic carbon, 4–6%; dissolved organic carbon, 14–87 mg/L) sediments of the outer New Bedford harbor [42]. These numbers are roughly one to three orders of magnitude lower than predicted from the OMP model and are even more divergent from all other field-observed numbers. The authors attributed their low $(K_{oc})_{obs}$ numbers to the overwhelming influence of colloidal sorption in their pore waters. This was suspected to be more important for larger PCBs due to both steric hindrance to solid-phase sorption sites and greater surface-to-volume ratio of the colloidal organic matter. As the K_{oc} values obtained in that study deviate to such a great extent from all other evaluated field data, they are not included in Figure 1.

Enhanced $(K_{oc})_{obs}$ values due to nonequilibrium caused by biodegradation of the dissolved fraction surpassing desorption cannot by totally ruled out. However, several studies have shown that the in situ degradation rates of these recalcitrant aromatic organochlorine compounds are not likely to create such large deficiencies of the dissolved concentrations (cf., [43]).

Overestimated dissolved exposures and sediment quality criteria

Because the ratio between observed and predicted K_{oc} values for a given compound is inversely correlated with the respective observed and predicted dissolved concentrations (Eqn. 3), the divergence between observed and predicted numbers is a direct measure of our current overestimation of the compounds' dissolved exposures,

$$FOE = \frac{(c_{water})_{pred}}{(c_{water})_{obs}} = \frac{(K_{oc})_{obs}}{(K_{oc})_{pred}} \quad (3)$$

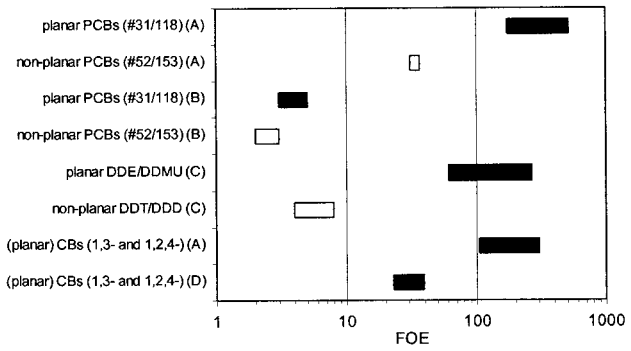

Fig. 6. Range of factors of overestimated dissolved exposures (FOEs) for selected compounds. Filled bars = planar compounds; open bars = nonplanar compounds. (**A**) Jonker and Smedes [24]; (**B**) Butcher et al. [26]; (**C**) Ö. Gustafsson, personal communication; (**D**) Ten Hulscher et al. [32]. CB = polychlorinated benzenes.

The factors of overestimated dissolved exposures (FOEs) observed in the data compiled in Figures 1 through 4 range from roughly one to three orders of magnitude. Selected examples for individual planar and nonplanar representatives of the different compound classes under investigation are presented in Figure 6. These ubiquitously observed large FOEs indicate that the mobility of HOCs in aqueous environments is likely to be significantly lower than currently expected. While ingestion may be an important uptake route for higher animals, the dissolved exposures constitute the directly bioavailable fraction of HOCs in the environment. Therefore, (enhanced) sorption to sediment reduces the bioavailability of organic pollutants (cf., [44,45]).

The separation and quantification of distinct subfractions of the bulk organic carbon pool such as soot and the determination of their specific affinities toward HOCs is likely to prove beneficial for a more accurate description of HOC solid–water-phase partitioning. An extension of the OMP model and sediment quality criteria (SQC) for aromatic organochlorines similar to the one earlier suggested for PAHs [9] might therefore be considered. The basis of SQCs is to ensure that the pore-water concentration, in equilibrium with the sediment, is not exceeding the final chronic water quality criteria values (FCV) [4,5]. Since the soot phase may be influencing the environmental speciation of organochlorines, a SQC for these compounds may, in analogy to the earlier formulation for PAHs [9], be defined as

$$SQC(\text{compound}_i) = (f_{oc}K_{oc} + f_{sc}K_{sc})FCV(\text{compound}_i) \quad (4)$$

where f_{sc} is the soot-carbon fraction of the sorbent (kg soot carbon/kg total solid) and K_{sc} is the soot-carbon normalized partition coefficient (L water/kg soot carbon).

Such an increased ability to anticipate the distribution of HOCs between particle-bound and dissolved forms would improve the possibility of society to prioritize and handle issues concerning these chemicals in the environment in many ways. The accurate quantitative prediction of phase speciation would, e.g., allow the a priori estimation of directly bioavailable, dissolved exposures and tendency for long-range dispersal. Large savings for society are to be made in using extended knowledge about pollutant speciation in risk evaluation. This would provide an efficient basis for setting priorities regarding which compounds and which contaminated sites are most efficiently and urgently remediated.

CONCLUSIONS

In summary, field-observed solid–water distributions of individual HOCs surveyed from the literature suggest that the traditional organic-carbon-normalized solid–water distribution model severely underestimates K_{oc} values for a wide range of compound classes (PCBs, polychlorinated benzenes, PCDDs and PCDFs, and DDXs). In several of the presented cases, the presence of soot-like subfractions of the bulk particulate organic matter was put forward as a likely explanation for these findings [24; D. Broman and P.H. Santschi and Ö. Gustafsson, personal communications]. This argument is additionally supported in certain cases by the preferential sorption of the planar representatives of these compound classes [24; P.H. Santschi and Ö. Gustafsson, personal communications]. For a given compound class, the divergence between observed and predicted K_{oc} values often appeared to be relatively small in surface water but much more pronounced in sediments. Based on this compilation, it appears likely that soot and possibly other subfractions of bulk organic matter with distinct structure and composition play a vital role for the distribution of not only PAHs but also of a wide range of other hydrophobic sorbates. The refined, soot-inclusive solid–water partitioning model has been demonstrated to significantly better explain the field-observed distributions than the OMP model [12,40,46]. The analysis presented here suggests that a soot-inclusive partitioning model may also improve prediction of the actual distributions for several other HOC compound classes. This would require the determination of soot–water distribution coefficients for the respective compounds either by theoretical estimations [12] or by laboratory-based soot partitioning experiments [16].

(*Received* 7 *March* 1996; *Accepted* 18 *October* 1996)

Abstract—Biota-sediment accumulation factors (BSAF; concentration in organism lipid/concentration in sediment on an organic carbon basis) of polyaromatic hydrocarbons varied with season and along an intertidal gradient in a coastal marsh in San Francisco Bay. The BSAFs were lowest during the local rainy season. During the dry season, BSAFs were lowest in the high intertidal zone closest to shore. Significant differences among species groups were also observed; BSAFs were lowest in polychaetes and highest in the asian clam (*Potamocorbula amurensis*), varying over almost three orders of magnitude (0.0069–5.4 g sediment organic C/g lipid). The BSAFs decreased with increasing percent fines in the sediments and with PAH concentrations on an organic carbon basis. We suggest that a determining variable is the content of highly aromatic soot particles, which increases during periods of surface runoff and which is expected in the dry season to be highest in the high intertidal zone where these finer particles preferentially accumulate. Correlations of BSAFs with the ratio of the logarithm of the activity coefficients in porewaters to those in sediments were generally stronger than with log K_{ow}, indicating a limitation of octanol as a surrogate for sediment organic carbon or organism lipid. These observations qualify but also strengthen the concept of equilibrium partitioning as the determining factor in bioaccumulation by benthic organisms of nonpolar organic compounds from sediments; the assumption that ''organic carbon'' can be considered in generic terms without allowance for aromaticity and probably other factors as well, must, however, be reconsidered.

Keywords—Bioaccumulation Bioavailability PAHs Benthic invertebrates Sediment quality criteria

INTRODUCTION

In a study of the distribution of polynuclear aromatic hydrocarbons (PAHs) in sediments and their interstitial waters of a mudflat in San Francisco Bay, we measured an order of magnitude variation in values of the in situ sediment porewater partition coefficient (K_{oc}') for a suite of 3–6 ring PAHs. The K_{oc}'s increased with the organic carbon and silt content of surface sediments collected along an intertidal gradient during the dry and wet seasons in 1993–1994 and were higher during the wet period of high surface runoff than during the dry season. Moreover, K_{oc}' decreased from the high- to the low-intertidal zone during the dry season, indicating heterogeneity in partitioning behavior along this spatial gradient [1].

Several studies of the distribution of hydrophobic compounds between sediments and interstitial porewaters have examined the role of dissolved organic matter in enhancing solubilities and thereby increasing concentrations of these compounds in the porewaters [2–5]. On the basis of concentrations in sediments, however, our measured porewater concentrations during the rainy season and in the high intertidal during the dry season were lower than predicted by the octanol–water partition coefficients and by simple two-phase equilibrium partitioning models [6–12]. Conversely, PAH concentrations on an organic carbon basis in the sediments were higher than would be predicted by these equilibrium models.

We proposed that the observed heterogeneity resulted from variations in the content of soot particles, which enter the system during periods of elevated surface runoff and which are expected to accumulate preferentially with other fine material in the high intertidal zone in the dry season [13]. These would provide a highly aromatic matrix for the PAHs; consequently their activity coefficients [14] would be lower in this medium than in other organic carbon matrices, and the in situ K_{oc}'s would be correspondingly higher [1].

This interpretation would therefore qualify but not necessarily negate the utility of equilibrium partitioning models in formulating chemical-specific sediment quality criteria (SQC), particularly those in which SQC are expressed on a sediment organic carbon basis. Presently, these models do not make allowance for heterogeneity in the organic carbon matrix and corresponding differences in activity coefficients of contaminant chemicals, which would in turn affect bioavailability.

The biota-sediment accumulation factor (BSAF)

$$\text{BSAF} = C_{b,lip}/C_{s,oc} \quad (1)$$

where $C_{b,lip}$ = chemical concentration in organism lipid (μg/g lipid) and $C_{s,oc}$ = chemical concentration normalized to sediment organic carbon (f_{oc}) (μg/g OC). This parameter has been recommended by several researchers for the development of SQC based on a three-compartment (sediment-porewater-biota) equilibrium partitioning model [10,15–17]. To date, these models have assumed that the organic carbon matrix can be considered in generic terms; this assumption has been supported by data from a study that examined the partitioning and toxicity of fluoranthene in sediments containing organic matter from several diverse sources [18]. These media did not include, however, sediments from areas of recent surface runoff from urban areas.

It has been assumed that the attainment of equilibrium concentrations of a hydrophobic compound between the lipids of biota and sediment organic carbon, i.e., of equal fugacity capacities [19], or alternatively, of equal chemical potentials [20]

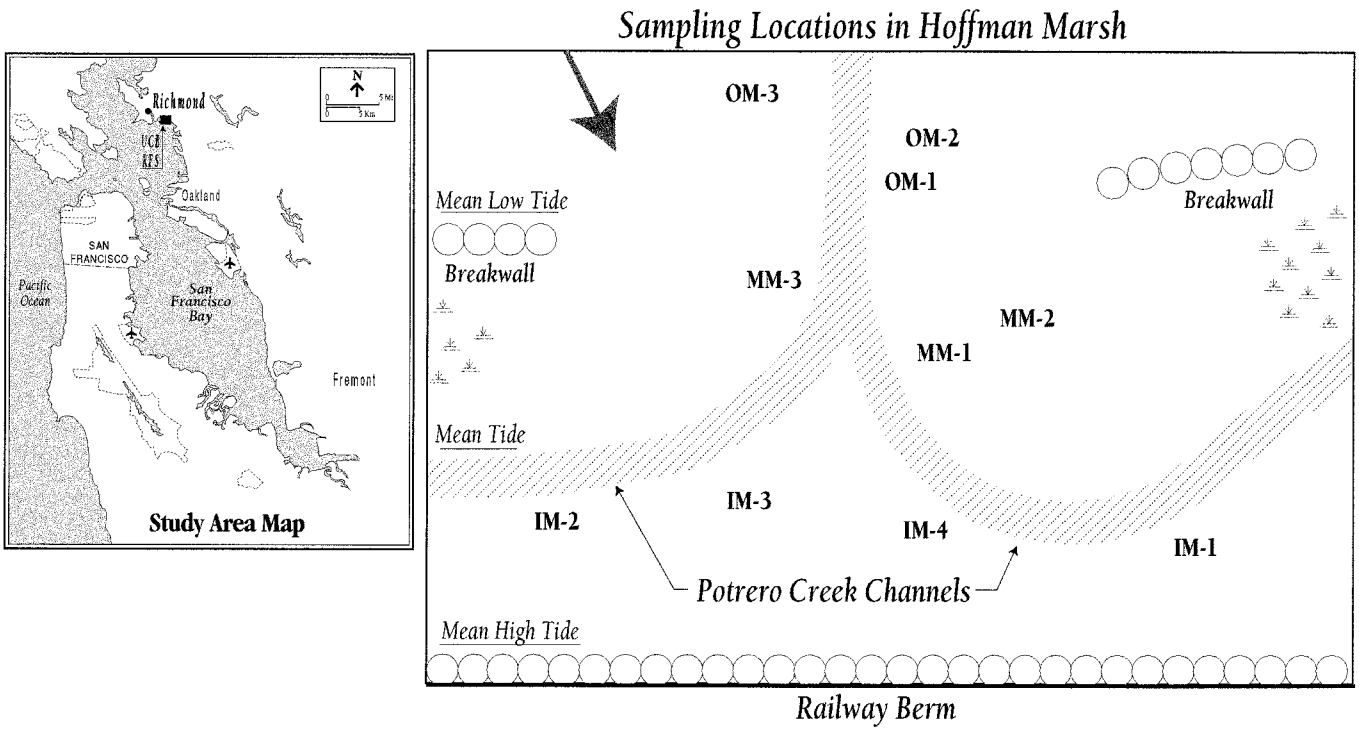

Fig. 1. Map of study area showing sampling locations in Hoffman Marsh, San Francisco Bay, California, USA.

would result in a value of approximately unity for the BSAF [10]. An abundance of both field and laboratory BSAF data, however, deviate significantly from unity [15,21,22].

In our study of the distribution of PAHs in the sediments and porewaters of an intertidal marsh in San Francisco Bay [1], we also measured PAHs in three groups of benthic intertidal organisms along an intertidal gradient during each season of a calendar year. In this paper, we examine how the order-of-magnitude variations in sediment-porewater partitioning that are associated with differences in the organic carbon matrix are related with the measured values of BSAF among the three species groups.

MATERIALS AND METHODS

All materials and methodologies utilized in this study were chosen to minimize contamination of all samples (and organic extracts thereof) by external sources. Prior to use, all sample handling/processing wares were carefully washed in hot, soapy water and rinsed thoroughly with tap water prior to use. After washing, borosilicate glasswares were kiln-fired (≥500°C) and stainless steel/teflon wares were rinsed with acetone. All organic solvents were of high purity (Optima grade; Fisher Scientific; Mountain View, CA, USA). A detailed description of the study site and all methods described herein is documented elsewhere [23].

Description of field site

Hoffman Marsh is a small (0.24 km^2) intertidal marsh along the eastern shore of central San Francisco Bay, California, USA, adjacent to the University of California Berkeley Richmond Field Station (UCB RFS), in the city of Richmond (Fig. 1). This marsh, whose area is roughly 50% brackish marsh vegetation, 30% mudflat, and 20% open bay water, has been modified by filling and installation of rock breakwalls. Two channels of a seasonally flowing creek meet near the center of the mudflats in the middle-intertidal zone. Both channels presently receive runoff from adjacent residential, commercial, and industrial developments and have historically received direct disposal of refuse and chemical contamination from neighboring munitions, lead paint and battery manufacturing, propane gas, and agrochemical manufacturing and research facilities.

The marsh supports a variety of flora and fauna including the macrophytes pickleweed and cordgrass (*Salicornia* and *Spartina* sp., respectively), benthic macro- and microalgae, and a host of benthic invertebrates that are consumed by large numbers of resident and migratory shorebirds. Several species of bivalves, dominated by the tiny gem clam (*Gemma gemma*), the Japanese littleneck clam (*Tapes japonica*), and the more recently introduced asian clam (*Potamocorbula amurensis*) can be found in the upper layers of mudflat sediments. Polychaetes are represented by small deposit-feeding species of the family Capitellidae and by larger omnivores/carnivores of the families Neptyidae and Nereidae. Several species of crustaceans (especially amphipods) are also plentiful in surface sediments.

Study design and sample collection/processing

Surface sediments and animals were collected in July and October of 1993 and again in January and April of 1994 at sites within three zones corresponding to the low, middle, and high intertidal. These zones, which correspond roughly to mean low, intermediate, and high tide zones (Fig. 1), are also referred to hereafter as the Outer, Middle and Inner Marsh (OM, MM, and IM, respectively). For each of the 10 sampling events, media were collected within a 10-m^2 quadrat. Quadrat locations are identified by their intertidal zone designation (i.e., OM) followed by a number (1–4) that signifies the sampling month (e.g., −1 = July 1993, −2 = October 1993, etc.). For the April 1994 event, only media from the Inner Marsh (IM-4)

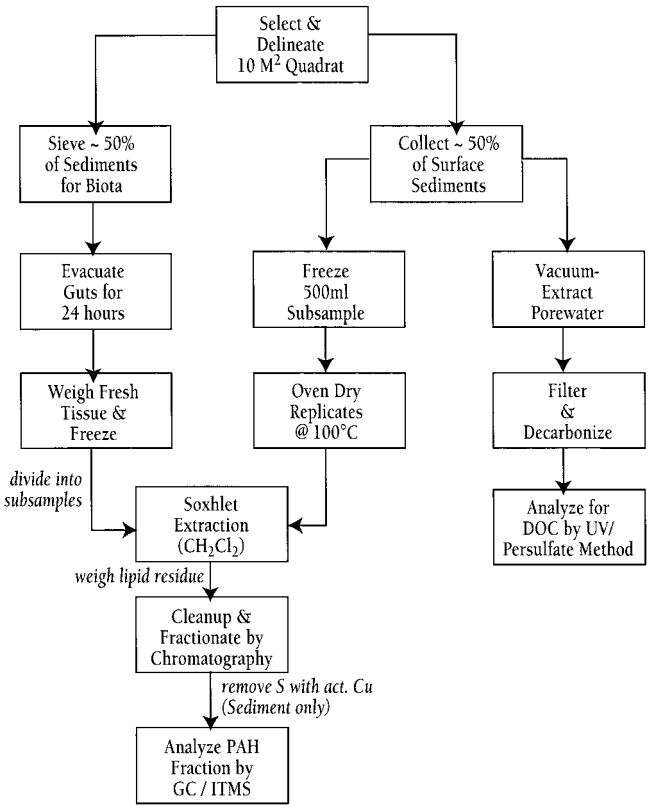

Fig. 2. Collection, processing, and analysis sequences for lipid and sediment samples.

were collected. Organisms of three major groups—*P. amurensis*, *T. japonica*, and polychaete species of the families Capitellidae, Neptyidae, Nereidae, Phyllocidae, and Spionidae—were collected in sufficient quantity for PAH analysis.

The collection, processing, and analysis sequence for sediments and organism tissues is illustrated in Figure 2. Once on site, the quadrat was delineated with a premarked nylon rope. Roughly half of the exposed sediments in the quadrat were collected to a depth of ~5 cm with a stainless steel scoop and bucket, mixing the contents periodically. The remaining sediment was sieved through a No. 10 mesh screen, and retained animals were placed in glass jars filled with ambient water using stainless steel forceps. All viable animals were collected; larger fragments of polychaete worms were also included. Immediately after collection, media were transported to our RFS laboratory where sediments were remixed and homogenized. A subsample (~500 ml) was then placed into a precleaned teflon or glass jar and frozen. Animals were separated by taxa, placed in filtered seawater, and left to stand for a 24-h period. Each specimen was then carefully rinsed with filtered seawater, tap, and finally with milli-Q grade water, placed in glass vials or kiln-fired aluminum foil, weighed, and promptly frozen.

Homogenized subsamples (10–50 g) of thawed wet sediment were weighed in a teflon beaker and oven dried at 100 ± 2°C for 24 h. Subsamples from each location were analyzed in duplicate (7/93 and 4/94) or triplicate (10/93 and 1/94). After weighing, dried sediment was homogenized with an equal amount of kiln-fired Na_2SO_4 in a glass pestle and mortar and extracted with 500 ml of CH_2Cl_2 in a soxhlet apparatus for 8 h minimum. Prior to extraction, perdeuterated PAHs (ULTRA Scientific; Kingston, RI, USA) were added to the sediment/Na_2SO_4 mixture as recovery surrogates. Soxhlet extracts were then reduced using rotary evaporation, redissolved in hexane, rereduced to 1 to 4 ml, and stored in glass vials with teflon-lined screw caps. Additional subsamples (~1 g) of dried sediment were homogenized with a small ceramic mortar and pestle and sent for TOC analysis (difference method) to Huffman Analytical Laboratories (Golden, CO, USA). The remaining frozen sediment aliquots were sent to Toxscan, Inc. (Watsonville, CA, USA) for grain size analysis (pipette method). Particle size distribution was reported for 14 size classes ($-4 \leq \Phi \leq 9$; 0.002 mm $< d_p \leq$ 32 mm), including sand ($d_p >$ 0.062 mm), silt (0.004 mm $< d_p \leq$ 0.062 mm), and clay ($d_p \leq$ 0.004 mm).

Frozen whole animals were thawed, pooled into one to three subsamples depending on expected lipid weight and/or sample availability, wet homogenized with Na_2SO_4, and soxhlet extracted as described previously for sediments. An exception was made for tissues of *T. japonica*, which were shucked and in some cases freeze-dried prior to extraction. Lipid extracts were protected from airborne fallout and allowed to evaporate to constant weight at room temperature. Lipid weight was then determined gravimetrically as the residue remaining after CH_2Cl_2 evaporation.

Sediment porewater was vacuum-extracted from homogenized whole sediments in a dark, cold room using a modified version of the vacuum-syringe extraction technique [24]. Extracted porewater was filtered with Whatman GF/F binder-free glass fiber filters (0.7 μm nominal pore size) under gentle vacuum. The filtrate was then decarbonized in 50-ml glass beakers by adding a few drops of concentrated H_2SO_4 and sparging with filtered, high purity (>99.99%) nitrogen for 10–15 min. Sparged aliquots were analyzed for dissolved organic carbon (DOC) using the persulfate-UV oxidation method [25] with a Xertex-Dohrmann DC-80 analyzer.

Sample cleanup, fractionation, and GC/MS analysis

Both tissue and sediment hexane extracts were cleaned up and fractionated using packed column chromatography, the detailed description of which is given elsewhere [1,23]. The PAHs were eluted from the sorbent (either Florisil or an alumina/silica gel combination) with a mixture of CH_2Cl_2 and hexane in the second fraction (F2) after elution of aliphatic/nonpolar interferences with hexane in the first fraction. Each F2 was then exchanged to hexane, reduced to ≤1 ml using a gentle stream of nitrogen, and analyzed on a Varian 3400 gas chromatograph (GC) coupled to a Saturn II ion trap mass spectrometer (ITMS) using helium as the carrier gas. The analysis conditions were as follows: sample volume, 1 μl; injection mode, splitless; GC column, DB-5MS, 30 m fused silica with 0.025 mm stationary phase film thickness (J&W Scientific); injector program, (1) 100°C for 0.10 min, (2) increase to 280°C at 300°C/min, (3) isothermal at 280°C for 5 min; column program, (1) 100°C for 5 min, (2) increase to 280°C at 4°C/min, and (3) isothermal at 280°C for the remaining 60-min program. The transfer line was held constant at 280°C. The ITMS was operated in the electron ionization mode with a mass detection range of 50–650 amu scanning at 1.0 scans/s and was turned on 4 min after sample injection.

thracene, and benzo[*g,h,i*]perylene—were identified by GC/ITMS based on injections of an authentic PAH standard mixture (ULTRA Scientific). Average response factors for benzo[*a*]pyrene were substituted for benzo[*e*]pyrene and perylene, the two compounds not present in the standard mixture. Retention times for these isomers were confirmed from parallel work in our laboratory [26]. Instrument sensitivity was closely monitored by periodic injections of a dilute standard mixture. Final PAH levels in media were computed using PC spreadsheet software after correction for recovery of perdeuterated PAH surrogates and relative instrument sensitivity.

Quality control

For the analysis of PAHs, 50-g aliquots of kiln-fired Na_2SO_4 were processed and analyzed as procedural blanks. The number of detections of individual PAH in these blanks was very few and in all of these cases represented less than 1% of the lowest reported PAH concentration in either tissue or sediment. A standard reference marine sediment (HS-6; NRC Canada) and a *Mytilus edulis* homogenate (SRM1974; National Institute of Standards and Technology, Gaithersburg, MD, USA) were also analyzed. The mean percent deviation (MPD) from reported values for 16 of the 18 PAHs was 24 ± 19 for HS-6. The MPD for 11 congeners (of which only 9 were certified) was 23 ± 19 for SRM 1974. Mean recoveries of perdeuterated surrogates in sediment extracts were 45, 82, 92, 88, and 47% for naphthalene-d8, acenaphthene-d10, phenanthrene-d10, chrysene-d10, and perylene-d12, respectively. The corresponding values for tissue extracts were 57, 42, 89, 98, and 80%. The PAHs were included in the computation of BSAFs if mass spectra confirmed their presence (S/N ≥ 5) and surrogate recovery was greater than 50% but less than 150%. Mean coefficients of variation (CVs) for all PAHs (except perylene) were 24% and 28% for sediment replicates and pooled tissue subsamples, respectively. Perylene was not detected in any of the tissue samples and therefore was reported in sediment samples only. Only two PAHs, acenaphthene (65%) and benzo[*a*]pyrene (58%), had CVs greater than 50%. Detection limits for individual PAHs under these conditions were on the order of 0.5 ng/g dry weight and 5 ng/g fresh weight.

For DOC analysis, calibration curves of standard dilutions of potassium hydrogen phthalate were highly linear ($r^2 > 0.99$) in all cases. Procedural blanks, consisting of 100 ml of milli-Q water extracted with the vacuum apparatus, typically contained <2 mg DOC/L; freshly prepared milli-Q water typically measured <1 mg/L. The blank was unsatisfactorily high for the January 1994 IM-3 porewater; hence, DOC was not reported for this sample. Because the remaining DOC levels typically exceeded 20 mg/L, samples were not corrected for blanks.

RESULTS

Sediment grain size, organic carbon, and PAHs

The sediments collected in this study were sandy to silty muds with a relatively low organic carbon content (Table 1). The amount of sediment fines (%fines = %silt + %clay) ranged between 6.0 and 44% wet weight; the mass fraction of sediment organic carbon on a dry weight basis (f_{oc}) varied by a factor of three (0.0033–0.0095). Total PAHs as the sum of 18 unsubstituted congeners (see Materials and Methods) on a dry weight ($TPAH_{dw}$) and on an organic carbon basis ($TPAH_{oc}$) were relatively moderate in concentration (mid ng/g to low μg/g range) and varied by more than a factor of 20. The use of TPAH as a relative measure of PAH contamination is justified because individual congener concentrations (e.g., phenanthrene, fluoranthene, chrysene) were correlated ($p < 0.05$) with both $TPAH_{dw}$ and $TPAH_{oc}$. Furthermore, the less-than-unity ratios of methylphenanthrenes (sum of four isomers) to phenanthrene (MP/P) indicated that PAHs in the marsh were primarily combustion in nature [27,28].

Biota sediment accumulation factors

Compound-specific BSAFs were computed using Equation 1 for *P. amurensis*, *T. japonica*, and polychaetes (Tables 2, 3 and 4). Polychaete BSAFs were further subdivided into a ''large'' (nereids and neptyds) and ''small'' (mostly capitellids) category (Table 4). In cases where sufficient tissue allowed for the analysis of subsamples, mean BSAFs are reported. Although median values were similar, the magnitude of individual BSAFs ranged from 0.0069 to 5.4 g SOC/g lipid, a spread of almost three orders of magnitude (Table 5). Within each organism grouping, polychaetes had the lowest variation (factor of 50) and *T. japonica* the highest (factor of 300).

Intertidal zone and seasonal variations

Three trends in BSAF were apparent, the first of which was the consistent increase in BSAF from Inner to Outer Marsh locations. The rankings of BSAF values for each of the three major organism groups were compared by intertidal zone using

[b] Sum of 17 2–6 ring unsubstituted PAHs on an organism lipid basis (μg/g lipid).

nonparametric ANOVA (Kruskal–Wallis method). In all cases, a difference at the 0.01 level was observed (Table 6). Individual multiple comparisons were made using Bonferroni's inequality; the overall type I error in these tests was selected as 0.05. The BSAFs for *P. amurensis* from the IM were determined to be different from (lower than) those from the OM ($p < 0.017$). For *T. japonica,* BSAFs in each intertidal zone (i.e., IM, MM, and OM) were different among themselves, with IM specimens having the lowest values and OM specimens the highest. For polychaetes, BSAFs for the IM were lower than those of either the MM and OM.

The second trend was the difference in BSAF by sampling season. The highest BSAFs for *P. amurensis* were measured in the fall event (October) followed by the summer (July) and winter (January) (Table 6). For *T. japonica,* BSAFs for three of the six possible seasonal comparisons were significantly different ($p < 0.0083$) with the fall BSAFs again being the highest. Similarly, polychaete BSAFs for July 1993 were different than those determined for January and April 1994 ($p < 0.017$). In each case, values were lowest in the rainy season (January and April).

The third trend was the decrease in BSAF with increasing PAH hydrophobicity, particularly for the two bivalves. This relationship, along with the intertidal zone and seasonal differences, can be seen in plots of BSAF versus log K_{ow}. Values of K_{ow} were taken from several sources [14,29–31]. The BSAF was negatively correlated with log K_{ow} ($p < 0.05$) for seven of the nine possible intertidal zone data sets (Fig. 3). The two exceptions were for polychaetes in the high- and middle-intertidal zones. In addition, the dependence of BSAF on log K_{ow} (as measured by the regression slopes) increased with decreasing intertidal height for all organism groups. This increase in slope corresponded to decreases in f_{oc} and %FINES. Furthermore, $TPAH_{oc}$ decreased along this transect. The effect of season on the relationship of BSAF and log K_{ow} was consistent among organism groups (Fig. 4), although fewer (4 of 10 possible) regressions were significant ($p < 0.05$).

Differences among taxa

A four-way ranking of BSAFs (categories were *P. amurensis, T. japonica,* large and small polychaetes) again using Kruskal–Wallis ANOVA revealed that a difference in BSAF among organism groups was significant ($\chi^2 = 30.51$; $p < 0.001$); however, individual multiple comparisons using Bonferroni's inequality indicated that BSAFs for small and large polychaetes were not significantly different ($Z = -1.01$; $p > 0.05$). These data were therefore pooled into a single polychaete composite. Repeating this analysis with three categories (*P. amurensis, T. japonica,* and polychaetes) revealed that a significant difference among BSAF values still existed among the organism groups ($\chi^2 = 29.5$; $p < 0.001$). Individual multiple comparisons showed that BSAFs for *P. amurensis* were different than both *T. japonica* and polychaetes ($Z = -5.27$ and -3.57, respectively; $p < 0.017$ for both).

Lipid content and porewater DOC

Lipid content (%lipid) ranged from 0.15 to 2.1% wet weight for the three groups of organisms; polychaete composites generally had the highest lipid content, shucked tissues of *T. japonica* had intermediate levels, and *P. amurensis* had the lowest (Tables 2–4). These levels are consistent with those reported for sandworms and mussels—1.78 and 1.42%, respectively—using a chloroform/methanol extraction procedure [32]. Lipids were generally highest at IM sites and lowest in specimens from the OM. Correspondingly, %lipid was linearly correlated with %fines for *T. japonica* ($r^2 = 0.81$, $p \leq 0.05$) and with f_{oc} for both bivalves ($r^2 = 0.53$ [*P. amurensis*] and 0.64 [*T. japonica*]; $p < 0.05$ for both). No relationships between %fines or f_{oc} and %lipid for polychaetes were noted. The sum of 17 PAHs (excluding perylene) in lipids, or $TPAH_{lip}$, varied by a factor of 10 (3.6–36 mg/kg lipid). No obvious trends were apparent across organism groups; however, $TPAH_{lip}$ were generally highest for bivalves whose %lipid were lowest (i.e., at OM locations). There were no significant correlations between $TPAH_{lip}$ and any of the other measured parameters (including $TPAH_{dw}$ and $TPAH_{oc}$).

Porewater DOC concentrations for our limited sample size ($n = 6$) ranged between 16 mg/L for IM-4 to 93 mg/L for OM-3. The remaining levels were 69, 28, 70, and 67 for IM-2, MM-2, OM-2, and MM-3, respectively. These levels were somewhat higher than those reported in Boston Harbor sediment cores (5.3–23 mg/L) [33] but were comparable in range

to those reported in a 36-cm core from New Bedford Harbor [34]. No seasonal or intertidal zone patterns were apparent for these data. In addition, DOC was not correlated with %fines or f_{oc}, or any other parameter, including total PAHs in sediments or lipids.

Relationships of BSAF with other parameters

The BSAF was also negatively associated with log K_{ow} (Fig. 5; Eqns. 2–4) at the 0.05 level of significance for each of the three organism groups.

P. amurensis

$$\text{BSAF} = 2.9 - 0.39 \log K_{ow} \quad (n = 84;\ r^2 = 0.15;\ p < 0.001) \tag{2}$$

T. japonica

$$\text{BSAF} = 1.6 - 0.23 \log K_{ow} \quad (n = 79;\ r^2 = 0.14;\ p < 0.001) \tag{3}$$

Polychaetes

$$\text{BSAF} = 0.93 - 0.18 \log K_{ow} \quad (n = 63;\ r^2 = 0.090;\ p < 0.05) \tag{4}$$

The magnitude of the dependence of BSAF on log K_{ow} (i.e., the slope of these equations) decreases from *P. amurensis* to *T. japonica* to polychaetes. The slope of Equation 2 for *P. amurensis* is significantly different than that for polychaetes (Student's *t*-test; $p < 0.05$).

Other parameters, however, explained portions of the variance of BSAF consistently as much or more than did log K_{ow}. Stepwise multiple regression analysis of BSAF against all study parameters (sediment fines, organic carbon and PAH concentrations, porewater dissolved organic carbon, organism lipid and PAH concentrations) showed that (1) for *P. amurensis*, a combination of f_{oc}, log K_{ow}, and %fines explained 55% of the total variation in BSAF, with individual contributions of 32, 18, and 5.3%, respectively; (2) for *T. japonica*, $TPAH_{oc}$, log K_{ow}, and %fines explained 30, 15, and 7%, respectively; and (3) for polychaetes, $TPAH_{dw}$, log K_{ow}, and

$TPAH_{lip}$ accounted for 9.5, 9.2, and 8.1%, respectively, of the BSAF variance.

In addition to the solubilities of PAHs in water, or specifically the ratio of their solubilities in octanol and water, both the organic carbon content (f_{oc}) and the nature of the organic carbon matrix appear therefore to influence the values of BSAF obtained in this study. Spearman's rank correlation analysis of BSAFs of individual PAHs also showed that BSAFs decreased significantly with increasing f_{oc}; moreover, BSAFs also decreased significantly with increasing PAH concentrations on an organic carbon basis (Table 7). A heterogeneity of the organic carbon matrix is therefore indicated.

Furthermore, the logarithms of measured values of K_{oc}' [1], the ratio of concentrations in the sediments on an organic carbon basis to concentrations in the porewaters were, except for the small polychaetes, more strongly correlated with BSAFs than were log K_{ow}s (Table 8).

DISCUSSION

The concept of equilibrium partitioning, as developed to date for the establishment of sediment quality criteria for nonionic chemicals, addresses varying bioavailability across sediments by normalizing concentrations on an organic carbon basis and using the octanol–water partition coefficients to establish a relationship between concentrations in water and those in sediments [10]. Contrary to the predictions of this theory, this study has shown that measured values of BSAF varied both seasonally and spatially in an intertidal marsh in San Francisco Bay. Moreover, the variation was considerably greater than the factor of two to three considered to be sufficient to account for unexplained variability.

Because the patterns of variability in BSAFs closely parallel the seasonal and spatial variability in measured values of K_{oc}', which we have attributed to seasonal and spatial variations in the soot content of sediments [1], we also attribute the major portion of the variability in BSAF that is unexplained by equilibrium partitioning [10] to the soot content of the sediments. In the San Francisco Bay area, the local rainy season typically begins in November and extends into April, with little or no rain between May and October. Input of combustion-derived PAH, associated with soot particles, into this highly urbanized estuary from surface runoff would therefore occur during the rainy season only. The PAHs would be expected to maintain their affinity with the highly aromatic soot particles [35] because their chemical activity coefficients would be lower in this medium than in other types of sediment organic carbon matrices (e.g., those derived primarily from ''natural'' or ''biogenic'' sources [18]). Proportionately more of the PAHs in this intertidal environment would therefore be associated with the organic carbon fraction of the sediments during the local rainy season, hence the lower values of the measured BSAFs.

During the dry season, continued resuspension of finer sediment particles in areas of wind and tidal activity would result in their preferential deposition in areas of lowest resuspension, particularly the high intertidal zone (IM) [13]. Moreover, the average diameter of soot particles (~0.004 mm) to which 97% of benzo[*a*]pyrene in air was sorbed was well within the silt/clay particle size regime [36]. The amount of sediment fines

(silt and clay fractions) and organic carbon-normalized sediment PAHs in our study were highest in this zone [1]; we propose that this would account for the observed spatial variations in BSAF.

Earlier conclusions that the nature of the sediment organic matrix did not affect the bioavailability of the PAH fluoranthene to benthic organisms might therefore be reconsidered because only ''natural'' sources of organic carbon were evaluated [18]. Based on our results, the organic carbon matrices of sediments exposed to recent surface runoff or in areas of deposition of fine particles in an urban environment are likely to be more ''soot-like'' with the corresponding effects on partitioning and bioavailability of combustion-source PAHs.

The stronger association of BSAFs with log K_{oc}', equivalent to the logarithm of the ratios of chemical activity coefficients in porewaters and sediments, than with log K_{ow}, equivalent to the ratios of these coefficients in water and octanol, indicates a limitation of octanol as a surrogate for all types of organic carbon matrices in sediments. The theoretical basis of equilibrium partitioning would therefore be more appropriately based on ratios of chemical activity coefficients, expressed as K_{oc}s, rather than on K_{ow}s. For most uses, these have to date been considered to be equivalent or near equivalent in the development of the equilibrium partitioning concept [10]. Phenomena previously unexplained, or apparently inconsistent with the predictions of equilibrium partitioning, such as the observed greater uptake clearance for 2,4,5,2′,4′,5′-hexachlorobiphenyl than for benzo[*a*]pyrene, in spite of a higher K_{ow} [37] are, however, more readily explained by media-associated differences of chemical activity coefficients under equilibrium or near-equilibrium conditions [1]. More specifically, we propose that by making allowances for K_{oc}s not always being equivalent to K_{ow}s, the predictability of BSAFs can be improved.

Several polychaete species have been shown to possess the enzyme systems that transform aromatic hydrocarbons, including PAHs, into polar metabolites [38–40], whereas there is very little evidence that bivalves possess similar capabilities [38,41]. Species that possess these systems show lower BSAFs when PAH concentrations are reported, as in our study, as parent compounds alone rather than as the sum of parent compounds and polar derivatives [42]. The lower BSAFs we have reported for polychaetes than for bivalves may therefore result from metabolism. The PAH profile, the relative amounts among the principal compounds, was similar in polychaetes and sediments. This does not necessarily indicate a lack of metabolism because there is no evidence for selective metabolism of either lower or higher MW compounds [43].

It has been proposed that kinetic limitations may affect PAH partitioning behavior and bioavailability [44]. These may in part explain the decreasing BSAFs with increasing K_{ow}s observed in both bivalve species in our study. Although these are primarily surface detritus feeders, they are also exposed to the sediment/water column interface. Data of Rubinstein et al. [45] analyzed by DiToro et al. [10] show, however, that decreasing BSAFs of a series of PCB congeners were also

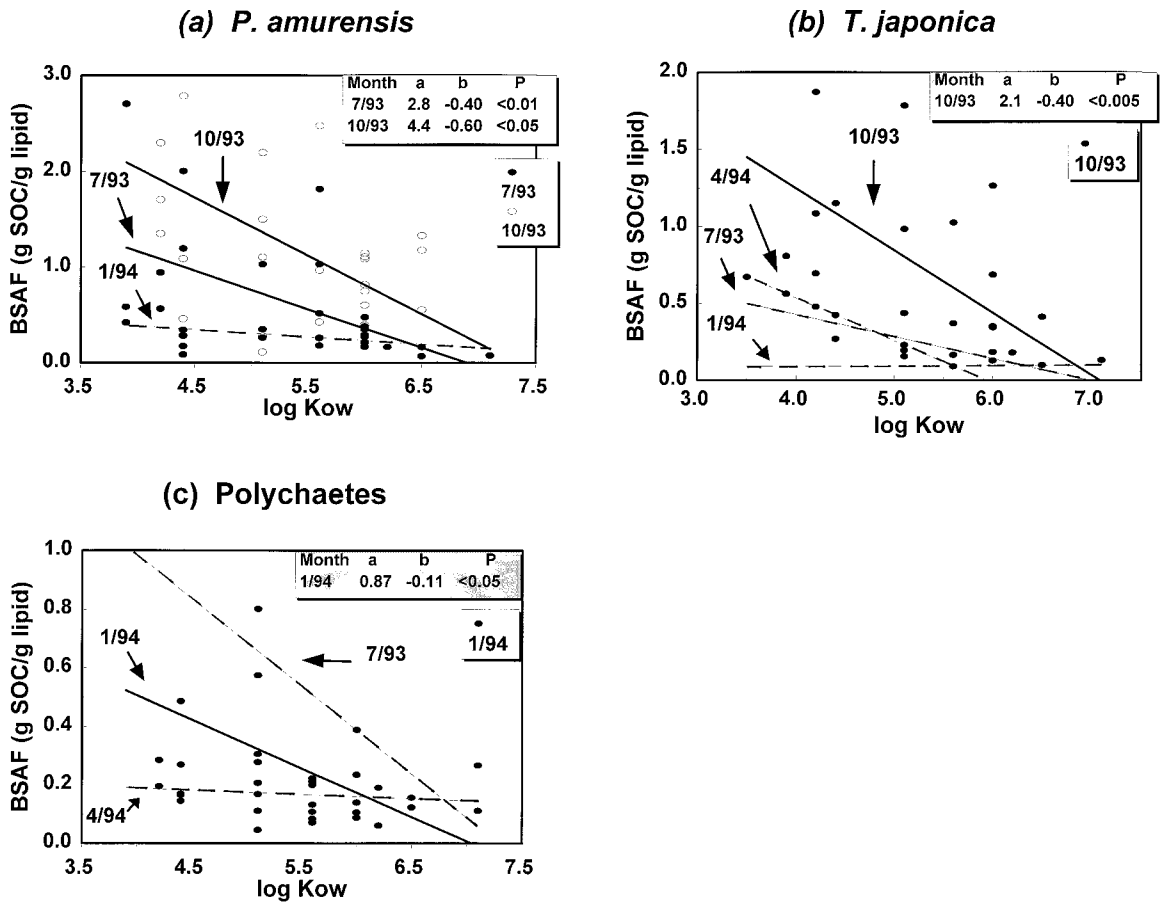

Fig. 4. Relationship between BSAF and log K_{ow} according to season for (**a**) *Potamocorbula amurensis*, (**b**) *Tapes japonica*, and (**c**) polychaetes. Regression equations are of the form $y = a + bx$; p = probability of no correlation. Solid lines denote significant correlations ($p < 0.05$); broken lines represent linear ($p > 0.05$) fits for comparison purposes only.

associated with increasing K_{ow}s when bivalves were exposed to spiked sediments over a period of time considered sufficient for attainment of equilibrium conditions. It appears likely therefore that the observed relationships between BSAFs and log K_{ow}s of the respective congeners result from the relationships among the chemical activity coefficients in bivalve lipid, local sediments, and local water.

The higher lipid content of the organisms in the higher intertidal zone and lower lipid content in areas covered by water for longer periods of time may be associated with the abundance and quality of food in this area; measurements of benthic algal productivity have shown that the high intertidal is three to four times more productive than other areas of San Francisco Bay (J. Gregg and A.J. Horne, unpublished data). We do not attribute differences in lipid content to any kind of contaminant effect. The levels of PAHs measured in this study are well below levels associated with induced tumors in bot-

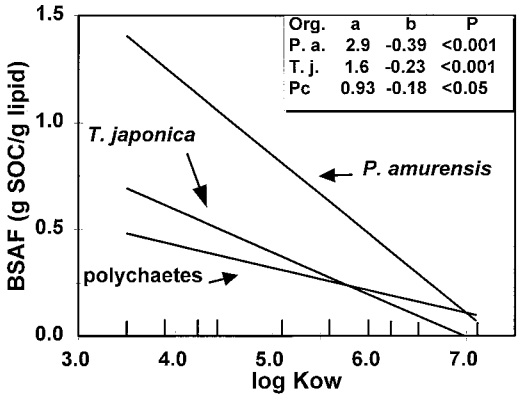

Fig. 5. BSAF and log K_{ow} by organism (*Potamocorbula amurensis* [P.a.], *Tapes japonica* [T.j.], and polychaete composites [Pc]). Regression equations are of the form $y = a + bx$; p = probability of no correlation.

tom-dwelling fish [46,47] and have not been associated with any documented effects on a population level.

Our suggested modification of the equilibrium partitioning concept, while enhancing the theoretical predictability of bioaccumulation factors, would in practice require that the uncertainty factor in predicting bioaccumulation of PAHs based on log K_{ow} be increased to a factor of about 10 in the direction of lower bioavailability. This is in agreement with an evaluation of equilibrium partitioning for pyrene based on measured sediment toxicity and toxicokinetic parameters [44]. This level of uncertainty, compared with the previously acknowledged unexplained variability of two to three in measures of bioavailability [10], would account for differences in organic carbon matrices in the real world.

The Role of Screening-Level Risk Assessments and Refining Contaminants of Concern in Baseline Ecological Risk Assessments

Screening-Level Ecological Risk Assessments (SLERAs)

Screening-Level Ecological Risk Assessments are conservative assessments in that they provide a high level of confidence in determining a low probability of adverse risk, and they incorporate uncertainty in a precautionary manner. It must be stressed that SLERAs are not designed nor intended to provide definitive estimates of actual risk, generate cleanup goals and, in general, are not based upon site-specific assumptions. Rather, the purpose of SLERAs is to assess the need, and if required, the level of effort necessary, to conduct a detailed or "baseline" ecological risk assessment for a particular site or facility. Therefore, refinement of contaminants of concern occurs in the baseline risk assessment rather than in the SLERA.

It is also important to note that SLERAs, like baseline ecological risk assessments, should take place with input from Regional Ecological Risk Assessors and/or the Biological Technical Assistance Group as well as in coordination with Natural Resource Trustees.

IN THIS BULLETIN

Introduction

This supplemental Ecological Risk Assessment (ERA) guidance is intended to provide further

clarification and direction regarding Screening Level Ecological Risk Assessments (SLERAs), as described in Step 1 - Preliminary Problem Formulation, and Step 2 - Preliminary Risk Calculation, of the Agency's program guidance: *Ecological Risk Assessment Guidance for Superfund: Process for Designing and Conducting Ecological Risk Assessments* (U.S. EPA 1997).[1] It also provides an approach for incorporating additional components into the Problem Formulation phase of more detailed (i.e., "baseline") ecological risk assessments, particularly in Step 3.2, which discusses refining contaminants of potential concern (COPCs). The Superfund program guidance, which may be applicable to RCRA Corrective Actions, describes a process that incorporates flexibility in refining COPCs in order to focus and streamline the overall ERA process while still ensuring a consistent approach. This guidance provides more detail on how to incorporate that flexibility.

The Purpose of Screening-Level Ecological Risk Assessments

Screening-Level Ecological Risk Assessments provide a general indication of the *potential* for ecological risk (or lack thereof) and may be conducted for several purposes including: 1) to estimate the likelihood that a particular ecological risk exists, 2) to identify the need for site-specific data collection efforts, or 3) to focus site-specific ecological risk assessments where warranted.

It is important to note that this guidance adopts the presumption that all data used in the SLERA are of adequate quantity and quality, and if data deficiencies are identified, either further data collection will be undertaken or other means employed to more fully characterize exposures (e.g., fate and transport modeling). If, for example, the SLERA indicates that adverse ecological effects are possible at environmental concentrations below standard quantitation limits, a "non-detect" based on those limits cannot be used as the sole basis for a "no risk" decision. Further lines of evidence (e.g., more refined/usable data, modeling results, or other measures) are needed to fully characterize the potential for adverse effects.

This guidance also reaffirms that a screening level assessment, while abbreviated, is nonetheless a complete risk assessment. Therefore, regardless of the findings of the Scientific Management Decision Point (SMDP) occurring after Step 2 (i.e., further assessment or no further assessment required), each SLERA should include documentation supporting the risk characterization and uncertainty analysis.

If the SLERA risk characterization indicates the need for further assessment, Step 3 is begun, and decisions are made regarding additional elements of problem formulation, analysis and decision point criteria. This supplemental guidance addresses how background, frequency and magnitude of detection, and dietary considerations may be used to reduce the COPCs. The use of site-specific information, as provided for in this *ECO Update*, should be discussed with the Regional Ecological Risk Assessors and/or Biological Technical Assistance Group (BTAG) early in the Problem Formulation phase of the baseline ERA.

It is the intent of this supplemental guidance to promote consistency in the screening process, yet allow for flexibility in application and timing of the elements that can help streamline more detailed assessments. Screening-Level Ecological Risk Assessments may be completed in relatively short time frames, whereas baseline ERAs may require much longer periods for planning and implementation, particularly when attempting to address seasonal or other cyclic events. Regional Ecological Risk Assessors can use this flexible approach when introducing components into the Problem Formulation phase based on regional and site-specific needs. This will effectively reduce the COPCs carried through the baseline ERA and the time required for its completion.

The Purpose of Baseline Ecological Risk Assessments

Within the Office of Solid Waste and Emergency Response (OSWER), the Superfund and RCRA Corrective Action cleanup programs generally use baseline ecological risk assessments to: "1) identify and characterize the current and potential threats to the environment from a hazardous substance release, 2) evaluate the ecological impacts of alternative remediation strategies, and 3) establish cleanup levels in the selected remedy that will protect those natural resources at risk." (U.S. EPA 1994e, OSWER Directive # 9285.7-17). The Superfund program guidance outlines an eight-step process that meets the three OSWER objectives for the baseline ERA while further implementing the Agency's policy of writing risk assessments that provide transparency in EPA's decision making process and clarity in communication with the public regarding environmental risk (U.S. EPA 1995, Risk Characterization Policy). In addition, application of the information in this ECO Update should further ensure that, for OSWER cleanups, core assumptions and science policy are consistent and comparable across programs, well grounded in science, and fall within a "zone of reasonableness."

[1] The first three steps of the Superfund ecological risk assessment process are described in the text box on page 3.

Standard Components of ERAs

The following text box highlights the risk assessment components common to both a SLERA and the Problem Formulation phase of a baseline ERA. In addition, the text helps to identify points in the ERA process where additional components may be considered in developing risk estimates.

Components of a SLERA

Although less detailed than a baseline ERA, screening assessments still include all of the following components:

- Screening level Problem Formulation and Ecological Effects Characterization (Step 1)
  - Identification of environmental setting and preliminary contaminants of concern
  - Determination of contaminant fate and transport pathways
  - Description of contaminant mechanisms of ecotoxicity and categories of receptors likely affected
  - Identification of complete exposure pathways and selection of generic assessment endpoints
  - Selection of screening ecotoxicity values
  - Evaluation of uncertainties
- Screening level Exposure Estimate and Risk Calculation (Step 2)
  - Determination of screening-level exposure estimate
  - Calculation of risk estimate
  - Risk characterization and evaluation of uncertainties
- Scientific Management Decision Point indicating either negligible risk or continuation to a baseline risk assessment

Components of a Baseline Ecological Risk Assessment Problem Formulation

Problem Formulation for a baseline ERA (Step 3) includes the following components:

- Refinement of the Contaminants of Potential Concern (COPCs) by examining the assumptions used in Steps 1 and 2
- Further characterization of ecological effects of contaminants
- Reviewing and refining information on contaminant fate and transport, complete exposure pathways, and ecosystems potentially at risk
- Selection of site-specific assessment endpoints
- Development of a conceptual model and associated risk questions
- Scientific Management Decision Point summarizing agreement on contaminants of concern, assessment endpoints, exposure pathways, and risk questions

Refining Contaminants of Concern

Screening is the comparison of site media concentrations with conservative toxicologically based numbers. Contaminants of concern may be refined to help streamline the overall ERA process by considering additional components early in the baseline ERA. After consultation with your Regional Ecological Risk Assessors and/or BTAG, one or more of the following components may be included in Step 3.2 of Problem Formulation. When added, it is important that the resulting Risk Characterization and Uncertainty Analysis fully address the issues listed for each component and describe the rationale underlying the selection of each component.

These components need not be implemented in the order presented in this document, nor do all the components need to be implemented. If, however, any contaminants are identified for exclusion from the baseline ERA through application of any or all of the three supplemental components described herein, it is essential to evaluate bioaccumulation, biomagnification, and bioconcentration of each such contaminant as well.

Supplemental Component 1: Background

Background concentrations of contaminants are those concentrations found in areas surrounding a site, but are unrelated to site releases. Contributions to these contaminant concentrations come from two major sources: first, natural sources (i.e., geologically derived concentrations of chemicals in the environment not influenced by human activity), and second, ambient or anthropogenic sources (i.e., concentrations present due to human activities, such as automobile use or pesticide dispersion in farming areas).

While contaminants of concern may be removed from further assessment through comparison with toxicological benchmarks, comparison with background levels generally cannot be used to remove contaminants of concern owing to the need to fully characterize site risk. Such comparisons, however, can be used effectively to focus the baseline risk assessment, if needed. An example of the application of background comparisons would be at a mining site with high levels of naturally occurring background metals due to local or nearby geological formations.

Consideration of background assumes that background contaminant levels have been properly determined. Until specific guidance on determining background levels is available, consult with your Regional Ecological Risk Assessors and/or BTAG to select an acceptable approach including minimum data requirements.

Issues to be discussed:

1. Potential toxicity of any contaminants identified as below background (particularly when toxicity benchmarks are lacking or when contaminants exceed toxicity benchmarks);
2. Potential for adverse effects caused by interactions between chemicals considered as background and those COPCs to be further investigated; and
3. Enumeration of all criteria by which contaminants are considered either background or site-related.

Supplemental Component 2: Frequency and Magnitude of Detection

Use of this component presumes that the sampling plan comports with *Guidance for Data Useability in Risk Assessment* (U.S. EPA 1992e). In particular, the sampling plan needs to characterize the full range of variability and distribution in the data and also needs to satisfactorily meet the criteria for completeness, comparability, representativeness, precision, and accuracy.

Similar to this supplemental guidance, current EPA human health risk assessment guidance discusses evaluation of COPCs based on frequency of detection and provides conditions under which compounds may be eliminated from further assessment. Owing to the typically small datasets available for ERAs, particularly screening-level assessments, compared to most human health risk assessments, a number of the conditions may not be applicable to ERAs. Nonetheless, given adequate data quality, further reduction of COPCs through application of this component may be determined acceptable following consultation with the Regional Ecological Risk Assessors and/or BTAG. Furthermore, the Project Manager's approval should be obtained before eliminating any chemicals from the risk assessment.

Issues to be discussed:

1. Influence of random and/or biased sampling on the frequency and magnitude of detected values within the distribution of data;
2. Spatial and temporal pattern of contaminants identified as low frequency and/or low magnitude;
3. Comparison of risk-based detection limits with toxicity benchmarks; and
4. Relationship of detected values to toxicity benchmarks.

Supplemental Component 3: Dietary Considerations

A number of chemicals that may be site-related function as nutrients in organisms serving as physiological electrolytes, such as calcium, iron, magnesium, sodium, and potassium. When present at concentrations that allow them to function in this manner, they typically pose little ecological risk. Conversely, nutrients such as selenium, copper, molybdenum, and boron, can transition from essential to toxic at only slightly higher concentrations.

Issues to be discussed:

1. The suite of nutrients relevant to the range of ecological receptors (wildlife vs. plants) considered at the site;
2. The potential for toxic effects resulting from site concentrations relative to the toxicological benchmarks for nutrients;
3. Whether contaminant interactions may result in a nutrient deficiency for organisms of concern; and
4. Whether the nutrient deficiency level and the toxicity benchmark are similar in magnitude.

Additional Considerations

For those COPCs identified by applying any of the components listed above, it is essential to evaluate their potential to bioaccumulate, bioconcentrate, and/or biomagnify prior to eliminating them from further consideration in the risk assessment. Compounds with a high potential to accumulate and persist in the food chain should be carried through the risk assessment.

Issues to be discussed:

1. The likelihood that contaminants identified for removal from the list of COPCs could exert adverse effects on higher trophic level organisms; and

2. A determination that bioaccumulation and/or biomagnification has been satisfactorily addressed through modeling, site-related tissue measurements, or other methods developed in consultation with the Regional Ecological Risk Assessors and/or BTAG.

The Role of Tiers and Sub-Tiers in ERA

The Superfund program guidance describes a tiered approach for conducting ERAs and further describes the potential need for additional sub-tiers or iterations of specific activities at large or complex sites. In addition to refining contaminants of concern, effective use of sub-tiering will help focus the ERA process and improve the quality of risk characterizations.

The Two-Tier Process

A two-tier process for implementing an ERA is outlined in Highlight 3-1 in the Superfund program guidance. The first tier of this process (Steps 1 and 2) is the screening-level ERA; the second tier (Steps 3 through 8) represents a baseline ERA. The two-tier process is a means by which to quickly and efficiently evaluate sites with minimal potential for ecological risk and eliminate them from further evaluation in the baseline ERA. The screening-level ERA also allows contaminants that do not pose a substantial ecological risk to be removed from the list of COPCs prior to conducting the baseline ERA.

Although a decision can be made to proceed with cleanup after any tier of the ERA process, for some sites of relatively small size or where the contamination has a sharply defined boundary, it may be preferable to cleanup the site to the screening values rather than to spend time and resources determining a less conservative cleanup number. For example, a pond receiving a discharge may contain contaminated sediments and removing these sediments (resulting in remediation to conservatively derived levels) may be less costly than the studies necessary to determine the site-specific risk based cleanup levels. Conversely, for many sites, it is preferable to move directly to a baseline ERA after the initial screening, and the guidance routinely provides for this second tier.

Sub-Tiering

A sub-tier may consist of any incremental iteration of the exposure, effects, or risk characterizations being conducted within the ERA and may occur at any point in Steps 3 through 7. It may be focused on a parameter, assumption, or assessment endpoint and may be necessitated through discovery of new information or new results from completed studies. Sub-tiering has the goal of focusing the evaluation of COPCs, so resources can be more effectively applied to the ERA process. The use of sub-tiers is primarily a function of the need to further reduce uncertainties in the baseline ERA, but incremental costs may also limit the amount or extent of additional activities.

To efficiently utilize sub-tiers, it is important to establish agreement early on the planning, execution, and documentation of the work to be performed. This is due, in part, to the time and effort needed to produce documents for the next sub-tier (e.g., conclusions of SLERA and follow-on work plan). In practice, the ecological risk assessor should provide support for effective sub-tiering by anticipating the potential sub-tiering options and facilitating agreement with the risk manager regarding criteria for acceptance of the resulting product. Anticipating results of successive risk calculations and facilitating agreements may take place at any appropriate time within the baseline ERA based on the existing information.

Example: Relationship Between Sub-Tiering and Reduction of COPCs

A screening-level ERA is to be conducted for a site with numerous COPCs. The stakeholders agree that the first evaluation will be to compare the maximum media contaminant levels to the most conservative ecotoxicity screening values, although they expect that this will result in removal of only a few COPCs from the list.

Moving from the screening phase into Problem Formulation, experience predicts that there will be COPCs with no toxicity benchmarks and other COPCs that are analyzed for, but not detected at risk-based detection limits. Therefore, the work plan for the baseline ERA states that contaminants included in the analysis of samples, but not detected, will be removed from the list of COPCs. Next, the plan states that a dietary exposure model will be used for specified and retained COPCs using conservative default assumptions, such as 100% absorption efficiency of all ingested material. The work plan further states that, for specific contaminants, an alternate lower absorption efficiency factor may be applied, if these contaminants are retained and if the lower factor is "pre-approved". This process could then continue as deemed appropriate and effective.

In this way, iterative evaluations (i.e., sub-tiering) can be done in an objective and technically sound manner, confidence may be increased in risk estimates, and bias (or perceived bias) in the risk characterization may be avoided by using input from both the risk assessor and the risk manager.

Documentation of Sub-Tiering

In terms of effectiveness of resource utilization, sub-tiering has its greatest potential benefit at the point in the ERA process before data intensive evaluations are designed. The experience and ability of the risk assessor to anticipate relevant risk questions and associated risk calculations and the ability of the site manager to organize the site documentation contribute to the most effective use of sub-tiering. What is often lacking and thereby a source of controversy, however, is the approach used to document and support the various decisions influencing work plans for each particular tier or sub-tier of the ERA. The rationale for each iteration, the questions to be answered, and intended use of the resulting information should be clearly defined and agreed upon with the Regional Ecological Risk Assessors and/or BTAG.

Analogy: Reduction of COPCs and Sieving Soil Particles

Reducing the list of COPCs within an ERA has a direct analogy to the physical separation of particles in soil particle size distribution analysis. The physical screens allow a known size particle to pass through the sieve (up to the diameter of the screen mesh size). What is not known is the absolute magnitude and size distribution of the material retained by the screen. This is precisely the rationale contained in the Superfund program guidance for the use of screening in the ecological risk assessment process. Upon the completion of a conservative screen, if no materials (contaminants) are retained by the screen, one can confidently state that there is a minimal potential for ecological risk to exist. Alternatively, if materials (contaminants) are retained by the screen, one cannot conclude that an ecological risk "actually" exists; the characteristics of the material retained by the screen are unknown, other than its size is above some specified minimum value. This is the basis for the statement in the Superfund program guidance that screening level values do not constitute technically defensible cleanup goals; those must be derived through the baseline ERA process.

Continuing to draw upon the physical analogy, the next challenge is to devise a means of sorting out desired material from extraneous material. Within the baseline ERA, we wish to focus on the contaminants that may actually pose an ecological risk (commonly referred to as the risk drivers) rather than on those COPC's that either do not actually pose an ecological risk, pose only a minimal ecological risk, or pose an ecological risk that is not related to the site and /or cannot be effectively reduced.

To sort through the "material," larger mesh sieves are used iteratively. This is done until: 1) all of the material has passed through the screen and it is concluded that the mesh size was not too large to allow wanted material to pass through, 2) it can be seen that additional iterations will not be functionally effective and a "different" approach is needed, or 3) the actual material desired is obtained. Correlating these outcomes with the SMDPs at the end of Step 2 of the Superfund program guidance document, the outcomes may be restated as follows: 1) "There is adequate information to conclude that ecological risks are negligible and therefore no need for remediation on the basis of ecological risk," 2) "The information is not adequate to make a decision at this point, and the ecological risk assessment process will continue to Step 3," or 3) "The information indicates a potential for adverse ecological effects, and a more thorough assessment is warranted."

What corresponds to these incrementally increasing mesh sizes within the ERA process? First, it must be recognized that the same things are always occurring in the thought process. Just as the same thought process occurs in Steps 1 and 2 as occurs in Steps 3 to 7, each iteration of the ERA, whether called a tier, a sub-tier, or any other name, includes similar considerations. In each successive tier, however, more information is used and assumptions and calculations are modified appropriately. The key transition in the process is from screening, which is conducted by comparison with benchmarks, to the baseline ERA, where comparisons generally require the use of negotiated values agreed upon with Regional Ecological Risk Assessors and/or BTAGs.

Summary

This supplemental guidance clarifies the two-tier process for conducting ERAs at Superfund sites and RCRA Corrective Action facilities discussed in U.S. EPA 1997. It describes the purpose of each tier (i.e., screening-level and baseline ERAs) and highlights those components common to both. It further provides an approach for refining contaminants of concern and streamlining the ERA process. Readers are referred to the references listed below for further information.

AN EVALUATION OF CAUSE-EFFECT RELATIONSHIPS BETWEEN DDT (AND METABOLITES) AND SEDIMENT TOXICITY TO BENTHIC INVERTEBRATES

Phyllis Fuchsman,[1] Elyse Perruchon,[1] Elisa Bizzotto,[2] Jaqueline Dillard,[3] Miranda Henning[4] • [1]ENVIRON, Cleveland Ohio, [2]ENVIRON, Milan, Italy, [3]Cornell University, Ithaca, New York, [4]ENVIRON, Portland, Maine

ABSTRACT

Widely applied, empirical sediment quality benchmarks for DDT and its metabolites (DDx) are intended to predict sediment toxicity but were derived in a manner that does not necessarily reflect cause-effect, concentration-response relationships. An alternative approach to evaluating risks of sediment-associated DDx to benthic invertebrates is thus needed. We review and synthesize information on DDx toxicity to invertebrates based on several lines of evidence, including (1) extensive spiked sediment toxicity studies, (2) toxicity testing and benthic invertebrate community assessments from major DDT-contaminated sites, and (3) extrapolation of aquatic toxicity data to sediment using the equilibrium partitioning approach. These lines of evidence show that the existing sediment quality benchmarks overestimate the toxicity of DDx to invertebrates, apparently reflecting the distribution of sediment DDx concentrations in the underlying databases rather than causal relationships between DDx exposures and biological outcomes. Alternative screening values identified from our review should provide a stronger basis for prioritizing and interpreting site-specific investigations of DDT-contaminated sediments.

INTRODUCTION

- Toxicity to benthic invertebrates is one of several concerns for sediments containing DDT and its major metabolites, DDD and DDE (collectively DDx).
- Existing sediment quality guidelines (SQGs) are problematic:

	SQGs (µg/kg dry weight)	SQGs (µg/goc assuming 1% TOC)
4,4'-DDT	1 - 710	0.1 - 71
4,4'-DDD	1.2 - 60	0.12 - 6
4,4'-DDE	1.4 - 370	0.14 - 37
Total DDx	1.6 - 570	0.16 - 57

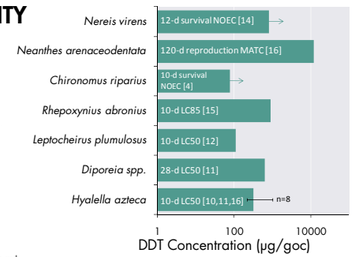
Source: http://rais.ornl.gov/tools/eco_search.php

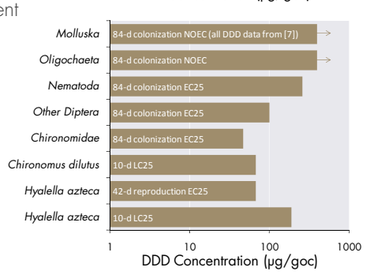
  - Based on associations between chemistry & toxicity for sediments containing many chemicals
  - Association ≠ Causation

- We examine causal evidence:
  - Spiked sediment toxicity studies
  - Biological & chemistry data for major DDx-contaminated sediment sites
  - Extrapolation of aquatic toxicity data to sediment using the equilibrium partitioning approach

SPIKED SEDIMENT TOXICITY TESTS

- Controlled experiments capable of characterizing cause-effect, concentration-response relationships
- Must understand bioavailability to apply to different sediments
  - DDx studies had sufficient equilibration time
  - Results normalized to organic carbon
- Most sensitive: Chironomid colonization
  - EC25 = 47 µg DDD/goc



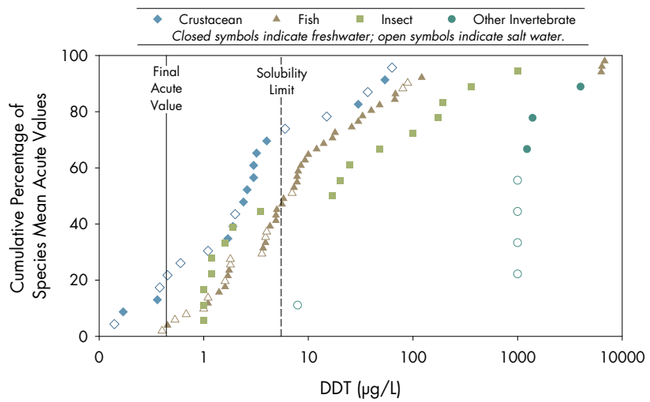


MAJOR DDx SITES

Benthic Invertebrate Total DDx Toxicity Thresholds from Major DDT Manufacturing Sites				
Site	Biological Endpoint	Effect	Total DDx Concentration (µg/goc)	Ref.
United Heckathorn (Richmond CA), Palos Verde (Los Angeles CA), Triana/Tennessee River (Huntsville AL)	Review & synthesis of amphipod toxicity tests and benthic community surveys	Amphipod LC50s Amphipod toxicity threshold Amphipod abundance threshold	1,040 - 2,600 300 100	[18]
United Heckathorn	Benthic invertebrate infaunal index (relative abundance of tolerant/sensitive species)	No effect Slight to intermediate effect Clear effect	1 - 2 **32 - 190** 2,700	[3]
Triana/Tennessee River	Midge (*Chironomus dilutus*) 10-d survival	Clear dose-response threshold	3000	[20]
Triana/Tennessee River	Amphipod (*Hyalella azteca*) 10-d survival	<20% mortality 20-30% mortality >30% mortality	1.2 - 9.8 17 - 3,110 340 - 7,920	[6]
Triana/Tennessee River	Benthic community composition: abundance of sensitive species	High variability; authors note consistency with Swartz et al. [18] threshold	100	[7]
Lake Maggiore, Italy	Benthic community composition; midge (*Chironomus riparius*) 28-d development/emergence; amphipod (*H. azteca*) 28-d survival/growth	No effects associated with DDx	>55	[5]

EQUILIBRIUM PARTITIONING

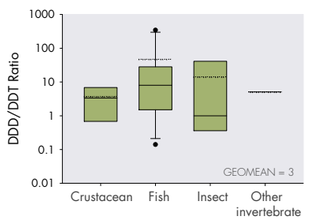
1. Calculate Final Acute Value (FAV) for DDT
   - FAV = 0.44 ug/L ≈ 5th percentile of 96-h LC50s

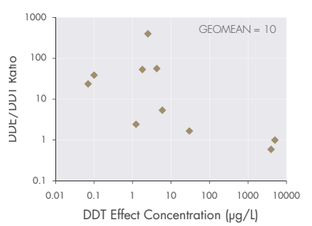


2. Calculate Acute Chronic Ratio (ACR) & Final Chronic Value (FCV)
   - Geometric mean ACR = 29; DDT FCV = 0.015 µg/L

Species	Chemical	Chronic Effect	ACR	Reference
Fathead minnow (*Pimephales promelas*)	DDT	Early life stage survival & growth	65	[9]
Copepod (*Nitocra spinipes*)	DDE	Reproduction	46	[1]
Amphipod (*Hyalella azteca*)	DDT, DDD, DDE	Reproduction	≈8	[10,8]

3. Identify relative toxicity of metabolites based on controlled comparisons





4. Calculate Equilibrium Partitioning Sediment Benchmarks (ESBs)
   - ESB = FCV x Koc x 0.001
   - This works because porewater concentrations are predictive of toxicity.

	FCV (µg/L)	Log Koc	ESB (µg/goc)
DDT	0.015	6.5	51
DDD	0.045	6.1	57
DDE	0.15	6.8	860

5. Calculate Total DDx ESBs based on DDx composition

DDT	DDD	DDE	DDx ESB (µg/goc)
33%	33%	33%	79
10%	15%	75%	180
10%	75%	15%	65

INTEGRATING THE EVIDENCE

- All lines of evidence support a cause-effect screening value for DDx on the order of 50-100 µg/goc.
- Data from major DDx sites suggest severe effects at about 2,000 – 3,000 µg/goc.
- Site-specific factors affect DDx toxicity:
  - Enhanced sorption to black carbon decreases bioavailability (Tomaszewski et al. 2007).
  - DDx is less bioavailable if present in crystalline form (Boese et al. 1997).
  - Total DDx is less toxic if DDE predominates.
  - Benthic community is less sensitive if habitat conditions exclude DDx-sensitive species.

CONCLUSIONS

- An appropriate screening value for potential DDx effects on benthic invertebrates is on the order of 50 to 100 µg/goc.
- Generic SQGs are typically orders of magnitude lower, due to limitations in SQG derivation methods.
- Site-specific effects thresholds may differ, due to differences in sediment characteristics, DDx composition and form, and benthic community characteristics.

Acknowledgements and disclaimer

We thank Bruce Thompson, Chris Beegan, Alicia Gilbreath, and Mike Connor for reviewing the draft report. Jon Arnot, M. James Allen, Lawrence Burkhard, Frank Gobas, Steve Weisberg, and members of the SQO Scientific Steering Committee[1] provided helpful technical guidance. Michael Anderson, Beckye Stanton, Fred Hetzel, Bridgette DeShields, and members of the BTAG provided helpful information and recommendations with tissue threshold and risk assessment. Jon Arnot is particularly acknowledged for technical contributions to this report including reviews of PCB octanol-water partitioning coefficients, temperature and salinity corrections, and input data requirements for the mechanistic food web model. Linda Wanczyk developed the framework conceptual graphic, with constructive feedback provided by Art Barnett and Darrin Greenstein. Martha Sutula, M. James Allen, and Don Cadien kindly provided unpublished data for the Newport Bay evaluation.

This report is produced as part of a subcontract from SCCWRP to SFEI, and is part of the products provided to the State Water Resources Control Board. The aim of the Sediment Quality Objectives science team (including SFEI and SCCWRP scientists) is to provide the State Water Board with scientific background information that may aid in development of Sediment Quality Objectives for bays and estuaries in California. This report represents the technical viewpoints of the authors, and not necessarily the viewpoint of the State Water Board or those acknowledged for technical assistance.

This study was funded in part by agreement 01-274-250-0 with the State Water Resources Control Board.

Abstract

Contaminated sediments can indirectly affect demersal fish, as well as piscivorous birds, marine mammals and humans. This report describes a general approach to evaluate sediments in bays and estuaries for these indirect (i.e., food web mediated) effects. The work described herein is part of a larger effort to assist the State Water Resources Control Board address technical issues that arise in developing Sediment Quality Objectives.

The approach is based upon a multiple line of evidence framework to determine the probability that sediments in a water body pose substantial risks to human or wildlife health. The three lines of evidence (LOE) utilized in this framework are tissue chemistry of resident prey animals (fish or invertebrates), sediment chemistry, and bioavailability tests. Key attributes of the framework include sequential application of the LOE, a probability-based approach with multiple categories, and evaluation of separate LOE at different spatial scales.

This report also includes technical guidance to support application of the framework. The guidance includes appropriate types of measurements for each LOE (e.g., fish species, ancillary parameters), tissue thresholds for interpreting the results, and a methodology for combining each LOE into a final assessment classification. To demonstrate the approach, the framework is applied to chlorinated organic contaminants in two case studies: Newport Bay and San Francisco Bay. The case studies apply the framework to evaluate PCBs and organochlorine pesticides.

Development of a defensible relationship between sediment and biota concentrations is an important aspect of the framework. Empirical data and mechanistic modeling should be combined to that end. The case studies evaluate use of empirical data and a steady-state food web model to calculate bioaccumulation factors for legacy pesticides in San Francisco Bay and Newport Bay. In all cases empirical field data should be compared to model results. When inconsistencies are observed, this helps to identify potential data gaps or model limitations. Resulting bioaccumulation factors are then combined with effects thresholds to identify sediment concentrations that would be protective of wildlife and human receptors.

Abbreviations and definitions

bioaccumulation – A process in which the chemical concentration in an organism achieves a level that exceeds that in its surrounding environment as a result of chemical uptake through all routes of chemical exposure (e.g. dietary and dermal absorption and transport across the respiratory surface)
bioaccumulation factor (BAF) – The ratio of wet weight contaminant concentration in biota to dry weight contaminant concentration in some other matrix. In this report, unless specified otherwise, the term "bioaccumulation factor" refers to wet weight concentration in fish or invertebrate tissue divided by dry weight concentration in sediment
bioaccumulation rate parameter – An estimate of the ratio of contaminant concentration in biota to contaminant concentration in sediment. In this report, "bioaccumulation rate parameter" is intended as a general term for some estimate of this ratio. The bioaccumulation rate parameter could be the bioaccumulation factor (BAF), the biota-sediment accumulation factor (BSAF), or some similar estimate of the ratio, depending on the data available and statistical findings in a given water body.
bioavailability – The ability of a pollutant to be transferred from an abiotic matrix, such as sediments, to the tissue of a living organism via ingestion, absorption, or other mechanisms
biota-sediment accumulation factor (BSAF) – This is the bioaccumulation factor for tissue vs. sediment, normalized for lipid and organic carbon. BSAF = (tissue contaminant concentration in wet wt. * sediment % organic carbon) / (sediment contaminant concentration in dry wt. * tissue % lipid)
BTAG – the Biological Technical Assistance Group, a multi-agency group responsible for developing toxicity reference values and other ecological risk assessment policy in California
CASQO – The California Sediment Quality Objectives Database, a database compiled for methods development for the SQO program as a whole
CDFG – California Department of Fish and Game
CSF - Cancer Slope Factor for carcinogens
DDTs (sum) –The combination of DDT (dichlorodiphenyltrichloroethane) and its degradation products, DDD (dichlorodiphenyldichlorethane) and DDE (dichlorodiphenyldichloroethylene)
DTSC – California Department of Toxic Substances Control, a Department within Cal/EPA, that protects human health and the environment by regulating hazardous waste, conducting and overseeing cleanups, and developing and promoting pollution prevention.
dw – dry weight
EPA – U. S. Environmental Protection Agency
indirect effects - adverse effects to humans and wildlife as a result of consuming prey items exposed to polluted sediments
K_{OW} – Octanol-water partitioning coefficient
LCL – Lower Confidence Limit (e.g., the lower limit of the95% confidence interval of the mean)
LOAEL – Lowest observed adverse effects level
LOE – Line of evidence
MLOE - Multiple Lines of Evidence

NOAA –National Oceanic and Atmospheric Administration
NOAEL – No observed adverse effects level
OEHHA – The Office of Environmental Health Hazard Assessment, an Office within the California Environmental Portection Agency (Cal/EPA responsible for assessing the risk posed by hazardous substances on human health and the environment and in addition, the development and posting of fish consumption advisories.
PAH – polycyclic aromatic hydrocarbons
PCBs (sum) – polychlorinated biphenyls
Receptor – an ecological entity (e.g., organism) that is exposed to a stressor (e.g., pollutants).
RfD - Reference dose for noncarcinogens
SE – Standard error of the mean
SQO – Sediment Quality Objective
SARWQCB – Santa Ana Regional Water Quality Control Board
SFBRWRCB - San Francisco Bay Regional Water Quality Control Board
SWRCB – State Water Resources Control Board of California
TMDL – Total Maximum Daily Load, a policy document to control pollutants in a water body
toxicity reference value - a level of exposure that is considered to be a threshold indicative of probability of adverse effects to a target organism. TRVs are a key piece of information in development of site-specific effects thresholds.
TRV – see Toxicity reference value
TRV – High - A toxicity reference value above which adverse effects to consumers are expected
TRV – Low - A toxicity reference value below which adverse effects to consumers are not expected
UCL – Upper Confidence Limit (e.g., the upper limit of the 95% confidence interval of the mean)
U. S. EPA ECO-SSL – A set of toxicity reference values developed by EPA, in collaboration with other agencies and stakeholders, for use in screening contaminated soils in risk assessments
ww – wet weight

1. Introduction

A primary technical challenge for natural resource managers of aquatic systems is assessment of sediment quality (Wenning *et al.* 2005). Sediment quality assessments typically evaluate direct effects of sediment pollution to benthic aquatic life. Several methods have been developed to evaluate these direct effects (e.g., Chapman 1996, Di Toro and McGrath 2000, Anderson *et al.* 2001, Vidal and Bay 2005).

Another issue in sediment assessment is evaluation of indirect effects to organisms that do not permanently reside within the sediments (Bridges *et al.* 2005, Chapman and Anderson 2005). DDTs, polychlorinated biphenyls (PCBs), methyl mercury, and many other sediment-associated compounds bioaccumulate[2], resulting in elevated concentrations in the tissues of exposed organisms (Boese *et al.* 1997, Mason and Lawrence 1999, van der Oost *et al.* 2003). These compounds may also biomagnify[2], exhibiting elevated concentrations in higher trophic levels of the food web (Rasmussen *et al.* 1990, Suedel *et al.* 1994). Bioaccumulation and biomagnification are of concern because deleterious effects to wildlife may occur at relatively low tissue concentrations (see for example, Beyer *et al.* 1996). Contaminants in fish can also reach concentrations sufficient to pose potential health risks to human sport and subsistence anglers (U. S. EPA 2000b, Burger *et al.* 2001, Davis *et al.* 2002, Greenfield *et al.* 2005, Schaeffer *et al.* 2006). These toxicological effects are referred to as indirect effects because they are not dependant on direct sediment contact by the wildlife or human receptors[3].

The inclusion of indirect effects in sediment evaluation is an important and challenging issue. The bioavailability[2] of contaminants (i.e., their potential for uptake by sediment dwelling organisms) varies widely among sediments and water bodies (Boese *et al.* 1995, Boese *et al.* 1997, Mason and Lawrence 1999, Kraaij *et al.* 2002, Battelle *et al.* 2005). Standard bulk chemical analysis of sediment does not differentiate between the contaminant fraction that is tightly bound to sediment and that which may be accumulated into tissues of an organism (Kraaij *et al.* 2002, Talley *et al.* 2002, Ghosh *et al.* 2003). Therefore, inclusion of other measures of exposure, along with sediment bioaccumulation tests, may improve the interpretability of chemical measurements (Chapman 1996, Chapman and Anderson 2005).

Multiple lines of evidence (MLOE) are frequently used to assess the direct effects of sediment pollutants. Virtually all of the estuarine ambient monitoring programs in the U. S. rely on some form of sediment quality triad (Chapman *et al.* 1997), evaluating measures of sediment toxicity, chemistry, and benthic community alteration[4]. In addition

---

[2] Defined in "Abbreviations and Definitions"

[3] In this report, *"receptor"* is defined as the ecological entity that is exposed to the stressor of concern, following U. S. EPA (1998). Specifically, the report describes a method for evaluating the effects of sediment pollutants (the stressor) on wildlife and humans (the receptors).

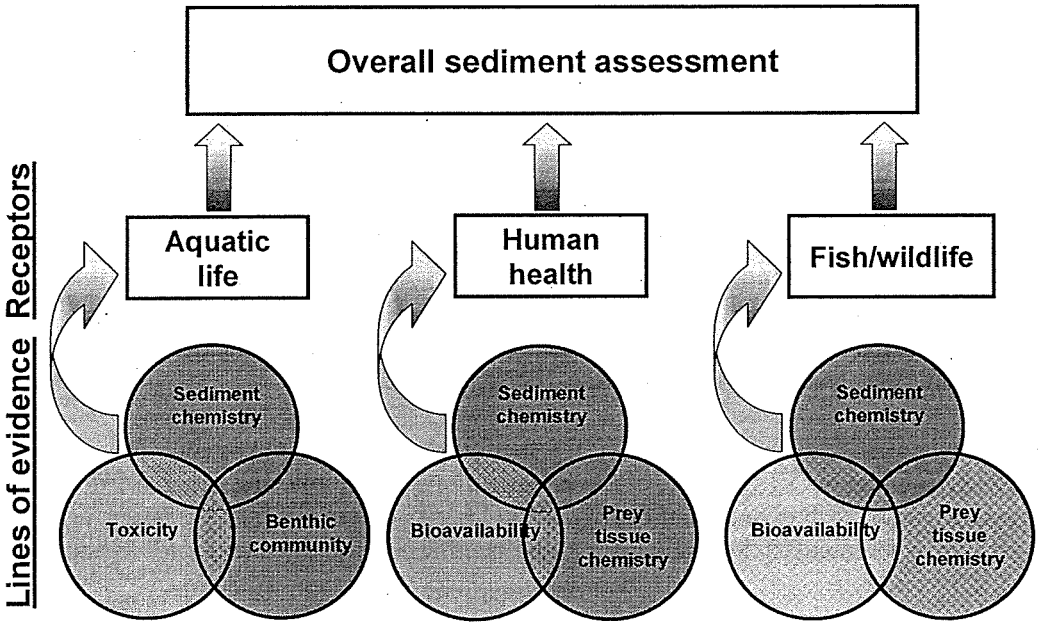
[4] These include the two largest nationwide estuarine monitoring programs, EPA's Environmental Monitoring and Assessment Program and NOAA's National Status and Trends Program, as well numerous regional monitoring programs, including those for the Great Lakes, Puget Sound, San Francisco Bay, Chesapeake Bay, the Southern California Bight, Tampa Bay, and New York/New Jersey Harbor.

to the evaluation of direct effects, the use of MLOE may also facilitate assessment of indirect effects (Figure 1.1).

To evaluate indirect effects, two technical issues must be addressed. First, a robust relationship must be developed between contaminant concentrations in sediments and receptor organisms. To this end, many studies have documented predictable relationships between contaminant concentrations in sediments and associated fish (Endicott and Cook 1994, Wong *et al.* 2001, Zeng and Tran 2002, Burkhard *et al.* 2004), and mechanistic models have been developed to describe these associations (e.g., Thomann *et al.* 1992, Gobas 1993).

A second issue in evaluating indirect effects is that contaminant effects thresholds must be developed based on potential risks to receptor organisms. Effects to human and wildlife receptors may be estimated using standard risk-assessment methods (Sample *et al.* 1996, U. S. EPA 1997, 1998, 2000c, 2006b). Thresholds are often calculated using exhaustive reviews of all available toxicity studies (California DTSC Human and Ecological Risk Division 2000, Zeeman 2004, U. S. EPA 2005, 2006b).

Figure 1.1. Components of multiple line of evidence (MLOE) framework for overall sediment assessments. Separate MLOE assessments could be conducted for direct effects to aquatic life, indirect effects to human health, and indirect effects to wildlife.



1.1. Regulatory background

Current government-established sediment quality guidelines generally don't address contaminant bioaccumulation or consequent effects to higher trophic levels (MacDonald

1994, Canadian Council of Ministers of the Environment 1999). Washington is the only U. S. state with legally enforceable sediment quality standards. In Washington, statewide sediment quality standards are based on direct measures of chemistry, benthic invertebrate toxicity tests, and benthic community composition (SAIC and Avocet Consulting 2002, Michelsen 2003, State of Washington 2005). Although narrative standards to protect fish, wildlife, and human health have resulted in some site-specific numeric thresholds for sediment and tissue (Tom Gries, Washington Department of Ecology, *Pers. comm.*), a standardized framework for evaluating indirect effects is lacking. Informal sediment quality guidelines have been adopted in a number of U. S. states, including New York, New Jersey, Florida, Texas, South Carolina, and Minnesota. However, none of these states prescribe measurement of tissue uptake or bioaccumulation (Ed Long, ERL Environmental, *Pers. comm.*). For example, in the guidelines adopted by the state of New York, potential hazards posed to wildlife and human health are estimated as a function of equilibrium partitioning into pore water, rather than direct measurement or estimation of food web trophic transfer (New York State Department of Environmental Conservation 1999).

Despite the absence of bioaccumulation-based regulatory criteria, human health and wildlife risk assessments are frequently undertaken to establish guidelines for specific water bodies. In the United States, a large body of ecological risk assessment methodology has been established by the Comprehensive Environmental Response, Compensation, and Liability Act (i.e., CERCLA, reviewed in Hamilton and Viscusi 1999). This program, commonly referred to as the Superfund Program, has resulted in a series of guidelines for performing ecological risk assessment (e.g., U. S. EPA 1997, 1998). Risk assessments performed in accordance with CERCLA require a series of steps and studies that are time consuming and costly to perform. Evaluation of individual Superfund sites often requires expenditure of tens of millions of dollars, in a process that can take a decade or more. In other management circumstances, more focused approaches to evaluating risk have been established. The conceptual model may be predetermined, including an a priori understanding of the contaminants of concern, exposure mechanisms, targets, and toxicological effects. It then becomes possible to use a straightforward procedure. For example, the U. S. government has established a streamlined procedure for evaluating exposure risks due to disposal of dredged materials (U. S. EPA and U. S. Army Corps of Engineers 1991, 1998).

For management circumstances when the focus is on a specific set of impacts and receptors, it may not be necessary or appropriate to perform a risk assessment at the level of breadth and expense of the CERCLA program. For example, if one wishes to evaluate the indirect effects of contaminated sediments to humans and wildlife, the approach should focus on key issues and transport pathways, including contaminant bioavailability, food web transfer, and effects thresholds.

1.2. Report objectives and organization

This report presents a standardized framework for evaluating indirect effects of contaminated sediments to humans and wildlife. The framework was developed to

differentiate unimpacted sediments from impacted sediments in bays and estuaries. It should be applicable to a variety of pollutants that may pose a risk due to indirect effects of contaminated sediments. The report also includes technical guidance and two detailed case study examples (Table 1.1).

The intent of the framework is to provide a consistent and cost-effective approach for sediment assessment. It focuses resources on resolving specific uncertainties and policy decisions that are known to be important for evaluating indirect effects of sediments. While most of the questions and needs identified in this approach can be resolved by applying sound scientific principals and appropriate measures, there are questions that can only be decided by the regulatory agencies within a formal and public administrative process. These include, among other topics, the target species and populations, and the degree of risk that is deemed acceptable for these targets. The goal of this report is to describe some potential choices and provide relevant technical background information. The use of a consistent approach should enable natural resource managers and stakeholders to focus on key policy decisions (e.g., how much risk is acceptable), rather than struggling with the assessment approach itself.

The report is organized as outlined in Table 1.1. Section 2 describes the conceptual model, which is the basis for the approach. Section 2 also includes an overview of how the entire process works, including how the individual lines of evidence (LOE) are combined in a sequential approach. Section 3 outlines key technical issues that must be addressed in applying the framework. Technical guidance on these issues is provided in Section 3 and a series of appendices. Sections 4 and 5 demonstrate the approach in two case studies. Section 6 presents conclusions.

Table 1.1. Summary of applicability of work presented to pollutants of concern.

Report Sections	Topic	Legacy Pesticides [a]	PCBs	Mercury	Other Pollutants [b]
2	Framework and application	X	X	X	X
3	Technical issues	X	X		
4	Case study - Newport Bay	X	X		
5	Case study - San Francisco Bay	X			

a. Including DDTs, chlordanes, dieldrin, toxaphene, aldrin, and heptachlor.
b. Including but not limited to selenium, arsenic, PAHs, and dioxins.

The case studies apply the assessment framework described in Sections 2 and 3 to San Francisco Bay and Newport Bay using data from prior studies. The purpose of these case studies is twofold: to illustrate the application of the assessment framework using realistic data, and also to explore many of the technical issues identified in Section 3 in order to develop recommendations for implementation. For both case studies, the evaluation includes corroboration of field-observed bioaccumulation factors with mechanistic food web model results. This entails comparing mechanistic modeling results on contaminant partitioning to actual observed partitioning between sediments and biota and the ecosystem. Consistent findings between mechanistic models and empirical data would support the assumptions and methods of the framework. If the findings are not

consistent, a combination of additional data collection and model revision may be required.

The case studies in this report will focus on nonpolar organic pollutants, including polychlorinated biphenyls (PCBs), and legacy pesticides (DDTs, chlordanes, and dieldrin). The case studies focus on these compounds for several reasons. First, they are known to bioaccumulate in tissues of invertebrates, fishes, and their predators, and have abundant field data available for evaluation (e.g., Suedel *et al.* 1994, Boese *et al.* 1997, Kidd *et al.* 1998, Schiff 2000, Connolly and Glaser 2002, Greenfield *et al.* 2005). Additionally, efforts are currently underway to manage these compounds in bays and estuaries (e.g., SFBRWQCB 2004, SARWQCB 2006). Furthermore, bioaccumulation of PCBs and legacy pesticides is more predictable than some other compounds. Specifically, bioaccumulation of non-polar organics may be predictably related to octanol-water partition coefficient (K_{ow}), biota whole body lipid content, and abundance and types of sediment organic carbon (Clark *et al.* 1988, Thomann 1989, U. S. EPA 2000a, Cornelissen *et al.* 2005). Bioaccumulation is more difficult to predict for trace metals, requiring ancillary data frequently not collected in monitoring programs (Hansen *et al.* 1996, Lee and Jones-Lee 2003). Lastly, general mechanisms of bioavailability and bioaccumulation are likely to be similar between legacy organochlorines and other compounds, including polybrominated diphenyl ethers and dioxins.

2. Conceptual approach and framework

2.1. Problem statement

The goal of the framework is to evaluate two potential risks posed by polluted sediments. The first is the risk of effects to human health via consuming fish and shellfish tissue. The second is the risk of effects to wildlife via consuming fish and shellfish tissue. Narrative benefits to be protected include preservation and enhancement of wildlife, wildlife habitats, and use of waters by humans for recreational or commercial fishing. In short, the framework focuses on protecting two groups of receptors: humans and wildlife.

A key component of the indirect effects framework development process is regular review and feedback by committees of scientific experts, regulatory agencies, and affected stakeholders. Appendix A summarizes feedback received by committees that had input on development of this framework. This report aims to address those issues.

2.2. Conceptual model

Figure 2.1 presents a general conceptual model for evaluating indirect effects. This conceptual model is not designed to depict all processes that influence contaminant fate in bays and estuaries; rather, it represents the most important processes for understanding indirect effects of sediments to wildlife and humans.

The conceptual model is intended to depict the aquatic ecosystem processes that are most important for indirect effects of contaminated sediments. This includes abiotic and biotic components and their linkages. Some degree of contaminant transfer between the sediments and the overlying water column is assumed. The relative concentrations in sediments vs. the water column are determined by a variety of processes. For organic pollutants, these processes include equilibrium partitioning (Di Toro *et al.* 1991, Mackay and Paterson 1991), water and sediment movement and mixing dynamics (Burkhard *et al.* 2003), and nonlinear sorption to carbonaceous particles (Ghosh *et al.* 2003, Cornelissen *et al.* 2005). In practical terms, this combination of processes often makes it difficult to distinguish between sediment vs. water column sources of contamination.

Sediment-dwelling invertebrates are exposed to sediment pollutants primarily via dietary uptake and respiratory exposure to sediment porewater. Invertebrates are also exposed to contaminants in the overlying water column as a result of filter feeding, particle feeding, and respiratory exposure. Food-web trophic transfer (as represented by dietary uptake of invertebrates) is the most significant route of exposure for fish (Figure 2.1). Additionally, fish can encounter pollutants via consumption of sediments (Laffaille *et al.* 2002, Almeida 2003) and respiration of water.

Wildlife (e.g., birds and aquatic mammals) and humans consume contaminated finfish (thick arrows) and invertebrates (thin arrows), resulting in contaminant exposure (Figure 2.1). That is, the conceptual model (and resulting framework) includes organisms that are not in direct contact with the sediments. These organisms are exposed to pollutants

indirectly by food web trophic transfer, and these indirect exposures may lead to indirect effects.

Figure 2.1. Conceptual model for assessment of indirect effects of pollutants in bays and estuaries. Boxes indicate key matrices, including sediments, water, and animal biota. Biota are further categorized as invertebrates, fishes, wildlife and humans. Arrows represent contaminant transfer pathways, with the size and direction of the arrow representing the significance and direction of the transfer mechanism. The vertical dashed line distinguishes between matrices evaluated for potential exposure using empirical data and contaminant fate models (left) , and matrices evaluated for potential effects using toxicological effect models (right).

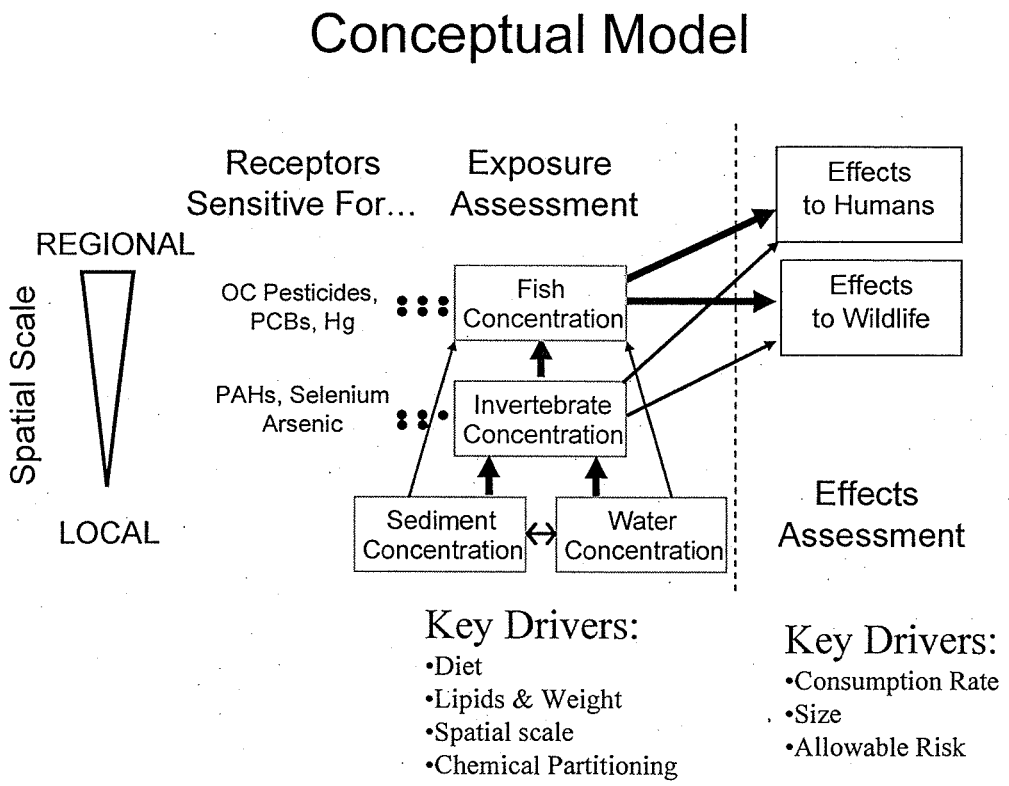


Figure 2.1 also indicates linkages between selected bioaccumulative compounds and the receptors that would be sensitive indicators of exposure to these pollutants. In particular, mercury (Hg), PCBs, and legacy pesticides (e.g., DDTs, dieldrin, and chlordanes) can biomagnify up the food web, resulting in elevated concentrations in fish tissue (Suedel *et al.* 1994, van der Oost *et al.* 2003). In contrast, PAHs are rapidly metabolized by fish (Eisler 1987, van der Oost *et al.* 2003), and arsenic and selenium are not consistently biomagnified from invertebrates to fishes (Suedel *et al.* 1994, Abernathy 2004); elevated concentrations of these compounds are therefore likely to be more evident in sediment-exposed invertebrate tissues than fish tissues.

Because the conceptual model focuses on the most important processes that govern indirect effects of sediment pollution to human and wildlife predators, it is simpler than some sediment risk assessment models (e.g., Bridges *et al.* 2005). The intent is to enable evaluation of individual bays and estuaries when resources are limited.

The relative simplicity of the model and approach is intended to reflect the limited scope and resources available to conduct individual evaluations. The intent is to avoid creating a program that is too burdensome to implement. Nevertheless, in-depth evaluation of scientific uncertainties outside the conceptual model may be useful in specific circumstances. These factors may include: 1. contaminant transfer between deep sediment, surface sediment, and the water column; 2. toxicological effects to aquatic plants or invertebrates; 3. predator tissue residue-based effects evaluation for humans or wildlife[5]; or 4. changes over time in contaminant concentrations and transfer pathways. All of these factors may be potentially important in site-specific evaluations, establishment of water body TMDL targets, or other regulatory objectives (Davis 2004, Bridges *et al.* 2005, Gobas and Arnot 2005, Greenfield and Davis 2005). Nevertheless, the approaches for evaluating these factors are outside the scope of this document.

The individual case study evaluations on San Francisco and Newport Bays each contain site-specific conceptual models (Sections 4 and 5). These models contain additional boxes to represent the water-body specific understanding of food-web trophic transfer pathways and local receptor organisms.

Both exposure and effects information must be used to determine the risk posed by sediment contamination to humans and wildlife. The conceptual model indicates that the exposure and effects assessment would focus on separate matrices. In the indirect effects assessment framework, exposure is evaluated using direct measurements of contaminant concentrations in the local water body. The following sections describes how exposure and effects evaluations are incorporated into the framework.

2.3. Multiple line of evidence framework

Based on the conceptual model, a multiple line of evidence framework may be developed to evaluate pollutant exposure. The framework would be applied separately to human vs. wildlife receptors (Figure 1.1). In this framework, three lines of evidence (LOE) are evaluated:

1. Prey tissue chemistry
2. Sediment chemistry
3. Bioavailability

The prey tissue and sediment chemistry LOE compare pollutant concentrations in field-collected sediments or tissues to thresholds based upon biological effects. The bioavailability LOE compares concentrations in laboratory test organisms or field benthic organisms to concentrations in sediments in order to establish bioavailability of sediment-

[5] That is, the framework focuses on risk evaluations based on pollutant concentrations in the tissues of prey organisms and sediments, rather than evaluations based on pollutant body residues in the predators, themselves.

associated pollutants. When all LOE are integrated, the result is a classification of sediments into four categories of probability of impact: unlikely impact, possible impact, likely impact, or clear impact.

2.3.1. Prey tissue chemistry

The first LOE (prey tissue) evaluates the tissue pollutant concentrations in field-collected fish or invertebrates. Prey tissue concentrations are measured to determine whether humans or wildlife are at risk due to consuming contaminated prey organisms. As indicated in the conceptual model, measurements could focus on fish or invertebrates, depending on the receptor and contaminant. If contaminant concentrations in prey are high enough, consumption of the prey would pose a risk of mortality or sublethal effects. Conversely, if contaminant concentrations in their prey do not pose a risk, humans and wildlife would be protected. The use of direct prey tissue measurements is central to dietary exposure risk evaluations (Lee *et al.* 1994, U. S. EPA 2000b, CH2M HILL 2004, U. S. EPA 2004, Battelle *et al.* 2005, Chapman and Anderson 2005).

For the prey tissue line of evidence, use of field-captured fish is sometimes questioned based on the concern that mobility of fish inhibits the ability to establish a predictive relationship between sediment chemistry and fish tissue chemistry. However, our analyses, and published literature, indicate that significant relationships are often observed (Appendix B).

2.3.2. Sediment chemistry

The second LOE evaluates whether sediment pollutant concentrations are high enough to pose risks to predatory wildlife or humans. If sediment concentrations are not high enough to cause the observed concentrations in prey, other contaminant sources are implicated. These may include external loads or water column concentrations. Pollutant concentrations are measured in sediments from multiple locations in order to identify locations where potential risk is relatively high.

To develop thresholds for this LOE, empirical data are used to determine ratios between pollutant concentrations in sediments versus prey organisms. These ratios will be more defensible if developed separately for individual bays and estuaries, rather than using a generalized bioaccumulation rate parameter (e.g., bioaccumulation factor) for all regions. Appendix C provides evidence that bioaccumulation factors vary significantly among water bodies, requiring local development of the ratio between sediment and prey organism. Mechanistic models (Arnot and Gobas 2004, Gobas and Arnot 2005) may be used to corroborate the empirical ratios. These ratios are then combined with diet-based effects thresholds to develop sediment thresholds.

2.3.3. Bioavailability

The third LOE (bioavailability) evaluates the tendency for a substance to accumulate in the tissue of sediment-exposed organisms. The purpose of this LOE is to confirm that

contaminants in sediments are bioavailable. This would establish the linkage between the boxes in the exposure side of the conceptual model (Figure 2.1).

A number of methods may be used to establish whether sediment compounds are bioavailable. These include laboratory bioaccumulation tests or field measurement of exposure in resident or transplanted organisms. New measurements would only be necessary for contaminants not known to be generally bioavailable. Thus, the first step for this LOE is an evaluation of recent peer-reviewed scientific literature to determine whether the pollutants in question are bioavailable, when associated with sediments in natural waters. If it becomes established that sediment-bound contaminants are biologically available, they become a probable exposure mechanism to all organisms associated with the benthic food web.

2.3.4. Evaluation of effects to receptors

Effects assessments must be made to determine whether the human and wildlife receptors are at risk. Likelihood of effects are estimated by comparing pollutant concentrations in the sediments and prey tissues to calculated risk thresholds. These risk thresholds are developed using risk assessment methodologies. A strength of risk assessment calculations is that they rely on a widely available, standardized, and peer-reviewed methodology. For example, human health risk assessments are based on the U. S. EPA IRIS database of toxicity reference values for humans (U. S. EPA 2006b).

Although effects assessments may be obtained by direct measurement of receptor organisms (i.e., human and wildlife predators), this is not included in the framework. There are several reasons for this. The first reason is that for humans and many sensitive wildlife species, legal and ethical barriers render such measurements illegal or highly impractical on a wide scale. Secondly, requirement of standardized measurements of biological effects to wildlife would be very costly to implement. Finally, it would be extremely difficult to develop guidance and criteria for standardized application of such measurements. When local data on effects to predators are available, they may be used as additional information to guide management decisions. Technical guidance on the use of local effects data is outside the scope of this report.

2.4. Assessment categories for the framework

The framework results in classifying sediments among four categories of impact. As the evaluation is based on exceeding risk-based thresholds, each category indicates progressively greater risk of adverse effects to wildlife or human predators. The four categories are: A. Unlikely impact. B. Possible impact. C. Likely impact. D. Clear impact. They may be described as follows:

A. Unlikely impact. Sediment contamination at the site is not expected to cause adverse impacts to human or wildlife consumers of prey captured within the water body. The probability of impact is low because concentrations in prey tissues and sediments are below protective risk thresholds, or because sediment pollutants are not bioavailable.

B. Possible impact. Sediment contamination at the site may be causing adverse impacts to human or wildlife predators. This classification occurs when sediment-associated pollutants are bioavailable and concentrations in sediments and prey tissues indicate intermediate levels of risk to chronically exposed predators.

C. Likely impact. There is a high degree of confidence that sediment contamination at the site is causing adverse impacts to human or wildlife predators. Prey tissue or sediment pollutant concentrations are high enough to indicate substantial risk of effects to chronically exposed predators. Additionally, sediment-associated pollutants are bioavailable.

D. Clear impact. There is a very high degree of confidence that sediment contamination at the site is causing adverse impacts to human or wildlife predators. Pollutant concentrations in both sediments and prey tissue are high enough to indicate substantial risk of impacts to human or wildlife survival, reproduction, or development. For human carcinogens, the expected rate of increased cancer in the population is deemed unacceptably high.

2.5. Integration of the framework

This section describes how the three LOE are integrated into the overall framework for evaluating sediments (see Figure 2.2 and Table 2.1).

The assessment begins by evaluating the prey tissue LOE. For this LOE, appropriate data on pollutant concentrations in prey tissues from the entire water body are compiled[6] and used to estimate average concentrations. To determine the risk posed by prey tissue contamination, the estimate of average tissue chemistry is compared to a low effects threshold and a high effects threshold. This comparison results in one of three possible classifications: low, moderate, and high prey tissue chemistry. This classification is the first step in the multiple line of evidence exposure assessment (Figure 2.2).

The low and high effects thresholds are developed using standard risk-based approaches[7]. Each threshold is developed using on probability-based assumptions appropriate for that level of risk. The low threshold represents a tissue concentration below which adverse effects to the consumer are unlikely. The high threshold represents a concentration above which adverse effects are probable.

---

[6]For the framework described in this report, the term "water body" is intended to be operationally defined, based on the needs of the agencies applying the indirect effects SQO. In the general case, the SQO would be applied for managing an entire bay or estuary, using all available data. However, if there is a regulatory need or basis to conduct evaluations at a scale smaller than the entire water body, the approach should not preclude this. For example, if the water body is divided into separate hydrological units (reaches or basins) for 303d listing purposes, and sufficient data are available on each of these units, the indirect effects SQO could be applied to evaluate each of these units separately.

[7] Further technical guidance is provided in Section 3 of this report.

For protection of humans, the prey tissue LOE would also be evaluated by determining whether the Office of Environmental Health Hazard Assessment (OEHHA - California EPA) has developed water-body specific consumption advisories for any contaminants. If OEHHA has recommended that people reduce their consumption of fish as a result of a specific contaminant or class of contaminants, then it follows that fish from that water body may pose a human health risk that needs to be further considered.

If prey tissue chemistry is in the lowest category, then the sediments in the water body are considered to be protective for wildlife or human consumers of fish, and the assessment is complete. This result is indicated by the decision tree ending at the green light in the top right panel of Figure 2.2. The receptors are considered to be unimpacted with respect to the pollutant of concern. Concentrations below the low threshold represent a stopping point in the assessment. Therefore, the low threshold must be calculated so that prey tissue concentrations below it pose an acceptable risk level.

The framework proceeds to the sediment chemistry LOE if prey tissue chemistry is in the intermediate (yellow light) or high (red light) category. Like the prey tissue chemistry LOE, the sediment chemistry LOE compares field-collected samples to a low threshold and a high threshold (Table 2.1). However, for the sediment chemistry LOE, sediments from individual collection locations are compared separately to the sediment chemistry thresholds. This results in a spatial map that characterizes sediments within the water body, among low, moderate, and high categories (Figure 2.2, middle left panel).

The sediment chemistry thresholds are calculated as the quotient of the prey tissue threshold and a bioaccumulation rate parameter:

$$\text{Sediment Threshold} = \frac{\text{Prey Tissue Threshold}}{\text{Bioaccumulation Rate Parameter}}$$

The bioaccumulation rate parameter should be either a bioaccumulation factor (BAF) [8], a biota sediment accumulation factor (BSAF) [9], or some combination of the two. The bioaccumulation rate parameter is water-body specific. It should be calculated based on measurements collected from the bay or estuary to be evaluated. These technical issues will be discussed in Section III.

In combination, the prey tissue and sediment chemistry LOE result in a provisional classification of each sediment station within the water body. Each station is classified into one of four categories described above in Section 2.4. This classification flows logically from how concentrations compare to the thresholds for each LOE (Table 2.1, Figure 2.2).

---

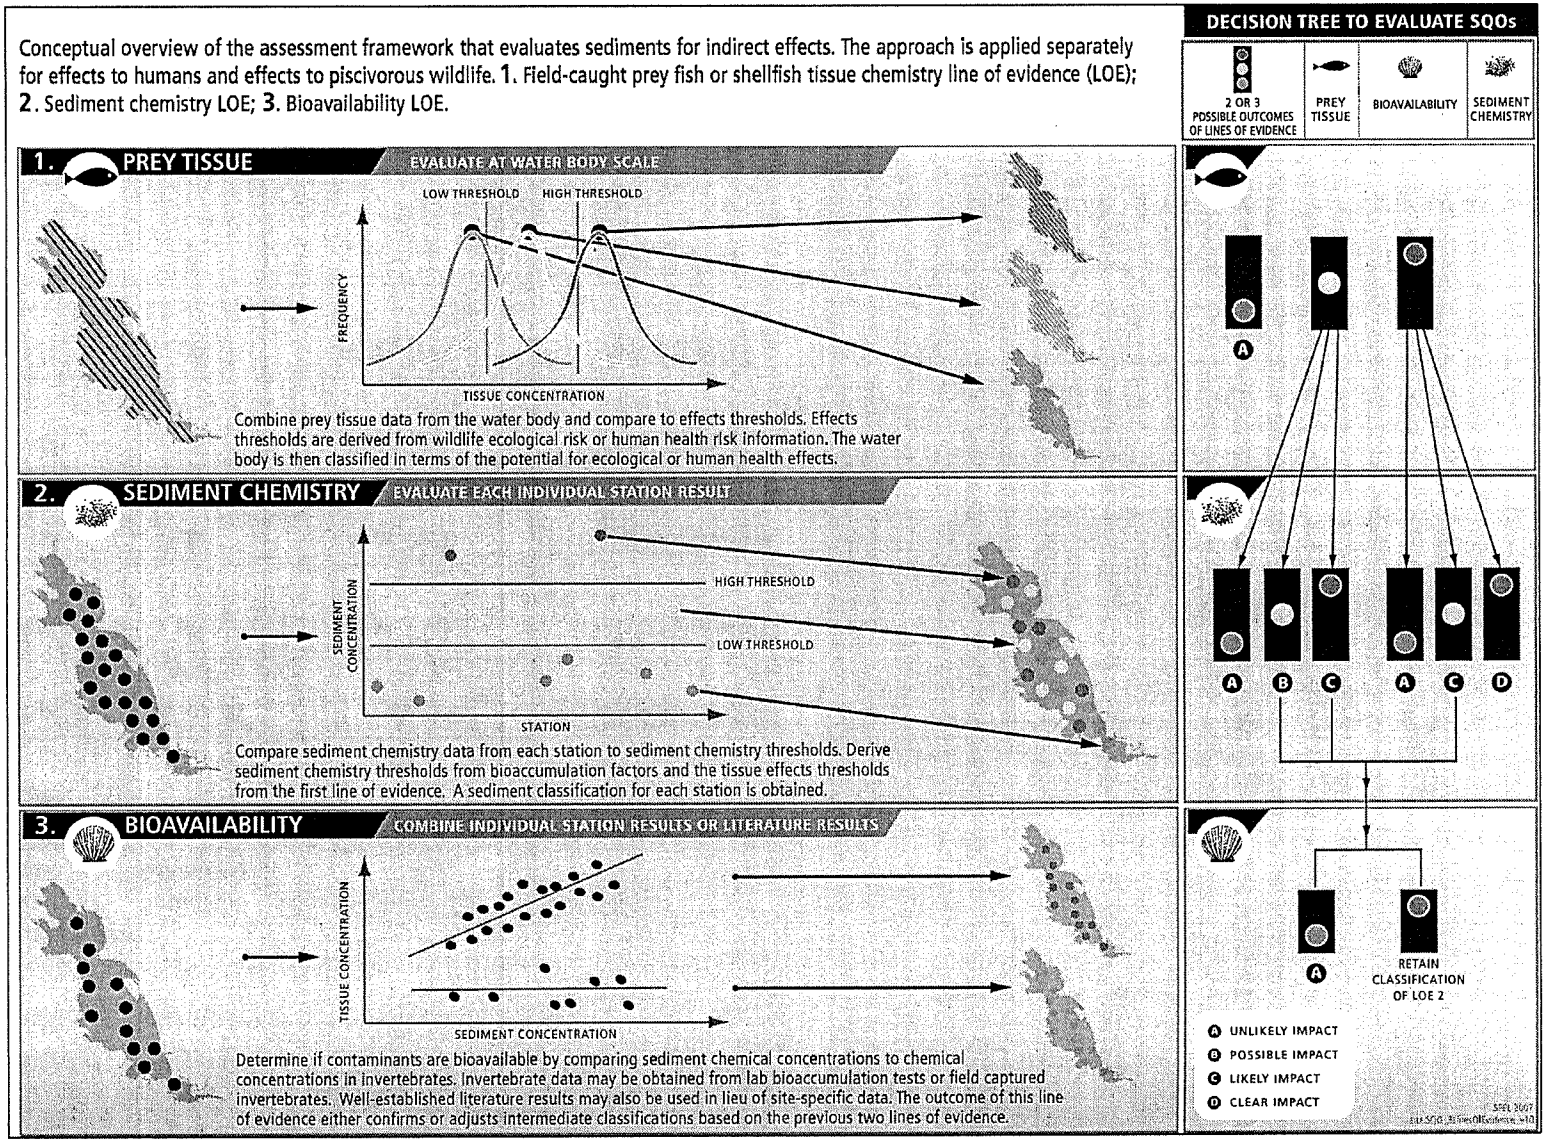
[8] BAF = tissue concentration (wet weight)/ sediment concentration (dry weight), as defined in "Definitions and Abbreviations"

[9] BSAF = tissue concentration (lipid weight)/sediment concentration (organic carbon normalized weight). Also defined in "Definitions and Abbreviations"

Table 2.1. Interpretation of MLOE for indirect effects. Symbols: ▲ = low chemistry threshold not exceeded (fish, sediment) or significant bioavailability not observed (bioavailability test). ◘ = chemistry between low and high thresholds. ● = high chemistry threshold exceeded (fish, sediment) or significant bioavailability observed (bioavailability test). - = evaluation not needed. NA = data not available.

Field Prey Tissue Chemistry	Sediment Chemistry	Bioavailability Test	Conclusion	Interpretation
▲	-	-	A. Unlikely impact	Field prey tissue chemistry indicates no evidence of risk to human or wildlife consumers above the defined level of concern. Therefore, additional assessment need not be done.
◘ or ●	▲ or ◘ or ●	▲	A. Unlikely impact	Although tissues are contaminated at a level of concern, the lack of bioavailability indicates that sediment contaminants are not the source.
◘ or ●	▲	● or NA	A. Unlikely impact	Sediment chemistry indicates that concentrations are below the level of concern. These sediments pose a low risk of impact to human or wildlife consumers (indirect effects).
◘	◘	● or NA	B. Possible impact	Sediment chemistry indicates that concentrations may be above a level of concern. The degree of impact to human or wildlife consumers (indirect effects) from these sediments is uncertain.
◘	●	● or NA	C. Likely impact	Sediment chemistry evaluated at individual sites indicates that concentrations are above a level of concern. Impact to human or wildlife consumers (indirect effects) from these sediments is likely.
●	◘	● or NA	C. Likely impact	Tissue chemistry indicates that adverse effects to wildlife or humans are likely, but sediments are not quite high enough to be certain that they are the major source.
●	●	-	D. Clear impact	Sediment chemistry evaluated at individual sites and prey tissue chemistry from the water body are above a probable risk threshold. This category represents the highest degree of certainty that sediments pose a risk of indirect effects.

Figure 2.2 (following page)



Conceptual overview of the assessment framework that evaluates sediments for indirect effects. The approach is applied separately for effects to humans and effects to piscivorous wildlife. 1. Field-caught prey fish or shellfish tissue chemistry line of evidence (LOE); 2. Sediment chemistry LOE; 3. Bioavailability LOE.
DECISION TREE TO EVALUATE SQOs
2 OR 3 POSSIBLE OUTCOMES OF LINES OF EVIDENCE
PREY TISSUE
BIOAVAILABILITY
SEDIMENT CHEMISTRY
1. PREY TISSUE
EVALUATE AT WATER BODY SCALE
LOW THRESHOLD
HIGH THRESHOLD
FREQUENCY
TISSUE CONCENTRATION
Combine prey tissue data from the water body and compare to effects thresholds. Effects thresholds are derived from wildlife ecological risk or human health risk information. The water body is then classified in terms of the potential for ecological or human health effects.
2. SEDIMENT CHEMISTRY
EVALUATE EACH INDIVIDUAL STATION RESULT
SEDIMENT CONCENTRATION
HIGH THRESHOLD
LOW THRESHOLD
STATION
Compare sediment chemistry data from each station to sediment chemistry thresholds. Derive sediment chemistry thresholds from bioaccumulation factors and the tissue effects thresholds from the first line of evidence. A sediment classification for each station is obtained.
3. BIOAVAILABILITY
COMBINE INDIVIDUAL STATION RESULTS OR LITERATURE RESULTS
TISSUE CONCENTRATION
SEDIMENT CONCENTRATION
Determine if contaminants are bioavailable by comparing sediment chemical concentrations to chemical concentrations in invertebrates. Invertebrate data may be obtained from lab bioaccumulation tests or field captured invertebrates. Well-established literature results may also be used in lieu of site-specific data. The outcome of this line of evidence either confirms or adjusts intermediate classifications based on the previous two lines of evidence.
RETAIN CLASSIFICATION OF LOE 2
A UNLIKELY IMPACT
B POSSIBLE IMPACT
C LIKELY IMPACT
D CLEAR IMPACT

The bioavailability LOE is used to confirm or modify the provisional classification obtained from the first two LOE. Specifically, the bioavailability LOE will either retain the provisional classification or convert it to "A. Unlikely impacted." The bioavailability LOE need not be evaluated if the first two LOE already result in a classification of "A. Unlikely impacted." The bioavailability LOE also does not need to be evaluated if the first two LOE result in the highest risk category: "D. Clearly impacted." That is, if concentrations in prey tissues and sediments are both above thresholds where risk is highly probable, the framework determines that sediments pose substantial risks to human or wildlife predators (Table 2.1).

For many compounds, the bioavailability LOE may be evaluated using existing literature and data[10]. If local bioavailability tests are to be performed, two methods may be used. The first method is to compare contaminant concentrations between collocated sediments and field-captured invertebrates. The second method is to perform a laboratory test in which invertebrates are exposed to the sediments to determine bioavailability. For either method, selection of appropriate invertebrate species, sample design, analytical detection limits, and sufficient sample size are all important considerations. These issues will be further discussed in Section 3.

For the bioavailability LOE, all available data are evaluated at the water body scale. This is similar to the prey tissue LOE, but different from the sediment chemistry LOE, in which data for each individual station are evaluated separately. Unlike the other LOE, the bioavailability LOE is applied using a simple hypothesis test (Figure 2.2, Table 2.1). The null hypothesis is that sediment contaminants are not biologically available to organisms in the water body. The alternate hypothesis is that these contaminants are biologically available.

If the bioavailability LOE conclusively indicates that sediment-associated contaminants are not bioavailable (i.e., no exposure), the water body is placed in the "A. Unlikely impacted" category (Table 2.1). If however, there is any indication of bioavailability, the category resulting from the other two LOE is retained. Also, if bioavailability test results are inconclusive, because the evaluation was not designed or applied properly, the category resulting from the other two LOE is retained. In short, the results of the field tissue and sediment chemistry LOE form the basis for the conclusion about the sediment, unless local data demonstrate that sediment-associated pollutants are not bioavailable (Figure 2.2, Table 2.1).

2.6. Key features and rationale of the framework

From the previous subsection, Table 2.1, and Figure 2.2, several key attributes of the indirect effects framework become apparent:

- **Separate assessment for humans vs. wildlife**
- **Risk-based approach**

[10] Support for the use of literature information in lieu of local data is provided in Section 3

- **Multiple categories**
- **Sequential approach**
- **Application at multiple scales**
- **Separate evaluation of specific contaminant classes**

2.6.1. Separate assessment for humans vs. wildlife

The use of separate evaluations for humans vs. wildlife receptors is standard practice in exposure and effects evaluations (Moore *et al.* 2005). Routes of exposure and effects thresholds can differ greatly between wildlife and humans. Humans and wildlife also have different endpoints. In risk assessments, standard human effects endpoints include disease incidence and other factors that may influence individuals in a population (U. S. EPA 2000c, Moore *et al.* 2005). In contrast, wildlife endpoints are typically limited to severe survival, developmental, or reproductive impacts likely to result in population-level effects (California DTSC Human and Ecological Risk Division 2000, Zeeman 2004, Moore *et al.* 2005). Although wildlife often have higher exposures, their effects thresholds may be higher because they are focused on stopping population effects rather than increased disease incidence.

2.6.2. Risk-based approach

A risk and probability based approach is used to develop and evaluate the fish tissue and sediment thresholds. The use of risk-based calculations in threshold development explicitly considers uncertainty in parameter estimation. Risk assessment parameters are generally estimated using probability distributions. Examples include probability of carcinogenic effects or other forms of toxicity, distribution of consumption rates, estimates of contaminant concentration, or bioaccumulation rate parameters. The approach is not a full-blown CERCLA-level ecological risk assessment, which may be too resource and labor intensive for widespread application. Rather, the approach uses key risk assessment principles, including identification of key local receptors to protect, use of probability theory, development of multiple risk-based thresholds, and a decision framework (U. S. EPA 1997, 1998, Bridges *et al.* 2005, Chapman and Anderson 2005).

2.6.3. Multiple categories

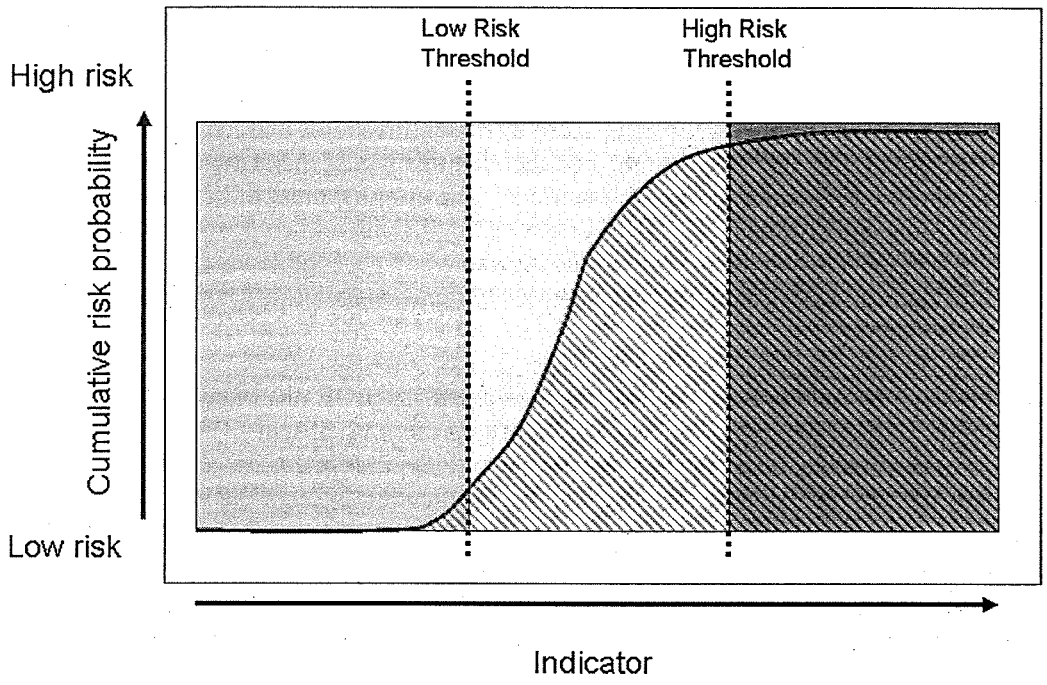
The proposed framework includes multiple categories for probability of indirect effects. The field prey tissue and sediment chemistry LOE are separately compared to three categories. The final classification results in sediments classified into four categories: unlikely impact, possible impact, likely impact, or clear impact.

Multiple categories address the uncertainty inherent in effects determinations. The use of multiple categories also allows straightforward application of a probabilistic risk-assessment framework.

The benefit of using multiple thresholds and categories for the indirect effects framework can be illustrated with a simple conceptual model (Figure 2.3). The blue curve in Figure

2.3 presents cumulative risk probability as a function of a given parameter such as pollutant concentration in sediments or tissues. The overall risk estimate depicted in this curve would be obtained by combining distributions from the parameters used in a risk assessment calculation. Thresholds may then be established across this probability distribution to represent relative probability of adverse effects. The two vertical dotted lines represent two thresholds (i.e., a low and high threshold), which partition the probability distribution into areas of low, intermediate, and high risk. For example, we may take the horizontal axis to represent exposure concentrations in biota, and the vertical axis to represent probability of adverse effects.

Figure 2.3. Conceptual model of the use of multiple thresholds for a numeric indicator used in sediment quality assessment. See text for details.



The use of two thresholds and three risk categories is an intuitive and straightforward way to combine aggregated risk information into an overall assessment of risk probability. Below the low threshold, cumulative probability of adverse effects (i.e., the shaded area under the curve) is relatively low. In the context of sediment quality assessment, an indicator below the low threshold would provide evidence of a lack of impact. Above the high threshold, this probability is relatively high. This would provide evidence indicating probable impact. Between the two thresholds, probability is intermediate; in the context of assessment, this would suggest that there is uncertainty regarding sediment impact.

The conceptual model in Figure 2.3 specifically depicts two risk thresholds resulting in three categories for a LOE. This also makes intuitive sense for partitioning risk in a

probabilistic assessment. For risk-based assessments, it is intuitive to identify the results as either above a benchmark where adverse effects are highly probable (i.e., probable exposure), below a separate benchmark where adverse effects are highly unlikely, or in between these two benchmarks (i.e., possible exposure). For example, wildlife effects threshold data are frequently presented as "no-effects" and "low-effects" levels, and therefore readily amenable to two benchmarks.

There is good precedent for partitioning individual LOE into three categories. The use of three categories is often seen in site-specific risk assessments, and has been recommended in recently published decision-making frameworks for soil and sediment risk assessment (Chapman and Anderson 2005, Hull and Swanson 2006). Three categories are also incorporated into the TrophicTrace bioaccumulation prediction software (Bridges and von Stackelberg 2003), and were used by U. S. EPA in its national screening level assessment of sediments (U. S. EPA 2004).

Despite the precedent of using three categories to partition risk and the conceptual model depicted above, one might ask whether more than two thresholds and three categories should be used for an individual LOE. We feel that this would make the assessment process unnecessarily complex and contentious. The establishment of benchmarks for the prey tissue and sediment chemistry LOE will be difficult and controversial. Policy judgments must be made about appropriate receptors and acceptable levels of risk. Given these difficulties, fewer categories are expected to focus decision-making and require less policy disputation.

In contrast to the field prey tissue and sediment chemistry LOE, the bioavailability LOE is interpreted using two categories: bioavailability present vs. absent. The purpose of this LOE is to verify a key assumption in the MLOE strategy: sediment-associated contaminants are bioavailable for uptake and magnification through the food chain. This question can be addressed using a yes/no type of evaluation. A number of factors limit the development of multiple thresholds for the bioavailability LOE. First of all, extrapolation of laboratory test data to other trophic levels or species (e.g., fish) is problematic due to constraints characteristic of the test (Moore *et al.* 2005). In addition, the relationship of laboratory body burdens to effects on receptors has not been established to the degree that it can be used for regulatory purposes.

2.6.4. Sequential approach

A sequential approach is frequently recommended in risk evaluation guidance. Examples include the Tiered Approach in the U. S. ACE dredged materials testing program (U. S. EPA and U. S. Army Corps of Engineers 1991, 1998, Bridges and von Stackelberg 2003), the multiphase risk assessments in the Federal Superfund program (U. S. EPA 1997), the decision-making framework for evaluating contaminated sediments developed by Chapman and Anderson (2005), and the risk assessment framework developed by Hull and Swanson (2006). The benefit of a sequential approach is focusing resources and effort on pollutants that pose high uncertainty or potential risk. For example, the dredged material testing program initially evaluates contaminant concentrations in the dredged

sediments to determine whether they exceed general regulatory thresholds, before proceeding to more costly bioaccumulation and toxicity testing.

The framework we describe follows a sequential approach of evaluating 1. prey tissue chemistry; 2. sediment chemistry; and 3. bioavailability testing. This approach is appropriate given that the goal of the framework is to protect wildlife and human health from food web mediated exposure to contaminants in local sediments. The field-caught prey tissue LOE is the only indicator that determines whether there are indirect effects to human or wildlife prey. If concentrations in prey tissues are not high enough to pose risks to humans or wildlife, these receptors are protected for that pollutant and there is no further need to evaluate the sediments. If, on the other hand, tissue concentrations indicate that indirect effects may be occurring, the framework proceeds to determining whether the sediments may be a source of the pollutants to the food web.

Determining thresholds for the sediment chemistry LOE involves greater uncertainty and more assumptions. In addition to determining tissue thresholds for humans and wildlife, translators that relate concentrations between sediments and biota must be developed. Collection of detailed site-specific data and modeling are often required (e.g., Connolly and Glaser 1997, Arnot and Gobas 2004, Gobas and Arnot 2005).

Finally, bioavailability tests or field invertebrate collections are performed to confirm that sediment contaminants are bioavailable. These approaches are time-consuming and costly to perform. They are therefore only required in circumstances where there remains significant uncertainty as to whether sediments cause the elevated exposure of local prey. For some pollutants, literature evaluations may establish general bioavailability of the pollutants in question.

2.6.5. Application at multiple scales

As indicated in Figure 2.1, the spatial scale of the transfer pathways is expected to increase with increasing trophic level. Contamination of sediments can be monitored at a local scale (i.e., evaluation of individual sampling stations), since sediment mobility is limited. Effects on benthic invertebrates might be monitored at an intermediate spatial scale. These organisms are generally sessile, and therefore expected to reflect contaminant exposure for local conditions. At the same time, degree of contaminant bioavailability may be similar across a water body as a result of similar contaminant sources and sediment binding properties. Higher trophic levels, including fish, wildlife, and humans, move and forage at multiple locations. Therefore, exposure of these receptors is expected to occur at broader spatial scales. Due to this spatial mobility, probabilistic evaluation of exposure and effects data may be appropriate at larger spatial scales (e.g., Linkov *et al.* 2002, e.g., Gobas and Arnot 2005).

In the framework, the field prey tissue and bioavailability test LOE are evaluated at the water body scale, while the sediment chemistry LOE is evaluated at the individual station scale. There are several reasons that the prey tissue LOE is applied at the scale of a whole water body, rather than individual sediment stations. Due to difference in

sampling methods and completeness, prey samples are usually not associated with the same locations as the sediment collection station. In addition, as discussed in the conceptual model, finfish typically move within the water body and thus integrate their exposure over a wider area than an individual sediment station (Linkov *et al.* 2002, Gobas and Arnot 2005). Finally, the risk to humans and wildlife is expected to occur at a scale better represented by the water body than the individual sediment station.

The sediment chemistry LOE is evaluated at the individual station scale. Characterization of sediments at a station scale would facilitate spatial evaluation of the water body to decide upon appropriate management actions. For example, management strategies for a large contiguous impacted area may be different from strategies for several isolated impacted areas. Although evaluation of sediment chemistry occurs on an individual station scale, development of the sediment chemistry thresholds is based on information from the entire water body. This will be further discussed in Section 3.

There are many reasons why the bioavailability LOE combines individual station results to make a determination across the entire water body. The intent of the bioavailability LOE is to determine whether the sediment-associated contaminant exhibits any measurable bioavailability in the water body. Laboratory bioaccumulation tests have uncertainty related to the duration of exposure, test conditions, degree of replication, and choice of reference stations (Boese *et al.* 1997, Moore *et al.* 2005). These uncertainties may reduce the accuracy and statistical power of the results for sediment samples from a specific site. Similarly, it may not be possible to examine bioavailability in field-collected organisms at all sites, due to lack of abundance. Due to these factors, as well as the high expense of bioaccumulation tests, the bioavailability LOE combines results from stations across the water body.

2.6.6. Separate evaluation of specific contaminant classes

For effects of bioaccumulative contaminants including PCBs and legacy pesticides, the cumulative evaluation of exposure risk due to contaminant mixtures (i.e., combined effects of PCBs, legacy pesticides, and other contaminant categories) is an ongoing area of research and development. However, federal and state guidance documents generally evaluate effects to wildlife and humans on a contaminant-by-contaminant basis (e.g., Brodberg and Pollock 1999, California DTSC Human and Ecological Risk Division 2000, U. S. EPA 2000b, Klasing and Brodberg 2006). That is, PCBs as a group are evaluated separately from DDTs, and so forth. In the absence of U. S. or California – sanctioned methodologies for combining effects of multiple contaminant categories, individual contaminant classes are evaluated separately in the current formulation of the framework.

3. Technical issues in implementation of the framework

There are a number of specific technical issues that arise in evaluating each line of evidence. This section outlines these technical issues as a series of questions. The use of questions emphasizes the thought process that is undertaken in applying the framework. Possible approaches and recommendations are then presented for each question. These recommendations are intended to meet the goal of the framework, as stated in Section 2.1: *to protect humans and wildlife against the risk of contamination as a result of dietary exposure to finfish and shellfish associated with contaminated sediments.* In some cases, Appendices develop more detailed guidance and background information.

3.1. Prey tissue chemistry

Table 3.1 lists technical and policy questions to be addressed in applying the prey tissue chemistry line of evidence (LOE). These questions pertain to two topics. The first topic is estimating tissue concentrations. To estimate tissue concentrations, decisions must be made about the types of data to be used, and statistical and probability issues that arise. The second topic is the selection of the low and high effects thresholds for evaluating this LOE. General guidance is provided in this section, with additional information about parameter selection described in Appendices and U. S. EPA (2000b).

Table 3.1. Questions to address in applying the prey tissue line of evidence.

Question	Section
Questions about estimating tissue chemistry concentration:	
What data are readily available and how should data be assembled?	3.1.1
At what spatial scale should data be compiled and evaluated?	3.1.2
How should consumption advisory information be included in the assessment?	3.1.3
What species and sizes of prey organisms should be included in the evaluation?	3.1.4
How recent should data be collected to be included in the evaluation?	3.1.5
What kinds of tissue preparations should be included in the evaluation?	3.1.6
How should reporting limits be considered in the analyses?	3.1.7
What sample sizes are adequate?	3.1.8
How should tissue contaminant concentrations be estimated from available data?	3.1.9
Questions about development of tissue chemistry thresholds:	
How should the low and high tissue thresholds be calculated?	3.1.10
What toxicity reference values are readily available for wildlife and humans?	3.1.11
How can wildlife body mass and consumption rate be estimated?	3.1.12
What are some standard risk assumptions for calculating human effects thresholds?	3.1.13
Once thresholds are developed, how should they be refined and updated?	3.1.14

3.1.1. What data are readily available and how should data be assembled?

There are many data sources of contaminant concentrations in finfish and shellfish from California estuaries (Table 3.2). It will be helpful to begin by compiling a database of all samples from the water body that contains data for contaminants of concern. Prey tissue chemistry data may be assembled simultaneously with sediment chemistry and bioavailability data. Prey tissue data may be obtained from sources listed in Table 3.2, in addition to other known, locally available sources.

Ancillary information in the database will help to identify appropriate samples for evaluating the different LOE. For the prey tissue LOE, useful parameters will include capture location, sample size, study, date, length, mass, species, and preparation method. Preparation method should be in a separate column, and should include whole body, skin-on fillet, skin-off fillet, or other tissue type (e.g., liver, gonads, etc.).

Table 3.2. Partial list of potential data sources for prey contaminant concentrations in California bays and estuaries.

3.1.2. At what spatial scale should prey tissue chemistry data be compiled and evaluated?

Sections 2.5 and 2.6.5 recommend that the prey tissue chemistry LOE be compiled and evaluated at the "water body" scale. This is because many prey and predator species will be mobile and data associated with individual sediment stations will often be unavailable.

The definition of "water body" may be based on the needs of the agencies applying the indirect effects framework. In most cases, the framework would be applied for managing an entire bay or estuary, using all available data. However, if there is a regulatory need or conceptual basis to conduct evaluations at a scale smaller than the entire water body, the framework could be adapted to this. For example, if the bay is divided into separate hydrological units (reaches or basins) for 303(d) listing purposes, and sufficient data are available on each of these units, the framework could be applied to evaluate each of these units separately.

3.1.3. How should consumption advisory information be included in the assessment?

Fish consumption advisories are an important data source for the prey tissue line of evidence. In State waters, finfish and shellfish consumption advisories are developed by OEHHA. Table 3.3 briefly summarizes current advisories relevant to California bays and estuaries. The most current listings may be found on the OEHHA website at http://www.oehha.ca.gov/fish/so_cal/index.html. If OEHHA has established a fish consumption advisory based on elevated risk of human exposure to a contaminant in a water body, this indicates that human consumption of fish captured from that water body may pose a risk to the consumers. These positive findings by OEHHA are important for determining that contaminant concentrations in prey tissues are high enough to pose a risk to human sport fish consumers.

Table 3.3. Summary of OEHHA fish consumption advisories for bays and estuaries of California.

Water body	Contaminant	Advisory
San Francisco Bay and Delta	Hg and PCBs	Interim advisory recommends limited consumption of some fish species.
Tomales Bay	Hg	Advisory recommend limited consumption of some fish species by all people, and no consumption of sharks by women of childbearing age or children.
Southern California locations between Point Dume and Dana Point	PCBs and DDTs	Advisory recommends limited consumption or no consumption for some fish species and locations.

For a given water body and individual contaminant having OEHHA consumption advisories, the prey tissue line of evidence should not be classified in the lowest risk category. Rather, it should be placed in the intermediate or high-risk categories,

depending on whether calculated tissue concentrations are above or below the high-risk threshold (See Table 2.1 and Figure 2.2).

3.1.4. What species and sizes of prey should be included in the evaluation?

Species for prey tissue monitoring should be local organisms commonly consumed by humans or by wildlife predators local to the water body (U. S. EPA 2000b). Separate species may be targeted for protection of human vs. wildlife predators. Prey organisms should also be selected based on available data and knowledge of behavior and life history. Peer-reviewed literature, local experts, and the FishBase website (www.fishbase.org) may be consulted to aid in selection of appropriate target species. Predictive relationships between sediment and tissue contamination are more likely in species that exhibit limited movement or migrations, reside close to the sediment during their adult life, and prey on animals that live in or on the sediment (Figure 3.1). For example, a sportfish such as striped bass would be appropriate for assessing the potential risk to human health, however due to this species' migratory pattern, tissue residue would demonstrate little correlation with localized sediment contamination.

Figure 3.1 Traits of ideal biota for assessing indirect effects.

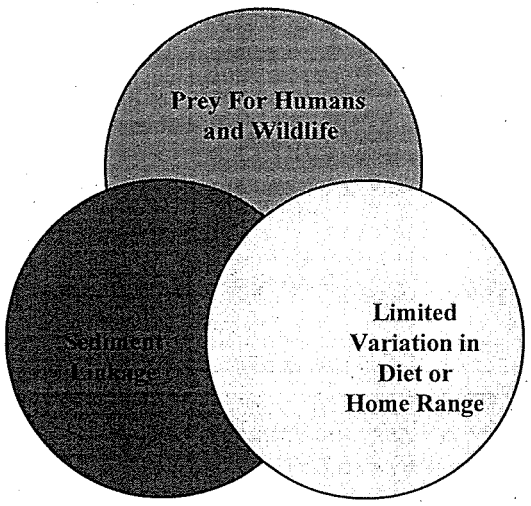

Table 3.4 lists some appropriate fish species for the prey tissue LOE. These species were selected based on life history information[11]. All species were previously captured in sediment quality and related studies assembled in the CASQO database[12]. These species were further ranked for use based on diet and movement. The top ranking (i.e., number

[11] Sources included Cailliet (2000), Tasto (1975), Domeier and Chun (1995), Orsi (1999), and Froese and Pauly (2006). Recommendations were also obtained from M. J. Allen (SCCWRP), G. Cailliet (MLML), Andy Jahn (Port of Oakland), and Kathy Hieb (CDFG).

[12] The California Sediment Quality Objectives (CASQO) database was compiled for methods development for the SQO program.

1) was reserved for species exhibiting exclusively benthic or epibenthic diets and relatively limited movement (Table 3.4).

Table 3.4. Recommended organisms for evaluation in the prey tissue chemistry line of evidence. Species listed in boldface exhibited significant positive associations between sediment and tissue concentrations for some legacy organochlorine pollutants (Appendix B).

Common name	Species name	Primary diet	Movement	Rank
Arrow goby	*Clevelandia ios*	Epibenthic	Resident	1
Bay goby	*Lepidogobius lepidus*	Epibenthic	Sedentary	1
Black perch	*Embiotoca jacksoni*	Epibenthic	Resident	1
California killifish	*Fundulus parvipinnis*	Epibenthic	Resident	1
California tonguefish	*Symphurus atricaudus*	Epibenthic	Sedentary	1
Dwarf surfperch	*Micrometrus minimus*	Epibenthic	Sedentary	1
Pacific staghorn sculpin	*Leptocottus armatus*	Epibenthic	Sedentary	1
Round stingray	*Urobatis halleri*	Benthic	Resident	1
Saddleback sculpin	*Oligocottus rimensis*	Epibenthic	Sedentary	1
Slender sole	*Lyopsetta exilis*	Epibenthic	Resident	1
Speckled sanddab	***Citharichthys stigmaeus***	**Epibenthic**	**Resident**	**1**
Starry flounder	*Platichthys stellatus*	Benthic	Resident	1
Three-spined Stickleback	*Gasterosteus aculeatus*	Epibenthic	Sedentary	1
Walleye surfperch	*Hyperprosopon argenteum*	Epibenthic	Resident	1
White surfperch	*Phanerodon furcatus*	Epibenthic	Resident	1
Barred sand bass	*Paralabrax nebulifer*	Pelagic/epibenthic	Resident	2
California corbina	*Menticirrhus undulatus*	Epibenthic	Transient	2
English sole	***Parophrys vetulus***	**Benthic**	**Transient**	**2**
Longfin sanddab	*Citharichthys xanthostigma*	Pelagic/epibenthic	Resident	2
Pacific sanddab	*Citharichthys sordidus*	Pelagic/epibenthic	Resident	2
Shiner surfperch	***Cymatogaster aggregata***	**Epibenthic**	**Transient**	**2**
Spotted sand bass	*Paralabrax maculatofasciatus*	Pelagic/epibenthic	Resident	2
Striped mullet	*Mugil cephalus*	Epibenthic	Transient	2
California halibut	***Paralichthys californicus***	**Pelagic/epibenthic**	**Transient**	**3**
White croaker	***Genyonemus lineatus***	**Pelagic/epibenthic**	**Transient**	**3**
Yellowfin croaker	*Umbrina roncador*	Pelagic/epibenthic	Transient	3
Bent-nosed clam	***Macoma nasuta***	**Benthic**	**Sedentary**	**1**

Notes to Table 3.4
Primary Diet: Benthic species primarily feed on organisms residing within the sediment; Epibenthic species primarily feed on organisms in contact with the sediment surface; Pelagic/Epibenthic species primarily feed on organisms in the water column or in contact with the sediment surface
Movement: Sedentary species move less than 1 km during adult lifespan; Resident species move between one and 10 km during adult lifespan; Transient species move more than 10 km during adult lifespan
Rank: Based on assumed sediment association and site fidelity for a species. Species that move little and prey on sediment-dwelling species are assigned the highest rank (1). The lowest rank (3) is assigned to species that are transient and feed in both sediment and the water-column.

Five fish species listed in boldface in Table 3.4 had sufficient data to demonstrate a positive statistical relationship between sediment and biota contaminant concentration and are common in coastal waters. These findings, further described in Appendix B,

suggest that these species bioaccumulate contaminants from nearby sediments and are spatially linked to the sites at which they were captured. Shiner surfperch exhibited significant positive relationships with sediments for all contaminants evaluated (Appendix B). This finding suggests that shiner surfperch may be a particularly appropriate species for sediment vs. biota comparisons. Based on the positive association with sediment contaminants, the following fish species are also strong candidates for monitoring for the prey tissue LOE: shiner surfperch, speckled sanddab, California halibut, white croaker, and English sole (Appendix B).

Among candidate invertebrate species, the bent-nosed clam (*Macoma nasuta*), and other *Macoma* species, are good indicators of prey exposure to sediment contamination (Pruell *et al.* 1993, Boese *et al.* 1997, U. S. EPA and U. S. Army Corps of Engineers 1998, MEC Analytical Systems 2003, Werner *et al.* 2004). The utility of *M. nasuta* is further discussed in Section 3.3.

In addition to species, body size is an important consideration in sample selection, particularly for finfish. Lengths may be compared to CDFG legal fishing sizes to determine whether fish samples are appropriate as human prey. Legal fishing size information may be obtained from the CDFG website http://www.dfg.ca.gov/ (California Department of Fish and Game 2006).

For assessment of effects to wildlife receptors, appropriate prey sizes will vary depending on local piscivorous wildlife. Appendix D reviews selected literature on fish prey captured by piscivorous birds. In general, small and medium shorebirds, such as western grebe, elegant tern, and least tern generally consume fish having total lengths less than 10 cm, or body depths less than 20 mm (Elliott 2005). Large birds, including double crested cormorants, osprey and bald eagle, may consume much larger fish, ranging from 100 to over 400 mm (Appendix D).

3.1.5. How recent should data be collected to be included in the evaluation?

It is preferable to use data from recently collected samples to characterize current risk. Many legacy pollutants, including organochlorine pesticides and PCBs, have shown declining concentrations since monitoring began (Greenfield *et al.* 2005, Connor *et al.* 2006, Davis *et al.* 2006a, O'Connor and Lauenstein 2006). More recent use compounds, such as PBDEs, have shown dramatic increases in recent years (de Wit 2002, She *et al.* 2002, Hites 2004).

The timeframe of data to be included may vary among pollutants and water bodies examined. Differences may result from expected or observed recent time trends for the pollutant in question, interannual variability, and availability of recent data. Time permitting, it would be appropriate to evaluate the impact of different data selection procedures on final interpretation.

As a general rule of thumb, it may be appropriate to flag data more than 10 years old and exclude it from further evaluations (i.e. at the time of publication of this report, only data

from 1998 – 2007 would be used). If information indicates temporal trends more recently than 10 years ago, and sufficient data are available, it may be appropriate to limit data to a shorter time period.

3.1.6. What kinds of tissue preparations should be included in the evaluation?

In general, tissue type and preparation can significantly influence contaminant concentrations in fish. Concentrations may vary between whole body vs. fillet tissue (e.g., Goldstein *et al.* 1996, Amrhein *et al.* 1999, Greenfield *et al.* 2001), and among tissue preparation methods (e.g., Reinert *et al.* 1972, Davis *et al.* 2002, Burger *et al.* 2003). These factors should be considered in sample preparation and selection.

Because piscivorous wildlife generally consume the entire fish, finfish sampled for the wildlife line of evidence are best evaluated as whole body samples. For risk to human consumers, all finfish samples should be analyzed as fillet tissue, unless local information indicates that the consumer population regularly consumes additional tissues. U. S. EPA (2000b) recommends analyzing all fish samples as skin-on fillets, with belly flap included for evaluating trace organic contaminant exposure to the general population or sport fishers. If evaluations are focused on Hg, skin-off fillet preparation will be more conservative, as Hg tends to accumulate in muscle tissue (U. S. EPA 2000b).

In some cases it may be necessary to estimate tissue contaminant concentrations in whole body vs. fillet samples. Appendix E provides a methodology for conducting this conversion for lipid-associated contaminants[13] based on estimating lipid concentrations among tissue types.

3.1.7. How should reporting limits be considered in the analyses?

Reporting limits (RL)[14] should be sufficiently low to quantify contamination in biota at concentrations relevant to the tissue LOE thresholds. One of the findings of the Newport Bay case study (Section 4) was that reporting limits for field-caught finfish were often too high to compare PCBs and legacy pesticides to the low tissue thresholds.

To have a good chance of quantifying PCBs and DDTs at environmentally relevant concentrations, tissue chemistry analytical RLs should be 1 ng/g or lower for individual PCB congeners and p,p'-DDTs[15]. Such RLs are readily achievable in analytical labs, provided that sufficient tissue is available for analysis (U. S. EPA 2000b).

In cases where most samples are below reporting limits (BRL), treatment of BRL samples can strongly affect the calculated average. This issue is further explored in the Newport Bay case study (e.g., Table 4.10). One method of dealing with these situations

[13] Including PCBs, legacy pesticides, and other halogenated organic pollutants

[14] A reporting limit (sometimes referred to as the sample quantitation limit) is the lowest concentration at which a numeric value is reported. Below the reporting limit, accurate concentration estimates cannot be made.

[15] Including p,p'-DDD, p,p'-DDE, and p,p'-DDT

is application of the robust method of Helsel and Hirsch (2002) for estimating summary statistics (Chapter 13 in Helsel and Hirsch 2002). Specifically, the observed data above the RL are plotted on a normal scores plot to determine the appropriate transformation, a linear regression model is applied, and estimates of all BRL values are imputed based on this regression. The imputed values are then combined with data above the RL to compute summary statistic estimates (Helsel and Hirsch 2002).

In some cases, it may be necessary to estimate concentrations when almost every analytical result is BRL. In the Newport Bay case study (Section 4), this was the case for heptachlor, dieldrin, aldrin and toxaphene. With a vast majority of BRL values, it is not possible to calculate the mean or confidence intervals of the results.

When all or almost all results are BRL, one option is to use the median of all RLs to estimate average tissue concentrations (Helsel and Hirsch 2002). A more conservative option is to use the maximum RL or the maximum reported value above the RL (whichever is higher); this second option will closer approximate an upper confidence limit estimate of concentration. Ultimately, it may not be possible to confirm whether tissue residues are above or below relevant tissue chemistry thresholds. If this turns out to be the case, supporting documentation should describe these inconclusive results, and additional analyses at lower RL may be advisable.

3.1.8. What sample sizes are adequate and how can data be interpreted given limited sample sizes?

Assessment of prey tissue chemistry should be based on sufficiently large sample sizes. Appendix F describes power analysis conducted using California fish tissue data to determine optimal sample sizes. These analyses suggest that sample sizes below 10 separate samples per water body may result in estimated average concentrations that deviate substantially from the actual average concentrations within the water body. Therefore, when planning additional analyses for the framework evaluation, it would be ideal to obtain at least 10 separate prey samples for each primary receptor.

If sample sizes are below 10, it may be appropriate to use lower and upper confidence intervals for comparison to the thresholds. For example, the average concentration could be replaced by the 95% upper or lower confidence interval of the average, for comparison to the upper and lower tissue threshold, respectively. If results were inconclusive due to low sample sizes, it may not be possible to make a confident determination regarding risk due to prey consumption. In such a situation, it would be appropriate to select the intermediate-risk category for the prey tissue LOE. This would reflect the uncertainty in the assessment and consequently place greater emphasis on the other lines of evidence (see Figure 2.2)

Sample size may also be increased by combining results for multiple sediment-associated prey species. Alternatively, variability of concentration estimates may be reduced by accounting for confounding factors, like tissue percent lipid. The approaches of

combining multiple species and lipid normalization are further evaluated in the Newport Bay case study (Section 4).

3.1.9. How should tissue contaminant concentrations be estimated from available data?

Selection of appropriate parameter estimates is important in probabilistic risk assessments. Prey tissue contaminant concentration is a key local parameter for the prey tissue chemistry LOE. In order to determine whether the prey tissue line of evidence indicates unlikely exposure, possible exposure, or probable exposure, estimates of contaminant concentration must be compared to low and high effects thresholds (Section 3.1.10). A probability-based approach is recommended to estimate the appropriate prey tissue concentration to compare to these thresholds.

Estimates of the central tendency of tissue concentrations include arithmetic and geometric means, and the median. In general, the arithmetic mean will be appropriate to provide an unbiased estimate of the average exposure of consumers to contamination in the prey (Appendix G).

Estimators of the potential range of the entire data set include various upper and lower confidence limits (including 75%, 90%, 95% and 99% upper and lower confidence limits). All of these estimates represent extremes in predator contaminant exposure. Their use in the threshold comparison would likely overestimate or underestimate actual exposure over the lifespan of a predator.

Confidence limits of estimates for the average are distinct from confidence limits for the range of the entire data set. The difference between average and range estimates creates substantial differences in predator exposure estimates. Figure 3.2 presents simulation results to illustrate this point. In Figure 3.2, estimates of the average of the data set (e.g., 95% upper confidence limit of the arithmetic mean[16]) exhibit a much smaller range of uncertainty than estimates of overall range of the data set (e.g., 95% upper confidence limit of the data[17]).

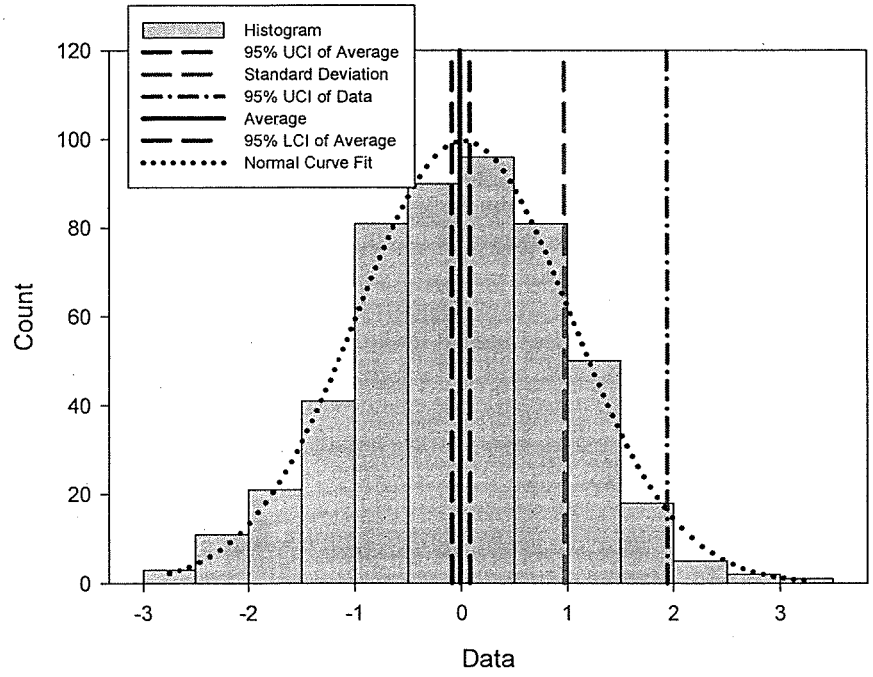
The difference between the two types of confidence interval calculation methods (Figure 3.2) is important in choosing appropriate estimates for the assessment. This is because predator lifetime exposure is best represented by average prey tissue concentrations. The population of receptors (humans) are expected, on average, to consume prey across the entire water body, rather than occurring at only one location. Therefore, we recommend estimations of the average, and calculations of uncertainty regarding the average, for use in the prey tissue LOE.

Selection of the exact tissue concentration estimation method for comparison to thresholds involves judgment about how conservative the approach should be. The high threshold represents a concentration above which adverse effects to the consumer are probable. For comparison to the high threshold, the simple arithmetic average

[16] i.e., 2 times the standard error
[17] i.e., 2 times the standard deviation

concentration may be used. The use of arithmetic average is appropriate for dietary uptake of contaminants due to prey consumption (Appendix G).

Figure 3.2. Potential estimators of a randomly generated simulated data set consisting of 500 data points. The data are simulated from a normal distribution with mean of zero and standard deviation of one. The grey bars represent a histogram of the data set. The different vertical lines represent different estimators of the data. For example, the solid black line represents the arithmetic average.



The estimated concentration for comparison to the low threshold should be conservative. This is because the analysis does not proceed to the next LOE (sediment chemistry) unless estimated tissue concentrations are above the low threshold (Section 2.5; Table 2.1; Figure 2.2)[18]. An appropriate estimate may be the 95% upper confidence interval (UCI) of the average tissue concentration (e.g., mean plus two times the standard error of the mean). When sample sizes are relatively small, use of the 95% UCI will account for difficulty in estimating the population average. When sample sizes are large, the 95% UCI will actually be very similar to the mean concentration (Figure 3.2), and will have negligible impact on the threshold comparison.

3.1.10. How should the low and high tissue thresholds be calculated?

For the indirect effects assessment framework, prey tissue effects thresholds are needed to classify the level of potential risk. Separate tissue thresholds are developed to be

[18] For water bodies having OEHHA fish consumption advisories (Table 3.3), the prey tissue chemistry assessment should automatically be placed into the intermediate or high-risk category, following 3.1.3.

protective of wildlife and human consumers of the prey organisms. Additionally, for each receptor, both low and high prey tissue effects threshold are developed, in order to address uncertainty inherent in effects of dietary exposure (Table 2.1, Figure 2.2).

The effects thresholds are developed based on a combination of policy decisions and scientific information. The State Water Board is the agency responsible for ultimately deciding policy related issues in regard to statewide water quality regulation control plans and policies for surface waters.

Policy decisions include the allowable level of risk (e.g., rate of allowable increased cancer risk for humans) and the specific receptors and target population to be protected. For wildlife, receptors should be species of management importance for the evaluated water body. For humans, the target population needs to be selected, particularly with respect to the rate of fish consumption. Examples of target populations include the general population in the region, sport fishers, or subsistence fishers (U. S. EPA 2000b).

Choices of receptor and allowable risk level strongly influence calculated thresholds for sediments or fish tissue. This report describes some potential choices and provides relevant technical background information, but is not intended to be the final word on policy development. If tissue thresholds are used in a policy framework, there should be many opportunities for stakeholder review and feedback.

Prey tissue effects thresholds can be calculated based on two parameters, which are commonly used in wildlife risk assessments (e.g., Sample *et al.* 1996, California DTSC Human and Ecological Risk Division 2000, von Stackelberg *et al.* 2003, Arcadis G&M Inc. and Matrix Design Group 2004, Zeeman 2004). The first parameter measures the relative toxicity of the contaminant to a particular wildlife species; as toxicity increases, the threshold will decrease. This parameter is referred to as the toxicity reference value (TRV). The second parameter is the expected rate of exposure by the wildlife receptor; as daily exposure rate increases, the prey tissue threshold will decrease. The rate of exposure is equivalent to the prey consumption rate by the predator, relative to the body mass of the predator. All of these relationships are mathematically depicted in following simple equation:

$$\text{Threshold concentration in prey tissue} = \text{TRV} * \frac{\text{MA}}{\text{CR}} \qquad \textit{(Equation 3.1)}$$

Here, TRV equals the toxicity reference value, which is defined as a level of exposure that indicates a probability of adverse effects to the target organism. The more toxic contaminants have lower TRVs. MA and CR are the body mass (MA) and daily prey consumption rate (CR) by the predator. Note that as MA/CR decreases, the mass-specific consumption rate increases, resulting in lower threshold values.

Detailed methodology for deriving thresholds to protect human consumers of fish may be found in U. S. EPA guidance documentation (U. S. EPA 2000d, 2000b). For non-carcinogens, the general approach is the same as for wildlife thresholds:

$$\text{Threshold} = \frac{\text{RfD} * \text{MA}}{\text{CR}} \qquad \textit{(Equation 3.2)}$$

where RfD = oral reference dose (mg/(kg*d)), which is in essence a TRV applied to humans. MA and CR are as above, but for a target human population. In short, the methodology requires good estimates of three parameters (RfD, MA, and CR).

For human exposure to carcinogens, the calculation also incorporates the carcinogenicity of the compound relative to the maximum acceptable risk level:

$$\text{Threshold} = \frac{\text{RF} * \text{MA}}{\text{q1} * \text{CR}} \qquad \textit{(Equation 3.3)}$$

where RF = Risk Factor (the maximum acceptable risk level; dimensionless), q1 = Oral cancer slope factor (a measure of carcinogenicity; kg*d/mg), and the other parameters are as above. The risk factor indicates the expected number of increased cancer occurrences in the human population. The decision about what risk factor to use is a policy decision, rather than a technical decision.

3.1.11. What toxicity reference values are readily available for wildlife and humans?

Toxicity reference values are an important component of threshold determination. Due to the large impact of TRV selection on threshold calculations, TRV development can be controversial. To reduce cost, it may be appropriate for previously calculated TRVs to be used in the framework. This section describes TRVs that have been developed and recommended elsewhere.

For protection of humans, TRVs (i.e., reference doses and cancer slope factors) are readily available from standardized U. S. Federal guidance on contaminant toxicity. In particular, the U. S. EPA's Integrated Risk Information System (IRIS) provides a consistent and updated data source, including reference doses and cancer slope factors for use in human health risk evaluation (U. S. EPA 2006b). For developing human health effects thresholds, cancer and non-cancer effects may be calculated based on these U. S. EPA IRIS cancer slope factors (CSF) and reference doses (RfD). Tissue thresholds may then be based on the CSF or RfD approach, whichever is more protective.

For protection of wildlife receptors, there is no single source for guidance on TRVs equivalent to the U. S. EPA IRIS website. However, a number of TRVs have been developed. Ideally, TRVs should fit three criteria:

1. Ecologically relevant endpoints that are likely to affect populations. These include mortality, growth, reproduction, and development (PRC Environmental

Management 1997, California DTSC Human and Ecological Risk Division 2000, U. S. EPA 2005).
2. A review of all available literature.
3. A consensus approach in development. Specifically, toxicologists from multiple agencies should reach agreement on the TRVs in a team-based effort.

Appendix H presents a set of toxicity reference values that may be considered for inclusion in the assessment framework.

Federal and state agencies in U. S. EPA Region IX have developed a Biological Technical Assistance Group (BTAG), which evaluates various issues in wildlife risk assessment in California[19]. The BTAG has established a formal process for developing and refining TRVs based on additional available data (California DTSC Human and Ecological Risk Division 2000). Where appropriate, TRVs developed by the BTAG are presented in Appendix H. The input of the BTAG would be beneficial in developing TRVs for the assessment framework. Input from regional stakeholders should also be considered when refining the TRV values used in the framework.

Another source of TRVs and related toxicity information is the U. S. EPA Ecological Soil Screening Levels (ECO-SSL). The ECO-SSLs are developed as a collaborative process including Federal and State agency toxicologists, in addition to consultants, industry scientists, and academics (U. S. EPA 2007). Although ECO-SSLs are not currently available for most organic pollutants, Appendix H includes a draft ECO-SSL developed for dieldrin (U. S. EPA 2005). Only a few syntheses of information on indirect effects of pollutants to predatory finfish have been published. Appendix I summarizes the findings of three recent studies (Johnson *et al.* 2002, Meador *et al.* 2002b, Beckvar *et al.* 2006) that recommend values for protection of finfish.

3.1.12. How can wildlife body mass and consumption rate be estimated?

To develop prey tissue thresholds (Equation 5.1), wildlife predator body mass and consumption rate must also be estimated. For protective thresholds in the absence of local data, generic body mass estimates may be used (Table 3.5) (B. Stanton, R. Donohue, and J. Yamamoto, CDFG-OSPR, *Pers. comm.*). Alternatively, if local body mass data are available, they may be used for local wildlife receptors.

Daily food consumption rates may be calculated based on body mass using allometric equations presented in Nagy (2001). Figure 3.3 presents an illustrative example, in which PCB low and high thresholds for small birds are calculated. Appendix J presents prey tissue concentration thresholds (dry weight) calculated using the TRVs from Appendix H, and the body masses and feeding rate equations from Table 3.5.

Note that dry weight concentrations may be estimated from wet weight concentrations as:

[19] EPA Region IX includes California, Nevada, Arizona, Hawaii, and the Pacific Islands. However, the BTAG focuses primarily on toxicology issues in California.

$$CDW = \frac{CWW}{(1 - Moist)} \qquad \textit{(Equation 3.4)}$$

where CDW = contaminant concentration in tissue (dry weight basis), CWW = contaminant concentration in tissue (wet weight basis), and Moist = proportion of total tissue mass that is moisture.

In the absence of local tissue percent moisture, it is common use a factor of five to convert from dry weight to wet weight for finfish prey (Jarvinen and Ankley 1999, Meador *et al.* 2002a). Therefore, if the proportion of tissue moisture is unknown, finfish dry weight concentration may be estimated assuming 80% tissue moisture as CDW = CWW*5.

Table 3.5. Generic size classes (based on mass) to calculate tissue concentration thresholds (B. Stanton, R. Donohue, and J. Yamamoto, CDFG-OSPR, *Pers. comm.*). These masses may be replaced with site-specific information on likely species, when such information are available. IR = ingestion rate.

Birds	Size range	Example species	Body mass to use in generic calculations	Equation to estimate food ingestion rate (IR) for generic calculations
Small	25 - 300 g	Snowy plover Western sandpiper Killdeer Least tern Forster's tern Black skimmer	25 g	Marine Birds (Nagy, 2001) IR (g dry mass/d) = 0.880*(g body mass)$^{0.658}$
Medium	300 – 1000 g	Clapper rail Lesser scaup Surf scoter Western grebe Black-crowned night heron	300 g	
Large	>1000 g	Brown pelican Bald eagle Osprey Double-crested cormorant Great blue heron	1000 g	
Marine Mammals				
Small	20 – 90 kg	Southern sea otter	20 kg	Carnivores (Nagy, 2001) IR (g dry mass/d) = 0.153*(g body mass)$^{0.834}$
Large	>90 kg	Harbor seal California sea lion Steller sea lion	90 kg	

Figure 3.3. Example to illustrate calculation methods for small bird effects threshold following guidance in Sample *et al.* (1996) and Zeeman (2004). dw = dry weight and ww = wet weight.

$$\text{Threshold value concentration in prey tissue} = TRV * \frac{MA}{CR} \qquad \textit{(Equation 3.1)}$$

where TRV = toxicity reference value, MA = predator body mass, and CR = daily consumption rate

For PCBs in small birds (Following Appendix H):

Low TRV = 0.09 mg dw/(kg*day); (California DTSC Human and Ecological Risk Division 2000)
High TRV = 1.27 mg dw/(kg*day); (California DTSC Human and Ecological Risk Division 2000)

MA for small bird = 25 g; (Table 3.5)

CR (in grams dw) = Allometric function of body mass (in grams dw) = $(0.880 * MA^{0.658})$; (Nagy 2001)

Low prey tissue threshold = TRV_{low} * Mass / Consumption rate
= $0.09 * 25 / (0.880 * 25^{0.658})$
= $0.09_{mg/(kg*d)} * 25_{g} / 7.32_{g/d}$
= 0.308 mg/kg
= 0.308 ppm dry weight

High prey tissue threshold = TRV_{high} * Mass / Consumption rate
= $1.27 * 25 / (0.880 * 25^{0.658})$
= $1.27_{mg/(kg*d)} * 25_{g} / 7.32_{g/d}$
= 4.34 mg/kg
= 4.34 ppm dry weight

3.1.13. What are some standard risk assumptions for calculating human effects thresholds?

The framework is intended to protect humans against the risk of contamination as a result of dietary exposure to finfish and shellfish associated with contaminated sediments Following Equations 3.2 and 3.3, two policy decisions must be made to determine appropriate thresholds for this goal. These policy decisions are the human population to be protected, and the allowable risk factor for carcinogens.

In human health risk calculations, the population to be protected is identified based on the daily fish consumption rate (i.e., CF in Equations 3.2 and 3.3). Consumption rates are typically chosen to be representative of the general population in the region, sport fishers, or subsistence fishers (U. S. EPA 2000b). Depending upon this choice, a wide range of potential consumption rates may be appropriate. For example, the U. S. EPA estimates consumption at 17.5 g/d for the general adult population and recreational fishers, and 142.4 g/d for subsistence fishers (U. S. EPA 2000b). The consumption rate for the general population listed in the California Toxics Rule was 6.3 g/d (U. S. EPA 2000d), based on prior U. S. EPA guidance (U. S. EPA 1995b). Empirical estimates of average consumption rate by sport fishers in California waters range between 18 g/d and 32 g/d (Allen *et al.* 1996, SFEI 2000). To develop fish tissue screening values, OEHHA has used consumption rates ranging from 21 g/d (Brodberg and Pollock 1999) to 90 g/d (Klasing and Brodberg 2006). Median consumption rates as high as 540 g/d have been reported for Native American subsistence consumers (Harris and Harper 1997); however, such high rates are unlikely in California (R. Brodberg, OEHHA, *Pers. comm.*). Among 501 recent sport fish consumers surveyed in San Francisco Bay, the highest individual consumption rate reported was 324 g/d (SFEI 2000).

Average lifetime consumption rate can be modified to account for expected variations in lifetime exposure. That is, the total risk will be proportional to the time period spent consuming the local fish averaged over the total lifespan. For example, the draft report of Klasing and Brodberg (2006) assumed that 30 years of a 70 year lifespan would be spent consuming fish at the current contaminant level. The calculated screening values were consequently based on exposure rates of 3/7 of maximum lifetime exposure (Appendix K, Table K.1).

For carcinogens, the allowable risk factor[20] (RF, following Equation 3.3) must also be selected. U.S. EPA has stated that risk factors between 10^{-4} to 10^{-6} are protective of public health under the agencies statutory authorities including the Federal Clean Water Act (Reference. USEPA 1995 *Water Quality Guidance for Great Lakes System Supplementary Information Document.* EPA 820-B95-001 Office of Water , March). As a result this represents the range typically applied in human risk evaluations. A 10^{-4} RF has commonly been used as an action level in Federal Superfund site assessments (i.e., CERCLA). At these sites, when total carcinogenic risk is lower than 10^{-4}, remediation activities may not be warranted (Hamilton and Viscusi 1999). A RF of 10^{-4} was also

[20] The population-level expected rate of increased cancer risk

proposed by OEHHA scientists in a recent draft report developing guidance fish tissue levels and screening values[21] (Klasing and Brodberg 2006).

A RF of 10^{-5} or 10^{-6} has been used in many Water Quality Control Plans, Basin Plans, and TMDLs throughout California. A 10^{-5} RF was also used by OEHHA previously in developing fish consumption advisories in California water bodies (Brodberg and Pollock 1999), and by U. S. EPA in recommending human health screening values (U. S. EPA 1995b, 2000b). A 10^{-6} RF was used in combination with a general population fish consumption rate (6.5 g/d) in the California Toxics Rule legislation (U. S. EPA 2000d).

Another consideration in human health threshold development is changes in tissue concentration as a result of tissue preparation and cooking method. Exposure to organic pollutants may be reduced by cooking the fish (Reinert *et al.* 1972, Puffer and Gossett 1983). This may be accounted for by calculating the population exposure rate as a portion of the raw tissue concentrations. For example, in their draft guidance document, Klasing and Brodberg (2006) reduce exposure rates to 0.7 of raw tissue concentrations in their calculations. For Hg, Burger *et al.* (2003) actually found concentrations to increase with cooking, and recommended a conversion factor of about two for increased Hg concentration in cooked fish. Finally, exposure rates can differ based upon preparation method. For finfish, concentrations of organic pollutants are generally higher in fillets with skin, than skin-off fillets (Davis *et al.* 2002). Consumption of digestive tract tissue or preparation of fish in soups has been reported by some anglers (Allen *et al.* 1996, SFEI 2000), and these methods may cause changes in contaminant exposure.

Appendix K presents a set of calculated tissue thresholds, incorporating various assumptions described above. Where possible, these thresholds are based on assumptions provided in previous national and state guidance documents.

3.1.14. Once thresholds are developed, how should they be refined and updated?

Once developed, thresholds should be reviewed periodically in order to reflect changes in national guidance and the availability of additional data. All relevant TRVs, cancer slope factors, reference doses, and consumption rates should also be reviewed. The U. S. EPA Region IX Biological Technical Assistance Group (BTAG) has established a formal process for developing and refining TRVs based on additional available data (California DTSC Human and Ecological Risk Division 2000). The input of the BTAG should be considered in the review. Scientists at OEHHA-California EPA should also be consulted, particularly regarding human health thresholds and underlying assumptions. Finally, feedback from stakeholders should be solicited and reviewed.

[21] OEHHA defines screening values as, "specific guidance tissue levels used to identify situations where contaminant concentrations in fish are of potential health concern and further action (e.g., additional sampling or developing consumption advice) is recommended." (Klasing and Brodberg 2006)

3.2. Sediment chemistry

Table 3.6 presents some technical and policy questions that must be addressed in applying the sediment chemistry line of evidence. The first three questions pertain to the collection and analysis of sediment chemistry data. Other questions evaluate methods for development and application of the sediment chemistry thresholds. The recommended approach is to develop thresholds based on prey tissue thresholds and a bioaccumulation rate parameter. The bioaccumulation rate parameter is needed to back-calculate sediment chemistry thresholds from tissue thresholds.

Each question in Table 3.6 is discussed in an individual section. Additional guidance on sampling and analysis for sediment chemistry will be provided in other documents prepared for the sediment quality objectives program. Zeeman (2004) also provides a good introduction to development of bioaccumulation rate parameters.

Table 3.6. Questions to address in applying the sediment chemistry line of evidence.

Question	Section
What compounds should be evaluated?	3.2.1
What data are readily available and how should data be assembled?	3.2.2
How should additional sediment chemistry data be collected?	3.2.3
Questions regarding calculation of the bioaccumulation rate parameter and the sediment chemistry threshold:	
How should the sediment chemistry thresholds be calculated?	3.2.4
What prey species should be included in bioaccumulation rate parameter development?	3.2.5
Should the bioaccumulation rate parameter be normalized to lipids or organic carbon?	3.2.6
How should the bioaccumulation rate parameter be estimated from available data?	3.2.7
How can mechanistic models be used to validate the bioaccumulation rate parameter?	3.2.8
How are sediment data compared to the low and high thresholds?	3.2.9

3.2.1. What compounds should be evaluated?

Target compounds should be selected based on results of the prey tissue chemistry LOE. Consistent with application of the assessment framework, separate evaluatations are conducted for human health vs. wildlife risk. If prey tissue chemistry concentrations are below the low tissue threshold, and there is no listing of the water body for fish consumption, then the framework determines that compound to pose "unlikely risk" (see Table 2.1 and Figure 2.2). It is only necessary to evaluate a compound in the sediment chemistry line of evidence if the prey tissue results are above the low tissue threshold or if that compound is listed by OEHHA for a human health consumption advisory (Table 3.3).

3.2.2. What data are readily available and how should data be assembled?

As with the prey tissue chemistry LOE, a sediment chemistry database should be assembled from all readily available sources. Some data sources are listed in Table 3.7. Additional data may also be sought from the U. S. Army Corps of Engineers, local ports responsible for dredging activity, and other local research and management agencies.

An extensive database of historical sediment chemistry has already been prepared, which should aid in database preparation for specific California bays and estuaries (Table 3.7, first row). Data from this California Sediment Quality Objectives (CASQO) database should be included in the survey of available sediment chemistry data sets.

Table 3.7. Partial list of potential data sources for sediment contaminant concentrations in California bays and estuaries.

U. S. EPA National Sediment Quality Survey	http://www.epa.gov/waterscience/cs/nsidbase.html	Bob Shippen, U. S. EPA shippen.robert@epa.gov

In addition to sediment chemistry for contaminants of concern, the database should also include ancillary information when available. Key parameters include sample location with GIS coordinates, date collected, sediment grain size, percent organic carbon, percent moisture, detection and reporting limits, and sample collection depth.

As with the prey tissue chemistry LOE, sediment chemistry may be expected to change over long time periods (e.g., Venkatesan *et al.* 1999). To minimize the risk of long-term changes, it may be appropriate to limit analyses to data collected within the last 10 years or a shorter time period.

3.2.3. How should additional sediment chemistry data be collected?

The primary uses of sediment chemistry data in the framework are: 1. development of empirical bioaccumulation rate parameters, and 2. assessment of sediments within the water body. Guidance documents exist on appropriate methods for sediment chemistry data collection and analyses (e.g., U. S. EPA and U. S. Army Corps of Engineers 1991, 1998).

To increase the usefulness of sediment chemistry data for the framework, several specific recommendations should be followed. Samples should generally be collected from the sediment surface (i.e., top 5 to 10 cm), as these are most representative of potential exposure to local prey species. Sample detection limits should be sufficiently low to allow for accurate comparison to the low and high sediment chemistry thresholds. For example, in the case studies (Sections 4 and 5), detection limits at or below 1.0 ng/g dry weight were generally needed to allow comparison to the low sediment chemistry thresholds. To enable development of normalized biota-sediment accumulation factors for organic pollutants, organic carbon concentration should also be collected alongside sediment chemistry.

Sampling design is an important consideration that will depend on the specific objectives of the data collection. If new data are needed for current assessments, a probabilistic survey design may be employed. The U. S. EPA Office of Research and Development[22] has developed extensive guidance on development of probabilistic survey designs, which would be appropriate for sediment surveys.

If available data are insufficient to characterize empirical bioaccumulation rate parameters, it may also be appropriate to perform a special study to characterize sediment vs. prey tissue contaminant concentrations. This would include assessment of multiple stations in a large water body. A gradient design may be employed, emphasizing a range from low to high sediment contaminant concentrations.

3.2.4. How should the sediment chemistry thresholds be calculated?

As discussed in section 2.5, the sediment chemistry thresholds are calculated as a quotient of the prey tissue thresholds and a bioaccumulation rate parameter:

$$\text{Sediment Threshold} = \frac{\text{Prey Tissue Threshold}}{\text{Bioaccumulation Rate Parameter}} \qquad \textit{(Equation 3.5)}$$

As with the prey tissue thresholds, development of the low and high sediment chemistry thresholds for the framework requires judgment regarding how conservative the assumptions should be. To this end, the low and high sediment chemistry thresholds should be based on the low and high prey tissue thresholds, respectively (Table 3.8). Additionally, it would be appropriate to use more conservative assumptions in estimating the bioaccumulation rate parameter for the low sediment threshold (Table 3.8).

[22] http://www.epa.gov/nheerl/arm/designpages/design&analysis.htm

Table 3.8. Summary of assumptions used for calculating low and high sediment thresholds. See also Table 3.9.

Parameter	Low sediment threshold	High sediment threshold
Prey tissue threshold	Low tissue threshold	High tissue threshold
Bioaccumulation rate parameter	More conservative estimate	Less conservative estimate

The bioaccumulation rate should be estimated empirically from measured concentrations in organisms and sediments, as well as ancillary variables known to be influential. Empirical models may be readily used to develop statistical associations between biota and sediment contamination (Mackay and Fraser 2000, U. S. EPA 2000a). These models are typically derived on a site- and species-specific basis (e.g., Froese *et al.* 1998, Wong *et al.* 2001, Burkhard *et al.* 2004). The next questions more specifically address development of the bioaccumulation rate parameter.

3.2.5. What prey species should be included in bioaccumulation rate parameter development?

The database developed for the prey tissue line of evidence may also be used for developing the bioaccumulation rate parameter for the sediment chemistry line of evidence. As with the prey tissue line of evidence, the ideal organisms for parameter development will exhibit three attributes: 1. a trophic linkage to the sediments; 2. strong local site affinity; and 3. consumed by human or wildlife predators.

One approach would be to select a single surrogate species for development of the empirical bioaccumulate rate parameter. This is performed in the San Francisco Bay case study (Section 5), in which shiner surfperch are evaluated as a representative surrogate prey species for parameter development in the water body. If a surrogate species is used, it should have a relatively sedentary life history, resulting in a relatively strong spatial association between tissue and sediment chemistry concentrations within a region and a lipid content that is similar to the prey species used in the assessment. The advantage of this association is that it will allow parameter development for individual sites or local areas within the water body, potentially reducing the uncertainty in parameter calculations. In the case of sessile benthic invertebrates, a spatial association may be assumed. For finfish, Appendix L describes a spatial regression procedure that may be used, data permitting, to identify such an association. The San Francisco Bay case study presents other approaches to demonstrate an association using existing data; these include evaluation of spatial patterns in contaminant concentrations using ANOVA, and use of stable isotope analyses (Section 5.3.1.1).

3.2.6. Should the bioaccumulation rate parameter be normalized to lipids or organic carbon?

For trace organic compounds, the most common methods of estimating the bioaccumulation rate are an uncorrected bioaccumulation factor (BAF) and a normalized biota-sediment accumulation factor (BSAF). The bioaccumulation factor (BAF) is the ratio of a chemical compound's concentration in tissue (C_t in mg/kg) to a compound's concentration in water (C_w in mg/L) or in sediment (C_s in mg/kg dry wt). For sediments:

$$BAF = \frac{C_t}{C_s} \qquad \textit{(Equation 3.6)}$$

Empirically measured BAFs integrate all environmental routes of exposure and take into account the bioavailability of the chemical in the system being studied.

The biota-sediment accumulation factor (BSAF) is the ratio of biota to sediment contamination concentration, corrected for lipid content of the biota and organic carbon content of the sediment (reviewed in Wong *et al.* 2001, Burkhard *et al.* 2004). That is:

$$BSAF = \frac{\left(C_t / f_L\right)}{\left(C_s / f_{OC}\right)} \qquad \textit{(Equation 3.7)}$$

where f_L is the fraction of lipid in tissue and f_{OC} is the fraction of organic carbon in sediment (U. S. EPA 2000a and references cited therein). The use of lipid and organic carbon normalization rests on the principle that many contaminants are predominantly associated with these matrices, producing more reliable relationships between them (Clark *et al.* 1988). Organic carbon normalization has been supported by empirical evaluations of contaminant fractionation among sediment types in multiple datasets (Di Toro *et al.* 1991, Di Toro and De Rosa 1998).

A bioaccumulation rate parameter may also be developed based on a model that is intermediate between the BAF and the BSAF. For example, wet weight tissue concentrations could be compared to concentrations in organic carbon-normalized sediment. Alternatively, lipid weight tissue could be compared to dry-weight sediment. There is less of a precedent for these approaches in the literature, as compared to a simple BAF or BSAF.

Which empirical model is used should ultimately depend on the available data and success of each model type in characterizing the sediment vs. biota relationship. Graphical and statistical analysis of the tissue lipid vs. contaminant relationship can help decide whether to lipid normalize prey tissue data. Similarly, the sediment organic carbon vs. contaminant relationship may be analyzed to determine if sediment data should be organic carbon normalized. Finally, a comparison of results from the models in terms of variance explained may aid in deciding which model to use. Linear regression analyses comparing sediment vs. biota concentrations will aid in this process.

Examples of these evaluations are provided in the Newport Bay case study (Section 4.4.1).

Accurate information on organism lipid content and sediment total organic carbon (TOC) content are needed for deriving a BSAF. In contrast, BAFs require no ancillary data other than biota and sediment contaminant concentrations. Given that these ancillary data are sometimes unavailable, a larger dataset is often available for estimating BAFs, than for BSAFs.

The BSAF has received more support and discussion in the peer-reviewed scientific literature. When thermodynamic equilibrium is reached, the BSAF is expected to range between 1 and 2 (Ankley *et al.* 1992, Moore *et al.* 2005). Equilibrium conditions may occur for short-lived benthic invertebrates, but fish and wildlife often exhibit BSAFs above or below these values, reflecting disequilibrium (van der Oost *et al.* 2003). For fish, the BSAF can vary as a result of food web trophic transfer, lack of equilibrium between the sediments and water column, variation in benthic-pelagic coupling, and metabolic breakdown of contaminants (Burkhard *et al.* 2003, Burkhard *et al.* 2004). Equilibrium conditions occur in some local studies (e.g., Froese *et al.* 1998), but BSAFs often differ from equilibrium, as a result of these factors (Morrison *et al.* 1996, Wong *et al.* 2001, Burkhard *et al.* 2004).

3.2.7. How should the bioaccumulation rate parameter be estimated from available data?

A number of decisions must be made to develop the bioaccumulation rate parameter:

a. Use of individual vs. pooled species data for prey tissue concentrations
b. The spatial scale at which biota vs. sediment samples are compared
c. Treatment of samples below reporting limits
d. How to address uncertainty of the parameter estimates
e. How to average tissue and sediment data (e.g., arithmetic vs. geometric average)

These decisions depend on the available data and require a degree of best professional judgment. The two case studies (Sections 4 and 5) present examples of how available data were evaluated to make appropriate choices for these issues. Beyond that, some general guidance can be provided.

For the optimal rigor, the decisions should be based on graphical and statistical analyses of the available empirical data. Much of the decision-making may be based on which approach minimizes uncertainty of parameter estimates. For example, uncertainty of average predator exposure may be compared between individual vs. pooled prey species data (a, above). Calculation of standard errors and confidence intervals will aid in determining whether pooling multiple prey species may improve estimates of average predator exposure. Appendix L describes an empirical method for identifying the best spatial scale at which to compare biota vs. sediment data (b, above). These analyses are also demonstrated in the case studies.

The impact of samples below reporting limits (BRL) can be significant for compounds with a majority of samples BRL (c, above). As for prey tissue chemistry (Section 3.1.7), BRL sediment chemistry values may be set to ½ the reporting limit (RL) or estimated for averaging by the robust methods of Helsel and Hirsch (2002). If analyses indicate that RL will strongly affect final determination, it may be appropriate to conduct additional sampling, using analytical labs with lower RLs.

As with prey tissue chemistry (section 3.1.9), a probability-based approach is needed to address uncertainty in parameter development (d, above). The bioaccumulation rate parameter is a quotient of prey tissue chemistry and sediment chemistry. Estimates of these individual parameters will depend on averaging method and distribution assumptions. In particular, more vs. less conservative estimates should be used to derive the low and high sediment thresholds, respectively (Table 3.8).

To account for uncertainty in the bioaccumulation rate parameter estimate (d, above), it may be appropriate to use upper and lower confidence intervals of the means in deriving the lower (i.e., more conservative) sediment chemistry threshold. This approach is employed in the case studies (Sections 4 and 5). In the case studies, the arithmetic average prey tissue and sediment chemistry concentrations are used for calculating the less conservative estimate of the bioaccumulation rate parameter, to be used in the high sediment threshold. In contrast, the bioaccumulation rate parameter for the low sediment threshold is calculated using the 95th percentile of the average tissue concentration divided by the 5th percentile of the average sediment concentration (Table 3.9). This results in a much more conservative estimate of the threshold, which is appropriate because the low threshold represents sediment chemistry concentrations below which there is a negligible expected risk of indirect effects.

Table 3.9. Summary of recommended probability approach used for calculating the bioaccumulation rate parameter in the case studies.

Parameter	**Estimates used for high sediment threshold**	**Estimates used for low sediment threshold**
Prey tissue concentration	50th percentile	95th percentile of the average
Sediment concentration	50th percentile	5th percentile of the average

Appendix G provides information on the general attributes of arithmetic vs. geometric averaging (e, above). As with prey tissue chemistry, the arithmetic mean of sediment chemistry best represents the average exposure of prey species to sediment-associated contaminants (Appendix G). The arithmetic mean sediment concentration will generally be higher than the geometric mean. Therefore, it may be appropriate to calculate both arithmetic and geometric averages and uncertainty estimates, and evaluate the impact of using one method vs. the other.

3.2.8. How can mechanistic models be used to validate the bioaccumulation rate parameter?

Mechanistic models use equations to quantify the specific contaminant uptake and loss processes (e.g., respiration, feeding, absorption, and excretion), in order to predict concentrations in biota from a specific ecosystem (Mackay and Fraser 2000). A number of mechanistic models have been developed to represent food web trophic transfer of trace organic compounds (e.g., Connolly 1991, Thomann *et al.* 1992).

A mechanistic model can aid the development and application of the bioaccumulation rate parameter in many ways. First, it may be used to ascertain whether the empirical parameter is a realistic depiction of sediment vs. biota partitioning. Second, the mechanistic model may be used to provide an independent estimate of uncertainty of bioaccumulation rate predictions, using probabilistic application, such as Monte Carlo simulation. Third, the mechanistic model may be used to identify the major sources of this uncertainty, as a means to focus future research efforts. Fourth, it may be used to evaluate the relative role of sediment vs. water column concentrations in influencing predictions. Finally, if mechanistic model results are validated by separate empirical data, the model can be used to conduct scenario testing, evaluating issues such as the potential bioaccumulation for other prey species or related contaminants, and forecasting the possible effects of specific management actions.

The comparison of the empirical vs. mechanistic models can be helpful to determine whether the empirical results indicate local sediments as a primary contaminant source. If the empirical bioaccumulation rate parameter were higher than mechanistic model results, this may indicate that a substantial proportion of the bioaccumulation is due to contaminant uptake from other sources. These may include locations outside of the water body, such as point source or non-point source discharges. Undocumented hotspots of elevated contamination may also be present within the water body. For non-sedentary species such as finfish, deviation between empirical and mechanistic results may also indicate movement and exposure to sources from outside of the embayment.

The case studies (Sections 4 and 5) use graphical evaluations to compare empirical vs. mechanistic results (see Sections 4.4.2.6, 5.3.2.2, and Appendix X). Graphical evaluations are appropriate when the number of compounds is relatively small. When evaluating a large number of compounds having detectable data for sediments and biota, as when evaluating individual PCB congeners, model bias should be estimated quantitatively. Gobas and Arnot (2005) document a simple methodology for calculating model bias.

The empirical vs. mechanistic comparison may also be helpful to determine distributional assumptions for developing the bioaccumulation rate parameter. If empirical data are limited and uncertain, use of arithmetic vs. geometric assumptions will cause substantial differences in the range between the average and the upper confidence interval. The coefficient of variation or other measures of variability in the mechanistic model results can help determine which distributional assumptions are more appropriate.

The model used in the case studies (Sections 4 and 5) is a steady state non-equilibrium model developed to assess transfer of non-polar organic contaminants through food webs (Gobas 1993, Arnot and Gobas 2004). This model simulates organic contaminant transfer from sediments and water through a multi-species food web by combining contaminant kinetics in biota (e.g., uptake and elimination) and food web dynamics (Gobas 1993, U. S. EPA 2000a). It is appropriate for evaluation of non-polar organic contaminants, such as PCBs, legacy pesticides, dioxins, and PBDEs. It is not appropriate for evaluation of metals or organometals, such as Hg, Sn, or Se.

The Gobas model is recommended as a tool in the assessment framework based on its relative ease of use, generally good correspondence with field results, and history of use in significant management applications. The model has been used in a wide range of research and regulatory applications by multiple agencies and scientists (Table 3.10). It can provide a simple estimate of the relative inputs of a particular chemical into an organism from the water column versus directly from the sediment and porewater (see Section 5.4). These estimates may be utilized in conjunction with food web interactions to estimate the direct contributions of sediment contamination to organisms throughout the food web. However, additional models and data would be required to contrast the amount of contaminant exposure due to resuspended sediments within the water column vs. direct surface water runoff or other sources. More complex kinetic models would also be required to incorporate time or age-dependant changes in biota concentrations or BSAFs (e.g., Borgmann and Whittle 1992).

A version of the model has been made available to the general public in the TrophicTrace software program developed by the U. S. Army Corps of Engineers (Bridges and von Stackelberg 2003). This version of the model was developed for dredged material disposal applications, but it is also appropriate for the present sediment assessment framework. TrophicTrace may be downloaded at http://el.erdc.usace.army.mil/trophictrace/ or by contacting Dr. Todd Bridges at Todd.S.Bridges@erdc.usace.army.mil. Technical information regarding use of TrophicTrace is also available through this website.

The model has recently been updated to incorporate new research regarding phytoplankton uptake and elimination, fish and invertebrate ventilation rates, chemical partitioning and mechanisms of gastrointestinal magnification of contaminants (Morrison *et al.* 1996, Arnot and Gobas 2004). The version applied to the work in this report contains these updates. The model equations are summarized in Appendix M. Appendix Y summarizes input data requirements for the model. A spreadsheet copy of the updated version parameterized for PCBs in San Francisco Bay is also available for free download from Frank Gobas at http://www.rem.sfu.ca/toxicology/models/models.htm. The MATLAB programmed version used for this report may be obtained by contacting the report authors.

Table 3.10. Partial list of previous applications that use or recommend the Gobas (1993) contaminant bioaccumulation and trophic transfer model.

Application	Summary	Reference
TrophicTrace[a] and FishRand	Software developed by U. S. ACE for dredged material disposal evaluation, applied at national scale	Bridges and von Stackelberg (2003)
Rhine Channel, Newport Bay	Focused ecological risk assessment	Anchor Environmental (2005)

b. Model spreadsheet available at http://www.rem.sfu.ca/toxicology/models/models.htm

If Monte Carlo simulations are performed to evaluate the uncertainty or variability in model predicted bioaccumulation rates, the probability distributions of model input parameters must be selected. Given that the primary objective of the Monte Carlo simulation is to compare empirical vs. model averages and uncertainties, probability distributions should be based on expected uncertainty in average parameter estimates. That is, standard errors about the mean should be developed and used as uncertainty input parameters. Each parameter should be based on the distribution observed in the source data, be it normal, lognormal, uniform, or some other distribution. For other objectives, other uncertainty estimates may be more appropriate. For example, if the objective is to generate the full range of possible individual estimates for the bioaccumulation rate parameter, then each uncertainty input parameter could be based on the full distribution of data available for that parameter. This would result in much wider error bounds about the model predictions, and would not be representative of the range of average exposures encountered by predators.

3.2.9. How are sediment data compared to the low and high thresholds?

Once sediment thresholds are developed, all sediment data are compared to these thresholds. Final determination of risk posed by sediments is on a station-specific basis, and results in one of four possible risk categories: unlikely risk, possible risk, likely risk, and clear risk (Table 2.1 and Figure 2.2). The spatial pattern of risk categories may be graphically evaluated using a simple map of sediment results (e.g., Figures 4.21 and 4.22).

3.3. Bioavailability

The bioavailability line of evidence (LOE) is used to establish that sediment-bound contaminants are bioavailable. This can be achieved by demonstrating that sediment-residing organisms exhibit elevated tissue contaminant concentrations when exposed to sediments from the bay or estuary being evaluated. This section provides general technical guidance in applying the bioavailability line of evidence.

A number of potential approaches are available for this line of evidence. For compounds having sufficient information in prior published studies, bioavailability may be evaluated using peer reviewed scientific literature. For relatively unstudied compounds, or compounds with inconsistent findings in the literature, local data should be used. Bioavailability tests may be conducted using either laboratory test organisms or field caught organisms. The line of evidence may be evaluated using a sampling design and statistical analysis approach based on linear regression, a t-test, or a straightforward demonstration of bioavailability at some sites in the water body.

In the proposed framework, if contaminants are demonstrated to be not bioavailable, the water body sediments would be placed in the lowest risk category: unlikely impact (Table 2.1, Figure 2.2). Due to the importance of the bioavailability LOE in determination of risk, the sampling design, data collection, and interpretation of results should be carefully considered. Specific concerns include the need for sufficient sample sizes, appropriate

test organisms, sufficiently low detection limits, and sufficient duration of laboratory tests (i.e., at least 28 days) (Table 3.11). These issues are further addressed as a series of questions listed in Table 3.12.

Table 3.11. General recommendations for the bioavailability LOE.

Issue	Recommendation
Sample size	If a statistical approach is applied, sample size should be sufficient to have adequate power to detect bioaccumulation
Test organism	All samples should be the same species; the species chosen should be a sediment dwelling and ingesting organism. If laboratory bioaccumulation tests are used, the clam *Macoma nasuta* is a good candidate test species
Detection limits	Detection limits should be sufficiently low (e.g., 1 ng/g or lower is recommended for PCBs or legacy pesticides)
Test duration	Laboratory bioaccumulation tests should be at least 28 days in duration

Table 3.12. Questions to address in applying the bioavailability line of evidence.

Question	Section
Should local data or the scientific literature be used?	3.3.1
Questions that arise if local data are collected:	
How should test results be interpreted statistically?	3.3.2
Should field-caught organisms or laboratory test studies be employed?	3.3.3
What are appropriate test organisms?	3.3.4
What factors should be considered in sampling design?	3.3.5
What sample sizes are needed?	3.3.6
What detection limits are needed?	3.3.7
What ancillary parameters should be measured?	3.3.8

3.3.1. Should local data or the scientific literature be used?

For contaminants that are well characterized, a simple review of the literature may indicate bioavailability. The focus of the literature review would be to demonstrate that the contaminants being evaluated, when associated with sediments, are generally bioavailable to benthic organisms, and are likely to bioaccumulate in the water body in question.

PCBs and legacy pesticides[23] are examples of contaminants with literature indicating bioavailability to benthic invertebrates across a wide range of conditions. Studies demonstrating associations between sediment and biota tissue concentrations include field studies of resident and transplanted bivalves (Lee *et al.* 1994, Nasci *et al.* 2000), and laboratory studies indicating that contamination in bivalves increases with increased

[23] E.g., DDTs, chlordanes, dieldrin, and toxaphene

sediment contamination (Lee *et al.* 1994, Boese *et al.* 1997, Anderson *et al.* 2001, Battelle *et al.* 2005). In addition, the cases studies in this report (Sections 4.5 and 5.5) indicate that PCBs and DDTs are generally bioavailable. Based on these findings, it may not be necessary to expend limited funds on further field studies or bioaccumulation testing for PCBs or chlorinated legacy pesticides. For these pollutants, if local data are not readily available, a conservative approach would be to assume bioavailability.

When literature results are inconsistent or uncertain, it may be appropriate to collect and analyze local data on bioavailability. The remaining questions address approaches for local data collection.

Prior to performing new studies, local agencies may be queried for readily available bioavailability data. As part of dredged materials testing protocols (U. S. EPA and U. S. Army Corps of Engineers 1991, 1998), local ports and the U. S. Army Corps of Engineers routinely evaluate bioavailability using standard laboratory test protocols. Additional bioavailability test information may be found at contaminated sites in the water body, as part of CERCLA risk assessments (e.g., Lee *et al.* 1994, Battelle *et al.* 2005) or monitoring funded by the state of California (e.g., Hunt *et al.* 1998, Anderson *et al.* 2001). These data may assist in determining whether there is bioavailability of specific sediment-associated compounds in the water body. However, data should be carefully interpreted, with attention to the questions and considerations discussed in the remainder of this section (Table 3.12).

3.3.2. How should test results be interpreted statistically?

Table 3.13 compares two statistical test types for evaluating bioavailability: regression analysis and a t-test. For both test approaches, paired samples of contaminant concentrations in sediment and biota are needed. For the regression model, paired samples would be collected from a number of locations throughout the water body, varying in sediment contaminant concentrations. Then, regression analysis (Draper and Smith 1998) would be performed, comparing concentrations in sediment vs. concentrations in tissue, to determine whether there was a significant slope. One issue with the regression analysis approach is that it would require a high sample size, resulting in increased costs. Power analyses described in Section 3.3.6 indicate that the sample size should be at least 18 to be confident of identifying a relationship using the regression approach with typical bioaccumulation data sets.

For the t-test, samples would be collected from several representative locations and statistically compared to control samples. The control samples would be either sediments from locations outside of the water body that are known to have very low contaminant concentrations or laboratory control sediments that are uncontaminated. A simple t-test for independent samples would then be conducted comparing the tissue samples from the water body to the control tissue samples. If the results of the analysis were significant, the contaminant would be considered to be biologically available.

Table 3.13. Comparison of alternative statistical evaluation approaches for bioaccumulation LOE.

	Regression analysis	**t-test**
Scale of evaluation	Samples collected throughout entire water body	Samples collected throughout entire water body or in highly contaminated area
Control sample	Not required	Control samples collected from uncontaminated location or uncontaminated laboratory test sediments
Minimum sample size	18 samples among different locations in water body	5 samples from within water body and at least 3 control samples
Sampling design	Must sample across a contamination gradient	Water body samples from random locations within water body or in location known to have high contamination

If there are substantial funding constraints, but local data are needed, a qualitative approach could be employed. In this approach, the biota tissue chemistry results would simply be assessed for any incidence of detectable pollutant residues. If any paired samples indicated detectable residues in both sediments and tissues, bioavailability would be considered to be present. This treats the bioavailability LOE as a simple check whether pollutants in sediments are biologically available to any extent. Clearly, this is an oversimplification, as the rate of bioavailability varies among contaminants, sediments, and tissues (Pruell *et al.* 1993, Boese *et al.* 1995, Boese *et al.* 1997, Kraaij *et al.* 2002, Battelle *et al.* 2005). Nevertheless, such an approach would reduce effort and expense.

3.3.3. Should field-caught organisms or laboratory test studies be employed?

There are relative advantages and disadvantages of using field caught organisms vs. laboratory test organisms for the bioavailability line of evidence (Table 3.14). Using field organisms, it can be difficult to obtain sufficient tissue sample mass. Another challenge is finding comparable organisms throughout the water body (Table 3.14). Therefore, scientists familiar with the benthic fauna and collection techniques in the water body should be consulted.

With laboratory bioaccumulation tests, concerns are frequently raised regarding extrapolations between field and laboratory conditions (e.g., equilibrium may not be achieved over the test time frame) (Boese *et al.* 1997, Moore *et al.* 2005). Due to this fact, laboratory test organisms are not reliable for developing bioaccumulation rate parameters for the sediment chemistry LOE. In particular, bioaccumulation rate could be significantly underestimated using laboratory test organisms.

Table 3.14. Comparison of field vs. laboratory test organisms for bioaccumulation test LOE.

	Laboratory test organisms	**Field caught organisms**
Causality	Possible to clearly establish that sediments are causing contaminant uptake	May be possible that contaminants are derived from other sources (e.g., the water column)
Disadvantages	Costly to apply	Difficult to obtain sufficient tissue mass. Difficult to obtain comparable organisms throughout water body
Applicability to other LOE	Not applicable due to differences between laboratory and field caught organisms	May be appropriate as prey tissue line of evidence for predators that consume invertebrates. May assist in development of mechanistic model
Prior knowledge	Substantial experience from Dredge Materials Testing Programs in California and this report	Prior application limited and inconsistent. Filter feeding bivalves used in the State Mussel Watch Program and the San Francisco Bay RMP are not appropriate test organisms.

3.3.4. What are appropriate test organisms?

To be appropriate for bioaccumulation testing, a test organism should have the following attributes:

- A sediment-associated life history, including sediment dwelling and feeding.
- For field organisms, sufficient abundance and distribution to be collected in adequate biomass without unreasonable effort.
- For laboratory organisms, sufficiently developed culturing procedures to allow routine application of 28 day exposure tests.
- Positive demonstration of a tendency to bioaccumulate contaminants at detectable concentrations.

Benthic invertebrates are most appropriate for measuring bioavailability from sediments. Sediment contaminant bioaccumulation tests are usually performed using benthic invertebrates, with preference to those that ingest sediments and where bedded sediment is the primary route of exposure. Polychaetes and bivalves are commonly selected for such studies, as they often possess the appropriate life histories to match these criteria (Lee *et al.* 1993, Lee 1998).

In many cases, historically used bioaccumulation test organisms are not appropriate for the assessment framework because they are water column filter feeders, and therefore do not have a strong dietary association with the sediment. For example, the State Mussel Watch Program (Stephenson *et al.* 1995) and the Regional Monitoring Program For Water Quality in San Francisco Bay (Gunther *et al.* 1999) sample resident and

transplanted filter-feeding bivalves, which are more appropriate to determine water-column contaminant bioavailability, rather than sediment contaminant bioavailability.

The bent-nosed clam (*Macoma nasuta*) is well suited for evaluating the potential for bioaccumulation in estuary waters. *M. nasuta* burrows in and ingests sediments, and is therefore a good indicator of bioavailable sediment-associated contaminants. *Macoma spp.* have been recommended previously for bioaccumulation evaluations based on known tolerance, exposure history, and data availability (e.g., Lee *et al.* 1993, U. S. EPA 2000a). *M. nasuta* has also been used extensively in laboratory bioaccumulation experiments due to life-history factors that cause high sediment exposure (Pruell *et al.* 1993, Boese *et al.* 1997, U. S. EPA and U. S. Army Corps of Engineers 1998, MEC Analytical Systems 2003, Werner *et al.* 2004).

Macoma nasuta is the only test organism with California data demonstrating that it would be an appropriate bioaccumulation test organisms for California estuary waters. The majority of *M. nasuta* samples analyzed in 28 day laboratory bioaccumulation tests had detectable residues of the target organochlorine compound (Table 3.15). There is also good evidence of a statistical association between *M. nasuta* and sediment contaminant concentrations for trace organic contaminants. Table 3.16 presents results of regression analyses pooling data from multiple studies by water body. All studies exhibited statistically significant relationships ($p < 0.05$), and amount of variation explained was often relatively high (Table 3.16). For example, a strong positive relationship was observed between *M. nasuta* and sediment concentrations for total chlordanes in San Francisco Bay (Figure 3.4).

Based on test results with legacy organochlorine pollutants, the polychaete species, *Neanthes virens* and *Nephtys caecoides* do not appear to be suitable for evaluating the bioaccumulation LOE. The sample sizes and proportion of detectable concentrations were relatively low in these species (Table 3.15). The large proportion of below detection samples may prevent confirmation of bioavailability. Similarly, Pruell *et al.* (1993) indicated that *Neanthes virens* has relatively low bioaccumulation rates for PCBs and dioxins, compared to *Macoma nasuta*. Pruell *et al.* (1993) also showed evidence of biotransformation of some organochlorines by *Neanthes virens*, as well as very long times (70 to 120 days) required for these test organisms to reach steady state concentrations.

As additional information becomes available, other species may be identified that are appropriate to evaluate bioaccumulation in a laboratory setting. These may include local species, or laboratory test species not considered in this report.

Table 3.15. Frequency of detection among laboratory bioaccumulation species. All samples were analyzed in 28 day laboratory bioaccumulation tests performed with California sediments. Test results were compiled from the CASQO database.

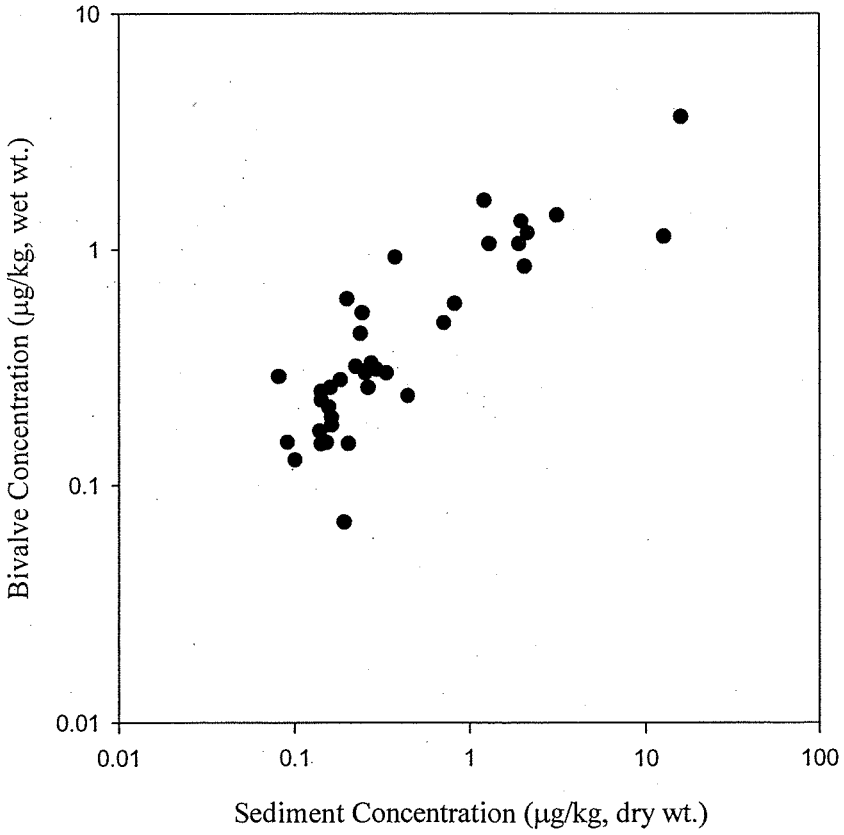
Species	Contaminant	Number of samples	Frequency of detection	Sample type
Macoma nasuta	p,p'-DDE	178	71%	All samples [a]
Macoma nasuta	p,p'-DDE	106	80%	Matched to sediment [b]
Macoma nasuta	alpha-Chlordane	112	50%	All samples
Macoma nasuta	alpha-Chlordane	68	50%	Matched to sediment
Macoma nasuta	Dieldrin	178	39%	All samples
Macoma nasuta	Dieldrin	105	40%	Matched to sediment
Macoma nasuta	PCB 118	67	100%	All samples
Macoma nasuta	PCB 118	39	100%	Matched to sediment
Macoma nasuta	Weighted average [c]		61%	
Neanthes virens	p,p'-DDE	53	58%	All samples
Neanthes virens	p,p'-DDE	27	100%	Matched to sediment
Neanthes virens	alpha-Chlordane	39	0%	All samples
Neanthes virens	alpha-Chlordane	24	0%	Matched to sediment
Neanthes virens	Dieldrin	65	8%	All samples
Neanthes virens	Dieldrin	40	12%	Matched to sediment
Neanthes virens	PCB 118	0		All samples
Neanthes virens	PCB 118	0		Matched to sediment
Neanthes virens	Weighted average [c]		27%	
Nephtys caecoides	p,p'-DDE	40	65%	All samples
Nephtys caecoides	p,p'-DDE	25	76%	Matched to sediment
Nephtys caecoides	alpha-Chlordane	9	0%	All samples
Nephtys caecoides	alpha-Chlordane	7	0%	Matched to sediment
Nephtys caecoides	Dieldrin	40	22%	All samples
Nephtys caecoides	Dieldrin	26	23%	Matched to sediment
Nephtys caecoides	PCB 118	3	33%	All samples
Nephtys caecoides	PCB 118	2	50%	Matched to sediment
Nephtys caecoides	Weighted average [c]		41%	

a. All samples: indicates the combination of all available data in California.
b. Matched to sediment: indicates data where sediment pollutant data were collected at the same location as laboratory test organisms.
c. Weighted average: average of all results for species, weighted by sample size for each compound.

Table 3.16. Results of linear regression analysis of log-transformed sediment concentrations vs. log-transformed *Macoma nasuta* tissue concentrations for different water body and contaminant combinations. All samples were analyzed in 28 day laboratory bioaccumulation tests performed with California sediments. In all cases, N = number of unique spatial locations sampled both for sediment and *M. nasuta* in a given water body. All slopes were positive. See Appendix N for compounds included in sums.

Water body	Contaminant	N (locations)	R^2	p-value
Newport Bay	p,p'-DDE	11	0.74	< 0.001
San Diego Bay	Total HPAHs	14	0.75	< 0.001
San Diego Bay	Total PCBs	14	0.93	< 0.0001
San Francisco Bay	Total chlordanes	37	0.74	< 0.0001
San Francisco Bay	Dieldrin	38	0.49	< 0.0001
San Francisco Bay	Total DDTs	38	0.42	< 0.0001
San Francisco Bay	Total HPAHs	39	0.15	0.014
San Francisco Bay	Total PCBs	37	0.72	< 0.0001

Figure 3.4. Scatter plot total of chlordanes in San Francisco Bay sediments vs. *Macoma nasuta* exposed to those sediments in 28 day laboratory tests. Note log scale.



3.3.5. What factors should be considered in sampling design?

The ability to detect a correlation between sediment and biota concentrations will increase with an increase in the range of measured concentrations. To achieve this, sampling locations may be selected to take advantage of spatial contamination gradients that exist in the water body. For example, samples could be targeted in proximity to contaminant sources, and in less contaminated locations. Depending on the contaminant, sources may include populated areas, industrial areas, and/or large freshwater inlets. Less contaminated locations may include estuary outlets, deep channels, areas with strong tidal mixing, or other locations expected to have a high degree of sediment interaction with uncontaminated waters. If currently available data suggest that sediment contamination is relatively uniform across the water body, it would be difficult to evaluate bioavailability across a contamination gradient. In these circumstances, the t-test approach may be more appropriate than regression analysis (see also Section 3.3.2).

To ensure sufficient sensitivity to detect contaminant bioavailability, laboratory tests should be at least 28 days in duration. For example, Boese *et al.* (1997) indicate a clear time dependence of bioaccumulation, and guidance documents recommend exposure durations of at least 28 days (U. S. EPA and U. S. Army Corps of Engineers 1998, U. S. EPA 2000a).

3.3.6. What sample sizes are needed?

If the regression analysis approach is employed (Section 3.3.2), sample size must be sufficient to detect a positive relationship between sediments and biota, should such a relationship exist. Power analysis may be used to determine sample size required to detect a linear trend for a given statistical power, R^2, and p-value. Sample size required to detect trend varies widely as a function of correlation coefficient between two factors (Figure 3.5). Evaluations using currently available *Macoma* sp. laboratory tests have indicated that strength of relationships (R^2) between *Macoma* and sediment results varied by system and contaminant. However, R^2 was above 0.49 for six of eight regression analyses conducted with DDTs, PCBs, chlordanes and PAHs (Table 3.16). At least 18 samples would be required to achieve a 90% probability of determining a significant trend ($p < 0.05$) when the regression R^2 is 0.5 (Figure 3.5).

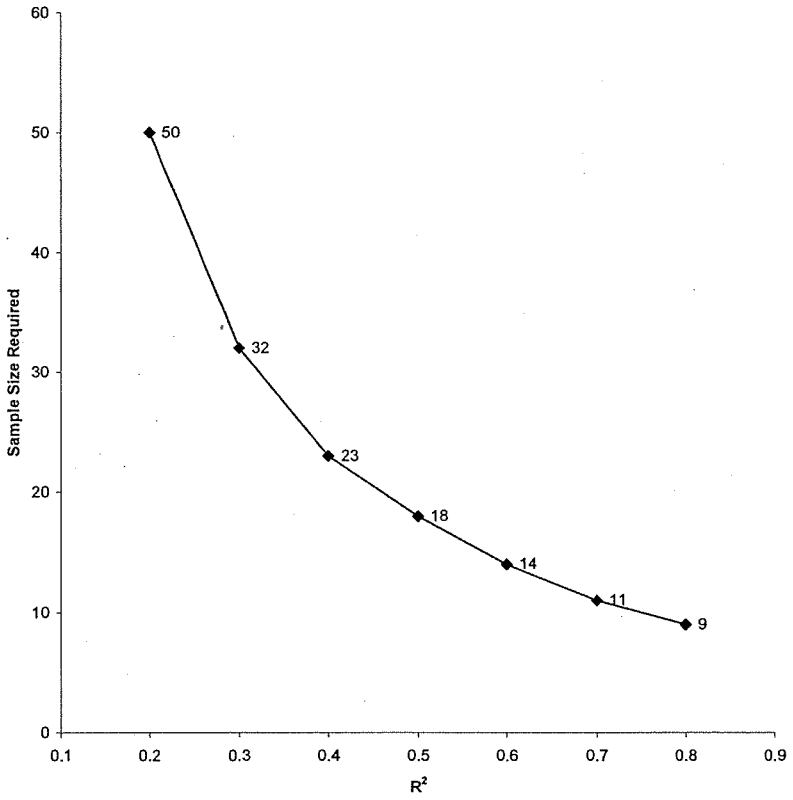
3.3.7. What detection limits are needed?

In the Newport Bay case study (Section 4), detection limits for available bioaccumulation test data[24] were too high to detect residues of PCBs or chlordanes despite the presence of these compounds in field caught organisms. Both case studies included low sediment thresholds of approximately 1-2 ng/g. Assuming chemical equilibrium between sediments and benthic organisms is achieved (McFarland 1998, Zeng and Tran 2002, Moore *et al.* 2005), bioaccumulation test detection limits should be similar. To be safe, it would be appropriate to use detection limits at or below one ng/g to determine bioavailability at relevant scales. Even lower detection limits are desirable given that

[24] Data from MEC Analytical Systems (2003)

laboratory tests may not reach steady state conditions in biota exposed to natural sediments (Boese *et al.* 1997, U. S. EPA and U. S. Army Corps of Engineers 1998, U. S. EPA 2000a).

Figure 3.5. Sample size required to achieve a 90% probability of statistical significance ($p < 0.05$) for varying R^2 in evaluations of correlations between two continuous variables. Results were calculated in SYSTAT 11.



3.3.8. What ancillary parameters should be measured?

In addition to chemical concentration in sediments and organisms, certain ancillary parameters may help in understanding bioavailability. For organic compounds, tissue percent lipid, and sediment percent organic carbon would be useful. As discussed in the Newport Bay case study (Section 4) and elsewhere (e.g., Clark *et al.* 1988, Di Toro *et al.* 1991), organic contaminants tend to be associated with lipid and organic carbon, and variability in contaminant concentration estimates may often be reduced by normalizing for these variables. Percent lipid is sensitive to analysis method and extraction solvent. Consistency across studies would be better achieved by using a gravimetric method for lipid analysis, using dichloromethane as the extraction solvent (Bligh and Dyer 1959, U. S. EPA 2000b).

For laboratory tests, data on mortality, growth rate and body condition of test organisms may be collected and evaluated. In some cases, these parameters may explain unexpected patterns in experimental results, such as variability in bioaccumulation rates (Gunther *et al.* 1999).

4. Application of the assessment framework to evaluate sediments in Newport Bay

4.1. Introduction to case study

This case study describes the application of the assessment framework to PCBs and legacy pesticides in Newport Bay, where a TMDL planning process is underway for these compounds (SARWQCB 2006). The Newport Bay case study includes a review of current data on fish bioaccumulation, and water body biotic and abiotic properties. Data review also includes characterization of contaminant residues in fish and sediments. For the prey tissue line of evidence, tissue thresholds are based on assumptions previously requested by the Regional Water Board responsible for development of the Newport Bay TMDL. The case study also details the approach and rationale for developing specific bioaccumulation rate parameters used to evaluate the sediment chemistry line of evidence.

4.2. Conceptual model for Newport Bay

For Newport Bay, the framework was applied to evaluate bioaccumulation of PCBs, DDTs, and chlordanes. PCBs and legacy pesticides are management concerns in Newport Bay. This is evidenced by 303(d) listing[25] of Upper Newport Bay for these and other compounds and consequent development of a TMDL for Upper and Lower Newport Bay (SWRCB - Santa Ana Region 2006). Following the application framework (Figure 1.1, Section 2.6.1), separate assessments will be conducted on human consumption of sport fish species (e.g., spotted sand bass) and wildlife consumption of forage fish species (e.g., arrow goby and California killifish).

Figure 4.1 presents a simplified food-web conceptual model for Newport Bay. The conceptual model combines literature information on dietary transfer pathways, guidance from local scientists[26], stakeholders, and agency representatives on important human and wildlife receptors[27]. The conceptual model displays the major pathways by which trace organic contaminants are expected to transfer from water and sediments, through the food web to primary producers, invertebrates, fishes, birds, and humans. Primary productivity occurs in the water column (i.e., phytoplankton) and in benthic algae attached to the sediment (Kamer *et al.* 2004a). Primary consumers rely on primary production, as well as organic matter sources resulting from detritus within the sediments. As with all estuarine environments subject to tidal and wind-driven mixing, significant contaminant flux may be expected to occur between the water column and sediments (Davis 2004, Kimmerer 2004). Benthic invertebrates, including crustaceans, mollusks, and polychaetes, feed on the sediments and attached algae. These invertebrates are consumed by multiple resident and transient fish species. In Newport Bay, striped mullet and topsmelt predominantly consume sediment and attached algae (Logothetis *et al.* 2001), and shiner perch augment their epibenthic diet with zooplanktivory (Allen 1980). Many fish species consume

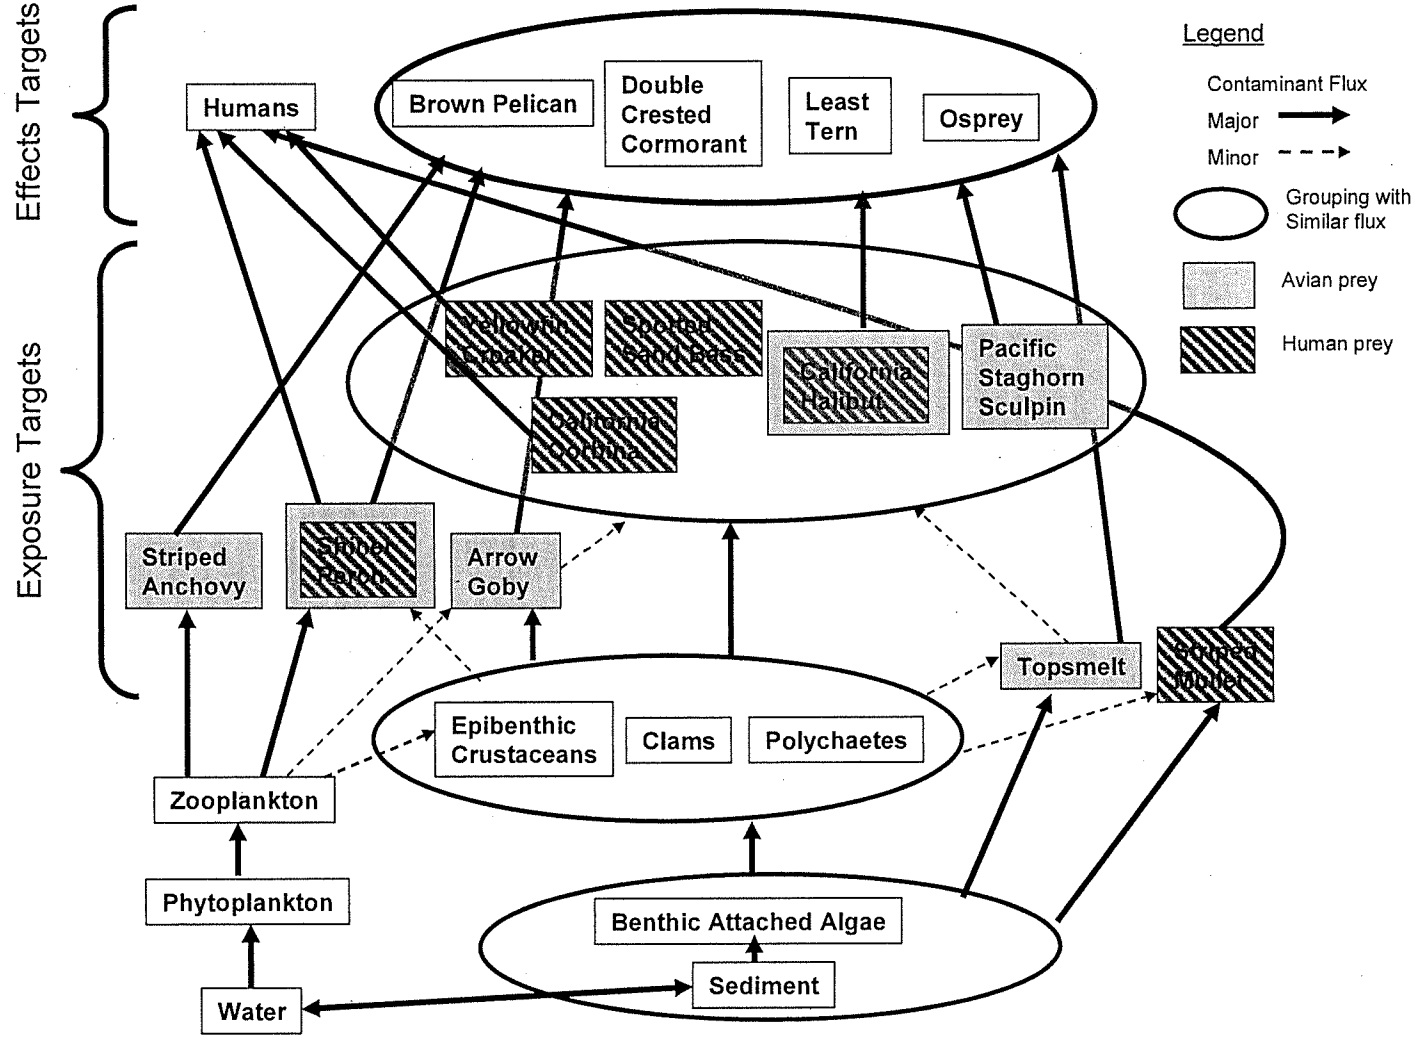
[25] The 303(d) list is a federal listing of water bodies impaired for specific pollutants or pollutant categories.
[26] M. James Allen, SCCWRP and Don Cadien, LACSD, unpublished data and personal communication
[27] Target species were identified by the SQO Bioaccumulation Work Group, the June 22, 2005 Newport Bay TMDL Stakeholders meeting, and SWRQCB – Santa Ana Region staff

mostly invertebrates, with some piscivory on smaller fish, including topsmelt and arrow goby. This information on dietary transfer is used in developing parameters for the mechanistic model on contaminant uptake.

Human sport fishers capture and consume a variety of fish species in Newport Bay, including shiner surfperch, striped mullet, California corbina, spotted sand bass, and yellowfin croaker (Allen *et al.* 2004). Piscivorous birds of concern include brown pelican, least tern, osprey, and double crested cormorant (Terri Reeder, SWRCB – SARWQCB, *Pers. comm.*; Figure 4.1).

This case study focuses on potential effects to wildlife and humans from consuming finfish prey. The case study does not include assessment of exposure due to humans and wildlife directly consuming contaminated benthic invertebrates. This simplification of the risk evaluation has been made in consideration of time constraints. Additionally, data on resident invertebrate tissue concentrations of PCBs and legacy pesticides are very limited in Newport Bay, making it difficult to determine potential exposure. Those data that are available indicate that invertebrate tissue concentrations are generally substantially lower than concentrations in fish (Allen *et al.* 2004, Sutula *et al.* 2005). Therefore, a more protective assessment of exposure and effects will focus on exposure due to consuming contaminated finfish.

Figure 4.1. Conceptual model of Newport Bay for indirect effects case study. Trophic position generally increases moving up the diagram. Arrows represent contaminant flux (dietary transfer for animals). Circled areas represent groupings to simplify understanding of contaminant flux. When an arrow points to a circle, all organisms within that circle receive that flux.



4.3. Prey tissue line of evidence

The first component of the framework (Figure 2.2) is to evaluate local prey tissue concentrations in order to determine the extent of potential risk posed to wildlife and human receptors. As indicated in the conceptual model (Figure 4.1), the receptors in Newport Bay are humans and several bird species. As discussed previously (Sections 2 and 3.1), tissue concentrations are compared to high and low numeric thresholds, to determine the extent of risk posed to these predators.

4.3.1. Methods

4.3.1.1. Database preparation

The case study for Newport Bay compares contaminant concentrations in fish to calculated threshold values. To evaluate fish from Newport Bay, a tissue database was compiled, including concentrations of total PCBs, total DDTs, total chlordanes, dieldrin, and toxaphene. Appendix N lists individual compounds that are included in each contaminant class. The database also includes ancillary information (*e.g.,* length and type of tissue analyzed). Additionally, the database identifies species preyed upon by humans (i.e., legal-sized sport fish) or wildlife (small fish). The database does not include samples from San Diego Creek and coastal samples collected outside of the Newport Bay entrance channel. The primary data source for the database is a two-year study of fish tissue contamination in multiple recreational and forage fish species (Allen *et al.* 2004). A small amount of additional data were obtained from the Coastal Fish Contamination Program, the Toxic Substances Monitoring Program, and the Southern California Bight Survey (Allen *et al.* 2002a).

In Newport Bay and other California waters, legacy pesticides and PCBs have been shown to decline significantly over time (Greenfield *et al.* 2004, Davis *et al.* 2006b), necessitating use of data only from a recent time horizon. For this reason, data collected prior to 1997 were not included in the fish tissue database.

4.3.1.2. Prey species

Following Section 3.1.4, the prey tissue line of evidence (LOE) focused on sediment-associated fish species that are known to be prey for humans or wildlife. Sediment association was defined by expected behavior (i.e., benthic association), or data on prey items (i.e., diets including infaunal or epifaunal animals). Due to the relatively small size of Newport Bay, and salinity conditions similar to coastal waters, some species captured within the Bay may be transient (i.e., spend a portion of their lives along the coast). In particular, the majority of the species targeted by human sport fishers are expected to be transient (Table 4.1). To evaluate the impact on findings of inclusion vs. exclusion of transient species, the comparison to human health thresholds was conducted in three ways: 1. resident species only, 2. all human prey species (both resident and transient), and 3. all species, including both human and wildlife prey (Table 4.1).

Table 4.1. Sample type, sample size (N) and arithmetic mean concentrations for compounds in Newport Bay fish samples. Resident = species resides within Bay; Transient = species likely to move between Bay and coast. NA = not available. For averaging, values below detection were set at ½ detection limits.

Species	Movement[a]	Tissue type	N	Total DDTs (ng/g wet)	Total PCBs (ng/g wet)	Total chlordanes (ng/g wet)
Human prey						
Brown smoothhound shark	Transient	Fillet	1	28	NA	0.5

a. M. J. Allen, SCCWRP, *Pers. comm.* b. California halibut < 20 cm reside in the Bay; halibut > 20 cm are likely to move to the coast (M. J. Allen, *Pers. comm.*).

4.3.1.3. Prey sizes and tissue types

Following Section 3.1.4, body size was considered in selecting appropriate samples for the prey tissue LOE. Review of the sport fish data showed that species that would be consumed by humans were generally greater than 15 cm (total length) (Appendix O, Table O.1). Samples less than 15 cm (total length) were not included as potential human prey species. Although minimum legal size requirements are in some cases higher than 15 cm (California Department of Fish and Game 2006), some undersized fish were included in the analysis due to data limitations. Size for wildlife prey was selected based

on published literature on avian predator prey size (Appendix D). Based on this review, only fish of 10 cm total length or less were included in evaluations of risk to wildlife predators. Fish tissue samples evaluated for human health risk were analyzed as skin-off fillets. Samples evaluated for wildlife risk were analyzed as whole body samples (Table 4.1, Appendix O).

4.3.1.4. Calculation of tissue concentrations for comparison to the low and high tissue thresholds

As discussed previously, (Section 3.1.9), the framework accounts for uncertainty in the findings by comparing two thresholds to estimates of the average tissue concentration. Following guidance in Section 3.1.9, a more conservative estimate of the average was used for comparison to the low threshold. Specifically, the mean concentration was compared to the higher (less conservative) tissue threshold and the 95% upper confidence limit of the mean concentration was compared to the lower (more conservative) tissue threshold (Table 4.2). For the Newport Bay prey tissue LOE, both arithmetic and geometric means and 95% UCIs were developed, to determine the impact of averaging method (see Appendix G). For data below detection, ½ the detection limits were used, as reported in Allen *et al.* (2004).

4.3.1.5. *Development and calculation of low and high tissue thresholds*

The assessment framework requires calculation of two risk-based effects thresholds. Specific policy judgments need to be made in developing these thresholds. These include factors such as the allowable level of risk (e.g., cancer risk factor) and the target population to be protected (e.g., human consumption rate or target wildlife; see Sections 3.1.10 and 3.1.13). To evaluate the impact of potential policy decisions on the results of this case study, two sets of human health thresholds were evaluated. The first set of thresholds was established based on feedback from SARWQCB. The second set was established based on prior recommendations by the California Office of Environmental Health Hazard Assessment (OEHHA).

Table 4.2. Description of three categories for prey tissue line of evidence for human and wildlife receptors.

Fish tissue score	General description	Humans[a]	Humans	Wildlife	Wildlife
		Threshold	Interpretation	Threshold	Interpretation
▲ Low exposure	95% upper confidence limit of average fish tissue concentration is below the low toxicity threshold for humans or wildlife	Fish tissue threshold based on protecting the 95 percentile of sport fish consumers such that no more than 1 in 100,000 faces an increased cancer risk	Using a conservative set of assumptions, dietary exposure to fish in water body poses a low risk to fishers who consume their catch and to the general public	Fish tissue threshold based on toxicity reference values representing no-effects levels (TRV-Low) to wildlife (Appendix H)	Using a conservative set of assumptions, dietary exposure is unlikely to pose a risk to the most sensitive wildlife endpoint.
◘ Moderate exposure	Tissue concentration is intermediate between low and high threshold	Both thresholds are relevant	Dietary exposure to fish in a water body may pose a risk to fishers who consume their catch	Both thresholds are relevant	Dietary exposure may pose a risk to the most sensitive wildlife endpoint
● High exposure	Average fish tissue concentration is above the high toxicity threshold for humans or wildlife	Fish tissue threshold based on protecting the average sport fish consumer such that no more than 1 in 100,000 faces an increased cancer risk	Dietary exposure to fish in a water body is likely to pose 1 in 100,000 increased cancer risk for sport fish consumers	Fish tissue threshold based on toxicity reference values representing mid-range adverse effects levels (TRV-High) to wildlife (Appendix H)	Dietary exposure is likely to pose a risk to the most sensitive wildlife endpoint

a. For the Newport Bay case study, two sets of human health effects thresholds are considered including this one, and the threshold resulting from assumptions in Appendix P.

Staff of theSanta Ana Regional Water Quality Control Board provided written guidance regarding the risk threshold calculations in the human health effects case study (Appendix P):

1. The low tissue threshold would be developed based on 10^{-6} rate of increased cancer risk.
2. The high tissue threshold would be developed based on 10^{-5} rate of increased cancer risk.
3. The consumption rate would be estimated based on the Santa Monica Bay Seafood Consumption Study (Allen *et al.* 1996). The median consumption rate from this study is 21 g/d.

Use of these assumptions resulted in low and high thresholds that differ from each other by a factor of ten (Table 4.3).

Table 4.3. Low and high thresholds for organochlorine contaminants in fish tissue, for application of the framework to evaluate human health effects in Newport Bay. Thresholds were calculated using methods in Sections 3.1.10, 3.1.11, and 3.1.13 of this report. All thresholds are in ng/g wet tissue mass.

Source	Threshold	DDT	PCB	Chlordane	Dieldrin
SARWQCB	Low human	9.8	1.7	9.5	0.2
Table 4.2 and Appendix K	Low human	64	11	63	1.4
SARWQCB	High human	98	17	95	2.1
Table 4.2 and Appendix K	High human	118	20	114	2.5

The second set of thresholds in Table 4.3 follows the categories outlined in Table 4.2. These thresholds varied consumption rate rather than allowable cancer risk factor. For this set, the low and high thresholds both incorporated a 10^{-5} increased cancer risk, following U. S. EPA guidance for tissue screening values (U. S. EPA 2000b). The low and high thresholds were distinguished by a varying fish intake rate, following OEHHA recommendations to calculate a threshold based on average intake and a threshold based on upper percentile intake rate from the fish consuming population (OEHHA 2001). The average intake rate was set at the U. S. EPA recommended consumption rate of 17.5 g/d for the general adult population and recreational fishers (U. S. EPA 2000b). The upper percentile consumption rate was set at 32 g/d, which is the 95^{th} percentile consumption rate of all sport fish consumers surveyed in the San Francisco Bay Seafood Consumption Study (SFEI 2000). Use of 10^{-5} or 10^{-4} risk factors for the low and high SARWQCB thresholds, respectively, would increase the values of these thresholds by a factor of ten. Additional information on derivation of these thresholds is available in Appendix K.

For the wildlife effects evaluation, the Regional Board did not make specific requests. These thresholds were calculated using the toxicity reference values and assumptions in Appendix H (Table H.1). Following Table 3.5, body mass estimates for large birds were used for brown pelicans, osprey, and double-crested cormorants. Estimates for small birds were used for least tern. Appendix Table J.1 presents appropriate thresholds for dry

weight prey tissue concentrations, but Newport Bay studies generally provide contaminant concentrations in wet weight (e.g., Allen *et al.* 2002a, 2004). Table 4.4 presents the thresholds converted to wet weight concentrations assuming 80% moisture in prey fish tissue (Jarvinen and Ankley 1999, Meador *et al.* 2002b)[28].

Table 4.4. Low and high prey tissue thresholds for application of the framework to evaluate effects to birds in Newport Bay. Ingestion rates are calculated following Table 3.5 and Nagy (2001). Tissue thresholds are calculated following Section 3.1.10, using toxicity reference values from Appendix H, and converting prey tissue from dry to wet weight, assuming 80% prey tissue moisture.

Species	Body mass (kg)	Daily ingestion rate (kg dw food/day)	Ingestion rate (kg dw food/ (kg body weight*day))	DDT low (ppb ww fish tissue)	DDT high (ppb wet weight)	PCB low (ppb wet weight)	PCB high (ppb wet weight)	Chlordane low (ppb ww)	Chlordane high (ppb ww)	Dieldrin low (ppb ww)	Dieldrin high (ppb ww)
Brown pelican	3.20[a]	0.178	0.056	32	2,156	324	4,562	502	25,142	255	3,772
Double crested cormorant	2.45[b]	0.149	0.061	30	1,966	296	4,164	458	22,948	232	3,442
Least tern	0.045[c]	0.011	0.239	8	502	76	1,062	116	5,848	59	878

a. Dunning (1993). b. Hatch and Weseloh (1999). c. Thompson *et al.* (1997), Zeeman (2004)

Many assumptions were made in application of the prey tissue LOE for Newport Bay. These assumptions and their likely impacts are summarized in Table 4.5.

4.3.2. Results

4.3.2.1. DDTs

In general, results indicated that total DDTs were intermediate between the low and high prey tissue thresholds. This finding was consistent among both human sport fish consumers and piscivorous birds (Table 4.6). For the high effects threshold comparison, both arithmetic and geometric average concentrations were below the threshold for humans (98 ng/g wet weight; Table 4.3) and birds (DDT high threshold ranging from 502 to 2156; Table 4.4). For the low threshold comparison, arithmetic and geometric 95% UCI concentrations were above the low effects thresholds for humans (DDT low threshold = 9.8 ng/g; Table 4.3) and birds (DDT low thresholds ranging from 8 to 32; Table 4.4).

[28] Wet weight thresholds = dry weight thresholds*(0.20)

Table 4.5. Summary of assumptions, their basis, and effects in prey tissue LOE evaluation for the Newport Bay case study.

Decision or assumption	Basis	Effect
Evaluate two alternative groups of species for prey tissue line of evidence, human health evaluation: 1. all routinely monitored species, and 2. only species with sediment association and permanent Bay residence	Evaluate sensitivity of assessment results to sport fish species selection	Slight effect on calculated tissue chemistry residues. No effect on comparison to thresholds
Pooling fish tissue concentrations for multiple prey species	Limited sample size for looking at individual species. Conceptual model of exposure risk and available data indicate that receptors (humans/wildlife) consume multiple prey	Simplifies tissue concentration calculation. Not examining exposure separately for individual prey species
Only including samples with sizes likely to be consumed by receptor. < 10 cm for wildlife; > 15 cm for humans	Not appropriate to use surrogate prey species unlikely to be consumed	No effect for human health evaluation since program targets legal sized fish species. Possible reduction in sample size and calculated tissue concentration residues for wildlife evaluation
Focusing on finfish prey, rather than shellfish	Use of finfish prey likely to be more protective for main target contaminants of concern (legacy pesticides and PCBs). Limited data availability for prey shellfish. Time and budgetary constraints preclude evaluating all possible prey	Uncertain
For human health evaluation, fish consumption rate based on sport fish consumers	Santa Ana Regional Board staff requested that thresholds be protective of recreational anglers (following Allen *et al.* 1996).	Thresholds are higher than if a subsistence fisher consumption rate were used, slightly lower if a general population consumption rate were used.
Carcinogen risk thresholds based on 10^{-5} allowable increased risk for high threshold and 10^{-6} allowable increased risk for low threshold.	Santa Ana Regional Board staff specifically requested these risk assumptions for development of low and high tissue thresholds (Appendix P).	Low threshold is 10-fold lower than if 10^{-5} carcinogen risk were used.
Calculate tissue chemistry average based on arithmetic mean	Arithmetic averages better reflect the average overall exposure due to consuming multiple fish	Risk determination generally the same as when geometric average is used
Calculate tissue chemistry 95% UCI based on arithmetic estimate of standard error, rather than standard deviation	Use of standard error better reflects the average overall exposure due to consuming multiple fish	95% UCI estimated exposure less conservative than if standard deviation were used
Only using samples prepared according to receptors' consumption patterns	Humans generally do not consume whole fish, and wildlife predators do. Contaminant concentration estimates will be related to tissue preparation	Sample size unchanged because most samples were prepared appropriately for target predator. Preparation method may cause increase or decrease in estimated tissue contaminant concentration

The finding of total DDTs intermediate between the two thresholds was robust to a number of assumptions in the averaging and threshold calculation method (Table 4.6). For the wildlife evaluation, concentrations were greater than the low threshold, regardless of averaging method or probability assumption (Table 4.6). Average concentrations were below the high threshold for all calculated high thresholds (as presented in Table 4.4) and averaging methods (Table 4.6). For the human evaluation, 95% UCI concentrations were greater than the low threshold regardless of whether the threshold was based on policy

assumptions requested by the Regional Board (i.e., 9.8 ng/g; Table 4.3, Appendix P) or assumptions described in Appendix K (Table K.1). Tissue concentrations were also greater than the 9.8 ng/g low thresholds, regardless of the averaging method (arithmetic vs. geometric), probability assumption (average vs. 95% UCI of the average), or data set (resident fish only vs. all locally captured sport fish). When all human prey data were combined, the arithmetic average concentration (112 ng/g ww) was greater than the 98 ng/g high effects threshold.

Table 4.6. Estimated total DDTs in Newport Bay fish samples calculated using different averaging methods and different sample inclusion criteria. Values highlighted in grey exceed the relevant threshold. N = sample size. 95% UCI = average + two standard errors. Geo mean = geometric mean (calculated on log scale). All values except sample size are ng/g wet weight.

DDT results[a]	Resident wildlife prey[b]	Relevant threshold[b]	Resident human prey[c]	All human prey[c]	All[b]	Relevant threshold
N	23		6	21	78	
Mean	122	High (>502)	62	112[d]	94	High (98)
95% UCI	144	Low (8 – 32)	92	164	112	Low (9.8)
Geo mean	111	High (>502)	50	71	68	High (98)
Geo 95% UCI	134	Low (8 – 32)	94	108	82	Low (9.8)
Median	116		63	68	67	

a. Values are different from Table 4.1 because Table 4.6 excludes samples collected prior to 1997. b. Compared to bird thresholds presented in Table 4.4. c. Compared to human thresholds presented in Table 4.3. d. Exceeds 98 ng/g but not alternate high threshold from Table 4.3 (118 ng/g).

Based on these results and the use of the framework described in Section 2 (see Table 4.2), consumption of resident sediment-associated fish may pose a possible risk due to DDT exposure. This risk may occur for human sport fish consumers and also predatory birds in Newport Bay. Following the assessment framework (Table 2.1), evaluation of the additional lines of evidence (sediment chemistry and bioaccumulation tests) is warranted.

4.3.2.2. PCBs

In general, total PCBs were below both effects thresholds for wildlife, and intermediate between the low and high effects thresholds for humans (Table 4.7). Both the arithmetic and geometric 95% UCI estimate of average wildlife prey concentrations were well below the most conservative wildlife effects threshold (76 ppb, for least tern, Table 4.4). In contrast, average concentrations were above the conservative human health thresholds (Table 4.3), regardless of averaging method (arithmetic vs. geometric) or species sampled (all human prey species vs. resident species only) (Table 4.7).

For human sport fish consumers, assumptions made in threshold calculation affected whether thresholds would be exceeded. If the PCB lower threshold described in

Appendix K (11 ng/g) had been used instead of the threshold requested by the SARWQCB (1.7 ng/d), this threshold would not be exceeded by the arithmetic mean, geometric mean, or geometric 95% UCI estimate of concentration. However, the 11 ng/g threshold would still be exceeded by the arithmetic 95% UCI concentration estimate (14.6 ng/g for resident human prey; Table 4.7).

The PCB average concentrations demonstrate a statistical artifact for data having skewed distributions; specifically, geometric average estimates are generally lower than arithmetic average estimates (Table 4.7). The arithmetic average is appropriate for categorizing prey tissue results within the assessment framework (see Appendix G). This is because it accounts for the potential for relatively high exposure due to occasional consumption of highly elevated samples (i.e., outliers) (Helsel and Hirsch 2002). The relatively large difference between average and 95% UCI estimates for PCBs (Table 4.7) results from the small sample sizes and skewed distributions of these data, with many samples below detection limits (Allen *et al.* 2004). This is a concern given that in this case study, detection limits (5 ng/g for each individual PCB congener) (Allen *et al.* 2004) are relatively close to and sometimes even exceed some of the human health effects thresholds (Table 4.3). The issue of treatment of samples below detection limits will be evaluated further in the sediment chemistry line of evidence evaluation.

Table 4.7. Estimated total PCBs in Newport Bay fish samples calculated using different averaging methods and different sample inclusion criteria. Values highlighted in grey exceed the relevant threshold. N = sample size. 95% UCI = average + two standard errors. Geo mean = geometric mean. All values except sample size are ng/g wet weight. Note that below detection were set to ½ the detection limit.

PCB results[a]	Resident wildlife prey[b]	Relevant threshold	Resident human prey[c]	All human prey[c]	All	Relevant threshold
N	23		6	18	78	
Mean	12.7	High (>1062)	7.4	7.7	12.9	High (17)
95% UCI	23.0	Low (76 - 324)	14.6	14.2	18.9	Low (1.7)
Geo mean	4.3	High (>1062)	4.6	4.1	0.7	High (17)
Geo 95% UCI	7.2	Low (76 - 324)	10.4[d]	6.3[d]	6.7[d]	Low (1.7)
Median	2.5		2.5	2.5	2.5	

a. Values are different from Table 4.1 because Table 4.7 excludes samples collected prior to 1997. b. Compared to bird thresholds presented in Table 4.4. c. Compared to human thresholds presented in Table 4.3. d. Exceeds 1.7 ng/g but not alternate low threshold from Table 4.3 (11 ng/g).

4.3.2.3. Chlordanes

Results for total chlordanes indicated concentrations below both relevant thresholds for wildlife and human health (Table 4.8). This finding was consistent regardless of averaging method, sample selection method, or use of locally requested thresholds vs. thresholds from Appendix K (see Table 4.3). Based on the results of the prey tissue line of evidence, using the assessment framework presented in Section 2 (e.g., Table 2.1 and

Figure 2.2), risk to humans and wildlife due to sediment exposure is unlikely. Specifically, fish tissue chemistry indicates no evidence of risk to human or wildlife consumers above the defined level of concern. Therefore, following the assessment framework, it is not necessary to proceed to the other lines of evidence for chlordanes. In general, chlordanes have declined significantly in California waters over the past two decades (Greenfield *et al.* 2004, Greenfield *et al.* 2005, Davis *et al.* 2006b). This is likely a result of biodegradation and other chemical properties leading to relatively rapid ecosystem loss of chlordanes (Leatherbarrow *et al.* 2006).

Table 4.8. Estimated total chlordanes in Newport Bay fish samples calculated using different averaging methods and different sample inclusion criteria. No values exceed the relevant threshold. N = sample size. 95 % UCI = average + two standard errors. Geo mean = geometric mean (calculated on log scale). All values except sample size are ng/g wet weight. Values below detection were set to ½ the detection limit.

Chlordane results[a]	Resident wildlife prey[b]	Relevant threshold	Resident human prey[c]	All human prey[c]	All	Relevant threshold
N	23		6	21	78	
Mean	6.0	High (>5848)	3.5	4.9	4.4	High (95)
95% UCI	8.5	Low (116 - 502)	4.7	7.2	5.5	Low (9.5)
Geo mean	3.5	High (>5848)	3.2	3.2	3.0	High (95)
Geo 95% UCI	5.7	Low (116 - 502)	4.4	4.8	3.6	Low (9.5)
Median	2.5		2.5	2.5	2.5	

a. Values are different from Table 4.1 because Table 4.8 excludes samples collected prior to 1997. b. Compared to bird thresholds presented in Table 4.4. c. Compared to human thresholds presented in Table 4.3.

4.3.2.4. Dieldrin

Evaluations for dieldrin are difficult to interpret because the detection limits of currently available data are above human health thresholds. For the most recent data (Allen *et al.* 2004), detection limits were 5 ng/g and all samples evaluated were below detection. Nevertheless, risk thresholds based on sport fisher consumption rates and 10^{-5} to 10^{-6} allowable cancer risk assumptions range from 0.2 to 2.5 ng/g (Table 4.3, Appendix K). Therefore, it is not possible to determine conclusively whether dieldrin in fish tissue poses a risk to human consumers above the case study thresholds. Since the fish tissue line of evidence is inconclusive, the appropriate course of action would be to proceed to other components of the framework (sediment chemistry and bioaccumulation test organism evaluation).

For wildlife piscivores, both the low and high-risk thresholds are well above the 5 ng/g detection limits, ranging from 59 (least tern low threshold) to 3,772 (brown pelican high threshold) (Table 4.4). Given that all samples were below detection, fish tissue chemistry indicates low risk and it is not necessary to evaluate other lines of evidence for wildlife piscivores in Newport Bay.

4.3.3. Summary of findings for the prey tissue LOE

Fish tissue concentrations were generally intermediate between the low and high effects thresholds for human health for DDTs and PCBs (Tables 4.6 and 4.7), and below both thresholds for chlordanes (Table 4.8). Tissue concentrations were also intermediate between the low and high wildlife thresholds for DDTs (Table 4.6), but were below the low threshold for PCBs and chlordanes (Tables 4.7 and 4.8). As expected, estimated contaminant concentrations in fish in Newport Bay were higher using arithmetic average than geometric average. Nevertheless, use of the arithmetic vs. geometric averaging methods often did not affect results in comparison to thresholds. An exception was PCBs in humans, for which changes in the general combination of assumptions resulted in changes between the low and intermediate categorization.

4.4. Sediment chemistry line of evidence

As described in the assessment framework (Table 2.1 and Figure 2.2), the sediment chemistry line of evidence (LOE) need only be applied for those compounds for which the prey tissue LOE was above the low threshold or inconclusive. For Newport Bay, this includes DDTs (human health and wildlife), PCBs (human health only), and dieldrin (human health results inconclusive). The development of sediment thresholds from tissue thresholds and a bioaccumulation rate parameter is a challenging technical issue. Therefore, much of this section describes approaches for sediment threshold development, followed by comparison of the thresholds to available sediment chemistry data.

4.4.1. Development of empirical bioaccumulation factor

4.4.1.1. Fish tissue data and lipid normalization

A number of criteria were used in selecting appropriate fish tissue samples for bioaccumulation rate parameter[29] development; these included appropriate body size of samples, use of species resident in Newport Bay, and appropriate tissue preparation methods. Table 4.9 summarizes key assumptions and their probable impact on bioaccumulation rate parameter development. Fish sample selection criteria were similar to criteria for the prey tissue line of evidence (Table 4.5). The final data set selected for fish tissue concentration estimation consisted entirely of fish analyzed as part of the survey conducted by Allen *et al.* (2004). The data set contained 18 human prey fish samples and 23 wildlife prey fish samples (Appendix O).

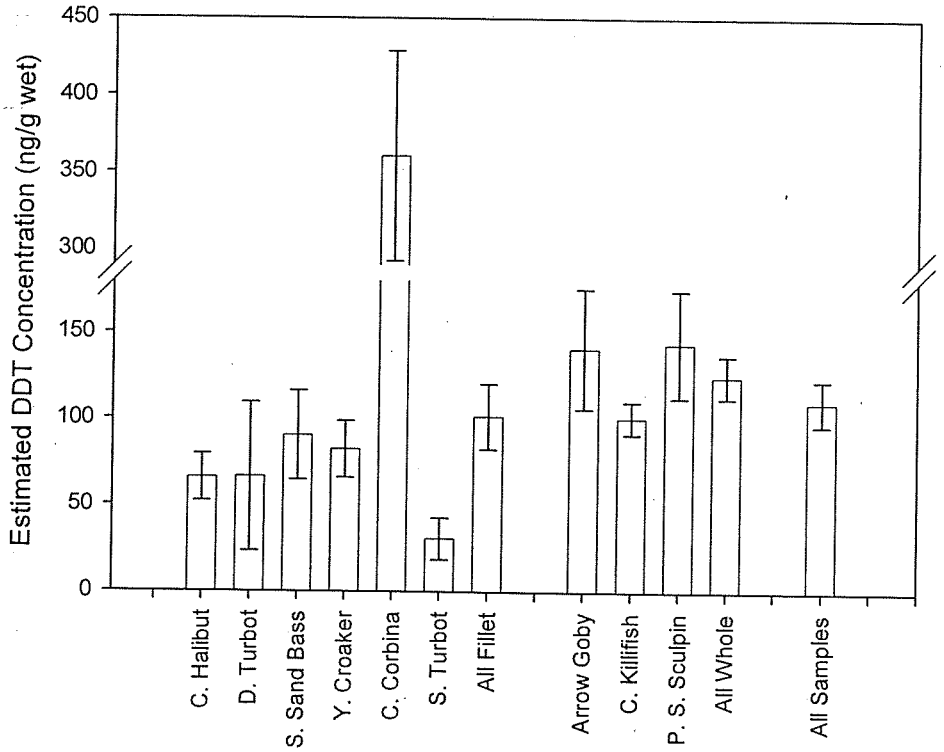
[29] As defined in "abbreviations and definitions"

Table 4.9. Summary of assumptions, their basis, and effects on developing BAF for sediment chemistry LOE, Newport Bay case study.

Decision or assumption	Basis	Effect
Compare results of BAF development based on arithmetic vs. geometric averaging for fish tissue and sediments	Results are generally lognormally distributed, suggesting geometric mean is more appropriate estimate of central tendency. Nevertheless, mechanistic model error estimates are more consistent with arithmetic averaging.	Range of predicted bioaccumulation factors would be wider for geometric averaging.
Lipid normalizing fish tissue concentrations	Lipid data are available and generally correlated with contaminant concentrations.	Will reduce variability of bioaccumulation estimate, by accounting for variation due to lipids. This is particularly true when pooling multiple species due to interspecific variation in lipid content.
Not normalizing sediment concentrations for organic carbon	Although sediment contaminant data are correlated with sediment organic carbon, a large proportion of the sites lack organic carbon data.	Greater variability of bioaccumulation estimate.
Pooling fish tissue concentrations for multiple prey species	Limited sample size for looking at individual species. Conceptual model of exposure risk indicates that receptors (humans/wildlife) consume multiple prey. Variability in average prey concentration estimate is reduced by pooling species.	Reduced variability of bioaccumulation estimate. Simplifies bioaccumulation calculation. Not examining bioaccumulation for individual prey species.
Convert sediment and fish values reported below detection to the detection limits	For PCBs, many fish samples are below detection and should be included in calculations. Model results indicate that actual total congener concentrations in fish may be well above detection. Similar treatment of sediment and fish data will minimize bias in BAF calculation.	Uncertain effect on BAF calculation results.
Develop BAF using only fish samples expected to be permanent residents of Newport Bay	Accounts for concern that fish may have migrated from other locations.	Considerably reduced sample size for human prey sample calculations. Little effect on wildlife prey sample calculations.
Include fish > 15 cm for BAF calculation for humans	Balance between need to use samples representative of human exposure, and need to use available local data.	Makes it possible to develop BAF for human sport fishers using available data.
Include only target sized (< 10 cm) fish for BAF calculation for wildlife	Sufficient samples available within target size range.	Risk evaluations are based on appropriate prey species sizes.
Only accept compounds in sediment for which N > 10	Confidence of average estimate very low when N < 10.	Not possible to calculate empirical bioaccumulation factor for dieldrin, mirex, 20 PCB congeners, and other compounds.
Only accept compounds in sediment for which > 10% of samples are above detection limits	Confidence of average estimate very low when a majority of samples are below detection. Nevertheless, due to relatively high detection limits and limited data, it was necessary to accept samples having a majority below detection.	Not possible to calculate empirical bioaccumulation factor for 7 PCB congeners. Remaining BAFs will be uncertain.
Calculate bioaccumulation factor of sum of compounds, rather than for each individual compound	Individual compounds often lacking in sufficient results above detection (particularly for fish). Pooling of compounds reduces impact of compounds having most results below detection. Effects comparisons are on a summed contaminant basis.	Calculation of average and variation in bioaccumulation factor more straightforward. Not possible to look at dioxin-like PCB effects.
Use of 2 * standard error rather than standard deviation to calculate 95% confidence interval of estimates	The objective is to calculate the central tendency and uncertainty about that central tendency for bioaccumulation in the water body. This is because the population of receptor species (humans and piscivorous birds) are expected, on average, to consume prey across the water body, rather than occurring at only one location.	The calculated uncertainty in estimated bioaccumulation factor will be lower using standard error, rather than standard deviation.
Only using samples prepared according to receptors' consumption patterns	Humans generally do not consume whole fish, and avian predators do. Contaminant concentration estimates will be related to tissue preparation.	Sample size unchanged. Preparation method may cause increase or decrease in estimated tissue contaminant concentration.

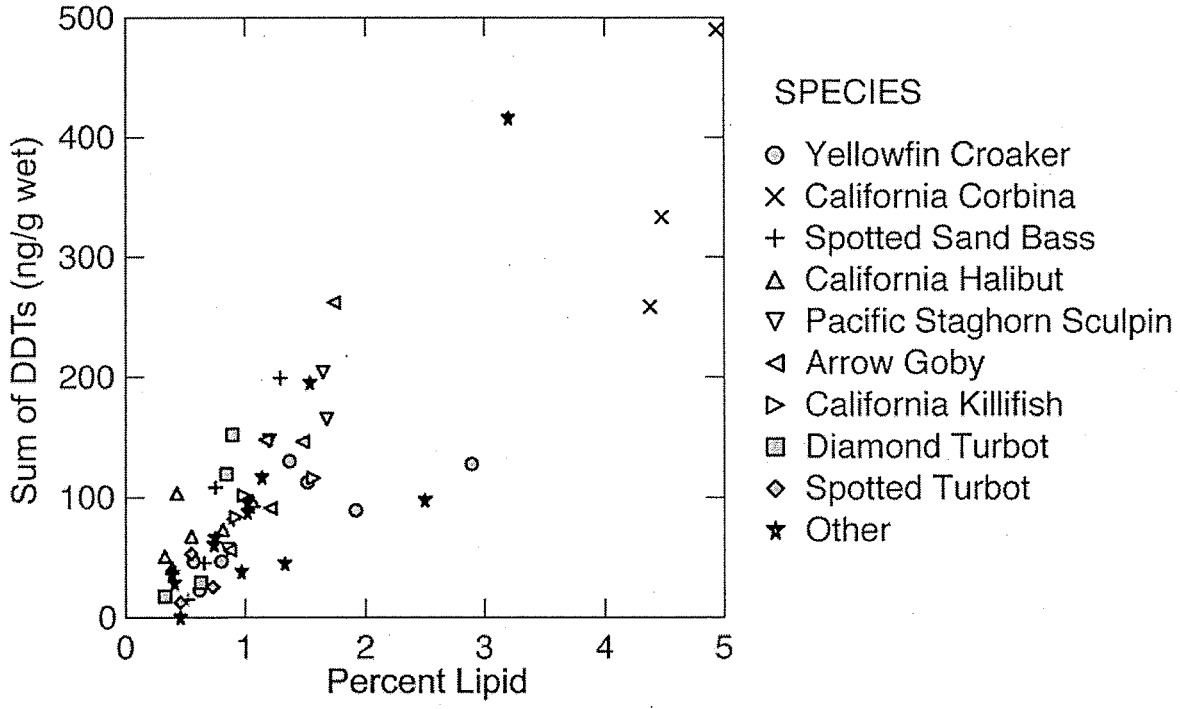
In the case of Newport Bay, the sample size of potential fish species was limited, with individual species ranging in number of samples analyzed from one to seven samples (Table 4.1). The limited sample size interferes with the ability to detect spatial patterns in tissue PCBs or DDTs. Therefore, it is not possible to develop meaningful spatially explicit statistical models of tissue vs. sediment chemistry relationships (i.e., Appendix L). As discussed in Section 3.1.8 and Appendix F, the ability to estimate average concentrations will also be reduced when sample sizes are small. This can be seen in Figure 4.2, which plots the average concentration and standard error of the mean for DDTs in all species in Newport Bay having at least three samples (Table 4.1). Figure 4.2 indicates that several fish species have relatively wide average estimates. In particular, standard errors of the mean are wide for diamond turbot, spotted sand bass, California corbina, arrow goby, and pacific staghorn sculpin. Generally, the standard error of the mean estimates for these species is larger than the standard error taking the combined average of all fillet samples, all whole body samples, or all samples (Figure 4.2). This indicates that, despite differences among species in exposure, the ability to estimate typical predator exposure in Newport Bay will not improve by focusing on specific individual species. Rather, a compilation of multiple species will be more appropriate to estimate expected exposure at a given sediment concentration.

Figure 4.2. Average DDT concentration (ng/g wet weight) by species. Error bars represent one standard error of the mean for each species. All fillet = all samples evaluated as fillet tissue. All whole = all samples evaluated as whole body samples. Note break in y-axis.



Another issue in bioaccumulation rate parameter development is whether tissue lipid and sediment organic carbon normalization are appropriate (Section 3.2.6). In some circumstances, calculation of the BSAF will improve the estimate of the relationship over using a standard BAF. For Newport Bay, tissue contaminant concentrations are significantly positively correlated with fish tissue lipid for total DDTs (Pearson's $r = 0.85$; $p < 0.001$) and total chlordanes ($r = 0.63$; $p < 0.001$), but not PCBs ($r = 0.22$; $p > 0.15$). A positive association is observed, with fish species high in lipid (e.g., California corbina, arrow goby, and staghorn sculpin) having elevated DDTs (Figure 4.3).

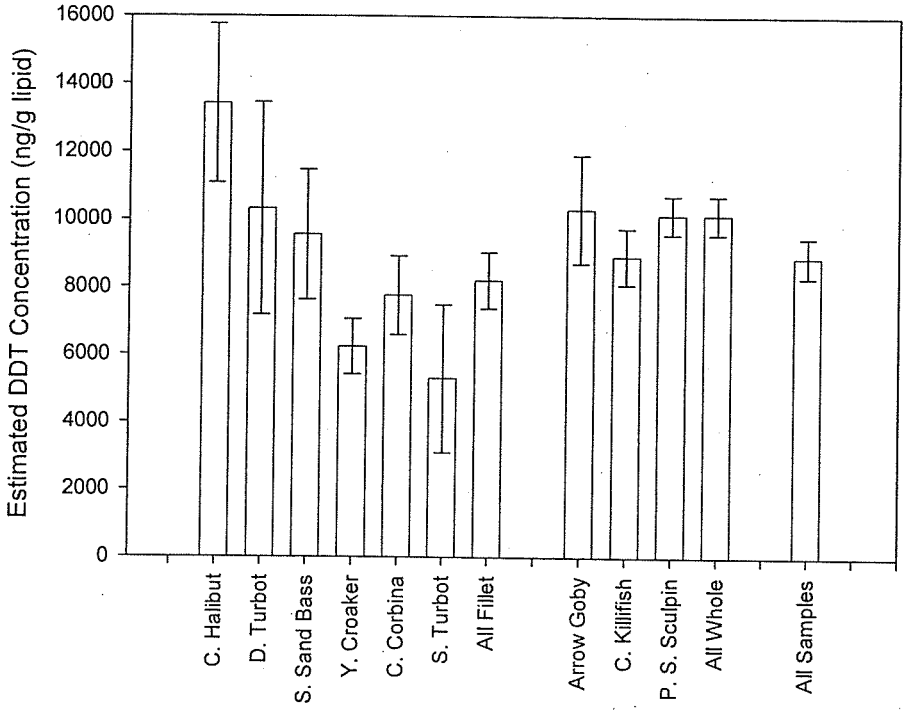
Figure 4.3. Fish tissue total DDT concentration (ng/g wet) vs. percent lipid for all fish species analyzed in Newport Bay.



The significant lipid vs. contaminant relationship in Newport Bay fish suggests that lipid normalization[30] will improve overall ability to estimate average contaminant concentration. In fact, lipid normalized total DDTs (Figure 4.4) do exhibit a lower ratio of standard error to mean, when compared to wet weight data (Figure 4.2). For example, the ratio of standard error to mean for total DDTs in fillet samples is 19% (i.e., 19.1/101.1) for wet weight, but only 10% (829/8197) for lipid weight. In order to reduce variance in the estimate of the bioaccumulation rate parameter, lipid weight data will be used.

[30] i.e., dividing wet weight tissue concentration by total percent lipid

Figure 4.4. Average DDT concentration (ng/g lipid weight) by species. Error bars represent one standard error of the mean for each species. Sample sizes in Table 4.1.



4.4.1.2. Sediment chemistry data and organic carbon normalization

Trace organic contaminant concentrations in sediments are generally correlated with organic carbon content (e.g., Figure 4.5). Significant correlations between total organic carbon and contaminant concentrations are apparent for p,p'-DDE (Pearson's $r = 0.50$; $p < 0.001$; $N = 56$) and total chlordanes ($r = 0.60$; $p < 0.001$; $N = 55$), but not for PCBs ($r = 0.35$; $p = 0.13$; $N = 44$).

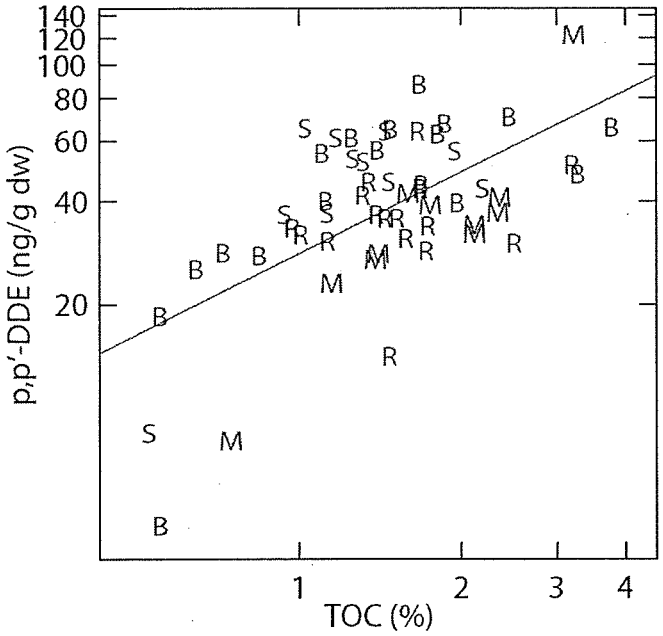
Of the studies that did collect contaminant data, the Bay Protection and Toxic Cleanup Program contains data from the early 1990's. As with the fish data, it is preferable to focus on relatively recent sediment data, given that legacy pesticides often have declining trends over the past decade (Greenfield *et al.* 2005, Connor *et al.* 2006, Davis *et al.* 2006a, O'Connor and Lauenstein 2006). Careful examination of Figure 4.5 indicates that samples collected in the Bay Protection and Toxic Cleanup Program (BPTCP; indicated in Figure by a 'B') tend to have higher total DDTs at a given organic carbon content. This suggests that concentrations were elevated in sediments in the early 1990s, as compared to more recently. BPTCP samples will therefore be excluded from BAF calculations.

The significant association between organic carbon and contaminant content suggests that organic carbon normalization would be appropriate. However, after exclusion of BPTCP

samples, much of the remaining data do not include organic carbon data. Therefore, in order to include all available data, sediment data will not be organic carbon normalized. Thus, for the Newport Bay case study, a modified BAF will be calculated as follows:

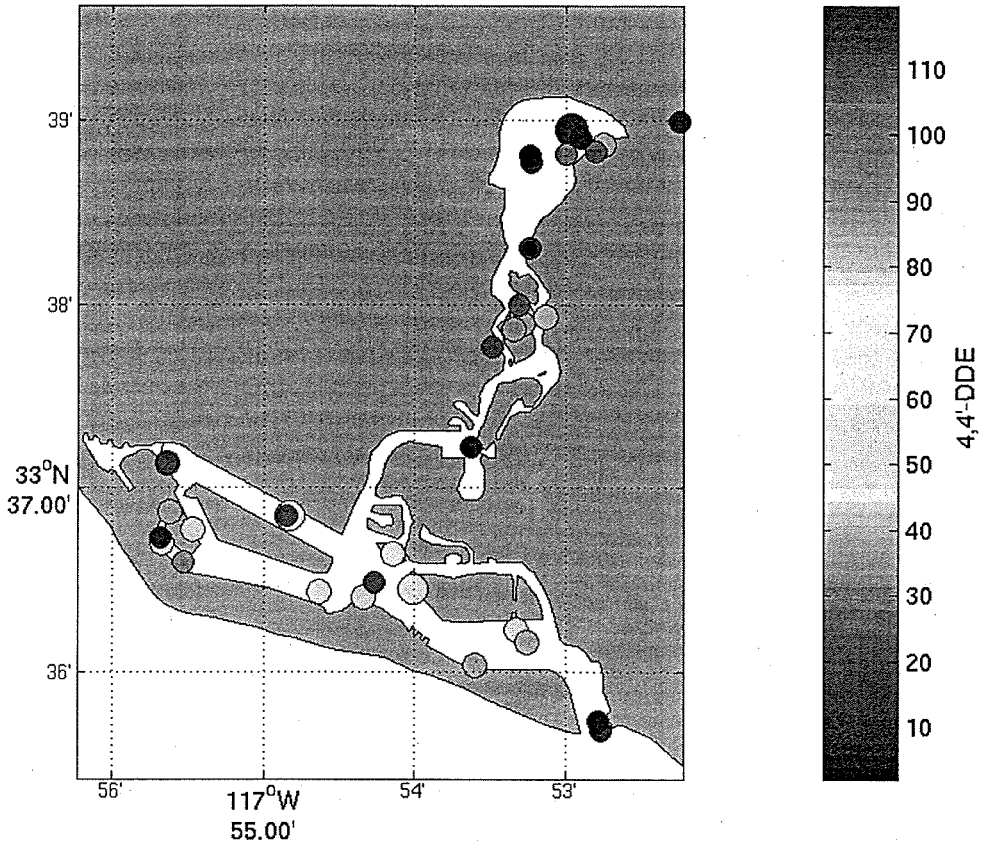
$$\text{BAF} = \frac{\text{Fish Tissue Concentration (ng/g lipid weight)}}{\text{Sediment Concentration (ng/g dry weight)}}$$

Figure 4.5. Percent total organic carbon (TOC) vs. p,p'-DDE concentration (ng/g dry weight) in Newport Bay sediments. Each letter represents a sediment collection location, with letters indicating collection study. B = Bay Protection and Toxic Cleanup Program; S = SCCWRP Southern California Bight 1998 Study (Noblet *et al.* 2002); R = Rhine Channel Study (Bay and Brown 2003); M = Masters and Inman (2000). The smoother line represents the best-fit linear regression model on log-transformed data. Note log scale.



The following sediment data were used in BAF development: Masters and Inman (2000), the Rhine Channel Study (Bay and Brown 2003), the Newport Bay Sediment Toxicity Study (Bay *et al.* 2004), and the Southern California Bight 1998 Survey (Noblet *et al.* 2002). Combining these studies resulted in relatively good spatial coverage across Upper and Lower Newport Bay (Figures 4.6 and 4.7). Concentrations varied spatially, with DDT concentrations highest at the mouth of San Diego Creek and in Lower Newport Bay (Figure 4.6). The elevated concentrations at the mouth of San Diego Creek likely result from upstream loading (Masters and Inman 2000). PCB concentrations were elevated in Inner Lower Bay, particularly in the highly industrialized Rhine Channel (Bay and Brown 2003), and were lower in Upper Newport Bay (Figure 4.7).

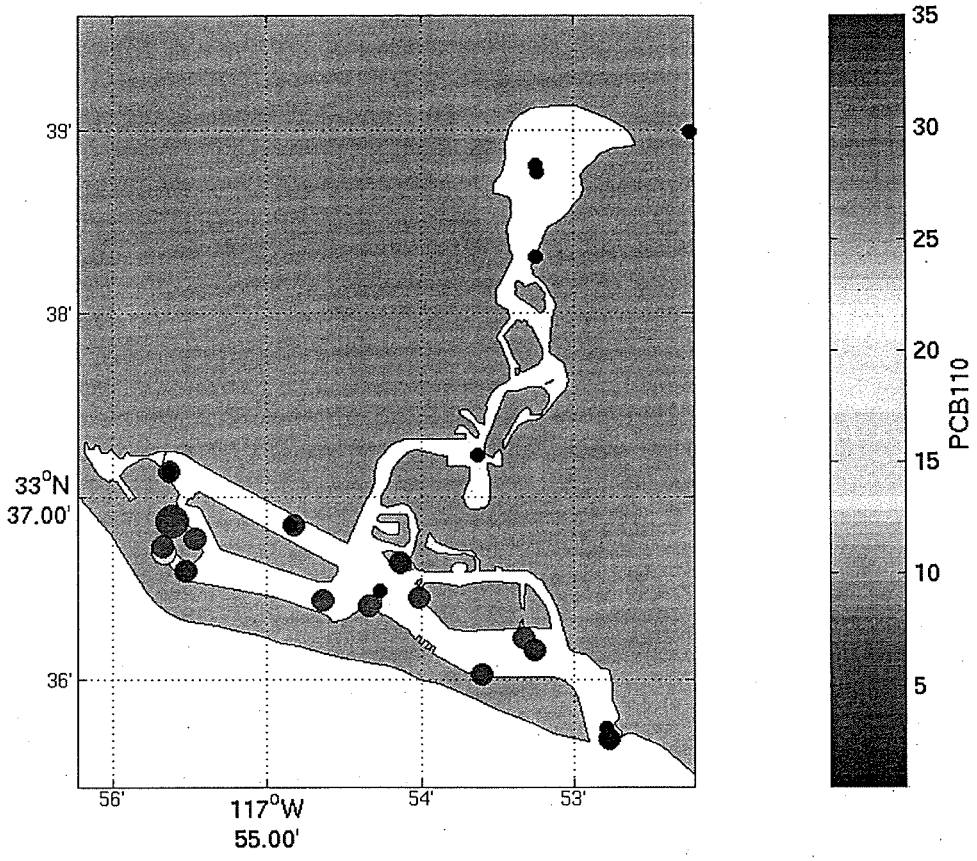
Figure 4.6. Spatial map of sediment contaminant data for p,p'-DDE in Newport Bay. Vertical bar indicates concentration of individual sediment samples (ng/g dry weight). Size and color of dots is proportional to concentration.



In order to calculate the empirical BAF, average and uncertainty estimates must be developed for sediments and fish tissue. However, as discussed elsewhere in this report[31], the method of averaging and treatment of samples that are below detection can strongly affect average estimates (Helsel and Hirsch 2002). For many compounds, a majority of Newport Bay sediment samples were below detection (Table 4.10; Appendix Q, Tables Q.1 and Q.3). The geometric mean was often far below the arithmetic mean, due to the relative greater influence of small values on the calculation (Table 4.10). In situations were a majority of samples were below detection (e.g., o,p'-DDT's), treatment of detection limits affected calculated averages. In particular, average calculations were lower when values below detection were replaced with the laboratory reported detection limits. Average calculations were higher when half of the laboratory reported limits of quantification were used (Table 4.10). For the case study BAF calculations, detection limit values were used for samples below quantification (Table 4.9).

[31] See Sections 3.1.7, 3.1.9, 3.2.7, and Appendix G.

Figure 4.7. Spatial map of sediment contaminant data for PCB 110 in Newport Bay. Vertical bar indicates concentration of individual sediment samples (ng/g dry weight). Size and color of dots is proportional to concentration.



4.4.1.3. Effect of assumptions on BAF

A number of data treatment assumptions will affect sediment and tissue data and consequent BAF calculations. These include averaging methods, sample selection, and treatment of samples below detection (Table 4.9). Without a sufficient number of detectable samples, concentration estimates become highly uncertain (Table 4.10). Appendix Q (Table Q.1) lists concentration estimates for 61 PCBs and legacy pesticides for which data have been collected in recent studies. Of these compounds, 24 have a vast majority (>90%) of measurements below detection. An additional seven compounds have very few (< 10) measurements total throughout Newport Bay (Table Q.1). In calculating totals for BAF estimation, these compounds were removed from the data set, with the remaining 30 compounds included (Table 4.9).

For the Newport Bay case study, averaging method and tissue sample selection were both evaluated to determine their impact on the BAF calculation. Average fish tissue and

sediment concentrations for total PCBs, DDTs, and chlordanes[32] were calculated using both arithmetic and geometric averaging methods. Tissue sample averages were calculated for all fish samples, only human prey, and only wildlife prey, following the designations in Table 4.1.

Table 4.10. Different estimates of concentrations of selected contaminants in Newport Bay sediments. Mean = arithmetic mean. Geometric mean = mean of log_{10}-transformed values, converted to arithmetic units. Median = central value. DL = samples below detection were replaced with limit of detection. ½ QL = samples below detection were replaced with 0.5*(limit of quantification). % ND = total percent of samples below detection.

Average Type:	Mean	Mean	Geometric mean	Geometric mean	Median	N	% ND
How treat NDs:	DL	1/2 QL	DL	1/2 QL	DL		
o,p'-DDD	0.51	0.98	0.18	0.78	0.07	45	80%
o,p'-DDE	1.25	1.46	0.27	0.78	0.46	45	56%
o,p'-DDT	0.27	0.76	0.10	0.70	0.04	45	84%
p,p'-DDD	6.69	6.81	1.85	3.61	6.97	45	27%
p,p'-DDE	29.02	29.02	20.54	20.54	26.46	45	0%
p,p'-DDT	3.27	3.54	0.46	1.47	0.06	45	58%
Total DDTs	41.02	42.56	23.39	27.87	34.05	45	0%
PCB118	2.01	2.25	0.26	0.97	0.04	34	71%
alpha-Chlordane	1.49	1.69	0.28	1.19	1.57	24	46%

4.4.1.4. Empirical BAF results

Empirical bioaccumulation factors were calculated based on tissue and sediment concentrations for total DDTs, total PCBs, and total chlordanes (Appendix N). Individual compound concentrations were averaged replacing ND concentrations with the method detection limit (e.g., Table 4.10, second and fourth columns).

Bioaccumulation factors tended to be higher and substantially more uncertain using geometric averaging methods, than arithmetic methods (Table 4.11). The uncertainty mostly resulted from the high variability in geometric estimates of sediment chemistry (Table 4.11, sediment rows). Uncertainty was very high in geometric estimates of sediment chemistry due to two factors. First of all, with so many individual chemicals below reporting limits, the uncertainty of concentration estimates became very high on a log-scale. This uncertainty propogated as individual chemical results were combined to obtain sediment chemistry average estimates. Bioaccumulation factors were generally similar for different prey groupings, with the exception that geometric average

[32] As the fish tissue line of evidence indicated low risk due to chlordane exposure, the chlordane results are presented for illustrative purposes only.

bioaccumulation factors were substantially lower for chlordanes in wildlife prey than human prey (Table 4.11).

Clearly, the selection of arithmetic vs. geometric averaging and error estimation will substantially influence the final thresholds selected. Results from the mechanistic model uncertainty evaluation will be used to help determine whether the arithmetic or geometric approach is more appropriate to represent the water body BAFs.

Table 4.11. Summary statistics and calculations for bioaccumulation factors. Results using both arithmetic and geometric averaging methods are presented. 95%iles are presented as upper confidence limits for tissue and lower confidence limits for sediments, based on standard error of the mean for individual compounds. For each row, the BAF is the quotient of the fish and sediment concentration. Note that all fish tissue concentrations are presented as ng/g lipid weight, sediment concentrations are ng/g dry weight and BAFs are on a (tissue lipid weight/sediment dry weight) basis.

4.4.2. Development of bioaccumulation factor using mechanistic model

It is beneficial to corroborate empirical estimates of bioaccumulation by independently applying a mechanistic model to predict bioaccumulation (Section 3.2.8). This will help to determine whether a variety of factors interfere with the ability to estimate bioaccumulation rates. For example, limitations in data availability may increase uncertainty in bioaccumulation estimates. Additionally, a number of processes may complicate efforts to predict bioaccumulation rates. At a given site, a portion of an organism's contaminant body burden may result from uptake from other sources, such as the overlying water column. For highly mobile organisms, variation in home range can

affect the relative impact of contamination at a specific site (Linkov *et al.* 2002). Variations in food web structure can also cause differences in contaminant bioaccumulation (Gobas and Wilcockson 2002). An uncalibrated model provides an independent estimate of the BAF; if model and empirical results are similar, this supports the empirical BAF approach.

Use of the mechanistic model in the case studies served several objectives. The primary objective was to ascertain whether the empirical bioaccumulation factor was a reasonable estimate of sediment vs. biota partitioning. If the empirical bioaccumulation factor were higher than mechanistic model results, this may support the hypothesis that a substantial proportion of the bioaccumulation was due to contaminant uptake from other sources. Other objectives included characterizing the uncertainty of BAF predictions and identifying possible areas for future research. The remainder of this section summarizes the input data for using the mechanistic model, and compares model output to empirical results. Additional information regarding model input parameters and their basis can be found in Appendices R – V and Appendix Y.

4.4.2.1. Model description

The case studies used a steady state non-equilibrium model developed to assess transfer of non-polar organic contaminants through food webs (Gobas 1993). This model has been updated to incorporate new research regarding phytoplankton uptake and elimination, fish and invertebrate ventilation rates, chemical partitioning and mechanisms of gastrointestinal magnification of contaminants (Morrison *et al.* 1996, Arnot and Gobas 2004). The model, and applications where it has been used previously, are further described in Section 3.2.8 and Table 3.10. Appendix M presents a listing of all model parameters and equations and Appendix Y indicates data needs for the model. Readers interested in further information on model assumptions and structure should also refer to Arnot and Gobas (2004) and to Gobas and Arnot (2005).

The food web bioaccumulation model was converted from a Microsoft Excel spreadsheet (provided by Jon Arnot and Dr. Frank Gobas) to a set of MATLAB routines (www.mathworks.com) in an effort to increase the transparency of model parameterizations. The current model is capable of incorporating an arbitrary number of species and contaminants, a feature that allows the model to be easily adapted for application to any appropriate region of interest.

4.4.2.2. Parameter development for Newport Bay

Estimation of model input parameters is an important part of any modeling exercise. For each case study, local data were compiled and used to generate parameter distributions and ranges. Based on previous sensitivity analyses in San Francisco Bay and other ecosystems, the model is likely to be relatively sensitive to particular environmental, biological and chemical parameters (Arnot and Gobas 2004). These include contaminant concentrations in water and sediments, organic carbon content in water and sediments, sediment-water partitioning coefficients, organism dietary composition, body weight, and

lipid content (Gobas and Arnot 2005). The model has previously been parameterized to calculate uptake of PCBs in selected San Francisco Bay fish and wildlife (Gobas and Wilcockson 2002, Arnot and Gobas 2004).

In general, all available model input data for Newport Bay were assembled with preferential use of site-specific data over data from similar sites. Appendix R describes data sources and compilation methods for use in the mechanistic model. Appendix S presents input parameters for octanol-water partitioning coefficient, which strongly influences contaminant bioaccumulation.

Table 4.12 summarizes input data for physical features of Newport Bay, which were estimated as described in Appendix R. Table 4.13 summarizes input data for biota diet, and biology, which were compiled based on a review of published and unpublished studies (Appendices T, U, and V). Estimates of food web structure are based on total mass proportion of prey items consumed, and reflect the proposed conceptual model for Newport Bay (Figure 4.1). Dietary information for fish represents a review of published and unpublished sources on dietary studies (Appendix T). Table 4.14 presents additional input parameters, and their distribution assumptions for Monte Carlo simulations (described further below).

To facilitate interconversion to the most appropriate tissue type for the contaminant exposure evaluation, concentrations were extrapolated between whole body and fillet samples, assuming lipid equivalence:

Whole Body Conc. = Fillet Conc. * (Whole Body Lipid % / Fillet Lipid, %)

When lipid concentrations were not available in both tissue types from the same species, a regression relationship was used to extrapolate whole body vs. fillet lipid content (Appendix E).

Table 4.12. Physical input parameters for mechanistic food-web contaminant uptake model application to Newport Bay. Appendix R describes source data used to estimate these parameters.

Constant	Value	Distribution	Standard deviation	Description
Cox	7.6	Normal	1	Dissolved oxygen concentration (mg O_2/L)
T	17.5	Normal	0.8	Mean water temperature
salinity	27.2	Normal	2	Water salinity (PSU)
ocsed	0.0145	Lognormal	0.0254 [a]	Organic carbon proportion in sediment (kg/kg)
vss	8.58E-05	Lognormal	0.0256 [a]	Concentration of suspended solids (kg/L)
xpoc	3.77E-06	Lognormal	0.0256 [a]	POC concentration in water (kg/L)
xdoc	1.19E-06	Lognormal	0.0392 [a]	DOC concentration in water (kg/L)

a. This is the log-scale standard deviation, and is applied to log-transformed data, which is then back-transformed to develop input parameters for Monte Carlo simulation.

Table 4.13. Biological input parameters for applying the mechanistic food-web contaminant model to Newport Bay (see also Appendices T, U, and V). % Respiration PW = percent of respiration that is pore water. 4.4.2.3. Calculation of total BAFs

Many of the chemical compounds included in the food web models of Newport Bay and San Francisco Bay comprise specific chemical groups (i.e., PCBs, chlordanes, or DDTs). Thus, in addition to calculating compound-specific BAF values, it is possible to estimate the BAF for a given chemical group, referred to as the total BAF (BAFt). The calculation of total BAFs from compound-specific values is as follows:

$$BAFt = \frac{\sum_i Cb_i}{\sum_i Cs_i} = \frac{\sum_i (Cs_i \times BAF_i)}{Cs_T}$$

where Cb_i is the model predicted compound-specific contaminant concentration in biota, Cs_i is the compound-specific contaminant concentration in sediment, BAF_i is the model predicted compound-specific BAF, and Cs_T is the sum of all compound-specific contaminant concentrations in sediment.

4.4.2.4. Monte Carlo uncertainty analysis

A Monte Carlo methodology was used to determine the uncertainty in model predictions of BAF resulting from the inherent variability and error associated with model input parameters. This methodology samples model input parameters from statistical distributions rather than point estimates. The methodology repeatedly samples the parameter distributions, executes the food web model, and stores the results. A distribution of model results is generated which represents the variability of model predictions due to the variability and error in model input parameters.

Monte Carlo distributions may be used to represent the multiple sources of variability inherent in model parameters, including geospatial, temporal, and behavioral variability and differences in sampling protocols. However, as discussed in the conceptual model for the indirect assessment framework (Section 2), it is expected that avian piscivores and human sport fish consumers integrate spatially and temporally across the water body. Based on this assumption, the input parameters for the Monte Carlo simulation are intended to represent average conditions that fish consumers may encounter. Therefore, input parameter distributions in this exercise represent uncertainty about the average, due to uncertain and variable input data. In particular, model input standard deviations were typically estimated based on standard error of the mean, rather than standard deviation of the entire data set (following Section 3.1.9).

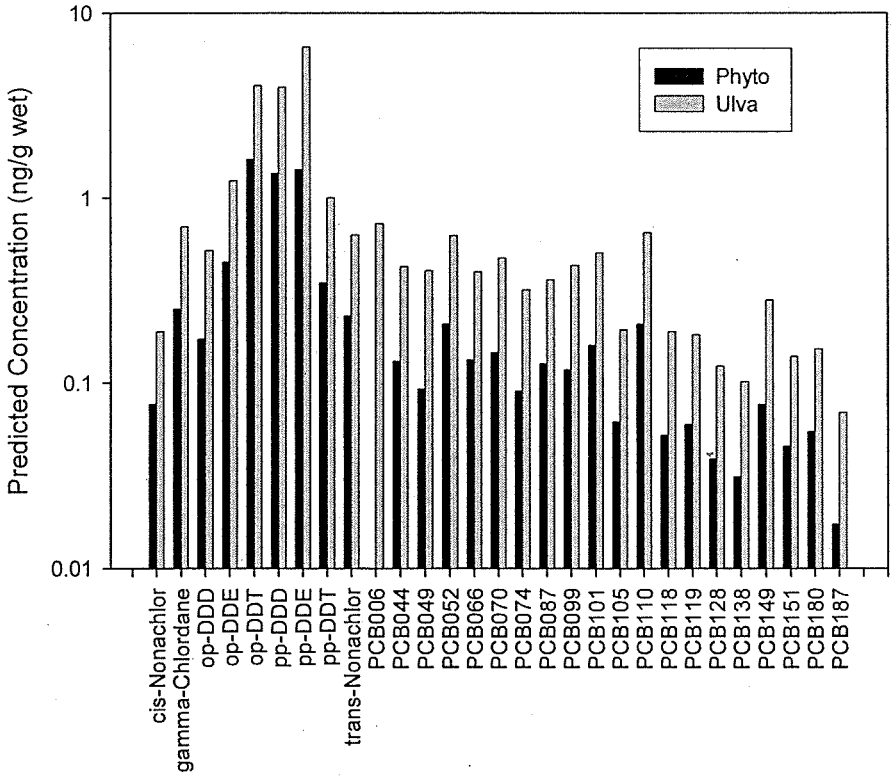
The Monte Carlo Simulation (MCS) analysis module of the food web model uses MATLAB's intrinsic random number generator to generate distributions of model input parameters. The parameter distributions are generated at model initialization and the model is run iteratively. The module is capable of generating normal, lognormal, triangular, and uniform distributions. Inputs to the MCS module are the parameter mean, standard deviation, distribution type (i.e., normal, lognormal, triangular, or uniform), and

the number of samples. Tables 4.12 and 4.14 indicate these values for MCS inputs. The MCS was performed for 5000 model runs.

4.4.2.5. Results of model simulations

General behavior of the model has been described in previous applications (e.g., Burkhard 1998, Arnot and Gobas 2004). Findings from the current application highlight key model assumptions, and their effects on the current case study. The model generates as output the BAF and biota whole body concentrations for individual organic compounds. These results are generated for all compounds and organisms modeled, including primary producers (Figure 4.8), invertebrates (e.g., Figure 4.9) and fish. Individual compound concentrations are summed within a compound category to obtain total PCB, DDT, and chlordanes in all organisms. These total concentrations may then be divided by original input sediment concentrations to obtain BAFs (Figures 4.10 – 4.14). Monte Carlo simulation results were approximately normally distributed about the mean for total DDTs and PCBs (e.g., Figure 4.13), and log-normally distributed about the mean for total chlordanes (e.g., Figure 4.14).

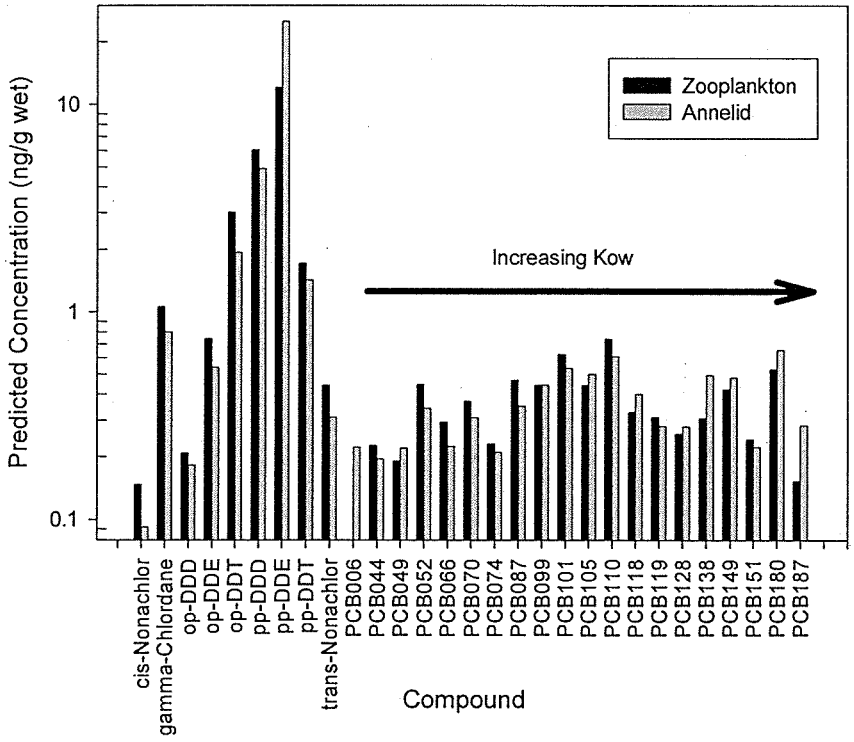
Figure 4.8. Concentrations of organic compounds predicted in phytoplankton (black bars) and benthic algae (e.g., *Ulva* sp.; grey bars) in the Newport Bay simulation. Note log scale y-axis.



In general, the model predicted progressively higher bioaccumulation rates for higher trophic levels and fattier organisms, consistent with known trophic fractionation behavior of organochlorine compounds (e.g., Clark *et al.* 1988, Kidd *et al.* 1995). Total PCBs, DDTs, and chlordanes were generally predicted to be highest in fishes, intermediate in benthic invertebrates, and lowest in aquatic plants (Figures 4.10, 4.11, and 4.12). Among fish species, predicted concentrations were relatively high in striped mullet, California corbina, and yellowfin croaker, which also had relatively high tissue lipid contents (Table 4.13; Figures 4.10 – 4.12). Predicted concentrations were relatively low in topsmelt (Figures 4.10 – 4.12). The low model predicted concentrations likely results from topsmelt's high dietary reliance on algae (Table 4.13 and Appendix T) (Logothetis *et al.* 2001).

Variability in Monte Carlo simulation output increased with increasing mean results (Figures 4.10 – 4.12) and was small enough to allow model predictions within approximately 50% to 150% of average values. The coefficient of variation (CV)[33] for all species was higher for total chlordanes (average CV = 36%; range = 18% to 40%; N = 18 taxonomic groups; e.g., Figure 4.14) than for PCBs or DDTs (average CV = 17%; range = 11% to 20% for both compound classes; e.g., Figure 4.13).

Figure 4.9. Concentrations of organic compounds predicted in zooplankton and benthic annelidae (e.g., *Pseudopolydora japonica kempi)* in the Newport Bay simulation. Note that y-axis is log scale and ranges from 0.08 to 30 ng/g.



[33] Coefficient of variation = Standard deviation/Mean

Figure 4.10. Model predicted bioaccumulation factor (BAF) in Newport Bay organisms for total PCBs. Results are from a Monte Carlo simulation with a sample size of 5000. Grey bars represent the mean BAF, and error bars represent the standard deviation.

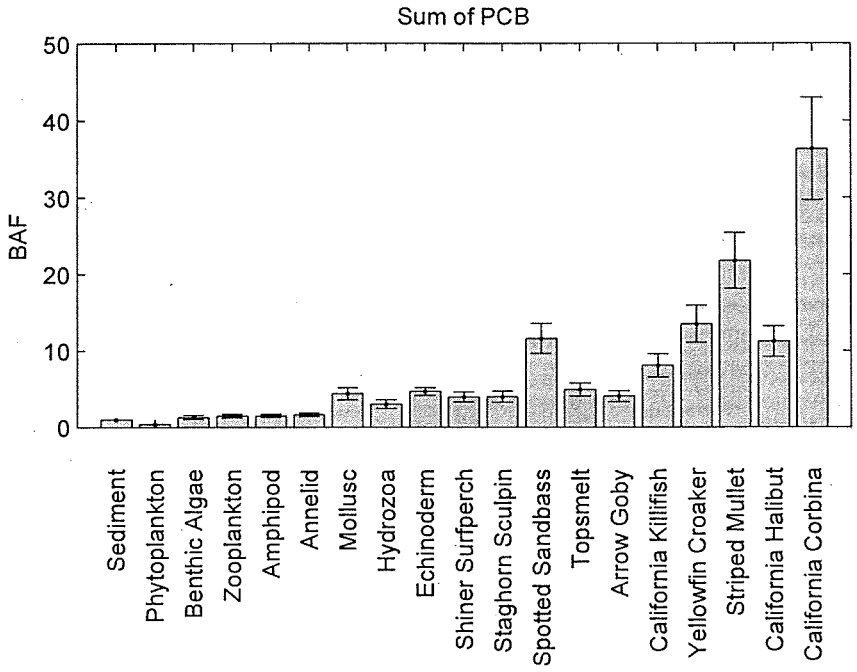


Figure 4.11. Model predicted bioaccumulation factor (BAF) in Newport Bay organisms for sum of six DDTs. Results are from a Monte Carlo simulation with a sample size of 5000. Grey bars represent the mean BAF, and error bars represent the standard deviation.

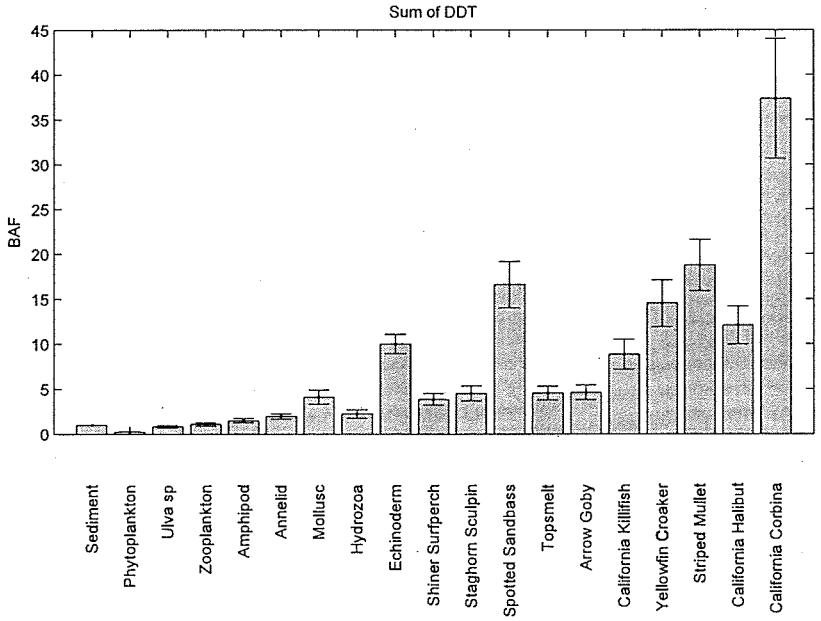

Figure 4.12. Model predicted bioaccumulation factor (BAF) in Newport Bay organisms for sum of three chlordanes (cis-Nonachlor, trans-Nonachlor, and gamma-Chlordane). Results are from a Monte Carlo simulation with a sample size of 5000. Grey bars represent the mean BAF, and error bars represent the standard deviation.

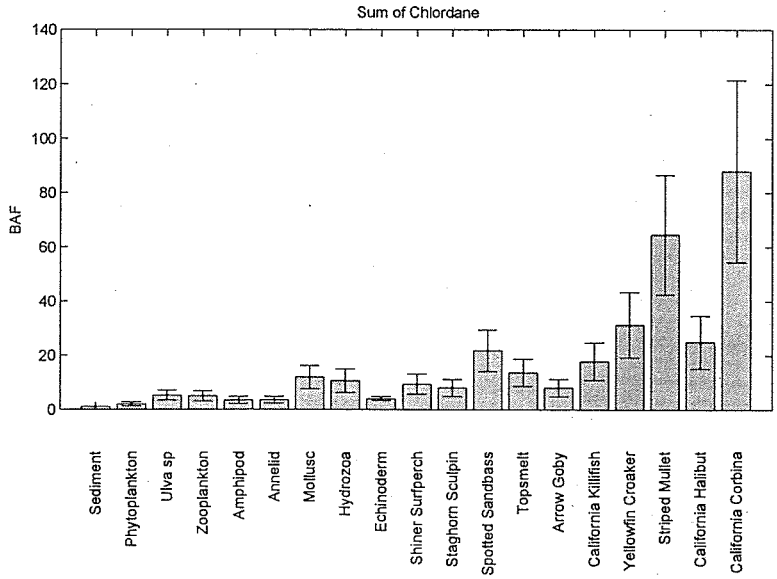

Figure 4.13. Monte Carlo simulation output for application of the model to estimate BAF for total PCBs in striped mullet.

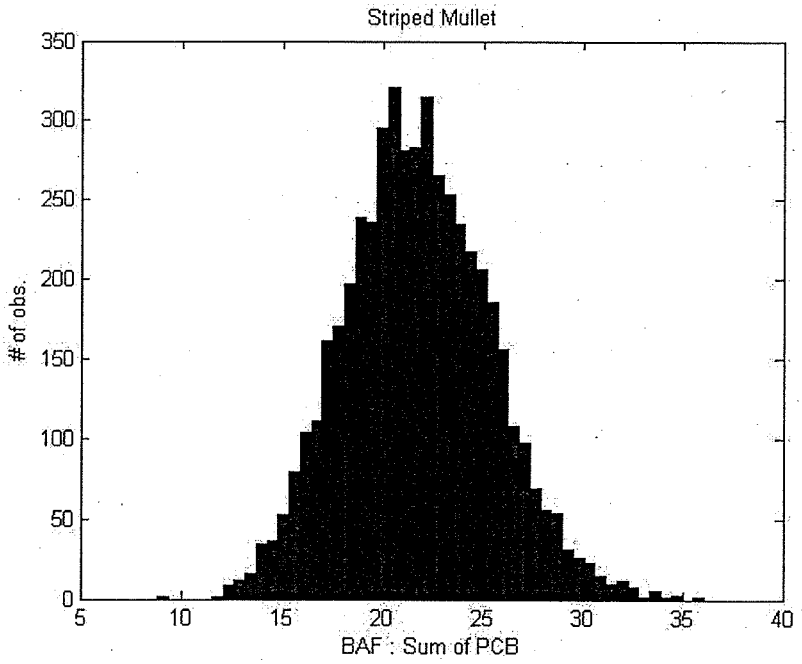

Figure 4.14. Monte Carlo simulation output for application of the model to estimate BAF for sum of three chlordanes in striped mullet.

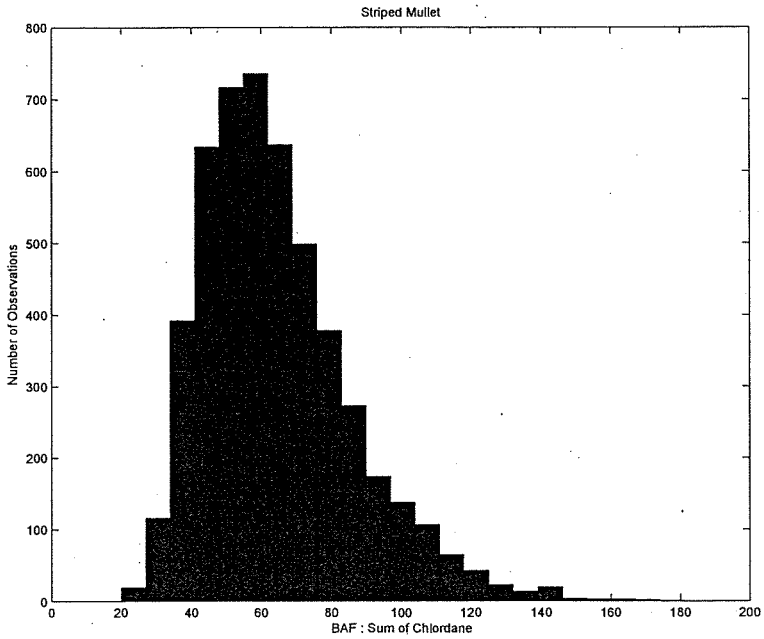


The model output assisted in determining whether to use arithmetic or geometric averaging to develop average and 95% UCI for empirical BAF predictions. As described in Section 4.4.1.4, empirical data indicated higher averages and substantially greater variance using geometric averaging methods, as opposed to arithmetic methods (Table 4.11). In general, the model Monte Carlo simulation output was more consistent with the variance of the arithmetic averaging method for PCBs and DDTs. In particular, model output was normally distributed and the coefficient of variation was less than 20% of the mean, suggesting that 95% UCI would be around 150% of the mean or less. This would not be consistent with the BAFs developed using geometric methods, which exhibited 95% UCI estimates that were 500% to 2000% of the mean (Table 4.11, last two columns).

Newport Bay differs from many estuaries in having a significant proportion of primary production due to benthic algae (Kamer *et al.* 2004a). Simulation results indicated consistently higher predicted contaminant concentrations for benthic algae, than for phytoplankton (Figure 4.8). Although substantial efforts were made to develop model parameters appropriate for benthic algae (e.g., Appendices R and V), local data are lacking. Input parameter uncertainties include tissue lipid content, non-lipid organic matter (NLOM), porewater exposure and contaminant uptake kinetics. Phytoplankton have been modeled previously (Gobas 1993, Burkhard 1998, Arnot and Gobas 2004, Gobas and Arnot 2005), and literature estimates of tissue lipid content and NLOM are lower for phytoplankton than benthic algae (Tables 4.13 and 4.14, Appendix V).

Manipulation of these parameters indicates that the higher predicted contaminant concentrations for benthic algae resulted from a combination of higher tissue lipid, slower growth rate and consequent growth dilution, and higher exposure to sediment porewater and associated compounds (results not shown). Confirmation of the higher concentrations in benthic algae would require field characterization of contaminants in these taxa.

Model results for benthic annelids vs. pelagic zooplankton indicated relatively similar exposure for the two taxa (Figure 4.9). Nevertheless, differences occurred as a function of K_{OW}. Close examination of Figure 4.9 indicates that for PCBs, modeled concentrations of less chlorinated congeners with lower K_{OW} were higher for zooplankton, whereas modeled concentrations of more chlorinated congeners (higher K_{OW}'s) were higher for annelids. Compound K_{OW} affects model results by affecting calculated sediment-porewater partitioning, chemical specific gut-transfer efficiency, and contaminant respiratory uptake rate (equations outlined in Appendix M). The net result of these processes is higher exposure of sediment dwelling organisms, consistent with the expectation that high K_{OW} compounds have greater sediment association (e.g., Clark *et al.* 1988).

4.4.2.6. Comparison of model vs. empirical results

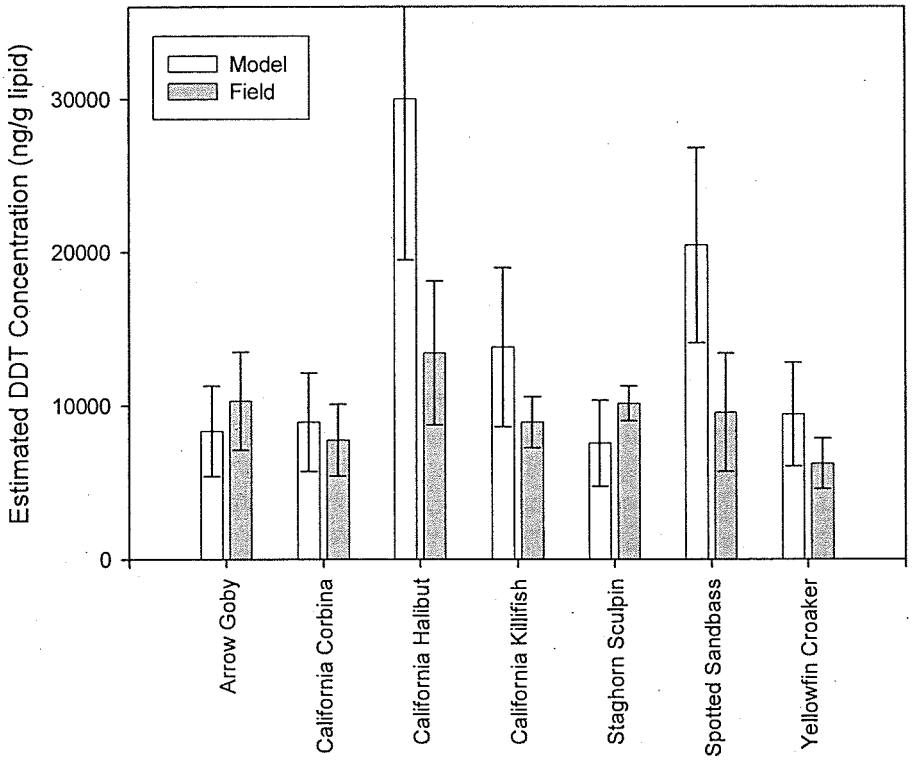
For the Newport Bay case study, the primary use of the model was to corroborate empirical observations of bioaccumulation in the ecosystem. Because model predicted bioaccumulation factors are independent of field measured bioaccumulation factors, consistency between these results would suggest that the empirical BAFs are appropriate. This, in turn, would support the use of the empirical BAFs to develop sediment thresholds. If model vs. field results were inconsistent, or field data were insufficient to facilitate comparison, this would suggest either incorrect model assumptions or additional data needs.

For this study, comparison of model vs. field tissue concentrations focused on total concentrations in the target compound classes (i.e., total PCBs, DDTs, or chlordanes). The model calculates whole body concentrations, while field data for some species were muscle fillet samples (Table 4.1). To account for possible concentration differences between whole body and muscle samples, some results are presented on a lipid weight basis, assuming that lipid normalized concentrations will be similar among tissue types (Bayen *et al.* 2005). When comparisons were conducted on a wet weight basis, interconversion between whole body and fillet types was conducted assuming lipid equivalent concentrations, and based on the tissue lipid estimates in Table 4.13 (following Appendix E).

Evaluation of lipid weight total DDTs indicated reasonably good overall correspondence between model and field results (Figure 4.15). However, there was some indication of model bias. Best estimate model results were higher than empirical results for all species except staghorn sculpin and arrow goby. Model results were about two times field results for California halibut and spotted sand bass, suggesting that some model assumptions

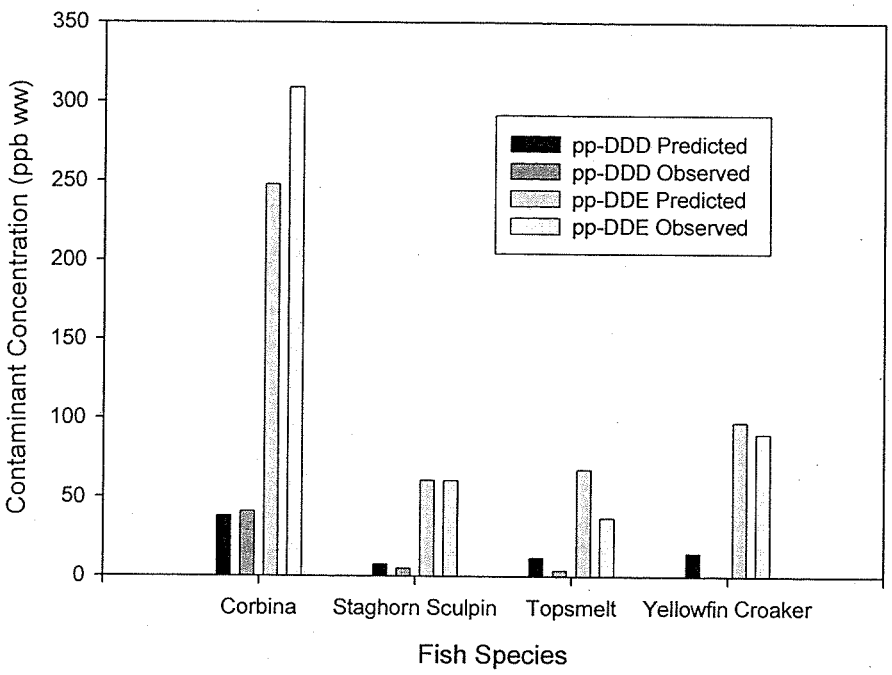
may have been incorrect (Figure 4.15). When the DDT congeners p,p'-DDE and p,p'-DDD were evaluated on a wet weight basis for four fish species, there was good correspondence between model output and field empirical data (Figure 4.16).

Figure 4.15. Comparison of mean model output (white bars) and empirical field data (grey bars) for fish tissue DDTs in Newport Bay. Results are presented on a lipid weight basis (ng/g lipid). Error bars represent model variation (two * standard deviation) and field mean estimates (two * standard error).



There are many possible explanations for the discrepancy between model and empirical results for California halibut and spotted sand bass. These include limited field sample availability and spatial coverage (Table 4.1) (see also Allen *et al.* 2004) or migration of the captured fish from less contaminated offshore locations. One possible explanation for model results higher than field concentrations is that the model does not include metabolic breakdown of DDTs. Although metabolic dechlorination of DDTs is known to occur in finfish (van der Oost *et al.* 2003) at higher rates than PCB breakdown, actual rates are not well characterized (van der Linde *et al.* 2001, Bayen *et al.* 2005). Another possible explanation for the discrepancy between model and field results is that dietary specifications for the model may have been incorrect. Many of the dietary studies for Newport Bay were not recent (Appendix T), and indicated high piscivory by California halibut and spotted sand bass, in addition to sand bass dietary reliance on echinoderms. Changing input parameters to increase reliance on benthic amphipods, mollusks, and annelids brought model results closer to field observations (data not shown).

Figure 4.16. Comparison of mean model output and empirical field data for fish tissue concentrations of p,p'-DDD and p,p'-DDE in Newport Bay. Results are presented on a wet weight basis. California corbina and yellowfin croaker results are for muscle fillets. Staghorn sculpin and topsmelt results are for whole body samples.



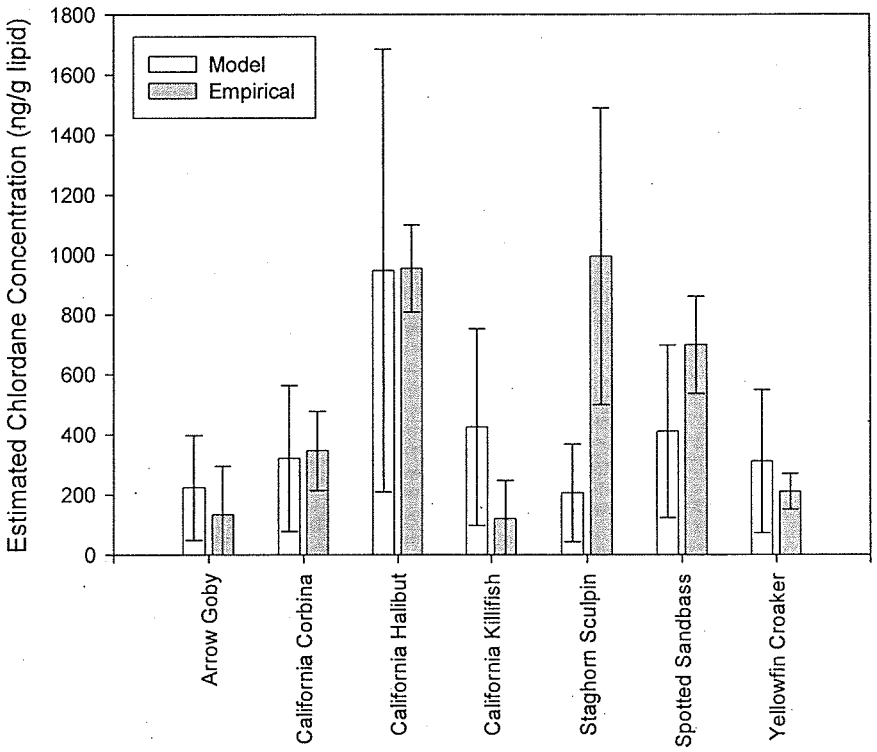
Although data are lacking on Newport Bay resident invertebrate contaminant chemistry, Sutula *et al.* (2005) did determine total DDTs in four amphipod and four bivalve samples collected from Upper Newport Bay. Comparing mechanistic model predictions with the field observations of Sutula *et al.* (2005) indicated that results corresponded only within an order of magnitude [34]. Model predicted amphipod BAF for total DDTs (1.5) was higher than the observed geometric average BAF (0.6) but similar to the observed maximum of 1.6. Model predicted bivalve BAF (4.1) was an order of magnitude higher than the observed BAF (geometric average = 0.3; maximum = 1.2). Given the small sample size and limited spatial scale of the field data set, it is difficult to generate broad conclusions based on these comparisons. The lack of correspondence for bivalves may result from DDT depuration within tissues, reduced bioavailability of sediment-bound DDT at the collection site, or spatial variation in pesticide concentrations and bioavailability (Masters and Inman 2000).

Correspondence between model predicted and field-observed chlordane concentrations was good for four of seven species examined (arrow goby, California corbina, California halibut, and yellowfin croaker; Figure 4.17). Model predictions were lower than field

[34] Dry weight BAF values reported in Sutula *et al.* (2005) are multiplied by 0.25 estimated proportion dry matter in total sample to achieve BAF in g wet wt. tissue/g dry wt. sediment.

observations for staghorn sculpin and spotted sand bass, and higher than field observations for California killifish.

Figure 4.17. Comparison of mean model output (white bars) and empirical field data (grey bars) for fish tissue total chlordanes in Newport Bay. Results are presented on a lipid weight basis (ng/g lipid). Error bars represent model variation (two * standard deviation) and field mean estimates (two * standard error).



For total PCBs, it was not possible to develop confident estimates of field concentrations because the vast majority of congeners were below method detection limits and the detection limits were relatively high (5 ng/g) (Allen *et al.* 2004). For example, if a field sample were below detection for all 20 modeled PCB compounds, the actual concentration could be between 0 ng/g and 100 ng/g, the latter value calculated as total number of compounds (20) multiplied by the detection limit for each compound (5 ng/g). Figure 4.18 shows the wide potential range of concentrations that would be consistent with the observed field data. Model calculated total PCBs were close to the low field concentration estimate for California killifish and yellowfin croaker, and were intermediate between the two field concentration estimates for the other five species compared (Figure 4.18).

Model results indicate that the PCB concentration estimates in Allen (2004), which are used in the fish tissue line of evidence (Table 4.6), are likely to be considerably less than actual PCB fish tissue concentrations in Newport Bay. This is because the model

predicted PCBs below the 5 ng/g detection limit, but above 0 ng/g for all congeners. As a result, model predicted total PCBs were between 19 and 108 ng/g, although measurable concentrations using 5 ng/g detection limits would often be zero (Table 4.15). Detection limits in other monitoring studies are often at 0.2 ng/g for individual congeners (e.g., Davis *et al.* 2000, Greenfield *et al.* 2003). Modeled fish tissue concentrations were generally above these achievable detection limits (Figure 4.19). Given that human health screening values for total PCBs can be as low as 2.5 to 20 ng/g (Appendix K, Table K.1), future fish tissue PCB analyses for human health risk characterization should attempt to achieve these lower detection limits.

Figure 4.18. Comparison of mean model output (white bars) and empirical field data (grey and blue bars) for fish tissue total PCBs in Newport Bay (ng/g lipid). Results are presented on a lipid weight basis. Field results are presented with two different treatments of values below detection limits. For the low estimate, all compounds below detection limits were treated as zero. For the high estimate, all compounds below detection limits were treated as equal to the detection limit (5 ng/g wet). Error bars represent model variation (two * standard deviation) and field mean estimates (two * standard error).

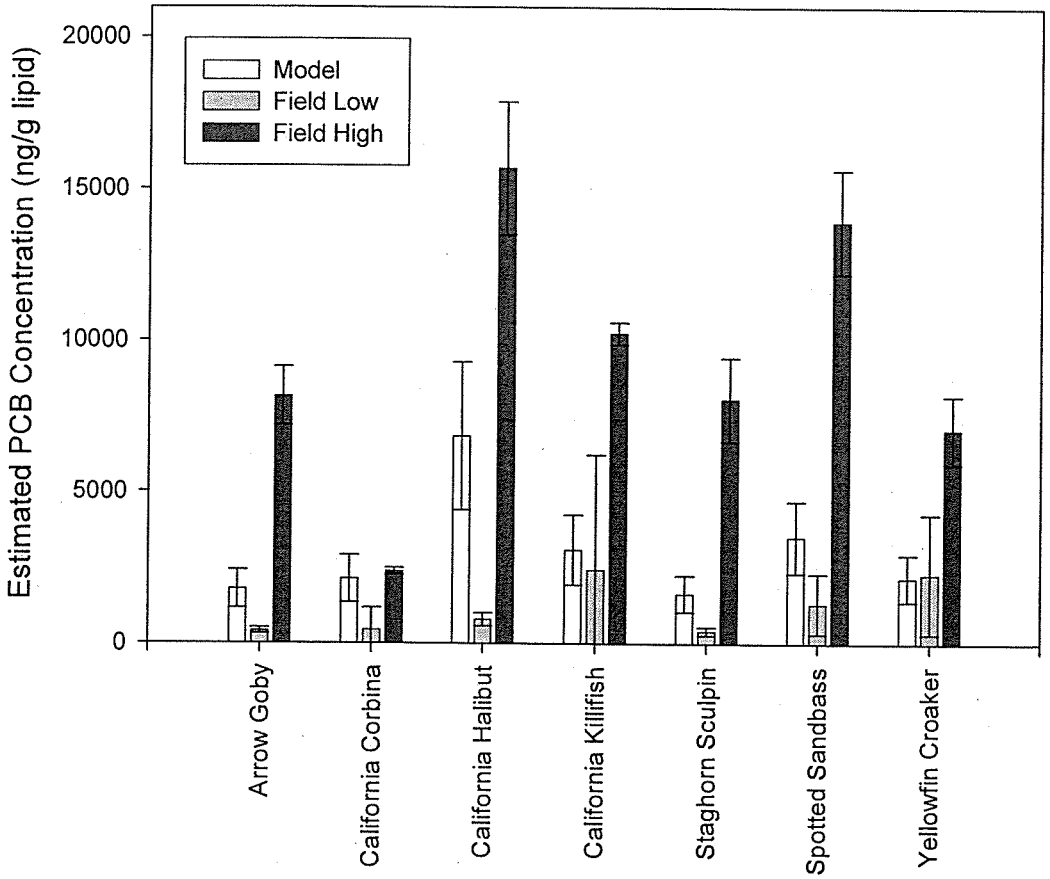


Table 4.15. Summary of results of model simulation evaluating individual PCB congeners as compared to detection limits in currently available studies. WB = whole body. % < DL = percent of the 20 modeled congeners that were present in Newport Bay sediments (Appendix N) but below tissue detection limits of 5.0 ng/g. Exposure estimate = the sum of model predicted PCB concentrations, including those residues that are below detection limits. Estimate with high DLs = sum of only those PCB congeners predicted to be > 5.0 ng/g.

Species	Tissue type	% < DL	Exposure estimate (ng/g wet)	Estimate with high DLs (ng/g wet)
Shiner surfperch	WB	100	19	0
Pacific staghorn sculpin	WB	100	19	0
Spotted sand bass	Fillet [a]	100	27	0
Topsmelt	WB	100	24	0
Arrow goby	WB	100	19	0
California killifish	WB	100	40	0
Yellowfin croaker	Fillet [a]	100	31	0
Striped mullet	WB	45	108	78
California halibut	WB	100	55	0
California halibut	Fillet [a]	100	36	0
California corbina	Fillet [a]	65	85	44

a. Fillet concentration estimated as lipid weight normalized concentration using model output whole ^{body} concentrations and the whole body vs. fillet lipid ratios in Table 4.13.

Overall, model simulation results were reasonably consistent with field observed BAFs for organochlorine contaminants in Newport Bay fish. DDTs and chlordanes corresponded well for many fish species, and modeled PCB concentrations were within the range of the relatively uncertain field values. In particular, field-observed tissue concentrations were not substantially greater than model predictions, based on Newport Bay sediment and water column concentrations. This result supports the conceptual interpretation that tissue concentrations in Newport Bay fish result from dietary and respiratory exposure to sediment and water column contaminants within the Bay. Monte Carlo simulation results indicated that uncertainty of predicted BAFs was more consistent with arithmetic (rather then geometric) techniques of estimating empirical uncertainty.

4.4.3. Sediment thresholds comparison

4.4.3.1. Approach - evaluation of multiple scenarios

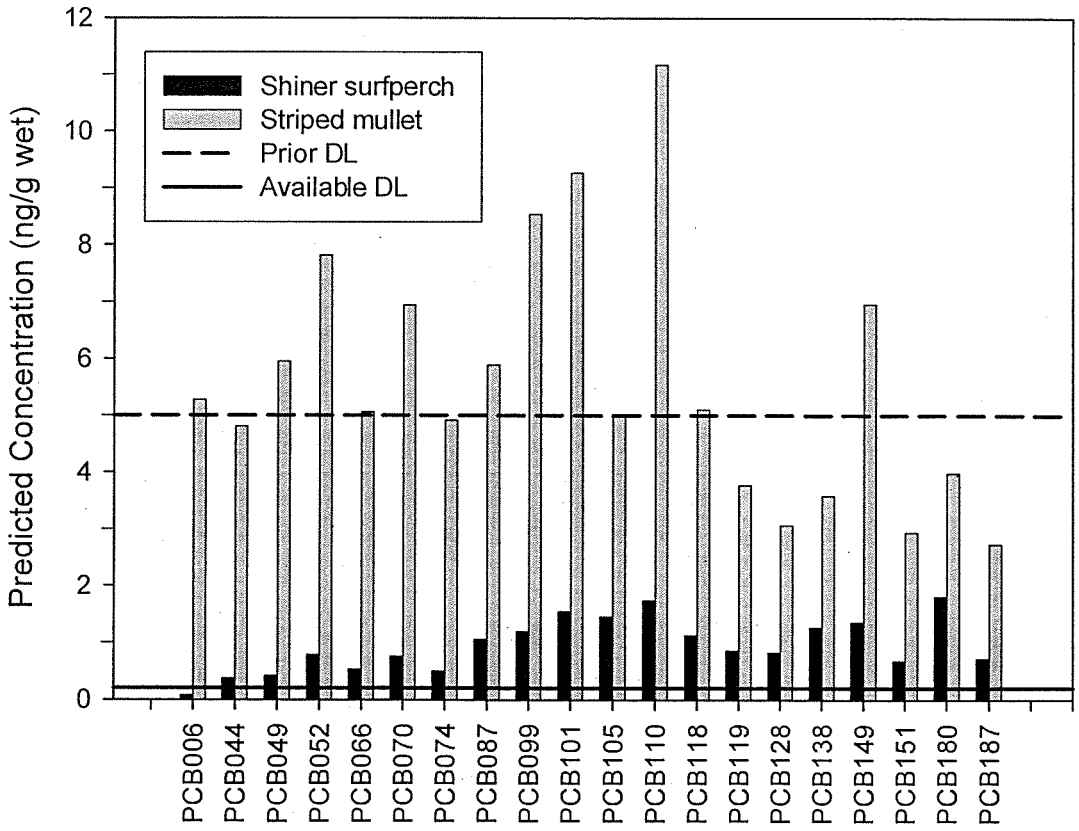
Given that the mechanistic model findings supported use of the empirical BAFs, the analysis proceeds to development of sediment thresholds and final sediment evaluation. However, a number of decisions affect the development of sediment thresholds (Tables 4.9 and 4.16). These include tissue percent lipid, assumptions that affect prey tissue thresholds (including consumption rate and allowable increased carcinogenic risk), and

BAF averaging method (arithmetic vs. geometric). The sediments selected for evaluation will also affect the results. In this section, multiple scenarios are performed to evaluate the effects of different assumptions on the final sediment assessment.

Because the empirical BAFs were developed based on lipid weight tissue concentrations and the effects thresholds are based on wet weight tissue concentrations, it is necessary to back-calculate to wet weight tissue concentrations in order to develop sediment thresholds:

$$\text{Sediment threshold (ng/g dw)} = \frac{\text{Prey tissue threshold (ng/g wet)}}{\text{BAF(g dw/g lipid)} \times \text{\% Lipid (g lipid/g wet)}}$$

Figure 4.19. Model output for 20 PCB congeners for shiner surfperch and striped mullet in Newport Bay. Horizontal lines represent the detection limit from recent studies (dashed line) and detection limits that are readily available in contract analytical labs (solid line).



Prey tissue thresholds for the Newport Bay case study were presented in Tables 4.3 and 4.4. Average and 95% upper confidence interval BAFs were presented in Table 4.11. Tissue lipid content must be estimated, and is influenced by assumptions such as prey

types and proportions. Appendix W describes the procedures used and results obtained for estimating prey tissue lipid content for the case study.

Table 4.16. Summary of assumptions, their basis, and effects on developing sediment thresholds for the sediment chemistry LOE, Newport Bay case study. This represents the baseline scenarios (Scenarios A and AA). The impact of key decisions is also evaluated using alternative scenarios (Tables 4.17 and 4.18). See also Table 4.9.

Decision or assumption	Basis	Effect
Use SARWQCB Staff requested human target population and cancer risk	See Table 4.5	Higher incidence of exceeding thresholds than other sets of assumptions (Tables 4.19 – 4.21)
Evaluate wildlife risk using least tern	The assessment framework should be protective of the most sensitive wildlife species, which is calculated to be least tern	Slightly higher incidence of exceeding low threshold than other assumptions. No effect on high threshold (Tables 4.19 - 4.21)
Use empirical arithmetic average BAFs (rather than geometric averaging) to develop sediment thresholds	Mechanistic model results and uncertainty more consistent with arithmetic averaging method	Lower incidence of exceeding thresholds for arithmetic calculations than geometric calculations (Tables 4.19 - 4.21)
Base the high threshold on an average (50%ile) estimate of bioaccumulation factor	Less conservative threshold protects the average consumer (see Section 3.2.7)	
Base the low threshold on an 95% upper confidence limit estimate of average bioaccumulation factor	More conservative threshold protects the average consumer, including a protection factor to account for uncertainty in the estimate of bioaccumulation (see Section 3.2.7)	Greater than 95% probability that the bioaccumulation estimate is equal to or greater than the actual average bioaccumulation in Newport Bay
Calculate prey lipid based on average of primary prey species	Actual prey consumption preferences are not known for Newport Bay (further discussed in Appendix W)	For humans, higher incidence of exceeding thresholds than other sets of assumptions (Tables 4.19 - 4.21). For wildlife, unknown effect.

To ascertain the impact of different assumptions on final sediment assessment, a number of scenarios were compared. These are summarized in Tables 4.17 and 4.18, and described below:

Baseline Scenarios A and AA Baseline scenarios were developed for both human and wildlife receptors (Tables 4.17 and 4.18). For the human receptor (Scenario A), prey tissue concentration thresholds were developed based on local agency requests (Appendix P). This included a variable 10^{-5} to 10^{-6} allowable increased cancer risk, and consumption rates based on Allen *et al.* (1996). The resulting tissue thresholds are summarized in Table 4.3. For the wildlife receptor (Scenario AA), prey tissue concentration thresholds were developed based on protecting least tern, which is the most sensitive wildlife endpoint[35] (Table 4.4). For both scenarios, BAFs were developed using

[35] Here sensitivity is defined based on having the lowest effects threshold, using the approach outlined in Section 3.1.

arithmetic average and upper confidence limits (following Table 4.11). Tissue percent lipid was calculated as the average of major human or wildlife prey species (Appendix W). All sediment samples collected in Newport Bay since 1997 were compared to the thresholds in the baseline scenario. Fifty-seven samples collected in four studies were evaluated (Table Q.3 in Appendix Q).

Table 4.17. Eight scenarios to evaluate effects of varying assumptions on sediment threshold development for human receptors in Newport Bay. A = arithmetic averaging; G = geometric averaging.

Scenario	Description	Prey species to estimate tissue lipid	Cancer risk factor	Fish consumption rate (g/d)	Statistical method for BAF	Sediment data included
A	Baseline scenario	All human prey	10^{-6} to 10^{-5}	21	A	All
B	Lipid estimate based on resident human prey	Resident species	10^{-6} to 10^{-5}	21	A	All
C	Lipid estimate based on catch rates in Allen *et al.* (1996)	Weighted by capture rate	10^{-6} to 10^{-5}	21	A	All
D	Subsistence fisher consumption rate (U. S. EPA 2000b)	All human prey	10^{-6} to 10^{-5}	142	A	All
E	10-fold increase in allowable cancer risk factor	All human prey	10^{-5} to 10^{-4}	21	A	All
F	Risk assumptions from Table K.1	All human prey	10^{-5}	17.5 to 32	A	All
G	Determine BAF using geometric average and error estimation	All human prey	10^{-6} to 10^{-5}	21	G	All
H	Excluding Rhine Channel data	All human prey	10^{-6} to 10^{-5}	21	A	Exclude Rhine Channel

Alternative scenarios

Varying prey species for tissue lipid estimation (Scenarios B and C). These scenarios determine the sensitivity of results to prey tissue estimated lipid content (Table 4.17). Source data and calculations for these scenarios are described in Appendix W.

In the baseline scenario for effects to human consumers, prey tissue percent lipid was calculated based on all human prey species. In these alternate scenarios, prey tissue lipid content were based on estimated dietary proportions from the Santa Monica Bay seafood consumption study (Allen *et al.* 1996) (Scenario B) or based on using resident Newport Bay fish species only (Scenario C).

Varying risk assessment policy decisions (Scenarios D, E, F, BB, and DD). The framework (and risk assessments in general) is highly sensitive to policy decisions about target population and allowable risk (Appendix K, Table K.1). Five scenarios were run to explore this issue (Tables 4.17 and 4.18). These scenarios evaluate different combinations of assumptions and their final effect on the case study results. In Scenario D, tissue thresholds are calculated based on expected consumption rates for human subsistence fishers (142 g/d) (U. S. EPA 2000b), which is more conservative than the baseline Scenario A. Scenario E modifies the allowable increased cancer risk by an order of magnitude, changing it from 10^{-5} for the lower threshold and 10^{-6} for the higher threshold to 10^{-4} and 10^{-5}, respectively. In Scenario F, thresholds are calculated based on the assumptions outlined in Table 4.2 and Appendix K (Table K.1, grey rows). These include a 10^{-5} allowable increased cancer risk and average and UCI sport fisher consumption rate estimates. This scenario results in a less conservative set of assumptions, particularly for the low threshold. Scenarios BB and DD (Table 4.18) develop thresholds based on protection of brown pelican. Because of its larger size and consequent lower specific consumption rate, brown pelican prey tissue thresholds are four times higher than least tern thresholds (Table 4.4).

Table 4.18. Five scenarios to evaluate effects of varying assumptions on sediment threshold development for wildlife receptors in Newport Bay. A = arithmetic averaging; G = geometric averaging.

Scenario	Description	Wildlife species	Statistical method for BAF	Sediment data included
AA	Baseline scenario	Least tern	A	All
BB	Larger bird species	Brown pelican	A	All
CC	Geometric method to calculate BAF	Least tern	G	All
DD	Larger bird species and geometric method	Brown pelican	G	All
EE	Exclude Rhine Channel data	Least tern	A	Exclude Rhine Channel

Calculating BAF using geometric calculations (Scenarios G, CC, and DD). BAF results differed substantially between arithmetic and geometric approaches. Using geometric methods, average and UCI BAFs were substantially higher than arithmetic methods (Table 4.11). Scenarios G, CC, and DD evaluate the impact of the geometric approach on sediment thresholds and on the consequent number of samples that exceed the thresholds. These scenarios are for humans, least terns, and brown pelicans, respectively.

Inclusion vs. exclusion of Rhine Channel sediments (Scenarios H and EE). Newport Bay exhibits spatially variable contaminant concentrations (Figures 4.6 and 4.7). For example, the highly industrialized Rhine Channel has been identified as a hot spot of contaminant concentrations and toxicity (Bay and Brown 2003, Bay *et al.* 2004, Anchor Environmental 2005). Sediment sampling locations across the Bay preferentially included the Rhine Channel, with a site-specific evaluation of Rhine Channel (Bay and Brown 2003) comprising 15 of the 57 Newport Bay sediment samples (Appendix Q, Table Q.3). To evaluate the impact of this contaminant hotspot on overall assessment

results, Scenarios H and EE were run following baseline assumptions for humans and least tern, but excluding the 15 Rhine Channel Study samples from evaluation.

4.4.3.2. Results

In the baseline scenarios, the low sediment chemistry thresholds for human health effects ranged between 1.3 and 1.9 ng/g dry weight (Tables 4.19, 4.20, and 4.21). Because detection limits for sediment compounds are around 1 ng/g in many studies (e.g., Masters and Inman 2000, Bay and Brown 2003, Bay *et al.* 2004), almost any detectable contaminant residue in sediment would exceed the low threshold. This finding supports the use of a sequential approach (Figure 2.2). The tissue chemistry LOE evaluates whether wildlife or human consumers are actually at risk due to consumption of contaminated prey in the water body. In cases where the prey tissue line of evidence indicates low risk to predators, the results of the sediment chemistry LOE would not affect the outcome of the analysis. For the Newport Bay case study, total PCBs for wildlife and total chlordanes for both humans and wildlife have already been placed in the low-risk category, based on the tissue chemistry line of evidence.

In the baseline scenarios, high sediment chemistry thresholds for human effects ranged between 22.4 and 27.3 ng/g dry weight (Scenario A in Tables 4.19 – 4.21). These thresholds are approximately ten times the low thresholds. Wildlife thresholds were generally well above the comparable thresholds for human effects. For example, the PCB low and high sediment thresholds for least tern were 76 and 2177 ng/g, approximately 50 to 100 times the human thresholds (Table 4.20). The one case where wildlife thresholds were similar to human thresholds was the low sediment threshold for DDT effects to least tern (Table 4.19; 2.1 ng/g for wildlife vs. 1.9 ng/g for humans). As discussed in Appendix H, these thresholds are based on the Navy/BTAG TRVs (California DTSC Human and Ecological Risk Division 2000), which in turn are based on field monitoring of impacts of DDT discharged off the southern California coast to brown pelicans (Anderson *et al.* 1975, Anderson *et al.* 1977).

As observed for the prey tissue line of evidence, results for the sediment chemistry LOE varied by contaminant. For DDTs, despite the variety of scenarios examined, the majority of sediments were consistently above the low sediment threshold for both human and wildlife receptors (Table 4.19). Following the assessment framework (Table 2.1; Figure 2.2), this would result in categorization of most sediments into two categories: possible impact and likely impact. For PCBs and chlordanes, results were more variable for both the low and high thresholds (Tables 4.20 and 4.21). However, the high thresholds for avian predators were not exceeded for any contaminant class (Tables 4.19, 4.20, and 4.21).

Table 4.19. Sediment threshold development assumptions and results for DDTs. Percentage of sediments above thresholds are based on actual data from Newport Bay (N = 57; see Appendix Q, Table Q.3). Proportion of baseline = how the scenario threshold compares to the relevant baseline threshold. E.g., 0.1 indicates that the new threshold is 10% of the baseline threshold.

Scenario	High tissue threshold (ng/g wet)	Low tissue threshold (ng/g wet)	Average BAF (g lipid/g dry) [a]	95% UCI BAF (g lipid/g dry) [a]	Tissue % lipid	Low sediment threshold (ng/g dry)	High sediment threshold (ng/g dry)	% sediments above low	% sediments above high	Proportion of baseline

a. From Table 4.11

In the scenario comparisons, both risk assessment assumptions and averaging method (arithmetic vs. geometric) substantially influenced sediment thresholds. Changing to geometric averaging methods (Scenario G), increasing allowable cancer risk tenfold (Scenario E), and switching to subsistence fisher consumption rates (Scenario D) each caused an order of magnitude or greater difference in sediment thresholds for DDTs, PCBs and chlordanes (Tables 4.19, 4.20, and 4.21). These changes often resulted in a different categorization of the majority of sediments. For example, when allowable increased cancer risk was switched from 10^{-5} to 10^{-4} (Scenario E), the percent of sediment samples exceeding the high human health threshold for DDTs changed from 63% to 0% (Table 4.19). Changes were particularly strong using geometric averaging for PCBs (Table 4.20). Evaluating human risk (Scenario G) and least tern risk (Scenario CC), thresholds were reduced 50 to 100 fold using geometric methods. However, because these thresholds were generally well above or well below observed contaminant

concentrations, there was little change in the number of sediments that exceeded the thresholds (Table 4.20).

Table 4.20. Sediment threshold development assumptions and results for PCBs. Percentage of sediments above thresholds are based on actual data from Newport Bay (N = 46; see Appendix Q, Table Q.3). Proportion of baseline = how the scenario threshold compares to the relevant baseline threshold.

a. From Table 4.11.

Changing the method of calculating prey lipid (Scenarios B and C) had less of an effect on the thresholds. Nevertheless, for DDTs, switching to the percent lipid for resident prey (Scenario B) resulted in the percentage of sediments above the high threshold declining from 63% to 11% (Table 4.19). This finding again indicates the high sensitivity of these evaluations to the chosen combinations of assumptions.

Exclusion of the Rhine Channel sediments (Scenario H) did affect the human health assessment for PCBs and chlordanes. With Rhine Channel sediments included, 63% and 37% of samples exceeded the low and high PCB thresholds, respectively. When these sediments were excluded from the analyses, the number of sediments above the thresholds declined to 45% and 10%, respectively (Table 4.20). For chlordanes (Table 4.21), the opposite effect occurred. Because all of the Rhine Channel sediments were below detection for chlordanes (Appendix Q, Table Q.3), excluding them from the

analysis actually caused the number of samples above the low threshold for humans to increase from 54% to 91%.

Table 4.21. Sediment threshold development assumptions and results for chlordanes. Percentage of sediments above thresholds are based on actual data from Newport Bay (N = 37; see Appendix Q, Table Q.3). Proportion of baseline = how the scenario threshold compares to the relevant baseline threshold.

Scenario	High tissue threshold (ng/g wet)	Low tissue threshold (ng/g wet)	Average BAF (g lipid/g dry) a	95% UCI BAF (g lipid/g dry) a	Tissue % lipid	Low sediment threshold (ng/g dry)	High sediment threshold (ng/g dry)	% sediments above low	% sediments above high	Proportion of baseline

4.4.4. Summary for sediment chemistry LOE

Based on thresholds calculated for Newport Bay, sediments were found to occur in all three risk categories, with more frequent exceedances for DDTs than PCBs or chlordanes. However, thresholds were very sensitive to a variety of assumptions and judgments. These assumptions included allowable risk, consumption rate, data statistical distribution and prey lipid. Table 4.22 categorizes the scenario results in terms of relative impact on overall conclusions for the sediment chemistry LOE.

For both the human and wildlife scenario evaluations, averaging method (arithmetic vs. geometric) strongly impacted outcome of the evaluation (Table 4.22, Scenarios G and CC). Calculation of geometric averages and standard deviations increased the uncertainty of estimates, resulting in much lower thresholds (Tables 4.19 – 4.21). For PCBs and chlordanes, these changes resulted in substantial increases in the number of

sediment samples exceeding one or both of the sediment chemistry thresholds (Tables 4.20 and 4.21).

Table 4.22. Summary of scenario evaluation. The relative impact on the outcome is summarized for each contaminant, based on proportion of baseline BAF and threshold comparison results (Tables 4.19 – 4.21). L = relatively low impact on outcome. M = moderate impact. H = relatively high impact on outcome.

Scenario	Description	Assumptions Changed	Impact of change on DDT results	Impact of change on PCB results	Impact of change on Chlordane results	Overall impact
A	Baseline scenario					
B	Lipid estimate based on resident human prey	Prey biology	M	M	L	M
C	Lipid estimate based on catch rates in Allen *et al.* (1996)	Prey biology	L	L	L	L
D	Subsistence fisher consumption rate (U. S. EPA 2000b)	Target population	H	H	H	H
E	10-fold increase in allowable cancer risk factor	Allowable risk	H	H	H	H
F	Risk assumptions from Table K.1	Allowable risk and target population	M	M	H	M
G	Determine BAF using geometric average and error estimation	Statistical assumptions	M	H	H	H
H	Excluding Rhine Channel data	Study spatial area	L	M	H	M
AA	Baseline scenario					
BB	Larger bird species	Target population	L	H	L	M
CC	Geometric method to calculate BAF	Statistical assumptions	L	H	H	H
DD	Larger bird species and geometric method	Allowable risk and statistical assumptions	L	H	M	M
EE	Exclude Rhine Channel data	Study spatial area	L	H	L	M

For humans, Scenarios D and E caused the greatest effects on outcome. These scenarios changed standard risk assessment parameters. Scenario D changed assumptions regarding the definition of the target population to protect and Scenario E changed the acceptable level of increased carcinogenic risk. Both of these parameters are strongly

influenced by policy decisions, which often vary among water bodies based on agency judgments (Hamilton and Viscusi 1999, U. S. EPA 2000b). These findings support the need for substantial efforts to engage stakeholders in framework application, to adequately resolve these policy issues (U. S. EPA 1997, 1998, Bridges *et al.* 2005).

4.5. Bioavailability line of evidence

The bioavailability line of evidence is recommended as a final step when there are questions raised as to bioavailability of sediment-associated contaminants. In particular, this line of evidence is applied when the first two lines of evidence result in intermediate risk categories (following Figure 2.2). In the Newport Bay case study, some of the sediment chemistry results combined with prey tissue chemistry did indicate intermediate levels of apparent risk (i.e., categories B and C in Figure 2.2). Based on the framework (Table 2.1, Figure 2.2), it would then be appropriate to proceed to the bioavailability line of evidence for this case study.

The purpose of the bioavailability line of evidence is to confirm that the contaminants in question are bioavailable from local sediments to biota. Literature evidence strongly indicates bioavailability of DDTs and PCBs in marine and estuarine sediments in California and elsewhere (Ferraro *et al.* 1990, Boese *et al.* 1997, Brown *et al.* 1998, Zeng and Tran 2002, Kuzyk *et al.* 2005b). Based on the framework, use of this literature information may be sufficient to assume bioavailability (following Section 3.3.1). Nevertheless, to demonstrate the method, bioaccumulation data were assembled and evaluated specifically for Newport Bay.

4.5.1. Methods

Data used to investigate bioavailability of contaminants in Newport Bay sediments were obtained from a study funded by the U. S. Army Corps of Engineers (MEC Analytical Systems 2003). The objective of this sampling and analysis program was to characterize the sediments to be dredged from Upper Newport Bay as part of a proposed restoration project. Bioaccumulation was investigated in laboratory tests on *Macoma nasuta* (clam) and *Nereis virens* (polychaete). The tests used sediments collected from eleven stations in Upper Newport Bay. Evaluation of bioaccumulation potential was not performed at Lower Newport Bay.

According to the study report (MEC Analytical Systems 2003), bioaccumulation testing followed guidance outlined in the Ocean Testing Manual (U. S. EPA and U. S. Army Corps of Engineers 1991) and U. S. EPA (1994). Homogenized sediment of known field concentration were administered to "contaminant-free" test organisms in a laboratory environment, with test conditions monitored throughout the experiments. Tissue analyses were subsequently performed after 28 days to determine the availability of sediment contaminants taken up by the test organisms. These 28 day Tier III bioaccumulation tests are generally considered to be sufficient to assess the potential for bioaccumulation, though equilibrium may not be reached in the 28 day time period (McFarland 1998, U. S. EPA 2000a).

The analyses were used to demonstrate whether a consistent relationship between biota contaminant concentration and sediment contaminant concentration could be shown. All tissue values for *Nereis virens* were below detection. Therefore, only *Macoma nasuta* could be evaluated for the bioavailability of contaminants. The arithmetic mean final p,p'-DDE concentration in *M. nasuta* from each station was compared to the administered homogenized-sediment concentration. Individual sample concentrations that were below detection limits were treated as half the detection limit. For p,p'-DDE, analysis methods employed in this study were sufficient to detect concentrations above 2 μg/kg. Methods to evaluate levels of PCBs, chlordanes, and dieldrin were only sufficient to detect concentrations above 5 μg/kg.

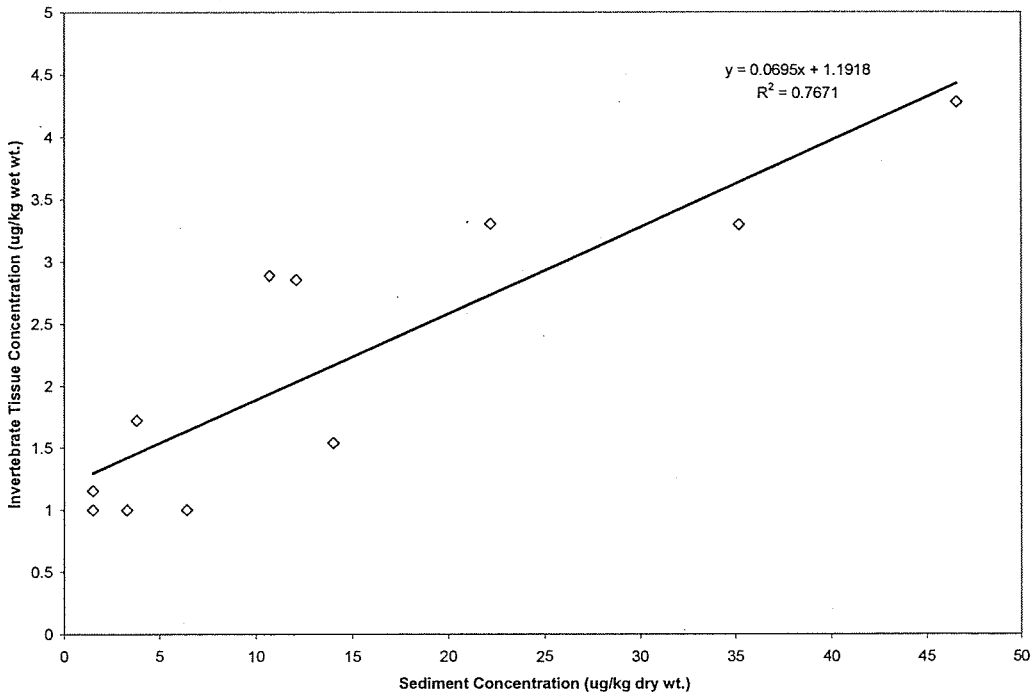
Linear regression analysis was applied to compare sediment concentration to *M. nasuta* tissue values (following Section 3.3.2). Data sufficiently met assumptions of normality, equal variance, and independence. A significant positive relationship in this comparison would indicate that a compound is bioaccumulating and is therefore bioavailable to *M. nasuta*.

4.5.2. Results

A statistically significant linear relationship ($R^2 = 0.77$, $p = 0.0004$) was observed in p,p'-DDE (Figure 4.20). The lowest sediment and tissue concentrations shown at the bottom-left of the plot represent the non-detectable results. The regression indicated a positive relationship between sediment and tissue p,p'-DDE concentration; as sediment concentration increases, there was a general linear increase in tissue concentration. The results were still significant when the values below detection were removed from the analysis.

Concentrations in all samples were below detection for PCBs, chlordanes, and dieldrin. However, the detection limits for these compounds were relatively high. The detection limits are 5 ng/g, which are higher than some of the sediment and prey tissue thresholds (Tables 4.3, 4.19 - 4.21). Therefore, bioaccumulation test results were inconclusive for these compounds.

Figure 4.20. Linear regression of sediment p,p'-DDE concentration vs. *Macoma nasuta* p,p'-DDE concentration.



4.6. Final assessment of Newport Bay sediments

To illustrate the framework, a "final assessment" of Newport Bay sediments may be conducted based on the baseline scenario assumptions laid out throughout this section (Tables 4.3, 4.5, 4.9, and 4.16 - 4.18). The intent of this assessment is for illustrative purposes only. The results of the prey tissue and sediment chemistry lines of evidence were particularly sensitive to many scientific and policy assumptions, and should be viewed in this light.

When results for all lines of evidence were combined following Table 2.1, the assessment framework indicated unlikely impact of sediment chlordanes to local wildlife or humans, and unlikely impact of PCBs to local wildlife (Table 4.23). This designation resulted from the prey tissue line of evidence being below the low threshold. The assessment framework indicated possible impact of DDTs to birds, because the prey tissue and sediment chemistry lines of evidence were both intermediate between the low and high thresholds. For impacts of DDTs and PCBs to humans, the assessment framework varied for individual stations among unlikely impact, possible impact, and likely impact. No sediments were categorized as having clear impact (the highest risk category). This is because average prey tissue concentrations were always below the high threshold (following Table 2.1). In this case study, the bioaccumulation test results did not change the initial findings reached with the prey tissue and sediment chemistry lines of evidence.

This is because the test either indicated bioavailability (for DDTs) or was inconclusive due to high detection limits (for PCBs and chlordanes).

Evaluating impacts to humans, distinct spatial patterns were observed in sediment assessment results. PCBs exhibited the higher risk category (likely impact) in sediments within and adjacent to the Rhine Channel, the "possible impact" category along the channels in lower Newport Bay, and the "unlikely impact" category throughout upper Newport Bay (Figure 4.21). DDT results varied between two impact categories, with "possible impact" and "likely impact" samples located throughout upper and lower Newport Bay (Figure 4.22).

In closing, it should be stated that the assessment framework is not designed to indicate whether remediation is needed; this is a management decision that must be influenced by policy and economic considerations beyond the scope of the framework. Nor does the assessment framework evaluate among remediation alternatives, such as dredging, capping, best management practices or monitored natural recovery. Nevertheless, the spatial pattern of sediment categories does indicate that for PCBs, relatively contaminated areas are all in the same location. This finding may have implications for the relative costs and benefits of specific remediation alternatives, if remediation is determined to be an appropriate course of action.

Figure 4.21. Final characterization of Newport Bay sediments for PCBs following the baseline scenario assumptions for risk to humans. Green squares = unlikely impact. Yellow diamonds = possible impact. Red circles = likely impact.

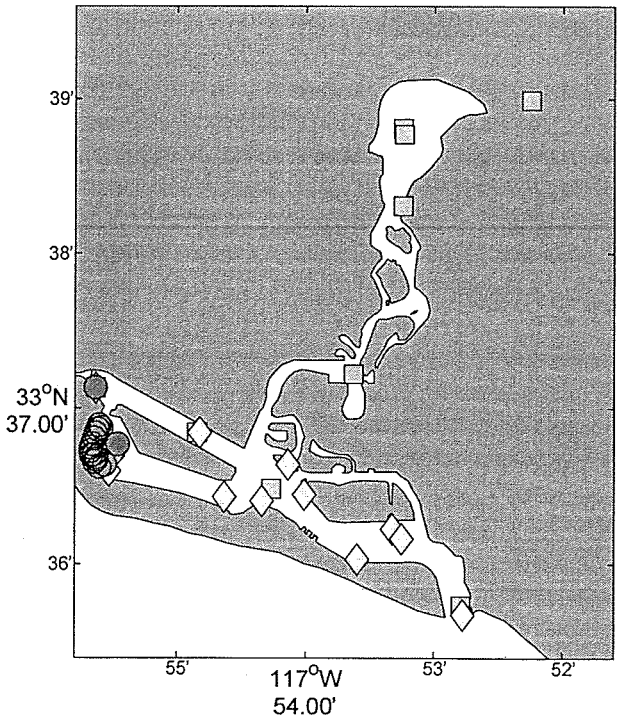


Figure 4.22. Final characterization of Newport Bay sediments for DDTs following the baseline scenario assumptions for risk to humans. Yellow diamonds = possible impact. Red circles = likely impact.

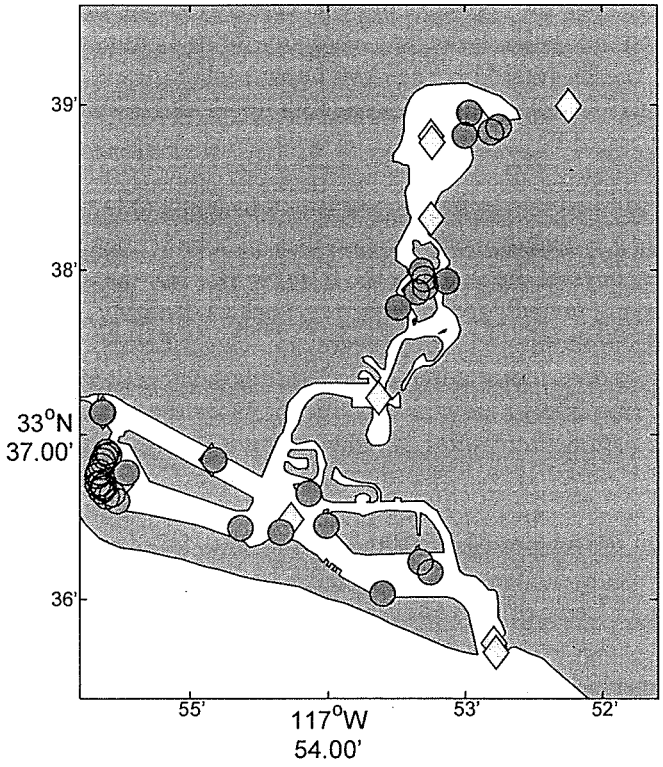

Table 4.23. Summary of results from individual lines of evidence and final characterization of Newport Bay sediments.

Compound	Receptor	Field prey tissue chemistry	Sediment chemistry			Bioavailability	Final determination[a]
			Below low	Between	Above high		
DDT	Humans	Between thresholds	0/57	21/57	36/57	Bioavailable	B. Possible impact (21 samples); C. Likely impact (36 samples)
DDT	Birds	Between thresholds	0/57	57/57	0/57	Bioavailable	B. Possible impact
PCBs	Humans	Between thresholds	17/46	12/46	17/46	Inconclusive	A. Unlikely impact (17 samples); B. Possible impact (12 samples); C. Likely impact (17 samples)
PCBs	Birds	Below low threshold	34/46	12/46	0/46	Inconclusive	A. Unlikely impact
Chlordanes	Humans	Below low threshold	17/37	18/37	2/37	Inconclusive	A. Unlikely impact
Chlordanes	Birds	Below low threshold	35/37	2/37	0/37	Inconclusive	A. Unlikely impact

a. Following Section 2.4

5. Application of the assessment framework to evaluate sediments in San Francisco Bay

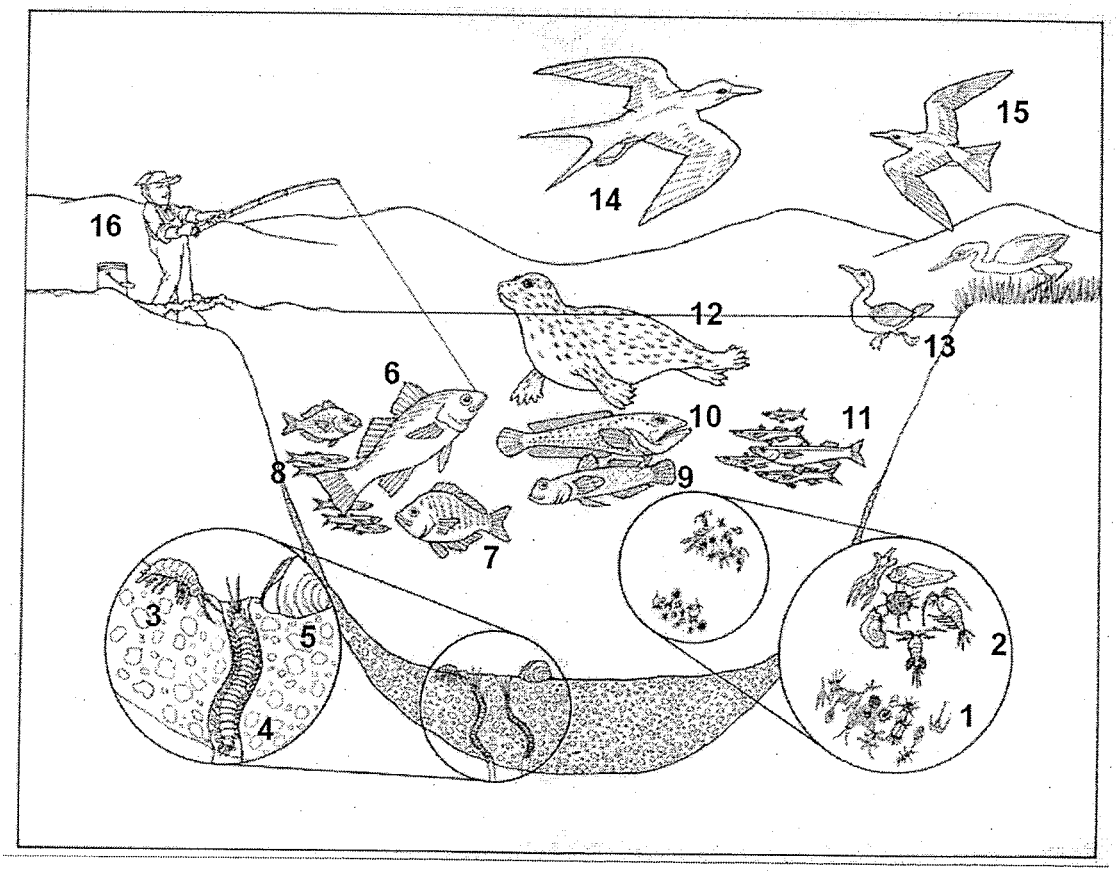
For the San Francisco Bay case study, the assessment framework will be applied to evaluate human health risks from three legacy pesticides: DDTs, chlordanes, and dieldrin. The case study demonstrates application of the framework in a water body having a large historical data set. Due to the extent and breadth of the data set, it is possible to demonstrate several techniques. Using empirical data, a representative fish species is selected for bioaccumulation factor development. The bioaccumulation factor is developed using spatially explicit information on the distribution and expected movement range of the fish. The empirical results are compared to the mechanistic model for pesticides. The model has previously been applied to San Francisco Bay for PCBs (Gobas and Wilcockson 2002, Gobas and Arnot 2005). The mechanistic model is also used to simulate the relative influence of water column vs. sediment contaminants on bioaccumulation. Finally, 28 day laboratory test results are used to illustrate another example of bioavailability of sediment associated DDTs.

5.1. Conceptual model for San Francisco Bay

San Francisco Bay is the largest estuary on the Pacific coast of the Americas, extending from the confluence of the Sacramento and San Joaquin Rivers to the Golden Gate, where the Bay meets the Pacific Ocean. The pesticides DDTs, chlordanes, and dieldrin remain in the San Francisco Estuary as a result of agricultural and residential applications from the early to late 20th century (Connor *et al.* 2006). The Bay is listed as impaired by legacy pesticides on California's 303(d) list because of an interim fish consumption advisory developed by OEHHA. The advisory was based on a 1994 fish tissue study (SFBRWQCB 1995), which indicated that legacy pesticides, PCBs, mercury, and dioxins were present at levels of potential concern. Sources of pesticides entering the Bay include runoff from the Central Valley, runoff from local watersheds, municipal and industrial discharges, atmospheric deposition, erosion of sediments buried beneath the active sediment layer, and dredging and disposal of deep sediments (Connor *et al.* 2006). The Regional Monitoring Program for Water Quality (RMP), a comprehensive contaminant and water quality monitoring program, has collected annual data on legacy pesticide concentrations in San Francisco Bay water, sediments, and bivalves since 1993 (SFEI 2005). The RMP also monitors concentrations of legacy pesticides in sport fish every three years, with the most recent sampling event in 2003 (Connor *et al.* 2006).

A conceptual model for the San Francisco Bay food webs has been described elsewhere (Gobas and Arnot 2005, Davis *et al.* 2006a) and is summarized in Figure 5.1.

Figure 5.1. Conceptual model for the San Francisco Bay food web. Legacy pollutants enter the food web via accumulation by phytoplankton (1) at the base of the food web. Concentrations then increase with each step up the food web, reaching maximum concentrations and posing the greatest health risks in species that consume Bay fish. Phytoplankton (1) are consumed by small animals including zooplankton (2) and invertebrates such as amphipods (3), worms (4), or clams (5). Invertebrates in the sediment also accumulate contaminants directly from sediment through ingestion of particles and from contact with sediment porewater. Fish consume the zooplankton and invertebrates and receive a higher dose of bioaccumulative compounds. Humans (16) and wildlife species consume the fish and receive higher doses. Wildlife consume smaller fish species such as yellowfin goby (9), plainfin midshipmen (10), and anchovy (11). Humans consume larger species such as white croaker (6), shiner surfperch (7), and jacksmelt (8). Wildlife species of concern for bioaccumulation and effects include harbor seals (12), cormorants (13), Forster's terns (14), and the endangered least tern (15). Figure and caption reprinted from Davis *et al.* (2006a).



5.2. Field prey tissue line of evidence

5.2.1. Methods

5.2.1.1. Database preparation

Legacy pesticides in San Francisco Bay have been shown to change significantly over time (Gunther *et al.* 1999, Greenfield *et al.* 2005, Connor *et al.* 2006, O'Connor and

Lauenstein 2006), necessitating use of data from a limited time horizon. For the prey tissue line of evidence, data were compiled from the RMP 2000 and 2003 fish sampling program[36]. All samples in this program are species consumed by local fishers (SFEI 2000), and are prepared for contaminant analysis by filleting, using preparation methods appropriate for human consumption (Davis *et al.* 1999, Greenfield *et al.* 2003).

5.2.1.2. Prey species

The Regional Monitoring Program samples seven species that are known to be consumed by human sport fishers (Davis *et al.* 1999, SFEI 2000) (Table 5.1). Four of these species (shiner surfperch, white croaker, California halibut, and leopard shark) exhibit life history traits that make them appropriate for the prey tissue line of evidence, including dietary benthic association and residence within the Bay for the majority of their life history (see Section 3.1.4 and Appendix B.). For example, contaminant and stable isotope analyses indicate that leopard shark captured within San Francisco Bay generally reside within a specific subembayment, rather than migrating between the Bay and coast (Greenfield *et al.* 2002, Greenfield *et al.* 2003). Total pesticide residues were calculated for these four species combined (N = 87 samples total) and separately calculated for all seven species combined (N = 135 samples total; Table 5.1).

Table 5.1. Potential fish species for tissue concentration evaluation in San Francisco Bay. Species in boldface fit criteria outlined in Section 3.1.4. Bay Resident = species likely resides within Bay throughout most of its lifespan.

Species	Bay resident?	Tissue type	Diet
California halibut	**Yes**	**Skin-off fillet**	**Pelagic/epibenthic**
Jacksmelt	Yes	Skin-on fillet	Pelagic
Leopard shark	**Yes**	**Skin-off fillet**	**Epibenthic**
Shiner surfperch	**Yes**	**Skin-on fillet**	**Epibenthic**
Striped bass	No	Skin-off fillet	Pelagic
White croaker	**Yes**	**Skin-on fillet**	**Pelagic/epibenthic**
White sturgeon	No	Skin-off fillet	Epibenthic

5.2.1.3. Prey sizes and tissue type

The RMP focuses on capturing fish that are legal sized for human consumption (Davis *et al.* 1999, Greenfield *et al.* 2003). Therefore, all fish evaluated for the prey tissue chemistry line of evidence were legal sized in accordance with state regulations (California Department of Fish and Game 2006). Samples evaluated for human health risk were analyzed as either skin-on or skin-off fillet samples, following the common preparation methods for particular species (Davis *et al.* 1999, Greenfield *et al.* 2003).

[36] Data collected for the RMP in 1994 and 1997 and other programs prior to 2000 were excluded due to concerns about trends over time.

5.2.1.4. Prey tissue thresholds

The San Francisco Bay Regional Water Quality Control Board did not have specific guidance regarding appropriate tissue thresholds for the case study (Fred Hetzel, SF Bay Regional Water Board, *Pers. comm.*). In the absence of local guidance to deviate from general thresholds, the case study evaluations were conducted following general assumptions and background information in Section 3.1 and Appendix K (Table K.1, grey rows).

For the case study, the thresholds were set to protect sport fish consumers at a 10^{-5} cancer risk factor. The high tissue threshold was based on the U. S. EPA (2000b) recommended average consumption rate for sport fish consumers of 17.5 g/d, which should protect the average sport fish consumer in San Francisco Bay (SFEI 2000). The low tissue threshold is based on protecting the 95 percentile of sport fish consumers (32 g/d; SFEI 2000, OEHHA 2001). The resulting categories for the prey tissue line of evidence are outlined in Table 5.2.

Table 5.2. Description of three categories for prey tissue line of evidence for human receptors.

Fish Tissue Score	General description	Humans	Humans
		Threshold	Interpretation
▲ Low exposure	95% upper confidence limit of average fish tissue concentration is below the low toxicity threshold	Fish tissue threshold based on protecting the 95 percentile of sport fish consumers such that no more than 1 in 100,000 faces an increased cancer risk	Using a conservative set of assumptions, dietary exposure to fish in the water body poses a low risk to the general public and to fishers who consume their catch
◘ Moderate exposure	Tissue concentration is intermediate between low and high threshold	Both thresholds are relevant	Dietary exposure to fish in a water body may pose a risk to fishers who consume their catch
● High exposure	Average fish tissue concentration is above the high toxicity threshold	Fish tissue threshold based on protecting the average sport fish consumer such that no more than 1 in 100,000 faces an increased cancer risk	Dietary exposure to fish in a water body is likely to pose an increased cancer risk of more than 1 in 100,000 for sport fish consumers

5.2.1.5. Calculation of average and 95% upper confidence interval concentrations

Arithmetic mean and 95% UCI of average concentrations were calculated for prey tissue chemistry. Geometric mean and 95% UCI were also calculated, following Appendix G.

General assumptions in the prey tissue line of evidence evaluation are summarized in Table 5.3.

Table 5.3. Summary of assumptions, their basis, and effects in prey tissue LOE evaluation for the San Francisco Bay case study.

Decision or assumption	Basis	Effect
Evaluate two alternative groups of species for prey tissue line of evidence: 1. all routinely monitored species, and 2. only species with sediment association and permanent Bay residence	Evaluate sensitivity of assessment results to sport fish species selection	Slight effect on calculated tissue chemistry residues. No effect on comparison to thresholds
Pooling fish tissue concentrations for multiple prey species	Limited sample size for looking at individual species. Conceptual model of exposure risk and available data indicate that receptors (humans) consume multiple prey	Simplifies tissue concentration calculation. Not examining exposure separately for individual prey species
Focusing on finfish prey, rather than shellfish	Use of finfish prey is likely to be more protective for main contaminants of concern (legacy pesticides and PCBs). Limited data availability for prey shellfish. Time and budgetary constraints preclude evaluating all possible prey species	Uncertain
Only including samples with sizes likely to be consumed by receptor. i.e., legal capture sizes for humans	Not appropriate to use surrogate prey species unlikely to be consumed	No effect for human health evaluation since program targets legal sized fish species
For human health evaluation, fish consumption rate based on average and 95th percentile of sport fish consumer consumption rates	San Francisco Bay Regional Board staff did not request specific risk assumptions. Following risk assumptions outlined in Section 3.1.9 and Appendix K, based on local consumption rate data (SFEI, 2000)	Thresholds are higher than if a subsistence fisher consumption rate were used, and lower than if a general population consumption rate were used (see Table K.1).
Carcinogen risk thresholds based on 10^{-5} allowable increased risk	San Francisco Bay Regional Board staff did not request specific risk assumptions. Following risk assumptions outlined in Appendix K, Table K.1, grey rows	Thresholds are 10-fold higher than if 10^{-6} carcinogen risk were used; 10-fold lower than if 10^{-4} carcinogen risk were used
Calculate tissue chemistry average based on arithmetic mean	Arithmetic averages better reflect the average overall exposure due to consuming multiple fish (Appendix G)	Risk determination unchanged given other sets of assumptions (Tables 5.4 and 5.5)
Calculate tissue chemistry 95% UCI based on 2 times the arithmetic estimate of standard error, rather than standard deviation	Use of standard error better reflects the average overall exposure due to consuming multiple fish (Section 3.1.9)	95% UCI estimated exposure less conservative than if standard deviation were used
Only using samples prepared according to predators' consumption pattern	Humans generally do not consume whole fish, and wildlife predators do. Contaminant concentration estimates will be related to tissue preparation	Sample size unchanged because most samples were prepared appropriately for predator consumption. Preparation method may cause increase or decrease in estimated tissue contaminant concentration

5.2.2. Results

Results indicated relatively low concentrations for total DDTs, total chlordanes, and dieldrin. For evaluation of potential human health effects, fish tissue concentrations were below thresholds when all seven human prey species were examined (Table 5.4). Concentrations were also below thresholds for just the four species selected for benthic association and residence within the Bay (Table 5.5). However, variability of predicted

average concentrations was greater for the four species (SE = 2.8) than when all seven species were combined (SE = 2.1), because of the smaller sample size.

Based on the assessment framework, these results indicate that prey tissue concentrations of legacy pesticides pose a low risk to human sport fishers of San Francisco Bay. Therefore, evaluation of the remaining lines of evidence wouldn't be necessary (Table 2.1, Figure 2.2). Results were slightly higher for the four species with strong sediment association (Table 5.5) than all species (Table 5.4); this discrepancy likely resulted from the relatively high tissue lipid content of two of the sediment-associated species, shiner surfperch and white croaker (Davis *et al.* 2002).

Table 5.4. Estimated total organochlorine pesticide concentrations in San Francisco Bay fish samples that are potential prey for human sport fish consumers. Concentrations were calculated for seven fish species (Table 5.1). Data are for all RMP sport fish samples from 2000 and 2003 (N = 135). 95 % UCI = average + two standard errors. Geo mean = geometric mean (calculated on log scale). Note: no values exceeded relevant thresholds.

Value	DDTs (ng/g wet)	Chlordanes (ng/g wet)	Dieldrin (ng/g wet)	Relevant Threshold
Low threshold[a]	64	63	1.4	
High threshold[a]	118	114	2.5	
Mean	31.8	5.3	0.7	High
Standard Error	2.1	0.6	0.1	
95% UCI	36.0	6.4	0.9	Low
Geo Mean	20.4	2.8	0.5	High
Standard Error[b]	0.0	0.0	0.0	
95% UCI	25.2	3.6	0.6	Low
Median	26.4	2.2	0.0	

a. From Table K.1, grey rows. b. presented in log-scale units, rounded to nearest decimal

Tissue concentrations of total DDTs in San Francisco Bay fish (arithmetic average for all fish = 32 ng/g) were considerably lower than Newport Bay (94 ng/g), indicating lower overall exposure to humans and other piscivores. It is worth noting that the 95% UCI of average DDTs in San Francisco Bay fish would be well above the 9.8 ng/g human health risk threshold used in the Newport Bay case study, highlighting the impact of policy choices (allowable risk and target population to protect) on the outcome of this assessment framework[37].

Although the average concentrations were well below the thresholds, concentrations in individual samples sometimes exceeded the low threshold for DDTs (64 ng/g; Figure 5.2) and other legacy pesticides. The human health tissue thresholds used in this case study would be protective of the average and 95th percentile of sport fish consumers, assuming

[37] As presented in Section 4, the choice of low tissue DDT thresholds (9.8 vs. 63 ng/g wet) would not impact the outcome of the Newport Bay case study as the 95% UCI of the average concentration is above both thresholds.

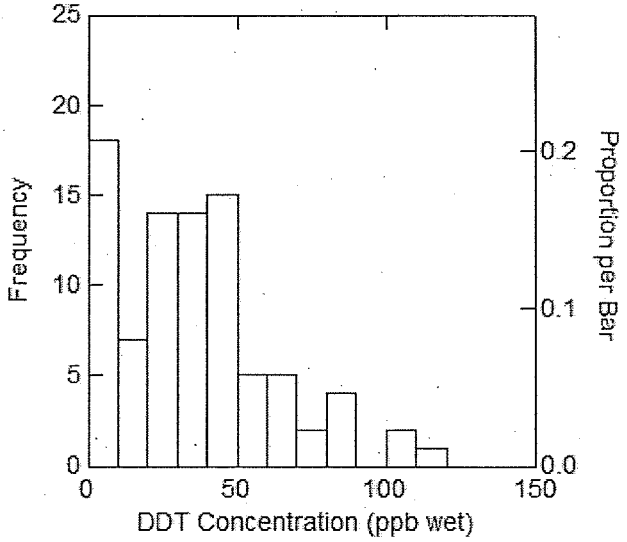
that their consumption samples across the distribution of sport fish present in the Bay. It follows that focusing on the results of individual samples that exceed the threshold would not be appropriate for the framework.

Table 5.5. Estimated total organochlorine pesticide concentrations in San Francisco Bay fish samples calculated using different averaging methods and different sample inclusion criteria. Data are for RMP species sampled in 2000 and 2003 that have life history attributes appropriate for sediment quality assessment (N = 87; Table 5.1). 95 % UCI = average + two standard errors. Geo mean = geometric mean (calculated on log scale). As in Table 5.4, no values exceeded relevant thresholds.

Value	DDTs (ng/g wet)	Chlordanes (ng/g wet)	Dieldrin (ng/g wet)	Relevant Threshold
Low threshold[a]	64	63	1.4	
High threshold[a]	118	114	2.5	
Mean	34.9	6.7	0.9	High
Standard Error	2.8	0.7	0.1	
95% UCI	40.5	8.1	1.1	Low
Geo Mean	20.3	4.0	0.6	High
Standard Error[b]	0.1	0.0	0.0	
95% UCI	27.5	3.8	0.7	Low
Median	33.6	5.5	0.0	

a. From Table K.1, grey rows. b. presented in log-scale units, rounded to nearest decimal

Figure 5.2. Frequency histogram of total DDTs in four sport fish species sampled in San Francisco Bay. Results include California halibut, shiner surfperch, white croaker, and leopard shark sampled in 2000 and 2003 (N = 87).



5.3. Sediment chemistry line of evidence

The evaluation of the prey tissue line of evidence indicated that 95% upper confidence of the average sport fish tissue concentrations were below the low threshold for sport fish consumers. Based on the assessment framework (Table 2.1; Figure 2.2), the evaluation would be complete for those legacy pesticide compounds, with the final determination that indirect effects of sediments are unlikely to pose a risk to humans. It is therefore not necessary to proceed to the sediment chemistry line of evidence.

The purpose of the case studies is to demonstrate technical issues that arise in applying the framework. To this end, we will proceed with developing the remaining lines of evidence, even though sequential application of the framework renders them unnecessary in this case. To conserve time and space, the remaining lines of evidence will be illustrated for total DDTs only. As in the previous case study, several steps are undertaken in the sediment chemistry line of evidence: development of empirical BAFs, comparing them to mechanistic model results, development of sediment thresholds, and comparing actual sediment concentrations to these thresholds.

5.3.1. Development of empirical bioaccumulation factor

In contrast to Newport Bay, San Francisco Bay has sufficient data to make highly specific choices regarding data selection and analysis. In particular, San Francisco Bay has a very large number of samples analyzed for sediment and tissue concentration. Sediment data include samples from the RMP (SFEI 2005), as well as the NOAA - EMAP (Environmental Monitoring and Assessment Program), conducted in 2000 and 2001 (U. S. EPA 2006a) (Figure 5.3). Both of these studies employed a random sampling design. Data from these studies were used in BAF development.

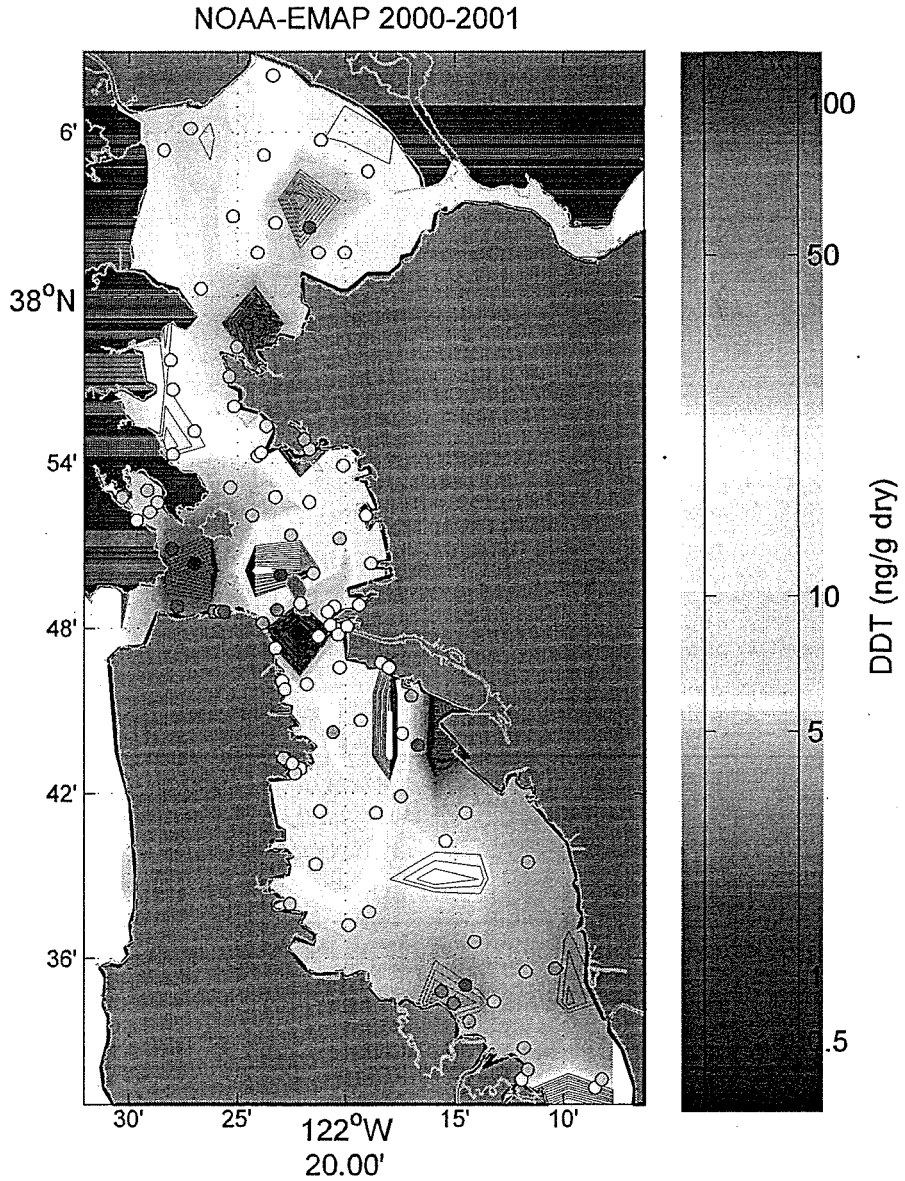
5.3.1.1. Selection and use of a surrogate prey species to develop a BAF

Fish data included large sample sizes ($n > 30$) for each of the multiple fish species(e.g., Greenfield *et al.* 2003). Given this fact, it is possible to develop empirical BAFs using a representative fish species as a surrogate for overall sediment exposure to prey fish (Section 3.1.8; Appendix F). The ideal surrogate species would have a benthic dietary association, a high probability of residing within the Bay throughout its life history, and be eaten as prey by the receptor (Section 3.1.4). As discussed elsewhere (Section 3.1.4, Table 5.1, and Appendix B), shiner surfperch, white croaker, and California halibut all have benthic dietary associations. Furthermore, they are all consumed by sport and subsistence fishers in the region (SFEI 2000).

White croaker, California halibut, and shiner surfperch were examined using a spatial regression analysis described in Appendix B to determine which had tissue contaminant residues significantly associated with nearby sediments. The results indicated that shiner surfperch had the strongest spatial associations between tissue and sediment concentrations. For shiner surfperch, R^2 ranged between 0.25 and 0.44 for PCBs, chlordanes, DDTs, and dieldrin, with p values less than 0.005 in all cases (e.g., Figure

B.2). Furthermore, shiner surfperch exhibited spatially distinct contamination (Figure 5.4) and stable isotope signatures[38] (Figure 5.5) in specific sampling locations. This combination of distinct contaminant and stable isotope signatures among sampling locations further support the contention that shiner surfperch do not move among different locations in San Francisco Bay.

Figure 5.3 Contour plot of total DDTs in San Francisco Bay sediments, based on results of the NOAA-EMAP study.



[38] Stable nitrogen and carbon isotopes are biochemical tracers that often exhibit spatial variation according to food source and geochemical baseline (Peterson and Fry 1987). They may be used to infer fish migration or site fidelity (e.g., Hesslein *et al.* 1991).

Figure 5.4. Total PCBs in shiner surfperch sampled in six San Francisco Bay locations in 2000. Each data point represents a composite of 20 individual fish. These results indicated highly significant differences among sampling locations (ANOVA $p < 0.01$). Reprinted from Greenfield *et al.* (2003).

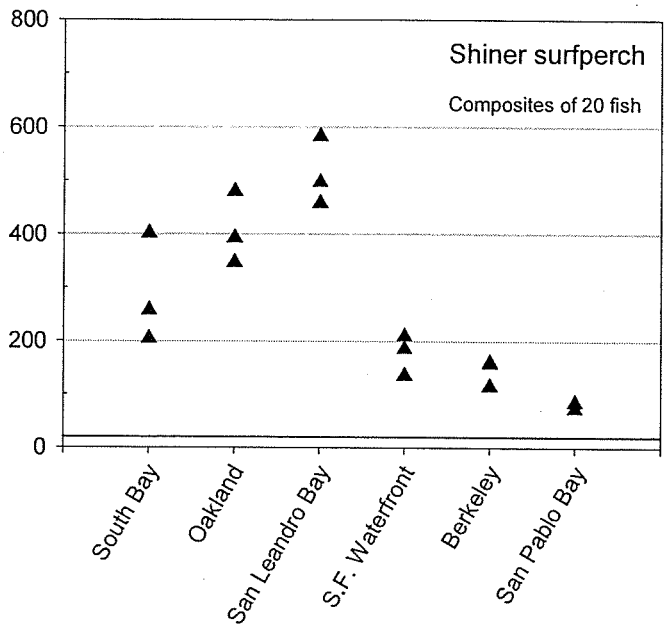


Figure 5.5. Stable carbon and nitrogen isotope signatures in shiner surfperch sampled in six San Francisco Bay locations in 2000. Isotope analyses followed standard protocols (Peterson and Fry 1987). Each data point represents a composite of 20 individual fish. Sampling locations are Berkeley Marina (black triangles), Oakland Inner Harbor (red circles), San Francisco Waterfront (green squares), San Leandro Bay (grey triangles), San Pablo Bay (blue diamonds), and South Bay (yellow hexagons).

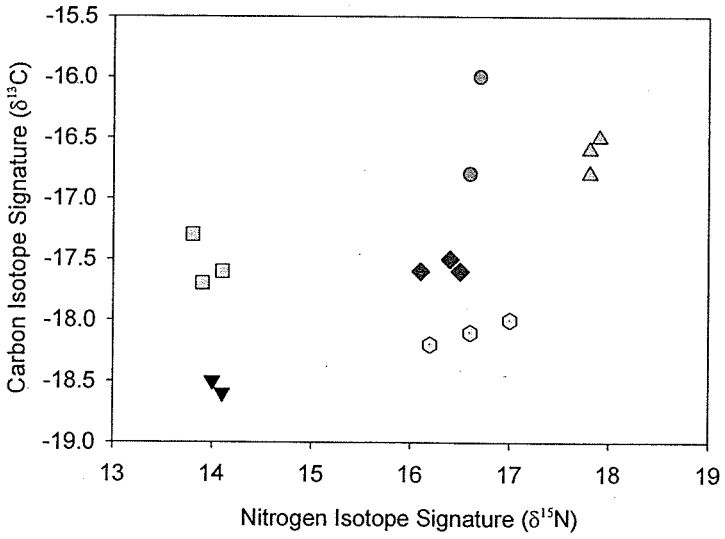
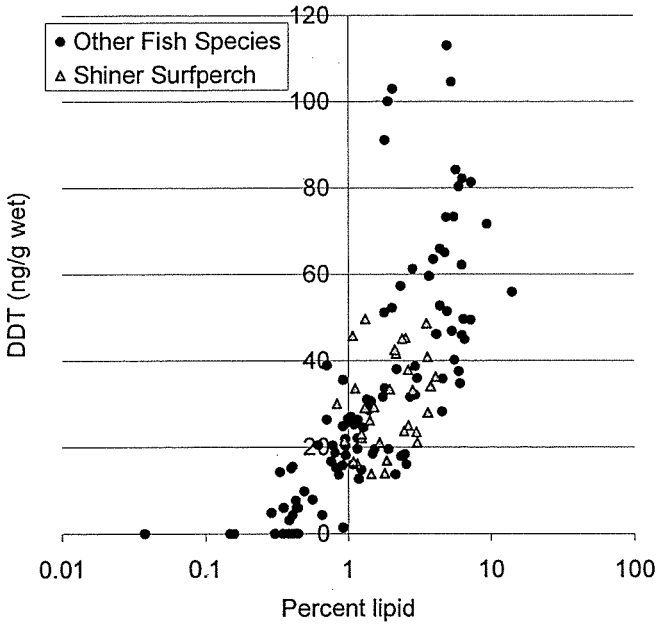


Another consideration in selecting a surrogate species is that they should represent the average contaminant exposure to the receptor (in this case, humans). Figure 5.6 illustrates that observed concentrations of DDTs and other organochlorine compounds in shiner surf perch are centered about the average concentration among Bay sport fish in general. In summary, shiner surfperch have several desirable traits for a surrogate species: 1. a spatial association with the benthic food web of a particular location; 2. DDT exposure that is representative of finfish in the water body; and 3. a reasonably large data set which includes co-occurring sediment chemistry data. Therefore, shiner surfperch were used in the case study to estimate a representative empirical BAF for DDTs in San Francisco Bay.

Figure 5.6. DDT tissue concentrations vs. tissue percent lipid for shiner surfperch (pink triangles) and 6 other species routinely monitored in San Francisco Bay (Greenfield *et al.* 2003) (blue circles).



5.3.1.2. BAF development

Empirical BAFs were generated by comparing shiner surfperch contaminant concentrations to concentrations in surrounding sediments. Linear regression was conducted to determine the optimal spatial scale for averaging sediments around the fish (following Appendix L). The results of this analysis indicated the strongest relationships when surfperch were compared to sediments in a 1 km radius disk surrounding each fish sampling location. Lipid and organic carbon normalizations did not improve BAF calculations (data not shown). Therefore, BAF was calculated as:

BAF = wet weight tissue concentration/dry weight sediment concentration

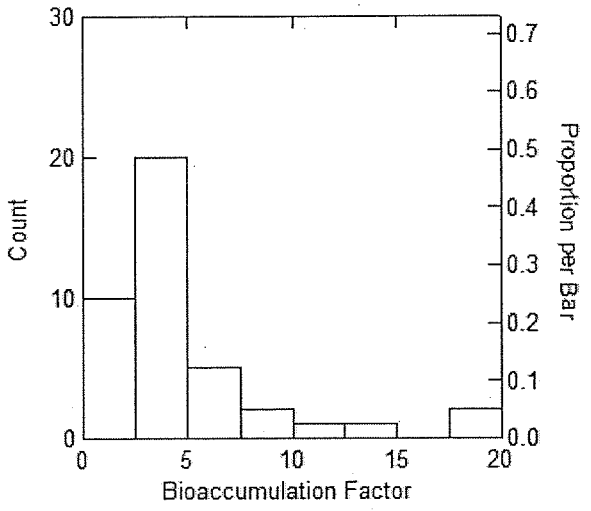
The results for multiple fish samples were combined to generate a distribution of BAFs. Table 5.6 summarizes the assumptions and decisions that went into the BAF calculation, their rationale, and probable impact on results. As illustrated in the Newport Bay case study, changes in many of the assumptions in Table 5.6 could substantially impact the sediment evaluation.

Table 5.6. Summary of assumptions, their basis, and effects on developing a bioaccumulation factor for the sediment chemistry LOE, San Francisco Bay DDT case study.

Decision or Assumption	Basis	Effect
Develop BAF based on shiner surfperch	Sufficient sample size to use a single representative species to develop BAF. Shiner surfperch has appropriate life history attributes. These include a small movement range, benthic dietary association, human sport fish consumption, and spatial association with sediments	Reduces variability and simplifies bioaccumulation calculation by focusing on a single species
Develop BAF based on arithmetic average concentrations in fish vs. average concentrations in sediment samples in a disk within 1-km radius of each fish site	Spatial scale-dependant regression model indicates a significant relationship between fish and nearby sediments, with the strongest relationship at 1-km scale	Reduces variability in bioaccumulation calculation
Using wet weight tissue concentrations	Lipid normalization does not improve the BAF calculation	Limited effect on results
Not normalizing sediment concentrations for organic carbon	Organic carbon normalization does not improve the BAF calculation	Limited effect on results
Only accept compounds in sediment for which > 25% of samples are above detection limits	Confidence of average estimate is very low when vast majority of samples are below detection	Not calculating BAF for o,p'-DDE, heptachlor, or heptachlor epoxide
Calculate bioaccumulation factor for the sum of compounds, rather than for each individual compound	Effects comparisons are on a summed contaminant basis	Calculation of average and variation in bioaccumulation factor more straightforward
Use of 2 * standard error rather than standard deviation to calculate 95% confidence interval of estimates	The objective is to calculate the central tendency and uncertainty about that central tendency for bioaccumulation in the water body (Section 3.1.9)	The calculated uncertainty in estimated bioaccumulation factor will be lower using standard error, rather than standard deviation
Only using samples prepared according to predators' consumption pattern	Humans generally do not consume whole fish and contaminant concentration estimates will be related to tissue preparation method	Sample size unchanged because most samples were prepared appropriately for predator consumption. Preparation method may cause increase or decrease in estimated tissue contaminant concentration

BAFs for total DDTs exhibited a skewed distribution, with most values below 5, and a small number of values ranging up to around 20 (Figure 5.7). The resulting arithmetic mean empirical BAF was 5.0. Although individual BAF results varied from 0.6 to 20, the standard error of the mean BAF was only 0.7. Using this standard error, the resulting 95% upper confidence interval of the mean BAF was 6.4.

Figure 5.7. Histogram of bioaccumulation factors determined for shiner surfperch vs. surrounding sediments (surrounding circle 1 km radius) in San Francisco Bay.



5.3.2. Comparison of empirical bioaccumulation to mechanistic model

The mechanistic model is used to corroborate the empirical relationships between sediment and biota exposure. To this end, several fish and bivalves species are compared.

5.3.2.1. Model description and parameter development

The mechanistic model is described in Section 3.2.8, with model equations summarized in Appendix M. It has previously been parameterized to calculate uptake of PCBs in several fish and wildlife species in San Francisco Bay as part of the PCB TMDL (Total Maximum Daily Load) studies (Gobas and Wilcockson 2002, Gobas and Arnot 2005). This included a detailed food web study to parameterize and validate the model for PCB uptake (Roberts *et al.* 2002). Parameter development for the present case study included developing chemical property estimates for the legacy pesticides: DDTs, chlordanes, and dieldrin (Table 5.7). These parameters included chemical K_{OW} and total concentrations in water and sediment. Data sources for K_{OW} are summarized in Appendix S. Concentrations in water and sediment were calculated using data from the RMP and NOAA-EMAP program (for sediment data only, U. S. EPA 2006a). RMP water and sediment data were combined from 1998 to 2002 collection dates and EMAP sediment data were collected in 2000 and 2001. For water and sediment data, the arithmetic mean was calculated for each individual site (N = 67 sites for water; N = 91 sites for sediment). The geometric mean was then calculated for all sites combined as the model input parameter (Table 5.7). Values below detection were replaced with one-half of the detection limit. Heptachlor, heptachlor epoxide, and o,p'-DDE had > 75% of values below detection limits, and were not included in the analysis (Table 5.6).

Monte Carlo uncertainty analysis was conducted to estimate uncertainty of model predictions. Analyses used parameters and distributions presented in Gobas and Arnot (2005). For pesticide properties (Table 5.7), Monte Carlo simulations assumed lognormal distributions, with standard deviations (log scale) of 0.1 for K_{OW} and concentration in water, and 0.146 (log scale) for concentration in sediment.

Table 5.7. Model input parameters for legacy pesticides. $K_{ow}TS$ = octanol water partitioning coefficient (log scale) corrected for temperature and salinity conditions of San Francisco Bay. Water concentration is total, rather than dissolved.

Compound	K_{ow}	$K_{ow}TS$	Concentration in sediment (ng/g dw)	Concentration in water (µg/L)
o,p'-DDD	5.49	5.66	0.138	2.63×10^{-5}
o,p'-DDT	5.85	6.03	0.088	8.10×10^{-6}
p,p'-DDD	6.48	6.65	0.902	9.62×10^{-5}
p,p'-DDE	7.08	7.24	0.783	8.61×10^{-5}
p,p'-DDT	6.54	6.72	0.307	2.34×10^{-5}
cis-Nonachlor	5.85	6.04	0.138	1.39×10^{-5}
dieldrin	5.63	5.81	0.242	4.27×10^{-5}
gamma-Chlordane	6.42	6.60	0.070	1.11×10^{-5}
hexachlorobenzene	5.67	5.79	0.061	3.62×10^{-5}
mirex	7.15	7.37	0.122	1.68×10^{-6}
trans-Nonachlor	5.85	6.04	0.070	9.86×10^{-6}

5.3.2.2. Results

Comparison of model results with field data indicated general correspondence for individual legacy pesticide compounds (Figure 5.8). In three fish species (white croaker, shiner surfperch, and jacksmelt), and two bivalve mollusk species, the model predicted tissue concentrations were generally similar to Bay wide observed concentrations for DDTs, chlordanes, and dieldrin (Figure 5.9; additional figures in Appendix X). This is similar to evaluations for 40 PCB congeners performed previously in San Francisco Bay (Gobas and Arnot 2005) and the Great Lakes (Arnot and Gobas 2004). This suggests that empirically derived BAFs may be used for San Francisco Bay fish and sediments (Figure 5.9). This finding is also consistent with the interpretation that the biota ultimately receive a proportion of their pesticide exposure from sediments in San Francisco Bay, as included in the model.

For chlordanes, dieldrin, and ortho-para DDT congeners, there was no systematic model bias; that is, the model predicted concentrations were not systematically higher than empirical concentrations, or vice versa. In many cases, the model predicted biota concentration were below field detection limits (yellow bars; Figure 5.9, Appendix X), and were therefore consistent with field results.

Figure 5.8. Comparison of model predicted vs. observed field data for individual DDT compounds. Results are for bivalve mollusks (e.g., *Mytilus* spp.), shiner surfperch, jacksmelt, and white croaker. Error bars indicate the standard deviation of field observations and the uncertainty of model results as estimated by a Monte Carlo analysis of model variables.

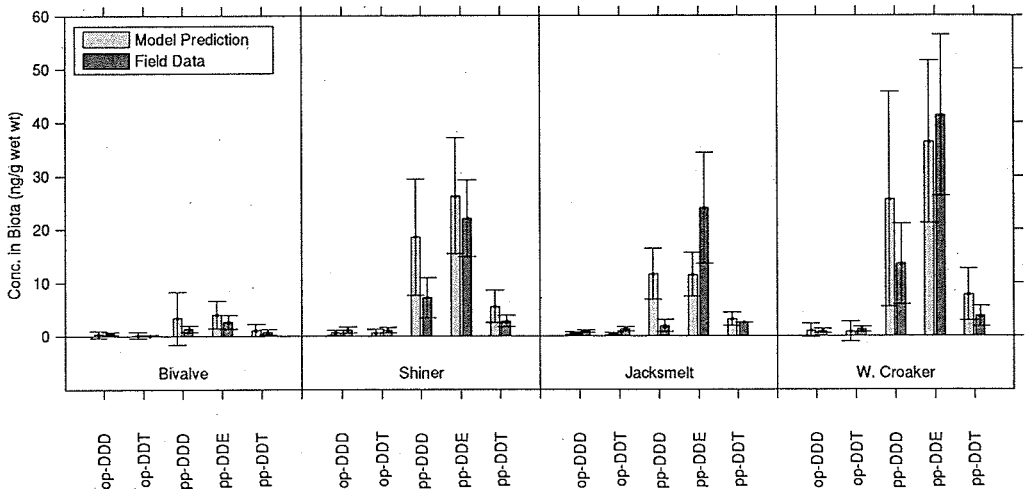


Figure 5.9. Comparison of model predicted vs. observed field data for individual pesticide compounds in shiner surfperch. Error bars indicate the standard deviation of field observations and the uncertainty of model results as estimated by a Monte Carlo analysis of model variables. Yellow bars indicate detection limits in cases where greater than 90% of field data were below detection limits.

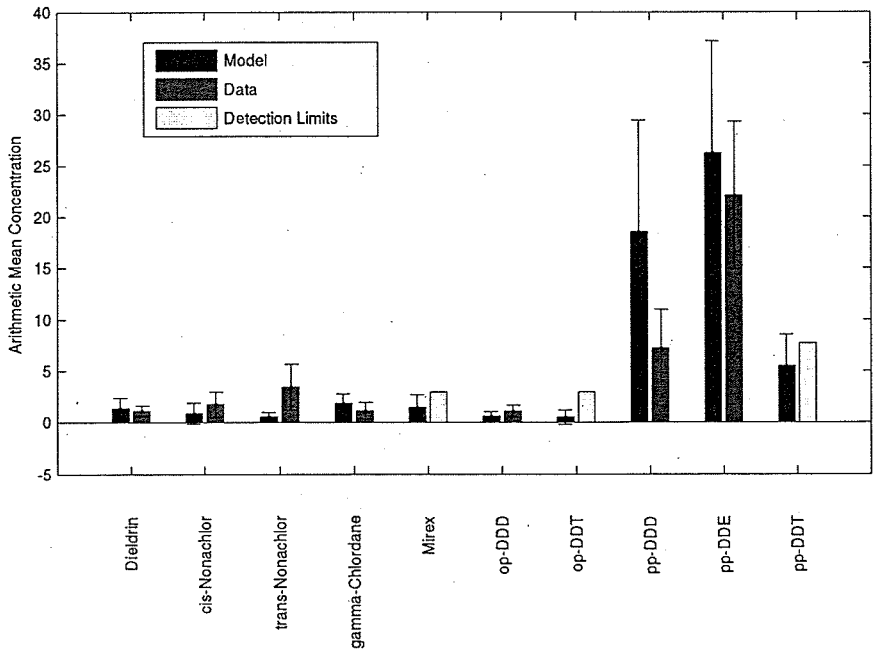

For para-para DDD (p,p'-DDD) and para-para DDE (p,p'-DDE), the model predicted concentrations were sometimes higher than field-observed concentrations. For example, model predicted concentrations were about 15 ng/g higher than field concentrations for p,p'-DDD in shiner surfperch (Figure 5.9). In the Newport Bay case study, model estimated total DDTs were also higher than field results for a number of fish species (Figure 4.15). This model bias for DDTs may result from a number of factors. First, model input data on K_{OW} may not accurately represent in-situ partitioning in San Francisco Bay due to incorrect specification (Pontolillo and Eganhouse 2001) or chemical disequilibrium (Zeng and Tran 2002, Burkhard *et al.* 2003). Additionally, the lack of contaminant metabolism in the model may not account for biodegradation that occurs in finfish or invertebrates (van der Linde *et al.* 2001, van der Oost *et al.* 2003, Bayen *et al.* 2005). In any case, given the sometimes elevated model results as compared to empirical results, it can be expected that BAF estimates made using the Gobas mechanistic model would be relatively conservative for total DDTs.

5.3.2.3. Sediment threshold comparison

Sediment thresholds for total DDTs may be calculated as the quotient of the human health tissue thresholds (Table 5.4), and the wet weight determined BAFs of 5.0 (arithmetic mean) and 6.4 (95% upper confidence interval of arithmetic mean). Assumptions and decisions made for sediment threshold development include BAF assumptions in Table 5.6, and policy-related assumptions about target population (human sport fish consumers) and level of allowable risk (Table 5.8). Following the framework, the high threshold is combined with the average BAF, and the low threshold is combined with the UCI BAF, resulting in two sediment thresholds (Table 5.9). As was explored in the Newport Bay case study, a substantial array of decisions and assumptions must be made prior to developing the sediment thresholds for use in the assessment framework (Tables 5.3 and 5.10). These include both technical and policy decisions and can significantly impact assessment results (as described in Section 4.4.3.2).

Table 5.8. Summary of risk assessment assumptions, their basis, and effects on developing sediment thresholds for the sediment chemistry LOE, San Francisco Bay case study. See also Table 5.6.

Decision or Assumption	Basis	Effect
Use risk assumptions in Table 5.2 to set low and high tissue thresholds (average and 95%ile sport fish consumer; 10^{-5} increased cancer risk)	San Francisco Bay Regional Board staff did not request specific risk assumptions. Following general risk assumptions outlined in Section 3.1 and Appendix K of report, based on local consumption rate data (SFEI, 2000)	As demonstrated in the Newport Bay case study (Section 4), the risk assumptions are policy decisions and can substantially impact the incidence of exceeding thresholds
Base the high threshold on an arithmetic average (50%ile) estimate of bioaccumulation factor	Less conservative threshold protects the average consumer (Table 5.2)	Higher incidence of exceeding thresholds than using geometric mean or median estimated BAF
Base the low threshold on an 95% upper confidence limit estimate of bioaccumulation factor	More conservative threshold protects the average consumer, including a protection factor to account for uncertainty in the estimate of bioaccumulation	Greater than 95% probability that the bioaccumulation estimate is equal to or greater than the actual average bioaccumulation for surfperch in San Francisco Bay

Table 5.9. Development of low and high sediment thresholds for total DDTs. Thresholds were developed based on human health effects of consuming contaminated sport fish.

Threshold type	Risk	Tissue threshold	BAF	Sediment threshold
High	Higher	118	5.0	118/5 = 23.6
Low	Lower	64	6.4	64/6.4 = 10.0

When individual sediment samples from San Francisco Bay were evaluated in comparison to the two thresholds for total DDTs, the majority (82%) of samples were below both thresholds (Table 5.10). This finding is not surprising given that the thresholds were developed to be protective of sport fish consumers, and average sport fish tissue concentrations were below their respective thresholds, as well. Based on the prey tissue LOE, the assessment framework conclusion would remain "unlikely impact" for all sediment stations. Clearly, the framework focus on specific beneficial uses of the water body (in this case, human sport fish consumption) strongly affects the interpretation of individual results.

Table 5.10. Comparison of San Francisco Bay sediment samples to the low and high thresholds developed for total DDTs. Samples evaluated included data from RMP, EMAP, and all studies assembled in the CASQO database.

Sediment category	Concentration	Number Samples	Percent
Below low threshold	< 10.0	577	82%
Between thresholds	10.0 - 23.6	58	8%
Above high threshold	>23.6	72	10%

5.4. Relative contribution of water and sediment to food web

The relative importance of various sources in biota exposure to contaminants is an important issue (Burkhard *et al.* 2003). As indicated in the assessment framework conceptual model (Section 2.2, Figure 2.1), exchange between water and sediments makes it difficult to distinguish between these two contaminant reservoirs. The relative importance of sediments vs. the water column for contaminant uptake can be explored using mechanistic models. In San Francisco Bay (Davis 2004) and in other water bodies (Burkhard *et al.* 2003), there may be significant contaminant flux between sediments and the water column in a dynamic process, making it impossible to treat them as independent sources of bioavailable contaminants. Nevertheless, a model that separately quantifies the biological uptake of contaminants from sediments and the water column provides a first order approximation of the relative importance of these two matrices to biota exposure.

5.4.1. Methods

Manipulations were performed on the mechanistic food web model used and described elsewhere in the report (Section 3.2.8 and Appendix M) and other sources (Gobas 1993, Arnot and Gobas 2004, Gobas and Arnot 2005). The mechanistic food web model is used to manipulate the relative contribution of water vs. sediment to total contaminant uptake by biota. This is achieved by running model simulations in which the sediment vs. water column sources are separately "turned off," by setting concentrations to zero. The resulting change in modeled biota concentrations are then determined. This exercise provides an estimate of the total proportion of exposure resulting from water column vs. sediment.

Two scenarios were evaluated. In the first scenario, the relative contributions of water and sediment to contaminant levels in biota were varied in 10% increments (Table 5.11). This scenario was performed using initial parameter estimates for p,p'-DDE from San Francisco Bay (Table 5.7), and results were evaluated for shiner surfperch and jacksmelt. The food web model was run using these concentrations as inputs, to determine sensitivity of the model BAF calculation to relative sediment vs. water column inputs. Model calculated BAFs were then compared to the ratio of model input concentration in sediment (C_s) vs. concentration in water (C_w) (i.e., C_s/C_w).

In the second scenario, sediment and water column concentrations were separately manipulated from their original values to zero. The relative contribution of sediment vs. water column to biota exposure and resulting BAF calculation was then determined as:

$$\text{Contribution of water column (\%)} = \frac{\text{Biota concentration when sediment} = 0}{\text{Biota concentration with original sediment and water}}$$

$$\text{Contribution of sediment (\%)} = \frac{\text{Biota concentration when water} = 0}{\text{Biota concentration with original sediment and water}}$$

5.4.2. Results

The model predicted p,p'-DDE bioaccumulation factor (i.e., concentration in biota/concentration in sediment) was inversely related to C_s/C_w (Figure 5.10). When concentration in sediment (ng/g) was greater than 10,000 times concentration in water (µg/L), the model predicted BAF was around 15 for jacksmelt and 30 for shiner surfperch. As C_s/C_w dropped below 10,000, the BAF began to increase sharply. At C_s/C_w of 1600, BAF reached almost 80 and 160 for shiner surfperch and jacksmelt (Figure 5.10). The reason for the model's sensitivity to C_s/C_w is that the model explicitly considers both sediment and water column exposure. Biota in the model may be exposed to sediment contaminant due to direct dietary uptake, as well as respiratory exposure to porewater contaminants, which are modeled assuming equilibrium with sediments. Biota may also be exposed to water column contaminants due to respiratory exposure, or transpiration in phytoplankton (Appendix M). At relatively low sediment concentrations, water column contaminants drive biota exposure, resulting in very high BAFs.

Table 5.11. p,p'-DDE concentrations in sediment (C_s) and water (C_w) used to investigate the relative contributions of each source to modeled p,p'-DDE levels in Newport Bay biota.

	(C_s) (ng/g dry wt)		(C_w) (µg/L)	C_s/C_w
Mean	0.78	Mean	8.61×10^{-5}	9,094
Mean-10%	0.70	Mean+10%	9.47×10^{-5}	7,441
Mean-20%	0.63	Mean+20%	1.03×10^{-4}	6,063
Mean-30%	0.55	Mean+30%	1.12×10^{-4}	4,897
Mean-40%	0.47	Mean+40%	1.21×10^{-4}	3,897
Mean-50%	0.39	Mean+50%	1.29×10^{-4}	3,031
Mean-60%	0.31	Mean+60%	1.38×10^{-4}	2,274
Mean-70%	0.23	Mean+70%	1.46×10^{-4}	1,605
Mean+10%	0.86	Mean-10%	7.75×10^{-5}	11,115
Mean+20%	0.94	Mean-20%	6.89×10^{-5}	13,641
Mean+30%	1.02	Mean-30%	6.03×10^{-5}	16,889
Mean+40%	1.10	Mean-40%	5.17×10^{-5}	21,220
Mean+50%	1.17	Mean-50%	4.31×10^{-5}	27,282
Mean+60%	1.25	Mean-60%	3.44×10^{-5}	36,376
Mean+70%	1.33	Mean-70%	2.58×10^{-5}	51,533

Based on Figure 5.10, one might expect that BAFs would be elevated due to the water column contribution. This expectation is supported when using the model to examine the relative contribution of p,p'-DDE in sediments vs. water column. For all fish species and benthic invertebrate species, water column exposure resulted in 50% to 100% of modeled body burden (Figure 5.11). Results were particularly pronounced for fish, for which water column sources resulted in at least 75% of body burden. Water column sources were most important for those species that prey predominantly on plankton, including *Mysis* sp., *Crangon* sp., and jacksmelt, while sediment exposure was greatest for the sediment dwelling and consuming annelid, *Neanthes succinea*. This emphasizes the importance of selecting species with sediment life history associations when developing empirical BAFs (Section 3.1.4).

Results were somewhat similar when evaluating PCB 118, in that water column vs. sediment exposure varied according to the life history of modeled species (Figure 5.12). However, in comparison to p,p'-DDE results, PCB 118 exhibited a higher overall sediment contribution to biota exposure in general. This difference results from the much higher ratio of sediment vs. water column concentration for PCB 118 (approximately 130,000), as compared to p,p'-DDE (9,000), in San Francisco Bay. In general, PCBs exhibited higher sediment to water column ratios than DDTs at a given K_{ow} (Figure 5.13). This discrepancy between the two compound classes suggests that K_{ow} is not the only factor driving sediment vs. water column concentrations in San Francisco Bay. Other potential factors may include external loading of DDTs to the water column or nonlinear sorption of PCBs to carbonaceous particles (Maruya *et al.* 1996, Ghosh *et al.* 2003, Cornelissen *et al.* 2005).

Figure 5.10. Model predicted bioaccumulation factor (BAF) for p,p'-DDE in jacksmelt and shiner surfperch as a function of C_s/C_w (from Table 5.11).

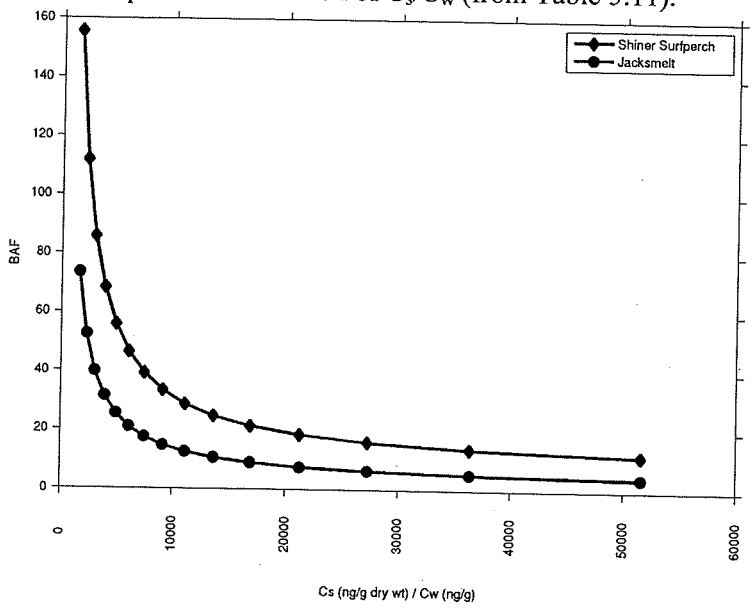

Figure 5.11. Relative contribution of water and sediment to p,p'-DDE bioaccumulation. Results are based on mechanistic model application to multiple species using parameters developed for San Francisco Bay.

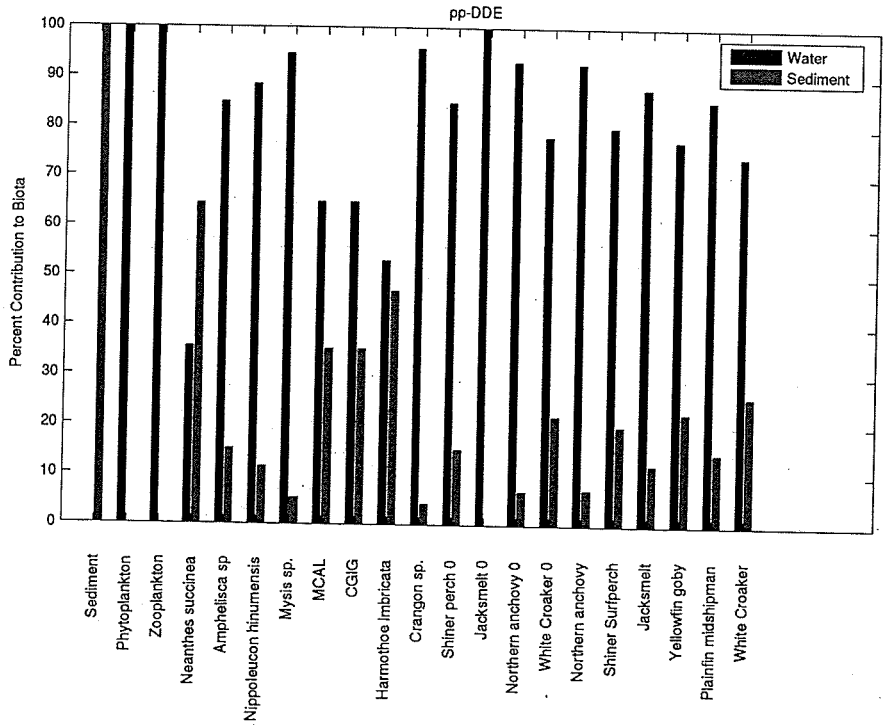

Figure 5.12. Relative contribution of water and sediment to bioaccumulation of PCB 118. Results are based on mechanistic model application to multiple species using parameters developed for San Francisco Bay.

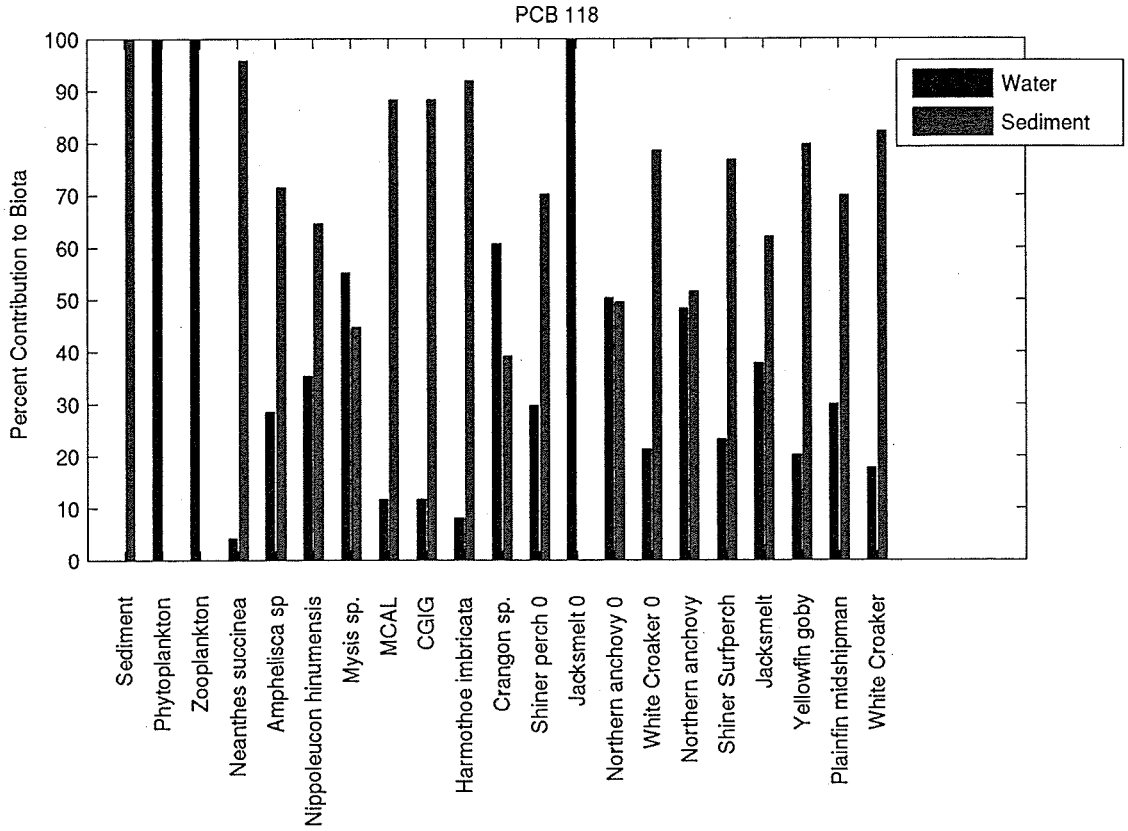

It would be possible to use mechanistic model results to modify the empirically developed BAFs to focus on the direct contributions of sediments to food-web contaminant exposure. For example, the BAFs developed for shiner surfperch (Table 5.8) could be multiplied by 0.20, based on the model estimation of 20% of total p,p'-DDE exposure to adult surfperch resulting from sediments (Figure 5.11). Although results would differ among DDT compounds, the vast majority of biota DDTs are in the form of p,p'-DDE, allowing the assumption that sediment partitioning for total DDTs will be similar to p,p'-DDE. Multiplying the BAFs by 0.20 would result in new BAFs of 1.0 and 1.3. This would produce considerably different threshold calculations and would result in a higher percentage of samples below the low threshold (92% as compared to 82%; Table 5.12 vs. Table 5.10). However, these modified BAFs would probably underestimate sediment exposure to biota due to indirect effects. This is because actual water column residues are likely to be substantially derived from resuspended sediments, which currently constitute a primary reservoir of PCBs and legacy pesticides (Venkatesan *et al.* 1999, Davis 2004). Additional contaminant fate modeling would be required to establish the relative proportion of water column concentrations derived from resuspended sediments vs. external loading or atmospheric deposition.

Figure 5.13. Relationship between literature-based K_{ow} and C_s/C_w for PCBs (triangles) and DDTs (circles) in San Francisco Bay. PCBs are from left to right: PCB 18, PCB 66, PCB 118, PCB 153, and PCB 194. DDTs are from left to right: o,p'-DDD, o,p'-DDT, p,p'-DDD, p,p'-DDT, and p,p'-DDE. Based on Bay-wide average concentration estimates (Table 5.7, and Gobas and Arnot (2005)). Note log scale y-axis.

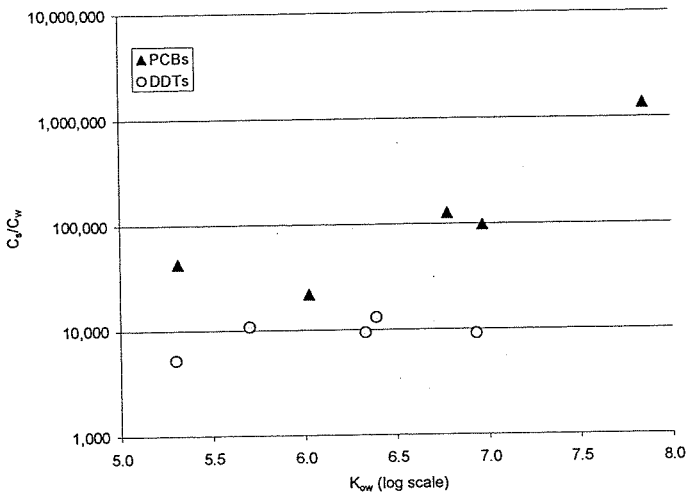

Table 5.12. Comparison of San Francisco Bay sediment samples to low and high thresholds developed for total DDTs, and calibrated based on modeled percent contribution of sediments to p,p'-DDE concentrations. Samples evaluated included data from RMP, EMAP, and all studies assembled in the CASQO database.

Sediment category	Concentration	Number Samples	Percent
Below low threshold	< 50	651	92%
Between thresholds	50 – 118	10	1%
Above high threshold	>118	46	7%

5.5. Bioavailability line of evidence

The bioavailability line of evidence is recommended as a final step when the previous LOE suggest that sediments may be impacted by indirect effects due to contamination. This LOE is used to demonstrate whether sediment-associated contaminants are available for biological uptake (Section 3.3). A relatively straightforward approach for the bioavailability LOE is to demonstrate a positive association between sediment contaminant concentration and biota contaminant concentration. To demonstrate this approach, bioaccumulation data were assembled and evaluated for DDTs and other legacy organochlorine compounds in San Francisco Bay.

As discussed in Section 5.2.2, the prey tissue LOE fell into the lowest risk category. Based on the assessment framework, this would result in an assignment of "Unlikely Impacted," with no need to proceed to the sediment chemistry or bioavailability LOE for the San Francisco Bay case study. The purpose of this Section is simply to illustrate the potential use of the bioavailability LOE, as well as likely results for legacy organochlorine compounds.

5.5.1. Methods

Data used to investigate bioavailability of contaminants in San Francisco Bay sediments were obtained from the California Sediment Quality Objectives database. Data included 28 day laboratory bioaccumulation tests conducted at Hunters Point, Oakland Harbor and Richmond Harbor, as well as control samples from other locations in the Bay associated with these studies (Lee *et al.* 1994, Battelle *et al.* 2005).

Studies were performed using standard protocols for 28 day laboratory bioaccumulation tests (U. S. EPA and U. S. Army Corps of Engineers 1991, 1998). Homogenized sediments of known field concentrations were administered to *Macoma nasuta* test organisms in a laboratory environment, with laboratory test conditions monitored throughout the experiments. Tissue analyses were subsequently performed after 28 days to determine the availability of sediment contaminants taken up by the test organisms.

Comparison between sediments and *M. nasuta* were performed for total DDTs, total chlordanes, total PCBs, dieldrin, and high molecular weight PAHs (as defined in Appendix N). Linear regression analysis was applied to compare sediment vs. corresponding *M. nasuta* tissue concentrations (Draper and Smith 1998). A significant positive relationship in the comparison was interpreted to indicate that the contaminants were bioavailable to *M. nasuta*.

5.5.2. Results

A statistically significant positive linear relationship was observed for total DDTs (Figure 5.14; $R^2 = 0.43$, $p < 0.0001$, $N = 38$). Significant positive relationships were also observed for total chlordanes ($R^2 = 0.74$), dieldrin ($R^2 = 0.49$), and total PCBs ($R^2 = 0.72$; $p < 0.0001$ in all cases), and a weak positive trend was observed for high molecular weight PAHs ($R^2 = 0.15$, $p = 0.014$). These results indicated bioavailability of DDT, chlordanes, dieldrin, and total PCBs in San Francisco Bay sediments. Results for PAHs were inconclusive, and suggest that other approaches may be warranted. For example, control (unexposed) bivalves could be analyzed in comparison to exposed bivalves, to determine whether exposure results in increased tissue concentrations (Section 3.3). Bioaccumulation of PAHs may vary widely as a function of PAH sources, sediment properties, non-linear sorption to carbon particles, and taxa-specific metabolism rates (Meador *et al.* 1995, Cornelissen *et al.* 2005). This suggests a need for assessment of bioaccumulation in local invertebrate prey organisms to apply the framework to PAHs.

6. Conclusions and recommendations:

6.1. Overview of the framework

The assessment framework aims to streamline and standardize the evaluation of indirect effects of sediment pollution. It is based on a simplified conceptual model of biota exposure to sediment pollution (Figure 2.1). It incorporates general risk assessment principles, including the use of site-specific receptors, probability-based evaluation of exposure and effects, and a sequential decision process. Exposure is evaluated based on local data using a weight of evidence approach. The exposure lines of evidence are intended to be reasonably straightforward to collect and analyze, though interpretation of the results presents some challenges. The effects evaluation predominantly relies on readily available published risk information, such as federal and state-recommended toxicity reference values for dietary exposure to pollutants.

A primary goal of the framework is to simplify risk assessment for dietary exposure to sediment pollution. Federal CERCLA risk assessments managed by the Superfund program are time consuming and costly to perform. For example, the Remedial Investigation and Feasibility study underway for the Lower Passaic River in New Jersey is expected to cost at least 10 million dollars, with a Record of Decision target date of 2014 (Hyatt 2007). The framework in our report is intended to be appropriate for a statewide program to characterize many water bodes. The aim is to reduce confusion and expense by: 1. focusing on clearly defined objectives (protection of human and wildlife from contaminated prey); and 2. using a simplified decision framework that targets pollutants of concern.

6.2. Case study findings and interpretations

The goal of the case studies was to illustrate some of the technical issues and policy decisions that arise in applying the framework. A number of important findings were revealed. First of all, bioaccumulation rates varied among the water bodies. This finding supported the collection and use of local exposure data. Second, empirical bioaccumulation rates were generally corroborated by an independent mechanistic model. This suggests that many of the confounding factors frequently discussed (e.g., migration, waterborne exposure, spatial and temporal heterogeneity, and dietary variation) do not fundamentally undermine the development of a site-specific bioaccumulation rate parameter for sediment-associated finfish. Third, evaluation of prey tissue chemistry sometimes revealed that the narrative objectives (i.e., reduction of risk to human or wildlife piscivores) were achieved. This finding supports the use of sequential application, beginning with prey tissue chemistry, to effectively focus effort and resources on those pollutants that pose the greatest risks. For example, since prey fish tissue concentrations were below the low pesticides thresholds in San Francisco Bay, efforts could be focused on evaluating or preventing other pollutants that pose potential risks.

The case study results indicated that policy decisions, such as target population and acceptable level of risk, sometimes affected the outcome of the assessment. Results were particularly sensitive to the allowable level of risk to humans. For example, in the Newport Bay case study, potential human health impacts of sediment PCBs would fall into the intermediate or low risk category, depending upon specific assumptions about allowable cancer risk. One goal of the framework is to focus the policy discussion towards developing low and high effects thresholds. The use of two thresholds may aid in developing compromises between multiple interested parties.

The case studies also revealed a number of technical uncertainties and data limitations. Mechanistic model simulations indicated that a significant portion of biota exposure to DDTs stemmed from dissolved and particulate compounds in the water column. In general, modeled BAFs were highly sensitive to water column concentrations, highlighting the potential uncertainty regarding the ultimate source of pollutants. Although it is likely that a large portion of the water column concentrations were linked to direct sediment resuspension, direct loading from the watershed and upstream rivers should also be considered.

In the Newport Bay case study, certain biota exhibited twofold differences between the empirical and mechanistic model results. These highlight the common limitations on input data needed for the mechanistic model, such as food web structure, and compound-specific metabolic transformation rates. The benthic algae specific to Newport Bay were also difficult to parameterize.

Empirical contaminant data in Newport Bay biota were sometimes rather poor. Surprisingly, this had a relatively limited impact on the outcome of the assessment. For example, the framework would characterize sediment impact due to PCB exposure as a combination of unlikely impact, possible impact, and likely impact across a wide range of assumptions and policy judgments (Table 4.20).

The technical approach and findings varied among the two case studies, according to differences in available data. San Francisco Bay may be viewed as a "best case scenario," in that extensive data are available on sediment chemistry, tissue chemistry, ancillary parameters, and biota life history. This enabled the use of a single surrogate species and a spatial averaging approach in BAF development.

Newport Bay had more limited data than San Francisco Bay, with relatively small sample sizes and chemistry data often marred by high detection limits. The data limitations were addressed to some extent by pooling multiple prey species and developing a modified BAF (based on lipid weight prey tissue and dry weight sediments). Probabilistic approaches, such as generation of average and upper confidence interval parameter estimates, enabled the framework to be applied even given the limited and uncertain data. Nevertheless, the data limitations likely reduced the overall certainty of the assessment. This uncertainty was illustrated by the sensitivity of the Newport Bay case study results to data distribution assumptions (i.e., arithmetic vs. geometric calculations). The data

uncertainty may have also caused a greater occurrence of intermediate risk classifications (i.e., the "possibly impacted" and "likely impacted" categories).

6.3. Avenues for future study

Thus far, application of the framework has been limited to assessment of the legacy organic contaminants: PCBs and organochlorine pesticides. This leaves open a wide array of topics that merit evaluation. The wildlife toxicity reference values and the bioavailability technical guidance may benefit from further review and revision. Potential avenues for future research include evaluation of contaminant mixtures, assessment of additional compounds, and effects to finfish.

Improved understanding of the bioavailability line of evidence

The guidance in this report predominantly focuses on use of standard laboratory test species in 28 day evaluations. Alternative options would result in a more flexible approach. Evaluation of bioavailability is an area of active research. Areas of development include semipermeable membrane devices, solid-phase microextraction fibers, in-vitro assays using gut extracts, and field deployment of caged biota (van der Oost *et al.* 2003, Moore *et al.* 2005). Data may also be available on additional appropriate test organisms. Another avenue for exploration is the development of approaches that can be readily translated to field bioaccumulation rates, to provide corroborative information for the prey tissue chemistry LOE.

Development of new and revised toxicity reference values

Most of the wildlife TRVs used in the case studies were developed about a decade ago. It is likely that new toxicity studies have been performed, resulting in improved TRVs. Additional TRVs should also be developed for recent use compounds, such as brominated flame retardants. The U. S. EPA Region IX BTAG has a procedure for developing or refining TRVs (California DTSC Human and Ecological Risk Division 2000). This procedure may be employed to update the TRVs for framework application to estuarine and bay sediments.

Evaluation of indirect effects of contaminant mixtures

The case studies and technical guidance in this report focus on evaluation of individual contaminants. Future research and development could consider applying the framework to evaluate effects of contaminant mixtures. In particular, additive mixture models could be employed to evaluate cumulative risks of carcinogenic or non-carcinogenic effects. Toxicity equivalency factors (TEF) models may also be employed, including dioxin TEFs for dioxin-like compounds (Van den Berg *et al.* 1998), and benzo[a]pyrene TEFs for PAHs (Nisbet and Lagoy 1992).

Indirect effects to finfish

So far, the focus of the framework has been on evaluating risks to birds, aquatic mammals, and humans. However, finfish also prey on benthic organisms, and may be indirectly exposed to contaminated sediments. Finfish tissue-residue based toxicity reference values are readily available for some compounds (e.g., Appendix I). For these compounds, it would be relatively straightforward to apply the framework to assess risks to fish.

Application of the framework to additional compounds

A wide range of compounds may be present at elevated concentrations in sediments due to anthropogenic sources. These include Hg, Se, and other metals, dioxins, PAHs, and multiple previously unmonitored compounds. Current use pesticides, such as organophosphates and pyrethroids, are of particular management concern in estuaries with agricultural or residential development. Each class of compounds is likely to present specific technical challenges for assessment of indirect effects. For example, the acid-volatile sulfide model has been proposed to predict bioavailability of metals (Hansen *et al.* 1996), but success has been limited (Lee *et al.* 2000, Meador *et al.* 2005).

Two approaches could be employed to evaluate additional compounds. The first approach is to undertake additional case studies, focusing on water bodies and pollutants that present specific challenges. For example, the effects of contaminant mixtures in the Sacramento-San Joaquin Rivers Delta could be evaluated. An alternative approach would be to conduct a general screening-level risk assessment to identify priority compounds for more careful consideration. This would entail application of the framework using simplified assumptions and representative parameter estimates. The objective would be to identify those compounds that pose the greatest potential risks to consumers of sediment-exposed prey organisms. This information would form the basis for future research and framework development.

8. Appendices

Appendix A. Key elements of a framework for evaluating indirect effects of sediment pollution.

A number of issues have been raised by committees involved in the California SQO development process. These committees include the Sediment Quality Advisory Committee, representing stakeholders that will be impacted by the program, the Agency Coordinating Committee, including staff of agencies that will apply the program, and the Scientific Steering Committee, composed of scientific experts in the field. Despite the diverse representation of these committees, feedback has consistently included the following:

- Before determining that sediments are impacted by pollutants, there should be some evidence that the sediments may be responsible for the impacts to wildlife or human health.
- In order to have benefit, the approach should be able to differentiate among individual sediments.
- The method should be flexible enough to be applicable for the range of conditions and bioaccumulative contaminants that may occur in California bays and estuaries. This may include incorporation of local data, including local fish consumption advisories, when available.
- The approach should explicitly incorporate uncertainty into the analysis. Uncertainty may be addressed using probability-based methods, and by having multiple categories reflecting different degrees of certainty regarding whether objectives are met or exceeded.
- Target receptors should be appropriate for the beneficial uses they are intended to protect. For example, receptors to represent wildlife prey may be different from receptors to represent human fish consumption.
- The issue of spatial scale should be considered, and the scale at which the framework is applied must be appropriate for the scale at which beneficial uses may be impacted. Fish, wildlife, and humans obtain food from a variety of sources and locations and site fidelity will vary among species. Fish captured at a certain location may not necessarily have been foraging in that exact location prior to capture. Comparisons should be made between foraging area of the receptor and areas of elevated sediment concentration. Whenever possible, receptors with limited movement and high site fidelity should be chosen.
- Recommendations should be made for circumstances when data availability or sample sizes are limited.
- California state agencies responsible for characterizing sediments will have limited funding and resources. Given these constraints, the assessment framework must be reasonably practical to apply. The conceptual framework and underlying methods should not be more complex than necessary.

Appendix B. Relationship between sediment and finfish contaminant concentrations.

Introduction

This Appendix provides technical support for the use of finfish tissue chemistry in the framework, by addressing two issues. First of all, it supports the use of finfish tissue concentrations as part of an indirect effects evaluation framework for sediments. Specifically, there is a statistically significant association between pollution in sediments and in fish captured near these sediments.

This Appendix also identifies finfish species that may be particularly useful for the prey tissue LOE based on their association with sediment chemistry. To accomplish this, empirical data are compared between finfish and sediment pollutant concentrations to identify candidate finfish species. When significant relationships are observed, this suggests that those fish species exhibit relatively strong affinity to sediments and pollutant exposure at local scales. Similar support for the use of invertebrate chemistry in the bioavailability LOE is provided in Section 3.3.

Methods

Results are based on reviews of published literature, and analyses of data available from the California Sediment Quality Objectives (CASQO) database[39].

To identify good candidate species for the prey tissue LOE, sediment-biota relationships were evaluated for PCBs, organochlorine pesticides, and other pollutants as available. Linear regressions were conducted on log-transformed data to improve normality and variance homoskedasticity of residuals (Draper and Smith 1998). Analyses focused on DDTs, total PCBs, total chlordanes, and dieldrin. Evaluations were conducted for those species having at least five separate fish tissue collections for a given water body in the CASQO database. Separate evaluations were conducted for the three water bodies having sufficient data: San Francisco Bay, San Pedro Bay, and San Diego Bay. These analyses used previously published organic pollutant data. The analyses were conducted comparing fish tissue concentrations to surrounding sediment concentrations at 1 km radius increments at spatial scales from 1 to 5 km. Appendix L describes the statistical procedure to characterize the spatial scale at which sediment pollutant concentrations were best related to those in fish tissue.

Results of literature review

There are many examples of spatial correlation between fish tissue and sediment chemistry in peer-reviewed literature and technical reports. Such relationships are frequently observed for PCBs and other chlorinated organic compounds (Table B.1). In southern California, statistically significant relationships have been shown for trace organic contaminants in sanddabs and other flatfishes (e.g., Schiff 2000, Allen *et al.* 2004), as well as white croaker (Table B.1). Laboratory results corroborate these field

[39] As described in Section 3.2.2

observations. For example, Ankley *et al.* (1992) observed elevated PCB concentrations in fathead minnows exposed to contaminated sediments in the laboratory. The study also observed BSAFs in the laboratory that were similar to field observed BSAFs. At least one study detected significant relationships for the trace metals, mercury and lead (Meador *et al.* 2005). Finally, a substantial literature demonstrates spatial associations between sediment PAH concentrations, and toxic effects in benthic fish. Effects include hepatic lesions, reproductive impairment, and DNA damage (Spies *et al.* 1990, Stehr *et al.* 1997, Johnson *et al.* 2002). Species exhibiting these relationships generally have benthic dietary associations. Relationships are generally stronger when spatial contamination gradients are stronger.

Table B.1. Selected literature sources indicating significant relationships between sediment and fish

Species	Contaminants with significant sediment association	Source
Shiner surfperch	DDTs	Lee (1994)
Sanddab guild, California halibut	PCBs, DDTs	Allen *et al.* (2002a, 2002b)
White croaker	PCBs, DDTs, chlordanes	This study, Connolly and Glaser (1997)
Shorthorn sculpin	PCBs	Kuzyk *et al.* (2005a, 2005b)
White croaker, English sole	Hg, lead	Meador *et al.* (2005)
White croaker, four-horn sculpin, flathead sole, English sole, starry flounder, hornyhead turbot, barred sand bass, and black croaker	PCBs, DDTs, chlordanes, dieldrin, PAHs, hexachlorobenzene	Brown *et al.* (1998)
White sucker, carp, sea bass, and other species	PCBs, dioxins, DDTs, chlordanes	Burkhard *et al.* (2005), Wong *et al.* (2001)
Longjaw mudsucker	PCBs, DDTs	Hwang *et al.* (2006)
Forage fish (Pacific staghorn sculpin, yellowfin goby, and chameleon goby)	PCBs	Battelle *et al.*(2005)

These findings indicate a common association between sediment and fish contamination. This supports the judicious use of data from field-captured fish for risk evaluation in the indirect effects assessment.

Results of empirical data analysis

Six species met the data criteria for empirical analysis: California halibut, English sole, shiner surfperch, speckled sanddab, staghorn sculpin, and white croaker. Each of these species exhibited a statistically significant correlation between fish tissue chemistry and sediment chemistry for at least one contaminant evaluated (Table B.2). For example, a strong association in total chlordanes was observed between sediment and white croaker collected in San Pedro Bay (Figure B.1). These results indicate that there is a spatial association between fish and sediment contamination for all species. This finding further

suggests that these species may have bioaccumulated contaminants from nearby sediments.

Table B.2. Empirical model results of linear regressions relating contaminant concentrations in sediment to biota tissue. **Bold** indicates a significant positive relationship ($p<0.05$). N = number of locations.

Water body	Species	Contaminant	N	R^2	p-value	Slope direction	Spatial scale
San Diego Bay	**California halibut**	**Total DDTs**	**11**	**0.63**	**0.003**	**positive**	**4 km**

San Francisco Bay	**Shiner surfperch**	**Total PCBs**	**39**	**0.33**	**0.0001**	**positive**	**1 km**
San Francisco Bay	**Speckled sanddab**	**Dieldrin**	**5**	**0.99**	**0.0001**	**positive**	**2 km**
San Francisco Bay	**Speckled sanddab**	**Total DDTs**	**5**	**0.99**	**0.0001**	**positive**	**2 km**
San Francisco Bay	Staghorn sculpin	Dieldrin	25	0.50	0.0002	negative	1 km
San Francisco Bay	Staghorn sculpin	Total DDTs	25	0.04	0.4	positive	1 km
San Francisco Bay	**Staghorn sculpin**	**Total PCBs**	**25**	**0.73**	**<0.0001**	**positive**	**1 km**
San Francisco Bay	**White croaker**	**Chlordanes**	**33**	**0.17**	**0.02**	**positive**	**5 km**
San Francisco Bay	**White croaker**	**Dieldrin**	**17**	**0.36**	**0.01**	**positive**	**1 km**
San Francisco Bay	White croaker	Total DDTs	28	0.04	0.33	negative	2 km
San Francisco Bay	**White croaker**	**Total PCBs**	**15**	**0.36**	**0.02**	**positive**	**1 km**
San Pedro Bay	**White croaker**	**Chlordanes**	**10**	**0.80**	**0.0005**	**positive**	**2 km**
San Pedro Bay	White croaker	Dieldrin	10	0.11	0.36	positive	4 km
San Pedro Bay	White croaker	Total DDTs	10	0.17	0.24	positive	2 km
San Pedro Bay	White croaker	Total PCBs	10	0.04	0.59	negative	3 km

Because the prey tissue line of evidence evaluates exposure risk at the water body scale, it only requires confidence that the sampled species bioaccumulate contaminants from sediments within the entire water body. Since all species evaluated exhibited some evidence of affinity at relatively small spatial scales (< 5 km), the results in Table B.2 suggest that all species evaluated would be appropriate candidate species for using the prey tissue chemistry line of evidence at the water body scale.

Shiner surfperch exhibited significant relationships in all pollutants tested. For example, in San Francisco Bay, PCBs in shiner surfperch were significantly related to PCBs in sediments (Figure B.2), though the amount of variation explained was limited. The small spatial scale (1-2 km) at which significant relationships were observed, suggests that

surfperch are resident species with a benthic association. This contradicts previous reports (Shaw 1974, Emmett 1991) that shiner surfperch is a transient species. Bane (1970) indicated that the diet of shiner surfperch was primarily derived from benthic sources (i.e., including small crustaceans, sand/mud, and plant material). Evidence (this study and others) therefore suggests that shiner surfperch would be a highly appropriate species for the indirect effects framework.

Figure B.1. Linear regression of sediment and white croaker total chlordane concentration in San Pedro Bay. Appropriate spatial scale was determined following the method in Appendix L. Note log scale. Compounds included in totals are in Appendix N.

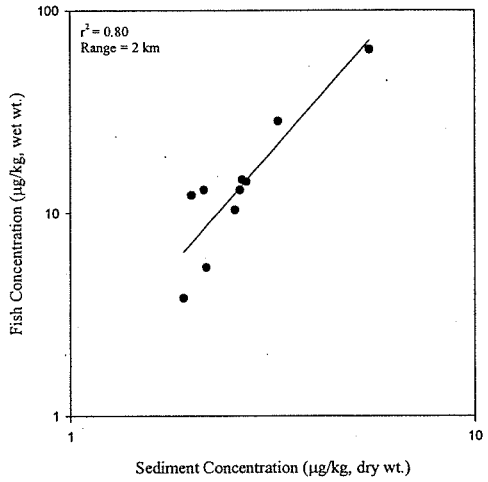

Figure B.2. Linear regression of sediment and shiner surfperch total PCBs (following Appendix L) in San Francisco Bay. Note log scale.

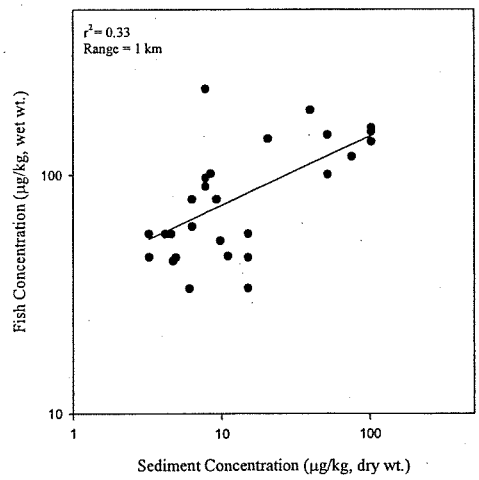
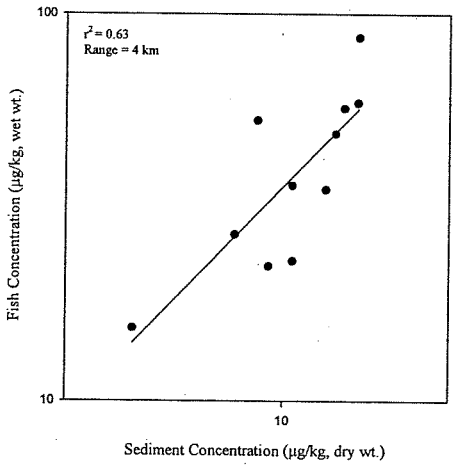


A number of species did not show significant relationships for some pollutants evaluated (Table B.2). One possible explanation is that we did not lipid-normalize the tissue data or organic carbon normalize the sediment data. For example, we did not observe significant relationships for PCBs or DDTs in San Pedro Bay white croaker. In contrast, Connolly and Glaser (1997), using the same data set, found an association between lipid weight PCBs and DDTs in white croaker vs. organic carbon normalized concentrations in sediment. The issues of lipid and organic carbon normalization are explored in the case studies (Sections 4 and 5).

Another possible explanation for the absence of significant spatial association between fish and sediments is that fish foraging ranges may be large enough to obscure spatial patterns in contaminant exposure at the scales examined (< 5 km). However this does not necessarily preclude using these fish species in the prey tissue line of evidence. For white croaker, results were inconsistent among contaminants and locations, with some contaminant-location combinations showing non-significant relationships (Table B.2), but with a very strong relationship for chlordanes in San Pedro Bay (Figure B.1). For white croaker, there is evidence of residence in a bay or estuary for the majority of the year, with some emigration to the coastal ocean during winter months (Fleming 1999). Flatfishes are known to vary their range depending on stage of development and time of year. For example, juvenile California halibut (less than 8 inches in length) are thought to remain relatively localized in bays and estuaries (Frey 1971). However, adult halibut generally migrate to deeper waters and may exhibit average movements of 13 km (Domeier and Chun 1995). In general, adults flatfishes limit movements to seasonal onshore-offshore migrations, but are generally resident within a given season (reviewed in Connolly and Glaser 1997). Despite potential for offshore movement, California halibut exhibited a positive association with sediment DDTs (Figure B.3).

Figure B.3. Linear regression of sediment and California halibut total DDT concentration in San Diego Bay. Note log scale.



Appendix C. The need to develop water-body specific bioaccumulation factors.

Introduction

The indirect effects assessment framework recommends that separate bioaccumulation factors be developed for individual water bodies, rather than using generic bioaccumulation factors (e.g., Arnot and Gobas 2003). This section critically evaluates the assumption that exposure parameters for sediment assessment should be developed separately for individual bays and estuaries. The sediment chemistry (Section 3.2) and case study (Sections 4 and 5) portions of this report provide more detailed guidance on how to develop these water body-specific parameters.

The theoretical basis for developing water-body specific bioaccumulation factors is that drivers of bioaccumulation will vary among water bodies. Differences among water bodies in biota vs. sediment relationships may result from multiple factors. These factors include differences in diet, food web structure, tissue lipid content, sediment organic carbon, and sediment vs. water column disequilibrium (Burkhard *et al.* 2003). There is substantial variation in BSAFs among locations, as observed in syntheses undertaken at national and global scales (Wong *et al.* 2001, Burkhard *et al.* 2005). The analyses in this section demonstrate the same phenomenon using California data.

Methods

This section used the CASQO database and empirical methods, as described in Appendix B. Analyses were conducted on finfish, and also on 28 day laboratory bioaccumulation test data for *Macoma nasuta* (bent-nosed clam) exposed to PCBs and DDTs in sediments collected from multiple water bodies.

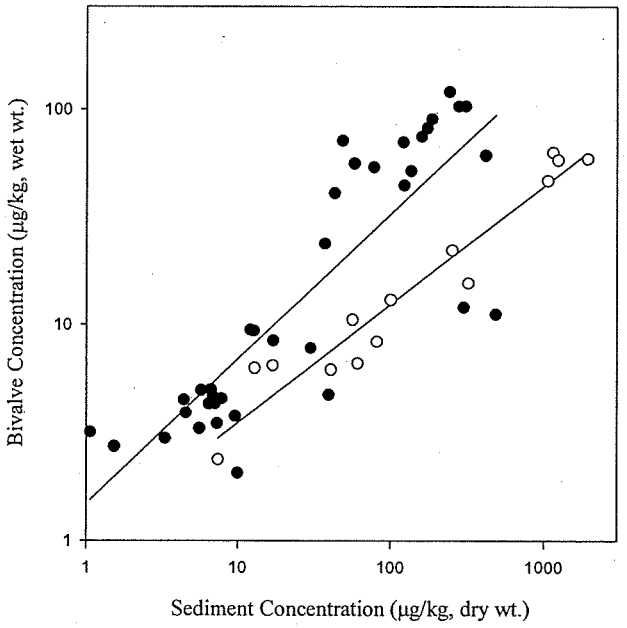
Data from were evaluated using general linear models. The focus of these analyses was determining whether statistically significant differences were observed between water bodies in sediment vs. biota pollutant relationships. The statistical approach was regression analysis using categorical (dummy) variables for individual water bodies. This is a generalization of the Analysis of Covariance model, in which general linear models are constructed and differences in slope or elevation of a linear relationship are evaluated for statistical significance (i.e., $p < 0.05$) of added parameters. This is a commonly used and well described statistical approach (e.g., Packard and Boardman 1988, Draper and Smith 1998, Tremblay *et al.* 1998, Greenfield *et al.* 2005).

The empirical comparisons among water bodies were complimented with mechanistic food web model simulations. Mechanistic model simulations were performed using the methods and parameters described in application guidance (Section 3.2.8) and the Newport Bay and San Francisco Bay case studies (Sections 4.4 and 5.3.2). Briefly, a steady state non-equilibrium food web model (Gobas 1993, Morrison *et al.* 1996, Arnot and Gobas 2004) was applied using local parameters for each water body. The model was run for selected contaminants for each water body to evaluate how model-predicted bioaccumulation factor varied between water bodies.

Results of empirical analysis

Analysis of bioaccumulation test data from multiple water bodies indicates that contaminant bioavailability varied significantly among water bodies. *Macoma nasuta* PCB tissue concentrations were significantly higher at a given sediment PCB concentration when the tests were conducted using San Francisco Bay sediments than San Diego Bay sediments (Figure C.1). Regression analysis of log-log data indicated a significant difference in the model constant (y-intercept) when a categorical variable was applied to distinguish among the data from the two bays (bay variable p-value < 0.001; N = 51). When the variable to distinguish among bays was added, the R^2 increased from 0.65 to 0.75. At the arithmetic mean sediment concentration of the data set (190 ng/g dry weight), the model predicted that laboratory *Macoma* concentrations in San Francisco Bay were 2.6 times the concentrations predicted in San Diego Bay (47 vs. 18 ng/g). Similar results were also observed comparing p,p'-DDE concentrations in paired samples from Newport Bay vs. San Francisco Bay. Both water bodies showed significant relationships between sediment and *Macoma* p,p'-DDE concentrations ($p < 0.001$), but *Macoma* concentrations were significantly higher in San Francisco Bay (for addition of categorical variable to distinguish among bays, $p < 0.0001$).

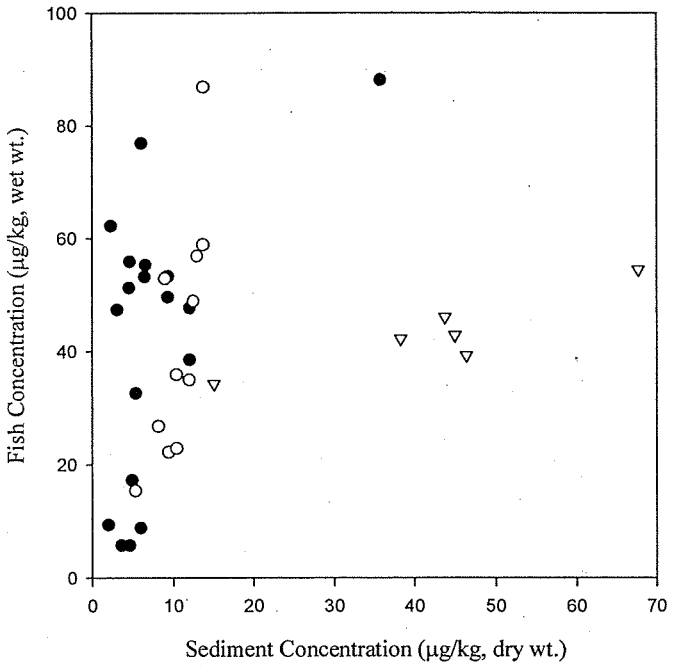
Figure C.1. Relationship between PCBs in sediments vs. *Macoma nasuta* exposed in 28 day laboratory tests. Black dots (•) = San Francisco Bay. White dots (○) = San Diego Bay. Lines represent best linear regression fit on log-log regression. Note log scale of axes.



Available field captured fish data also indicated differences in bioavailability among water bodies. California halibut vs. sediment DDTs were compared among San

Francisco Bay, San Diego Bay, and San Pedro Bay (Figure C.2). Evaluated individually, regression relationships differed among water bodies, with San Pedro Bay ($R^2 = 0.75$; $p = 0.03$; $N = 6$) and San Diego Bay ($R^2 = 0.63$; $p = 0.003$; $N = 11$) exhibiting positive relationships, while San Francisco Bay ($R^2 = 0.18$; $p = 0.08$; $N = 18$) exhibited only a weak positive trend. Figure C.2 indicates that the slope of these relationships also varied among water bodies, with fish increasing much more rapidly at a given sediment concentration in San Diego Bay, than San Pedro Bay.

Figure C.2. Relationship between total DDTs in sediments vs. California Halibut captured from different embayments. Black dots (●) = San Francisco Bay. White dots (○) = San Diego Bay. Triangles (Δ) = San Pedro Bay.



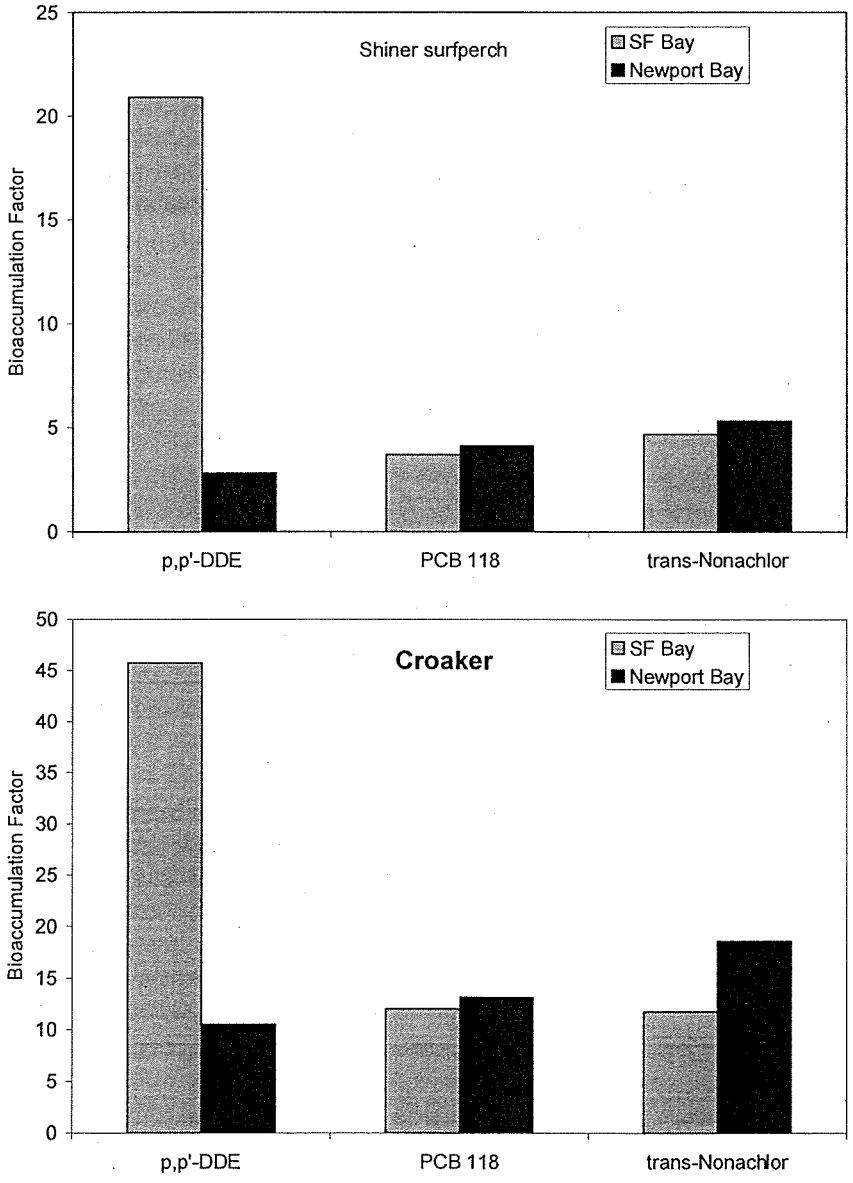
Results of mechanistic modeling

When the mechanistic model was applied using parameters from the San Francisco vs. Newport Bay case studies, differences in bioaccumulation factor were observed. Differences were most apparent for p,p'-DDE (Figure C.3). These model results suggest that BAFs may differ among the same or similar fish species, as a result of chemical or biological differences among water bodies.

Taken in combination, the empirical data analyses and mechanistic model results suggest that contaminant bioavailability may vary greatly among different bays and estuaries. Therefore, attempts to predict bioaccumulation factors using generalized equations are likely to introduce uncertainty or inappropriate sediment chemistry thresholds.

If predictive translators between sediments and biota were to be developed on a statewide basis, it would be advisable to conduct a special study examining the range of conditions among multiple water bodies of interest, by collecting new data on sediment vs. biota concentrations for widely distributed fish species.

Figure C.3. Results of mechanistic food web model predicting bioaccumulation factor (BAF) for p,p'-DDE, PCB 118, and trans-Nonachlor in similar fish from San Francisco Bay (blue) vs. Newport Bay (black). All results based on application of the food web model developed by Arnot and Gobas (2004), as described in Sections 4 and 5 of this report. Top panel: shiner surfperch (juvenile). Bottom panel: white croaker (SF Bay) vs. yellowfin croaker (Newport Bay).



Appendix D. Literature review on body length of fish consumed by piscivorous birds.

Table D.1. Results of a literature review on body length of fish consumed by piscivorous birds. The review targeted California species and locations, where possible. For large birds (Table 3.5), maximum body length of prey consumed was 473 mm. For medium sized birds, maximum prey body length was 165 mm. For least tern, fish up to 107 mm were captured (Atwood and Kelly 1984, Elliott 2005).

Predator species	Predator type [a]	Prey fish length average (mm)	Prey fish length range (mm)	Location	Reference
Bald eagle	Large bird		230-380	Shasta Co., CA	Jenkins and Jackman (1994)
Bald eagle	Large bird	274	127 - 473	Arizona	Haywood and Ohmart (1986)
Double-crested cormorant	Large bird		45 - 300	Maine and Florida	Scattergood (1950)
Osprey	Large bird		130 - 430	Minnesota	Dunstan (1974)
Western grebe	Medium bird		< 100	British Columbia	Forbes and Sealy (1990)
Western grebe	Medium bird		27 - 88	Clear Lake, CA	Lawrence (1950)
Elegant tern	Medium bird		40 - 165	San Diego, CA	Schaffner (1986)
Black skimmer	Small bird		21-55	Florida	Leavitt (1957)
Black skimmer	Small bird		< 73	Louisiana	Arthur (1927)
Least tern	Small bird		< 100	California Coast	Atwood and Kelly (1984)
Least tern	Small bird	52	17 – 107	Alameda, San Francisco Bay, CA	Elliot (2005)

Appendix E. Method for extrapolating between whole body and muscle fillet organochlorine contaminant content in fish.

In the case of lipophilic contaminants, approximate lipid equivalence among tissue types may be assumed. This assumption should be appropriate for PCBs, DDTs, and other legacy organochlorine pesticides. It may also be appropriate for dioxins, PBDEs, and other compounds having a high K_{OW}. To facilitate interconversion to the most appropriate tissue type for contaminant exposure evaluation, concentrations may be extrapolated between whole body and fillet samples, assuming lipid equivalence:

$$\text{Whole Body Concentration} = \text{Fillet Concentration} * \frac{\text{Whole Body \% Lipid}}{\text{Fillet \% Lipid}}$$

When lipid concentrations are not available in both tissue types from the same species, an empirical relationship may be used to extrapolate whole body vs. fillet (skin off) lipid content, based on published literature. The equation for this relationship is:

$$\text{(Whole Body \% Lipid)} = 2.1372\ \text{(Fillet \% Lipid)}^{1.0025}$$

This empirical model is based on published literature on the ratio between whole body and muscle (skin off fillet) lipid (Table E.1, following page). For development of this model, each separate species was treated as an individual data point, regardless of the number of trials in an individual study. The comparison results indicated a strong relationship ($R^2 = 0.93$; N = 11; Figure E.1).

Figure E.1. Relationship between whole body and muscle fillet lipid content in fish. Data from Table E.1 are graphically depicted and results of a regression on log-transformed data are presented. Note log scale, both axes.

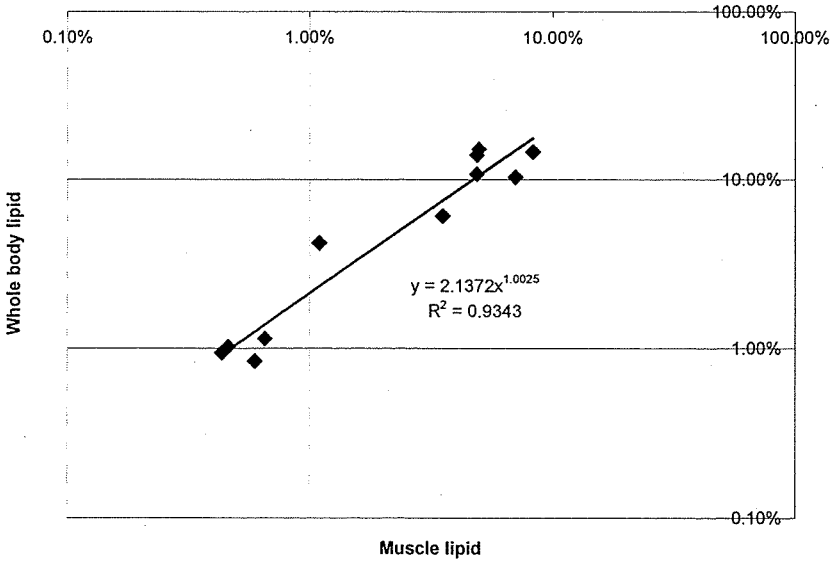

Table E.1. Summary of published data on whole-body vs. fillet tissue lipid contents in fish.

Appendix F. Power analyses to determine appropriate sample sizes for prey tissue line of evidence.

For the prey tissue line of evidence (LOE), field collections and chemical analyses can be costly. Nevertheless, accurate estimate of chemical concentrations in prey tissue is a key data need for the framework. To address this, power analyses were performed to determine appropriate sample sizes to estimate concentrations in prey tissue.

Methods

Power analyses were performed using representative data on finfish tissue concentrations of legacy contaminants. Analyses determined the upper and lower 95% confidence intervals of average tissue concentration estimates, based on the average and standard deviation of the representative data, across a range of potential sample sizes. To evaluate a range of potential conditions, two data sets were modeled. Prior to analysis, both data sets were square-root transformed to achieve normal distributions.

The first data set evaluated was 1994 data for total DDTs in white croaker in San Francisco Bay (N = 25 composite samples), obtained by Fairey *et al.* (1997). Error bars were estimated based on the average square root concentration (7.63 in square root units; 58 in linear units), the standard deviation of this average (1.77 in square root units), and the sample size. This analysis likely represents a low-end estimate of total variance (leading to relatively high power), because the data represent a single species in a single water body.

The second data set evaluated included all fish tissue data from the CASQO database for total PCBs in California fish (N = 378). Error bars were estimated based on the average square root concentration (9.08 in square root units; 82 in linear units) the standard deviation of this average (3.87 in square root units), and the sample size. This analysis likely represents a high-end estimate of total variance (leading to relatively low power), because the data represent multiple species in multiple water bodies.

Results and interpretation

The first power analysis was based on parameters estimated for total DDTs in white croaker analyzed in 1994 in San Francisco Bay. Based on this analysis, sample sizes below 10 resulted in upper and lower confidence estimates of averages between 70% and 130% of the actual average concentration (Figure F.1). In the second analysis, parameters were estimated using PCB concentrations in all fish in California waters. The analysis indicated that sample sizes below 10 resulted in upper and lower confidence estimates of averages between 50% and 170% of the average concentrations (Figure F.2). It should be noted that this latter simulation is likely to overestimate actual variability in concentrations in individual bays or estuaries, because of the additional variation between estuaries.

Based on these results, sample sizes should be at least 10 to make assessments for the fish tissue line of evidence for a particular water body.

Figure F.1. Results of power analysis on ability to estimate average tissue concentrations (wet weight), for DDTs in white croaker collected in 1994. Bar represents average concentration, and error bars represent upper and lower 95% confidence intervals of the average.

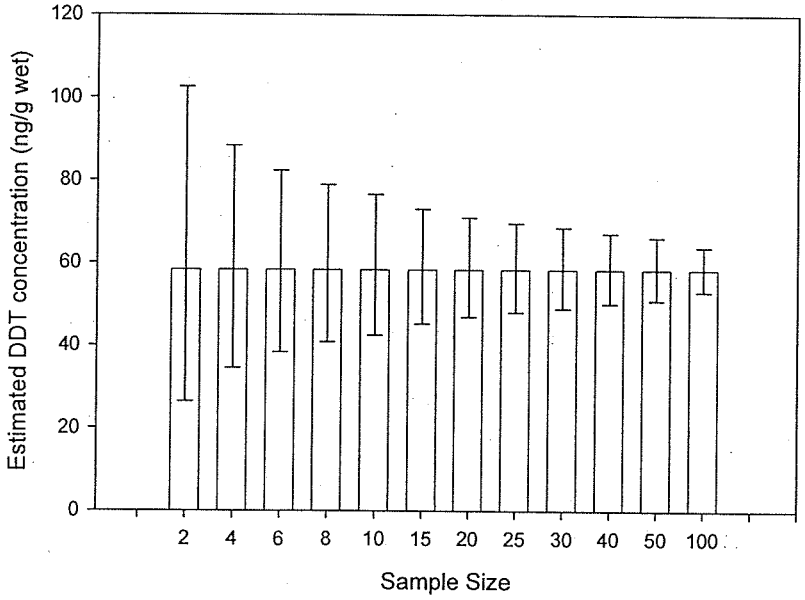

Figure F.2. Results of power analysis on ability to estimate average fish tissue concentrations (wet weight), for total PCBs in California fish. Bar represents average concentration, and error bars represent upper and lower 95% confidence intervals of average.

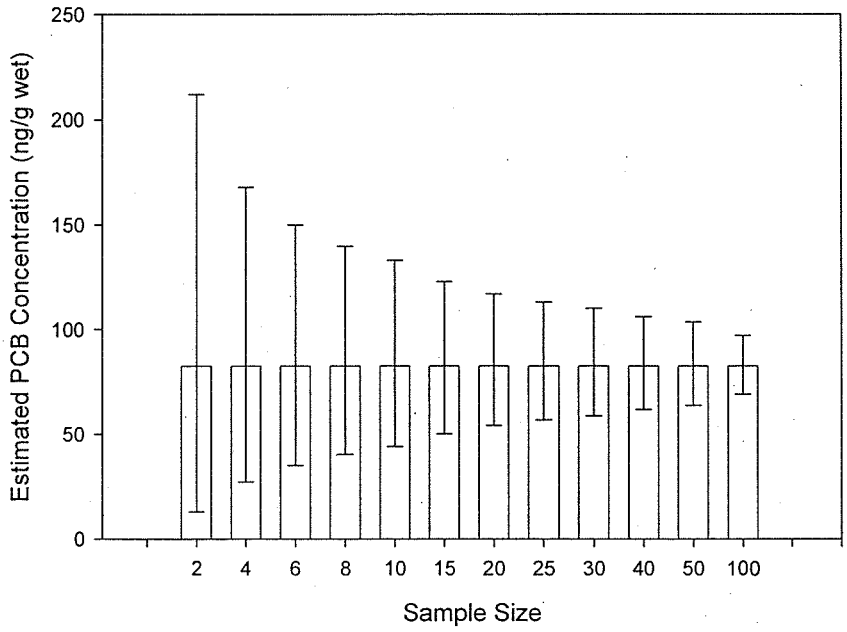

Appendix G. Background information on averaging methods

Typical methods of averaging data include arithmetic mean, geometric mean, and median. For the purposes of estimating contaminant concentration and exposure, each method has relative advantages and disadvantages (Helsel and Hirsch 2002). Contaminant concentrations are typically lognormally distributed, rather than normally distributed, suggesting that geometric mean better represents the central tendency of the distribution (MacLeod *et al.* 2002). Medians are less sensitive to outliers, such as concentrations below detection limits.

Arithmetic mean is most appropriate to represent mass transfer processes such as overall contaminant exposure of predators due to consuming contaminated prey. This is because arithmetic mean will best represent the importance of uncommon occurrences of high magnitude, such as occasional consumption of highly contaminated prey items (Helsel and Hirsch 2002). Arithmetic mean will be higher, and thus more conservative for estimating contaminant exposure. In general, averages and upper confidence intervals should be estimated using arithmetic and geometric mean, in order to estimate the skewness of the data-set[40]. If the different averaging procedures yield differing results, it would be more appropriate to use the arithmetic mean because it accounts for the relative importance of rare but highly contaminated samples.

In addition to calculating the arithmetic mean (μ), the 95% upper confidence interval (UCI) of the mean should be calculated as:

$$95\%\ UCI = \mu + 2^{*}\sigma$$

$$\text{where } \sigma = \text{standard error of mean} = \frac{\text{standard deviation}}{\sqrt[2]{n}}$$

and n = total number of samples.

The geometric mean is calculated as:

$$10^{\left[\frac{\sum_{i}^{n} Log_{10}(x_i)}{n}\right]}$$

where x_i = each individual sample measurement, and n = the total number of samples.

However, in many cases, some sample concentrations will be below detection limits (ND). It is not possible to determine geometric mean concentrations, estimating ND values as zero (as log(0) does not exist). To handle ND values, values may be set to ½ of

[40] For data skewed towards lower values (i.e., long tail of higher concentrations), the geometric mean will be lower than the arithmetic mean.

the detection limit or values may be estimated for averaging by the robust methods of Helsel and Hirsch (2002).

To estimate geometric mean in instances with ND values set at zero, it is also possible to obtain an estimate of geometric mean by adding 1 to each value, obtaining the geometric mean, subtracting 1 from the geometric mean, and exponentiating. That is, geometric mean estimate equals:

$$10^{\left[\frac{\sum_{i}^{n} Log_{10}(x_i+1)}{n}\right]} - 1$$

where x_i = each individual sample measurement, and n = the total number of samples.

Geometric standard error of the mean (σ) is simply the standard error of all log transformed values.

The 95% upper confidence interval (UCI) of the geometric mean may be calculated as:

$$10^{\left[\frac{\sum_{i}^{n} Log_{10}(x_i+1)}{n}\right]} + 2*\sigma$$

Appendix H. Toxicity reference values (TRVs), reference doses (RfD), and cancer slope factors (CSF) for birds, mammals, and humans.

Table H.1. A compilation of toxicity reference values (TRVs), reference doses (RfD), and cancer slope factors (CSF) for birds, mammals, and humans. Prey tissue chemistry thresholds in the framework could be based on these or other appropriate TRVs, as decided by risk assessors.

Contaminant	Mammal Low TRV mg dw/(kg ww*day)	Mammal High TRV mg dw/(kg ww*day)	Ref.	Avian Low TRV mg dw/(kg ww*day)	Avian High TRV mg dw/(kg ww*day)	Ref.	Human Noncarcinogen RfD (mg/kg*d)	Human Carcinogen CSF (kg*d/mg) More protective	Ref.

Description of toxicity reference values in Table H.1

Table H.1 presents a set of wildlife and human TRVs that may be considered for use in the assessment framework. These TRVs may be input into Equations 3.1, 3.2, and 3.3 (from Section 3.1.10), following the example in Figure 3.3. For avian and mammalian targets, Table H.1 includes low (no observable adverse effects level) and high (mid-range of lowest observable adverse effects) toxicity reference values (TRVs). This corresponds with the assessment framework's use of two risk thresholds. In particular, for wildlife targets, the low TRV may be used to derive low prey tissue thresholds and the high TRV may be used to derive high prey tissue thresholds. Example thresholds for generic bird and mammal targets are presented in Appendix J.

The human TRVs in Table H.1 include reference doses for non-carcinogenic effects, and cancer slope factors for carcinogenic effects. All of these values were taken from the U. S. EPA's IRIS database (U. S. EPA 2006b),. Example thresholds for human targets are presented and discussed in Appendix K.

Whenever possible, the TRVs in Table H.1 were developed using a multi-agency consensus approach. Two sets of such values were available for inclusion. These are the Navy/BTAG TRVs (California DTSC Human and Ecological Risk Division 2000) and the U. S. EPA ECO-SSL values (U. S. EPA 2005). Navy/BTAG TRVs have been used in recent risk assessments in California estuaries (von Stackelberg *et al.* 2003, Arcadis G&M Inc. and Matrix Design Group 2004, Zeeman 2004). The derivation and basis for these TRVs are presented elsewhere (PRC Environmental Management 1997, California DTSC Human and Ecological Risk Division 2000). For dieldrin, the Navy/BTAG TRVs are not available; U. S. EPA ECO-SSL values are presented instead (U. S. EPA 2005) (Table H.1).

Where warranted, TRVs for specific compound classes are discussed further in the remainder of this section.

DDTs

Of the TRVs presented, the lowest is the avian TRV-Low for DDTs. This TRV is based on a field study of brown pelicans in California (Anderson *et al.* 1975, Anderson *et al.* 1977). It was recommended by the U. S. EPA as part of the Great Lakes Water Quality Initiative (U. S. EPA 1995a), and by BTAG for risk assessment in California (California DTSC Human and Ecological Risk Division 2000). It has also been used by the U. S. Army Corps of Engineers for a risk assessment in Moss Landing Harbor, California (von Stackelberg *et al.* 2003), by the U. S. Fish and Wildlife Service for risk assessment in San Diego Bay (Zeeman 2004), and in a risk assessment for the former Oakland Army Base (Arcadis G&M Inc. and Matrix Design Group 2004). In Anderson *et al.* (1975), concentrations of DDD, DDE, and DDT from 1969 to 1974 were associated with adverse impacts to eggshell thickness and reproductive success. A dose-response relationship was observed, and adverse effects were still observed in the least contaminated population. An uncertainty factor of 3 was used to convert this LOAEL to an NOAEL

value, resulting in a final TRV of 0.009 mg/(kg body weight*day) (Anderson *et al.* 1975, Anderson *et al.* 1977, U. S. EPA 1995a).

Dieldrin

For dieldrin, the U. S. EPA ECO-SSL would be appropriate for a TRV-Low (values are presented for birds and mammals in Table H.1). The ECO-SSL TRV is based on NOAELs, and may therefore be too conservative for a TRV-High. To obtain a TRV-High for dieldrin, the synthesis of appropriate studies conducted to generate the ECO-SSL may be used (U. S. EPA 2005). Specifically, the geometric mean of all avian and mammalian LOAELs for survival, growth, and reproductive effects would be an appropriate TRV-High. Based on this calculation, the TRV-High for dieldrin in mammals is 1.80 mg/kg/d (N = 34 studies) and the TRV–High for dieldrin in birds is 1.05 mg/kg/d (N = 37) (Table H.1).

PCBs

Table H.1 does not include a TRV – Low for mammals. Instead, footnote g of Table H.1 references use of a prey tissue concentration of 0.5 mg/kg. The Navy/BTAG TRVs for PCBs in mammals are based on rodents, which are not the most sensitive indicator, and are also not aquatic animals. Of aquatic mammals evaluated, mink is the most sensitive indicator for PCBs (Jones *et al.* 2001). A recent review conducted in the Great Lakes Region has summarized the literature on NOAELs and LOAELs in mink (Chapman 2003). Based on this review, a PCB concentration TRV of 0.5 mg/kg in prey tissue would be an appropriate TRV-Low (Chapman 2003). Note that this is a prey tissue concentration TRV (units of mg/kg), rather than a dose-based TRV (units of mg/[kg*d]).

Chlordanes

Chlordane TRV development presents a challenge, because there have been few studies of dietary uptake in animals, and no consensus evaluations. For total chlordanes in birds, Table H.1 includes TRVs based on Stickel *et al.* (1983). This set of values is based on dietary uptake of chlordanes by red-winged blackbird, and was recommended for TRV calculation by Sample *et al.* (1996). It was also recommended by staff members of the CA Department of Toxic Substances Control (M. Anderson, DTSC, *Pers. comm.*), and has been used in a number of ecological risk assessments in California (von Stackelberg *et al.* 2003, Arcadis G&M Inc. and Matrix Design Group 2004).

Chlordane calculations for birds were as follows. Stickel et. al (1983) reports a mortality NOAEL of 10 mg chlordane/kg food and a mortality LOAEL of 50 mg chlordane/kg food. The study exposure duration was 84 days, which may be interpreted as chronic or subchronic exposure (Sample *et al.* 1996). Food intake rate is 9 g/day based on allometric calculations for omnivorous birds and a reported body mass of 64 g (Nagy 2001). A TRV-High was calculated based on the LOAEL, and assuming that 84 days represents chronic exposure, as:

(50 mg chlordane/kg food)*(0.009 kg food intake/day)/0.064 kg body mass
= 7.0 mg/(kg body weight*day)

A TRV-Low was calculated based on the NOAEL, assuming that exposure was subchronic and reducing by a factor of 10 as a conservative estimate of chronic exposure from the subchronic exposure (Sample *et al.* 1996):

(10 mg chlordane/kg food)*(0.009 kg food intake/day)/
(0.064 kg body mass * 10 correction factor)
= 0.14 mg/(kg body weight*day)

For total chlordanes in mammals, Table H.1 includes a TRV - Low based on Khasawinah and Grutsch (1989) and a TRV – High based on World Health Organization (1984) (primary citation Keplinger *et al.* 1968). These values are based on dietary uptake of chlordanes by mice. Khasawinah and Grutsch (1989) was recommended for TRV calculation by staff members of CA Department of Toxic Substances Control, and has been used in a number of military base ecological risk assessments in California (M. Anderson, DTSC, *Pers. comm.*). Keplinger *et al.* (1968) were recommended for TRV calculation by Sample *et al.* (1996), and subsequently used by von Stackelberg (2003).

The chronic LOAEL in Keplinger *et al.* (1968) is 50 mg chlordane/kg food. Food intake rate is 4.6 g/day based on allometric calculations for rodents and a reported body mass of 30 g (Nagy 2001). A TRV-High based on this LOAEL is:

(50 mg chlordane/kg food)*(0.0046 kg food intake/day)/0.030 kg body mass
= 7.7 mg/(kg body weight*day)

Khasawinah and Grutsch (1989) report a chronic NOAEL of 1 mg chlordane/kg food. Food intake rate is 4.6 g/day based on allometric calculations for mice and a reported body mass of 30 g (Nagy 2001). A TRV-Low based on this NOAEL is:

(1 mg chlordane/kg food)*(0.0046 kg food intake/day)/0.030 kg body mass
= 0.15 mg/(kg body weight*day)

Based on evaluation of the CASQO database and other studies, exceedance of these chlordane thresholds (both low and high) is highly unlikely for California fishes collected in the recent past.

Heptachlor, aldrin and toxaphene

The BTAG has previously developed mammalian TRVs for the pesticides, heptachlor and aldrin (Table H.1). However, avian TRVs have not been developed for these pesticides by BTAG or by Sample *et al.* (1996), and published dose-response studies on these compounds are lacking. The BTAG has not developed mammalian or avian TRVs for toxaphene. Heptachlor and aldrin are not currently present in detectable concentrations in fish in California waters, and toxaphene concentrations are rarely

detected (Davis *et al.* 1999, Greenfield *et al.* 2003, Allen *et al.* 2004, Greenfield *et al.* 2004). Therefore, development of additional TRVs for these contaminants is a relatively low priority.

Appendix I. Potential thresholds for protection of fish

Fishes represent another receptor that may be adversely impacted due to indirect effects from sediment contamination. Finfish may be impacted by dietary exposure to contaminated prey residing in contaminated sediments, as well as consumption of and direct contact with contaminated sediments.

Table I.1 lists thresholds from several recent syntheses of biological effects to fish. Each of these syntheses was a careful well-documented development of an effects threshold based on appropriate studies. Each synthesis conducted a broad review of available literature, and included a screening step to remove inappropriate studies. These studies were also discussed and favorably reviewed by members of Region IX BTAG (Laurie Sullivan, NOAA-National Ocean Service, *Pers. comm.*), although no formal statement has been made.

Table I.1. Literature recommended values for protection of finfish. All studies represent syntheses of the latest available literature at the time of publication. ww fish = wet weight fish tissue concentration; lw fish = lipid weight fish tissue concentration; dw = dry weight sediment concentration

Appendix J. Selected prey tissue thresholds for protection of generic wildlife consumers of finfish and shellfish.

Table J.1. Selected prey tissue thresholds for protection of generic wildlife consumers of finfish and shellfish. Wildlife categories are based on generic estuary wildlife in California, following Table 3.5. Thresholds are calculated based on information in H.1, following methodologies in the text (see Equation 3.1 and Figure 3.3). Note that all thresholds are tissue dry weight thresholds (ppm). MA = Body Mass. NA = Not available due to insufficient data

Group	Body Mass (kg) [a]	Allometric Equation [a,b]	Daily Ingestion Rate (kg dw food/day)	Ingestion Rate (kg dw food/(kg body weight*day))	DDT Low (ppm dry weight fish tissue)	DDT High (ppm dry weight)	PCB Low (ppm dry weight)	PCB High (ppm dry weight)	Chlordane Low (ppm dw)	Chlordane High (ppm dw)	Dieldrin Low (ppm dw)	Dieldrin High (ppm dw)	Heptachlor Low (ppm dw)	Heptachlor High (ppm dw)	Aldrin Low (ppm dw)	Aldrin High (ppm dw)	Mercury Low (ppm dw)	Mercury High (ppm dw)

a. From Table 3.5.
b. Note that units are in grams.
c. Following Appendix H, the PCB Mammal Low TRV is a tissue concentration reference value (500 mg/kg), rather than a dose-based TRV (Chapman 2003).

Appendix K. Selected prey tissue thresholds for protection of human consumers of finfish and shellfish.

Table K.1 illustrates some potential tissue thresholds for protection of human consumers of fish. These thresholds are calculated based on a range of assumptions recently presented by California and national regulatory agencies for protection of consumers of wild-caught fish (Brodberg and Pollock 1999, U. S. EPA 2000b, 2000d, OEHHA 2001, Klasing and Brodberg 2006). All thresholds were calculated according to U. S. EPA guidance (U. S. EPA 2000b), summarized in Section 3.1.10, 3.1.11, and 3.1.13). Reference doses and cancer slope factors were taken from Appendix Table H.1, based on U. S. EPA (2006b). Body masses were set at 70 kg. The risk factor for carcinogens varied between 10^{-4} and 10^{-6}, and consumption rates varied from subsistence fishers, to sport fishers, to the general population. The risk calculation that uses a less conservative combination of assumptions is in the top row of the table, and each following row is increasingly more conservative.

Table K.1 includes the following sets of thresholds and assumptions:

- Risk calculations presented in a draft guidance document prepared by OEHHA scientists for developing guidance tissue levels in California waters (Klasing and Brodberg 2006).
- The risk calculation following U. S. EPA recommendations for screening values to protect sport fishers and the general public (U. S. EPA 2000b).
- A risk calculation presented by OEHHA as a screening value to protect human consumers of sport fish in California waters (Brodberg and Pollock 1999), and used in calculating many OEHHA consumption advisories (R. Brodberg, OEHHA, *Pers. comm.*).
- A risk calculation based on an estimated 95 percentile consumption rate by sport fish consumers in San Francisco Bay (SFEI 2000)[41].
- The risk calculation that was legislated in the California Toxics Rule (U. S. EPA 2000d).
- The risk calculation following U. S. EPA recommendations for screening values to protect subsistence fishers (U. S. EPA 2000b).

The case studies in the report (Sections 4 and 5) use the U. S. EPA screening values and the calculation based on 95 percentile sport fish consumer as the bases for the high and low tissue thresholds. These are highlighted in grey in Table K.1. These selections should not be viewed as specific recommendations for statewide sediment quality

[41] U. S. EPA does not provide recommendations for an upper percentile intake rate for recreational sport fishers or the general public. As discussed in OEHHA (2001), the San Francisco Bay Seafood Consumption Study is the most recent peer-reviewed study to calculate confidence distributions for sport fish consumers in California. This study calculates consumption rates based on 12 month recall or 4 week recall. The 12 month recall is more likely prone to errors, and was not adjusted for avidity bias (a sampling bias introduced by positive correlation between consumption rate and frequency of fishing). Therefore, the 4 week recall rate was used to calculate the 95 percentile sport fish consumer consumption rate. In short, this set of thresholds was based on a consumption rate of 32 g/d, which is the 95th percentile consumption rate of all sport fish consumers surveyed (4 week recall), adjusted for avidity bias (Table 5.6) (SFEI 2000).

evaluation guidance. As discussed elsewhere in the report[42], threshold development involves policy judgments, and must occur in a policy arena with sufficient opportunity for stakeholder review and feedback.

[42] See the Acknowledgements and Disclaimer section, as well as Sections 3.1.10 and 3.1.13.

Table K.1. Some fish tissue thresholds for protection of human consumers of finfish and shellfish in California bays and estuaries. Bold values are the lower threshold among the cancer risk and non-cancer risk (reference dose) approaches. Grey rows are used to develop high and low fish tissue and sediment thresholds in report case studies (Sections 4 and 5). All scenarios assume a consumer body mass of 70 kg (U. S. EPA 2000b).

Appendix L. Description of procedure to determine spatial association between sediment and biota contaminant concentrations.

A statistical procedure was developed to address difficulty evaluating animal home range, and need for overlapping fish and sediment samples (CH2M HILL 2004). In this procedure, fish or other mobile organisms are averaged at each discrete sampling location. The average concentration is then compared to sediment samples located in a circle centered at the spatial coordinates of that sampling location (Figure L.1). Sediment results are averaged over the entire pooled spatial area, and the average result is paired with the average of organism tissue concentrations at that location. Regression analysis is conducted to evaluate the paired results. Following standard practice in linear regression analysis, residuals should be checked for normality and variance homoskedasticity, and biota and/or sediment concentrations transformed if necessary (Draper and Smith 1998). Frequently, log-transformation of both sediment and biota data is necessary. The procedure may be applied using lipid normalized or wet weight tissue data and organic carbon or dry weight sediment data. The procedure does not work on data sets having less than five separate biota sampling locations, as a lot of spurious correlations occur. The size of the circle may be varied at increasing radial distance (e.g., 0 – 10 km at 1 km increments) to evaluate overall correlation between biota and sediment concentrations, and identify the spatial scale at which the correlation is greatest (Figure L.2).

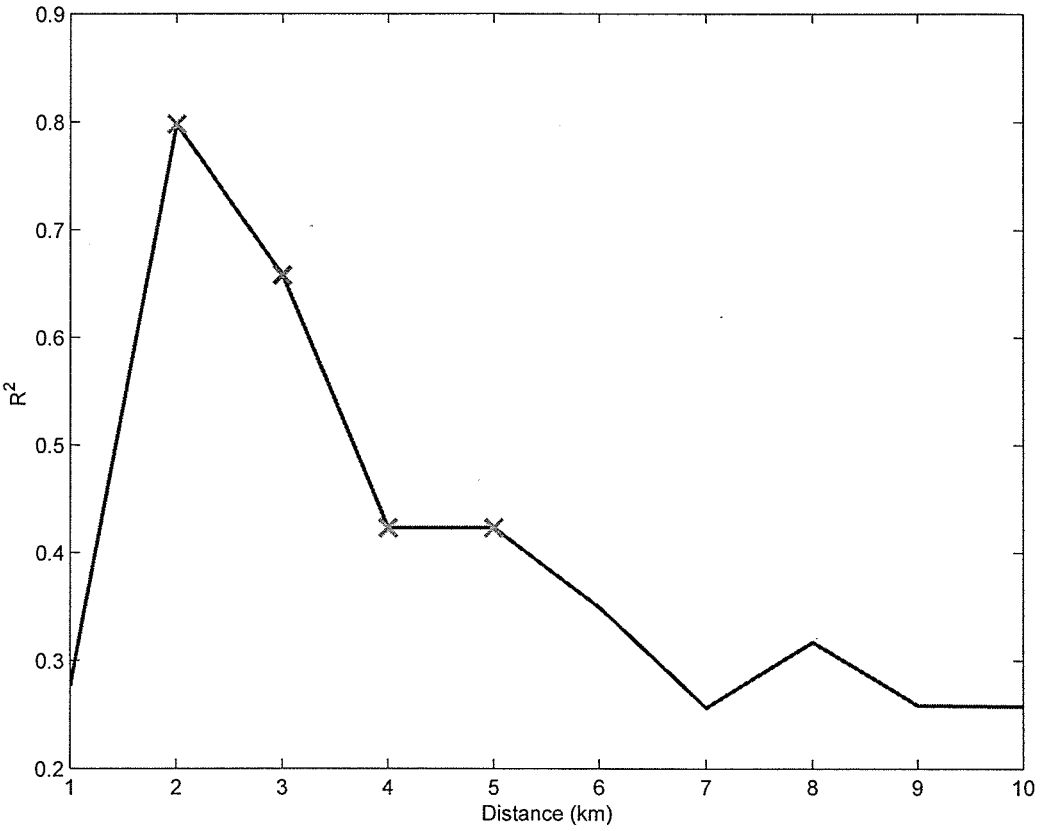
This method can be used for several purposes:

- Identify the spatial scale of biota exposure to sediments, when fish may be expected to range across a large area.
- Identify species with relatively strong spatial association to sediment contamination, based on significant sediment vs. biota concentrations. Such species can be appropriate for developing empirical BAFs for the sediment chemistry line of evidence.
- Develop a data set for determining empirical BAFs when biota and sediment sampling were not at identical locations, as is frequently the case when combining sediment and fish chemistry databases.

Conceivably, this method could also be used to develop linear regression models for predicting BAFs across a range of sediment concentrations. In theory, this provides the advantage of allowing BAF to vary according to the statistically determined slope and y-intercept of a particular empirical data set (Packard and Boardman 1988, Hebert and Keenleyside 1995). In practice, however, these models tend to have high predictive uncertainty and not be very useful. This results from limited available data, the log-transformations, and high variability of the data set. Though such a use could certainly be explored to develop bioaccumulation models in specific circumstances, it was determined to be inappropriate for the Newport Bay and San Francisco Bay case studies.

Figure L.1. Graphical depiction of comparison of fish vs. sediment data in a circle at increasing radial distance from the fish. Red dots represent fish samples, and blue dots represent sediment samples.

Figure L.2. Example of model output from spatial association procedure. Results are presented for chlordanes (wet weight) in white croaker in San Pedro Bay (N = 10). Red X's indicate significant relationships ($p < 0.05$) at the given spatial scale. Note that this is the same relationship as presented in Figure B.1 and Table B.2.



Appendix M. Summary of parameters and equations for Arnot and Gobas mechanistic food web model.

This model is used to corroborate empirical field results in this report. All model equations and assumptions have been presented elsewhere (Gobas 1993, Arnot and Gobas 2004, Gobas and Arnot 2005).

Abiotic Input Parameters

Cox = dissolved oxygen concentration (mg O_2/L)
T = mean water temperature
Kow = octanol water partitioning coefficient
KowTS = octanol water partitioning coefficient (corrected for temperature and salinity)
cwater = contaminant concentration in waters
csed = contaminant concentration in sediments
salinity = water salinity (PSU)
MCS = molar concentration of seawater at 35 ppt (mol/L)
SPC = Setschenow proportionality constant (L/cm^3)
ocsed = organic carbon proportion in sediment (kg/kg)
vss = concentration of suspended solids (kg/L)
xpoc = POC concentration in H_2O (kg/L)
xdoc = DOC concentration in H_2O (kg/L)
dpoc = disequilibrium factor for POC partitioning
ddoc = disequilibrium factor for DOC partitioning
alphapoc = proportionality constant describing phase partitioning of POC and DOC
alphadoc = proportionality constant describing phase partitioning of POC and DOC

Biotic Input Parameters

A, B = constants for phytoplankton aqueous uptake rate
Wb = body weight
assimEff(i) = assimilation efficiency for lipid(i = 1) nlom (i = 2) and water (i = 3)
EdA = Constant A in dietary uptake efficiency equation
EdB = Constant B in dietary uptake efficiency equation
lipid = tissue lipid content
nlom = tissue non-lipid organic matter content
beta = lipid-equivalency conversion factor for bioconcentration factor for non-lipid organic matter
betap = plant lipid-equivalency conversion factor for bioconcentration factor (for nlom)
wc = tissue water content
mo = proportion of respiration or transpiration due to overlying water column
mp = proportion of respiration or transpiration due to porewater
kM = metabolic rate constant for contaminant in biota (set to zero in this study)
scav = filter feeding particle scavenging efficiency
preyprop = proportion of diet due to individual prey (calculated from prey proportion matrix)

vld = proportion of diet that is lipid (calculated from prey proportion matrix)
vnd = proportion of diet that is non-lipid organic matter (calculated from prey proportion matrix)
vwd= proportion of diet that is water (calculated from prey proportion matrix)
kGconst = growth rate equation constant
scav = scavenging efficiency of particles absorbed from water by filter feeders (percent)

Table M.1. Constant values set for model simulations (following Arnot and Gobas 2004, Gobas and Arnot 2005).

Constant	Value	Description
MCS	0.5	Molar concentration of seawater at 35 ppt (mol/L)
SPC	0.0018	Setschenow proportionality constant (L/cm^3)
A	6.00E-05	Constant for phytoplankton aqueous uptake rate
B	5.5	Constant for phytoplankton aqueous uptake rate
alphapoc	0.35	Proportionality constant describing phase partitioning of POC
alphadoc	0.08	Proportionality constant describing phase partitioning of DOC
dpoc	1	Disequilibrium factor for POC partitioning
ddoc	1	Disequilibrium factor for DOC partitioning
EdA	8.50E-08	Constant A in dietary uptake efficiency equation
EdB	2	Constant B in dietary uptake efficiency equation
scav	100%	Scavenging efficiency of particles absorbed from water by filter feeders (percent)

Model Variables (calculated for each contaminant and organism combination)

k1 = aqueous uptake rate constant
k2 = elimination rate constant
kG = growth rate
Gv = gill ventilation rate
Gd = feeding rate
Gf = fecal egestion rate
vlg = lipid fraction of gut
vng = nlom fraction of gut
vwg = water fraction of gut
kgb = gut-biota partition coefficient
ke = fecal egestion rate constant (1/d)
kd = dietary uptake rate constant
Ew = contaminant-specific gill chemical uptake efficiency
Ed = contaminant-specific dietary chemical transfer efficiency (also called gut uptake efficiency)
phi = freely dissolved contaminant fraction in overlying water column
cpw = contaminant concentration in porewater
kbw = biota-water partition coefficient (i.e., bioconcentration factor)
cbiota = contaminant concentration in biota

cprey = contaminant concentration in prey diet

Model Calculations

Ew = 1/(1.85+1.55/KowTS)

Ed = 1/(EdA*Kow + EdB)

phi = 1/(1 + xpoc*dpoc*alphapoc*KowTS + xdoc*ddoc*alphapoc*alphadoc*KowTS)

cpw = csed/(ocsed*0.35*KowTS)

Calculations for phytoplankton and benthic algae

k1 = 1/(A + B/KowTS)

kbw = (lipid*KowTS+ nlom*betap*KowTS + wc)

k2 = k1/kbw

cbiota=k1*(mo*phi*cwater + mp*cpw)/ (k2 + kG + kM)

Calculations for invertebrates and fishes

Gv = (1400*Wb^0.65)/Cox

k1 = Ew*Gv/Wb

kbw = (lipid*KowTS + nlom*beta*KowTS + wc)

k2 = k1/kbw

Gd = 0.022 * (Wb^0.85) * exp(0.06*T) [For non filter feeders]

Gd = Gv*vss*scav [For filter feeders]

kd = Ed*Gd/Wb

kG = kGconst * Wb^-0.2

Gf=Gd*((1-assimEff(1))*vld+ (1-assimEff(2))*vnd+ (1-assimEff(3))*vwd)

vlg= (1-assimEff(1))*vld/ ((1-assimEff(1))*vld+ (1-assimEff(2))*vnd+ (1-assimEff(3))*vwd)

vng= (1-assimEff(2))*vnd/ ((1-assimEff(1))*vld+ (1-assimEff(2))*vnd+ (1-assimEff(3))*vwd)

vwg= (1-assimEff(3))*vwd/ ((1-assimEff(1))*vld+ (1-assimEff(2))*vnd+ (1-assimEff(3))*vwd)

kgb=((vlg*Kow + vng*beta*Kow + vwg)/ (lipid*Kow + nlom*beta*Kow + wc))

ke = Gf*Ed*kgb/Wb

cprey = preyprop*cbiota

cbiota=(k1*(mo*phi*cwater + mp*cpw)+ kd*cprey) / (k2 + ke + kG + kM)

Appendix N. Individual molecules for inclusion in total organochlorine compounds.

Summation procedures for sediment and tissue data followed the procedures developed by the SQO Science Team.

Total DDTs

The following compounds comprised total DDTs for all analyses: o,p'-DDD, o,p'-DDE, o,p'-DDT, p,p'-DDD, p,p'-DDE, and p,p'-DDT

Total chlordanes

The following five chlordanes comprised total chlordanes for all analyses: alpha-Chlordane, gamma-Chlordane, Oxychlordane, trans-Chlordane, and trans-Nonachlor.

Total PCBs

Total PCBs were calculated by summing individual congeners. Individual congeners measured often vary among studies. In order to reduce inconsistencies and artifacts associated with compounds always found below detection limits, it was necessary to use two different groups of summed compounds for analyses in this project. This report does not conduct explicit comparisons between these groups of samples summed in different fashions.

The first group of congeners were included in total PCBs for analyses involving the laboratory bioaccumulation test organisms *Macoma nasuta*, *Neanthes virens* and *Nephtys caecoides* (including sediment vs. biota comparisons): PCB 008, PCB 018, PCB 028, PCB 044, PCB 052, PCB 066, PCB 101, PCB 105, PCB 118, PCB 128, PCB 138, PCB 153, PCB 180, PCB 187, and PCB 195. These congeners were selected to be consistent the summation procedure developed for the CASQO database, from which laboratory bioaccumulation test data were obtained.

The second group of congeners were included in total PCBs for the fish tissue and sediment chemistry lines of evidence in the Newport Bay case study: PCB 006, PCB 044, PCB 049, PCB 052, PCB 066, PCB 070, PCB 074, PCB 087, PCB 099, PCB 101, PCB 105, PCB 110, PCB 118, PCB 119, PCB 128, PCB 138, PCB 149, PCB 151, PCB 180, and PCB 187. These congeners were selected for the case study because they were present at detectable concentrations in Newport Bay sediments in at least 10% of samples and analyzed for at least 10 samples (see also Appendix Q, Table Q.1).

Total high molecular weight PAHs (HPAH)

The following compounds comprised total HPAHs: benz(a)anthracene, benzo(a)pyrene, benzo(e)pyrene, chrysene, dibenz(a,h)anthracene, fluoranthene, perylene, and pyrene. Note that in this report, total HPAHs are only evaluated in laboratory bioaccumulation test organism vs. sediment comparisons (Sections 4.5 and 5.5).

Appendix O. Fish data used for developing empirical bioaccumulation factors (BAFs). All data are from Allen *et al.* (2004).

Table O.1. Data used to evaluate human sport fish consumption in Newport Bay.

Re: Human Health Risk Parameters to Use in Newport Bay Model

Dear Ben:

The following values should be used in the Newport Bay modeling effort evaluating human health risk:

Risk Threshold:

We request that you evaluate three thresholds reflecting "no problem (green)," "caution (yellow)," and "problem likely (red)." These thresholds correspond to the $<10^{-6}$ risk, 10^{-5} to 10^{-6} risk, and the $>10^{-5}$ risk, respectively.

Consumption Rate:

We request that you use the consumption rates that were reported in the Santa Monica Bay Seafood Consumption Study (Allen, 1994).

Please give me a call at (951) 782-4468, or Kathy Rose at (951) 321-4585, if you have any questions.

Sincerely,

Wanda Mais-Smith
Chief, Coastal Waters Planning Section

Appendix Q. Summary statistics for water and sediment contaminants in Newport Bay.

Table Q.1. Summary statistics for individual sediment compounds monitored in Newport Bay. All sample values below quantification were set at the detection limits. Samples in grey were accepted for bioaccumulation factor calculation based on sufficient sample size and incidence of samples above detection. For data sources, see Appendix R.

Compound	Class	Geometric mean (ng/g dw)	Log SE	Arithmetic mean (ng/g dw)	Arithmetic SE (ng/g dw)	Median (ng/g dw)	Number samples (N)	Below detection (%)	N > 10	Below detection < 90%	Accepted

Table Q.2. Summary statistics for individual water compounds monitored in Newport Bay. Results are for total constituent (i.e., dissolved + particulate). All sample values below detection were set at ½ detection limits. ND/N = proportion of samples below detection/total sample size (N = 3 in all cases). All data were collected by SCCWRP scientific staff in 2005 (Appendix R).

a. Masters and Inman (2000) b. Bay *et al.* (2004) c. Bay and Brown (2003) d. Noblet *et al.* (2002)

Appendix R. General description of data sources used for Newport Bay case study.

Sediment contaminant concentrations – Data from the CASQO database were combined with data from Masters and Inman (2000). The CASQO database included data from the Rhine Channel Study (Bay and Brown 2003), the Newport Bay Sediment Toxicity Study (Bay *et al.* 2004), and the Southern California Bight 1998 Survey (Noblet *et al.* 2002). Although data were available from the Bay Protection and Toxics Cleanup Program (BPTCP) (Hunt *et al.* 1998), these data were collected in 1994 and do not represent current conditions. Therefore, BPTCP data were not included. Evaluation of these source data sets indicated that a substantial proportion of the measured values for many PCBs and pesticides were below quantification limits (BQL), necessitating decision-making regarding the imputed values when results were below quantification limits (QL). To evaluate the best model fit, BQL values were imputed using both values at ½ the QL and at the detection limit (DL). These imputation methods resulted in substantially different results for geometric means. Both geometric means were evaluated to determine which exhibited better model fits.

For comparison of model calculated biota contaminant predictions vs. empirical results, only certain contaminants had sufficient source data for sediment contamination. Rejection of data resulted when there were not at least 10 occurrences of sediment contaminant measurements or when more than 90% of results were BQL.

Water contaminant concentrations In 2005, SCCWRP collected water column contaminant data for this study using an in-situ pump. Study methods were similar to those in Bay *et al.* (2004). Samples were collected from three locations: Sheriff Station, Nautical Museum, and Carr's Deck. A fourth station (Lido Island) was rejected because water flow volume could not be estimated accurately. Following Gobas and Arnot (2005), particulate and dissolved phase results were combined to determine total concentrations.

Sediment organic carbon – Estimates of sediment organic carbon were based on data from the CASQO database (see **Sediment contaminant concentrations**, above), Masters and Inman (2000), and BPTCP data (Hunt *et al.* 1998).

Water total suspended solids (TSS), particulate organic carbon (POC), and dissolved organic carbon (DOC) – TSS, POC, and DOC were provided by Martha Sutula (SCCWRP, *unpublished data*). Data were collected at three Newport Bay sites, at two depths for each site (surface and bottom). Results represent the average across these sites, and include six sample collection dates in 2004 (1/15, 2/10, 3/23, 6/8, 9/15, and 11/11).

Water dissolved oxygen, temperature, and salinity – Temperature and salinity data were assembled from Table 5 of Kennison *et al.* (2003). Dissolved oxygen data was combined from this source and from Figure 4.1, Figure 4.2, and Table 4.1 of Kamer and Stein (2003).

Contaminant octanol-water partitioning coefficients (K_{OW}) – Contaminant K_{OW}'s are presented in Appendix S. K_{OW}'s for PCBs were obtained from Gobas and Arnot (2005). For those PCBs not evaluated in Gobas and Arnot, K_{OW}'s were the median of results combined from five published sources: Li *et al.* (2003), Mackay *et al.* (2000), Beyer *et al.* (2002), Hansen *et al.* (1999), and Hawker and Connell (1988). K_{OW}'s for pesticides were taken from Shen and Wania (2005), or Leatherbarrow *et al.* (2006), which compiled K_{OW}'s from Mackay *et al.* (2000).

K_{OW}'s were temperature and salinity corrected to be appropriate for the water body average temperature and salinity. Methods followed Gobas and Arnot (2005), and references cited therein. Specifically, the Kow values were corrected for temperatures using the following equation (Li *et al.* 2003):

$$\log K_{ow}E_T = \log K_{ow}D_T - \frac{\Delta U_{OW}}{\ln(10)\cdot R}\cdot\left(\frac{1}{E_T}-\frac{1}{D_T}\right)$$

where E_T is the environmental temperature (Kelvin) and D_T is the data collection temperature (Kelvin), ΔUow is the internal energy of octanol-water phase transfer and R is the gas law constant (0.0083145 kJ/mol K). Empirically-derived ΔUow are currently unavailable for pesticides, and were therefore estimated to be -25 kJ/mol (Shen and Wania 2005).

Salinity corrections followed Xie *et al.* (1997):

$$Kow = Kow \times 10^{(SPC\cdot Vh\cdot MCS\cdot SAL/35)}$$

where SPC is the Setschenow proportionality constant (0.0018 L/cm^3), Vh is the LeBas molar volume (cm^3/mol) of the chemical (calculated following Tucker and Nelken 1982), MCS is the molar concentration of seawater at 35 practical salinity units (0.5) and SAL is the salinity for the system of interest (psu).

Attached algae - According to dietary studies, a significant proportion of prey for some Newport Bay animal species are benthic attached algae (e.g., Logothetis *et al.* 2001). These attached algae are important primary producers in the system, growing densely in intertidal areas, particularly in the upper Bay (Kamer *et al.* 2004a). They include *Ulva expansa, Ulva lactusa, Ulva foliosa, Enteromorpha intestinalis*, as well as other *Ulva* spp. and *Enteromorpha* spp. (Krista Kamer, MLML, *Pers. comm.*). The plant-water two compartment model developed for uptake/elimination kinetics and described by Arnot and Gobas (2004), and summarized in Appendix G, was parameterized for phytoplankton. For the Newport Bay case study, the same model is applied to attached benthic algae. Although the specific parameters have not been calibrated for attached algae, the general model assumptions have been supported by laboratory studies (e.g., Gobas *et al.* 1991).

Algae growth rate, lipid content, porewater exposure - Tissue lipid content and non-lipid organic matter have not been measured for Newport Bay benthic algae or

phytoplankton. For phytoplankton, parameters were taken from Gobas and Arnot (2005). For benthic attached algae, these parameters were estimated by reviewing literature values for *Ulva* spp. and *Enteromorpha* spp. (Appendix V). Growth rates were based on *Enteromorpha intestinalis* laboratory mesocosm studies from Newport Bay (Kamer *et al.* 2004a, Kamer *et al.* 2004b) and a study of similar salinity conditions (Martins *et al.* 1999). These studies exhibited an order of magnitude difference in daily growth rates, warranting a wide range in the probabilistic estimation of growth rate, including the use of a lognormal distribution for probabilistic simulations. Combining results from both sets of studies, the geometric mean growth rate was 4.7% / d, with a standard deviation (log scale) of 0.25 (Table V.2). When plants are submerged (i.e., during high tides), tissue buoyancy causes the plants to float and have no porewater exposure (K. Kamer, *Pers. comm.*). Thus, the nominal value for porewater transpiration exposure (i.e., Mp in Appendix M) was set at zero.

Respiratory exposure to porewater – The proportion of respiratory exposure to porewater was varied between 0% and 10%. Values for benthic invertebrates were obtained from Gobas and Arnot (2005). Values for local fish were based on life history information. Arrow goby, which has a strong benthic association due to dwelling within sediment burrows (M. James Allen, SCCWRP, *Pers. comm.*), was assigned 10%. Other fish with close benthic associations were assigned 5% exposure. Fish with a weaker benthic association were assigned 0%.

Invertebrate diet, body mass, and lipid content – A search for published literature on mass or lipid content in local invertebrates was largely unsuccessful. Invertebrate species selection, body mass estimates, lipid content and dietary proportions were based on local expert guidance and unpublished data (Don Cadien, LACSD, *Pers. comm.*), and on Gobas and Arnot (2005).

Fish body mass and lipid content – Fish tissue lipid content was taken from Allen *et al.* (2004), and confirmed using published literature sources as well as data from the Regional Monitoring Program for Water Quality in San Francisco Bay (Appendix U). The method for extrapolating lipid content between whole body and muscle tissue is presented in Appendix E. Body mass was combined from a variety of published and unpublished sources (Appendix U), and averaged to represent a typical organism from Newport Bay. Body mass is a relatively insensitive parameter (Gobas and Arnot 2005).

Fish diets - Fish dietary proportions were determined from gut content analysis presented in published journal articles and grey literature. The model calculates uptake using a mass-balance approach; therefore, model input data were generated based on relative mass or volume of prey consumed, rather than number captured or frequency of occurrence. For most species, these included data from Newport Bay, as referenced in Appendix T. For staghorn sculpin and California corbina, no dietary data were found specific to Newport Bay, so estimated diets were based on published studies from other sites (Appendix T).

Contaminant dietary assimilation efficiencies – All assimilation efficiencies followed Gobas and Arnot (2005). Assimilation efficiencies for invertebrates were 72% for lipids, 75% for NLOM, and 55% for water. Assimilation efficiencies for fish were 90% for lipids, 50% for NLOM, and 55% for water.

Animal growth rate equation constants (kG) – Following Gobas and Arnot (2005), growth rate equation constants were set at 3.5×10^{-4} for invertebrates and 7×10^{-4} for fishes.

Appendix S. Octanol-water partitioning coefficients (K_{ow}) used in model simulations for Newport and San Francisco Bays.

Note: TS = corrected for local temperature and salinity for Newport Bay or San Francisco Bay.

Appendix T. Summary of published information and grey literature on diets of selected Newport Bay fish species.

Results include all available studies from within Newport Bay, in addition to appropriate literature off the Southern California coast. All results indicate % prey mass in diet, except where ** indicates % frequency of occurrence. All studies were based on gut-content analyses. Grey results indicate averages and ranges for species having at least two studies with percent mass data.

Tissue % NLOM	15.5%	Normal	μ = 15.5%; SD = 3%; SE = 1.7%
Growth Rate	4.7%	Lognormal	GeoMean = 4.7% (Log= -1.32); Log SD = 0.25

Appendix W. Method for estimating overall prey tissue lipid content encountered in Newport Bay case study.

There are a number of approaches one could take to average percent lipid across all of the fish species consumed by a predator. For estimation of the sediment threshold in the Newport Bay case study (Section 4.4.3), sensitivity to two factors is considered: 1. whether the prey species are likely to be resident of Newport Bay; and 2. the relative importance of the prey species, based on sport fish consumption studies.

The simplest approach to determining average percent lipid is to simply average the percent lipid of major prey species of human or wildlife piscivores. Table W.1 lists major prey species, type of tissues and percent lipid for human and wildlife predators. Averaging across all prey species evenly, the arithmetic mean of percent lipid is 1.88 for human prey, and 1.19 for wildlife prey. Human prey concentrations higher due to expected consumption of the fatty California corbina and striped mullet (Table W.1).

Table W.1. Major prey species, type of tissues and percent lipid consumed by human and wildlife predators. Survey results are obtained from Allen *et al.* (1996).

Prey Species	Receptor	Tissue Type	% Lipid [a]	Resident?	Survey Analogous Species[b]	Survey Number Captured[b]	Survey % Captured
Barred sand bass	Human	Fillet	1.0	N	Barred sand bass	388	32%
California corbina	Human	Fillet	4.6	N	None	0	0%
California halibut	Human	Fillet	0.4	Y	California halibut	62	5%
Spotted sand bass	Human	Fillet	0.9	Y	Kelp bass	327	27%
Striped mullet	Human	Fillet	4.4	N	None	0	0%
Yellowfin croaker	Human	Fillet	1.7	N	White croaker	339	28%
Black perch	Human	Fillet	0.7	N	Black perch	26	2%
Jacksmelt	Human	Fillet	1.3	N	Jacksmelt	74	6%
Total	Human					1216	
Arrow goby	Wildlife	Whole	1.3	Y			
Black perch	Wildlife	Whole	1.1	Y			
California killifish	Wildlife	Whole	1.5	Y			
California halibut	Wildlife	Whole	0.9	Y

Staghorn sculpin	Wildlife	Whole	1.4	Y			
Shiner surfperch	Wildlife	Whole	1.0	Y			

a. From Table 4.13 and Appendix U of this report, and Allen *et al.* (2004). b. Santa Monica Bay Seafood Consumption Survey (Allen *et al.* 1996).

Percent lipid may also be estimated using weighted averages based on relative consumption rates of different types of prey. In the case of Newport Bay, although

relative consumption rates are not known, they may be estimated for human sport fishers based on results of the Santa Monica Bay Seafood Consumption Survey (Allen *et al.* 1996). This survey indicates local consumption practices (OEHHA 2001), and includes total number of each fish species taken across the entire survey. Proportionate number captured in the survey may be combined with percent lipid in fillet tissue from the same or analogous species in Newport Bay (Table W.1) to derive an estimate of tissue percent lipid, weighted by popularity of the prey item. This weighted average estimate of tissue percent lipid (1.15%) is lower than the simple average of all species targeted by sport fish consumers (1.88%) because the fattier species were not captured in Santa Monica Bay. The absence of striped mullet and California corbina from this average, when these species are known to be recreational sport fish (www.fishbase.org), highlights the substantial uncertainty in actual human sport fish consumption estimates in Newport Bay. Weighted averages were not conducted for wildlife predators because local information on relative prey preferences are lacking.

An alternative approach to prey attribute estimation is to focus on resident species only. The rationale for this approach is that non-resident species may receive some contaminant burden from other locations, and therefore not be representative of Newport Bay sediment exposure. All wildlife prey are considered to be resident species, but among human prey, only California halibut and spotted sand bass are resident (M. J. Allen, SCCWRP, *Pers. comm.*). The average tissue percent lipid of these two species (0.65%) is substantially lower than other averages (Table W.2).

Table W.2. Summary of estimated tissue percent lipids for human and wildlife prey using different selection and averaging methods.

Treatment	Tissue % lipid
All wildlife prey	1.19
All human prey	1.88
Human prey resident only	0.65
Human prey Santa Monica Survey	1.15

Appendix X. Comparison of model vs. empirical tissue concentrations of pesticide pollutants in San Francisco Bay

Figure X.1. Results of model vs. data comparison for white croaker (*Genyonemus lineatus*). Results are derived from the Gobas and Arnot food-web model (model) vs. empirical data (data). For all figures, error bars represent one standard deviation of the mean. When the empirical data are represented by a yellow bar, this indicates the detection limit, as greater than 90% of empirical results were below detection for that compound.

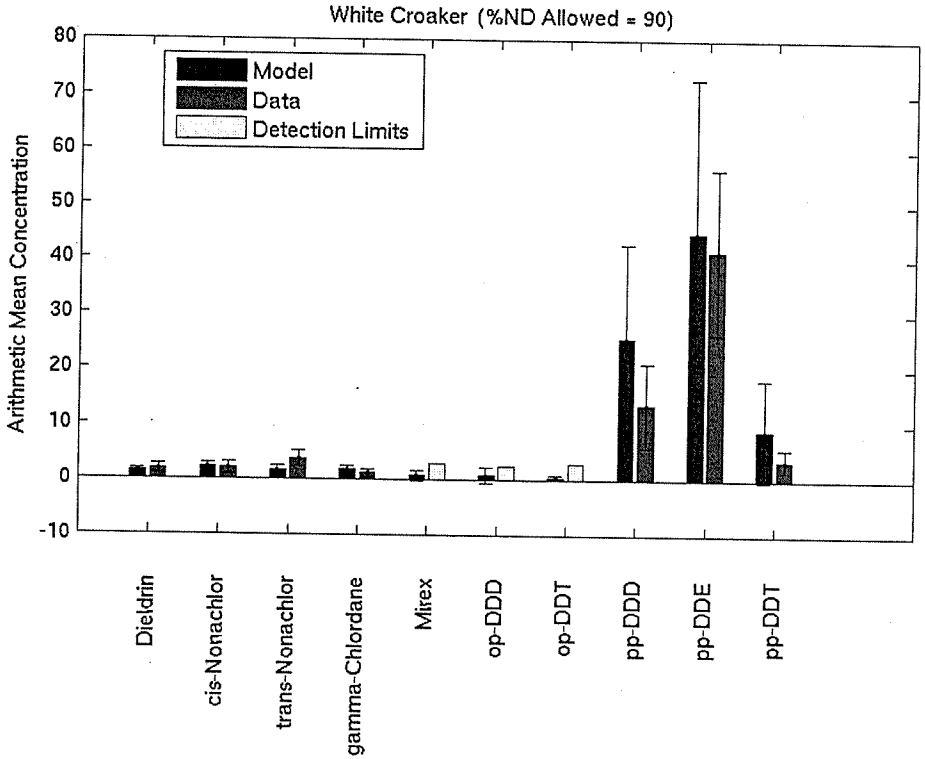

Figure X.2. Results of model vs. data comparison for jacksmelt (*Atherinopsis californiensis*). See caption for Figure X.1.

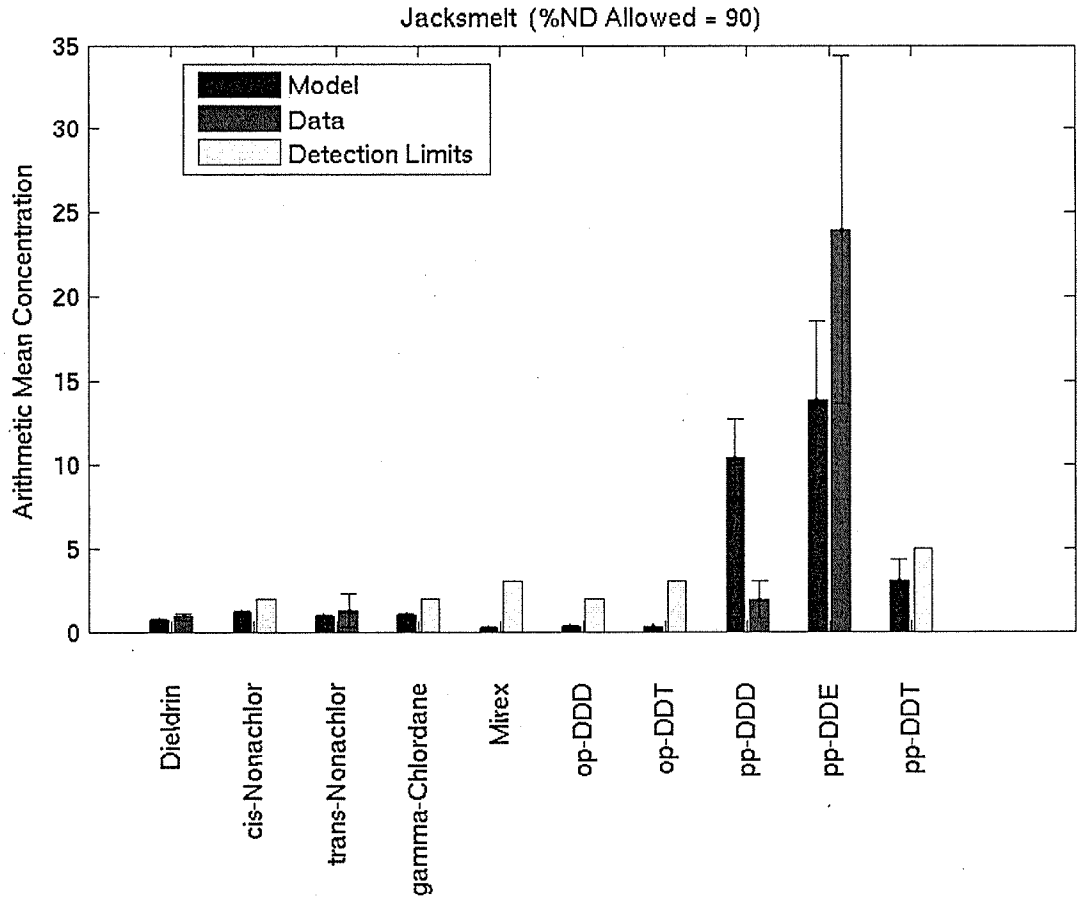

Figure X.3. Results of model vs. data comparison for oysters (*Crassostrea gigas*). See caption for Figure X.1.

Appendix Y. Summary of input data for application of Arnot and Gobas (2004) mechanistic food web model used in this report.

Physical data

1. Mean water and air temperature
2. Salinity
3. Dissolved organic carbon content - water column
4. Particulate organic carbon content - water column
5. Concentration of suspended solids – water column (TSS)
6. Percentage of organic carbon - sediment

Contaminant data

7. Concentrations of target contaminants in water and sediments. This is preferably sampled according to similar temporal and spatial scales as the biota.
8. Concentrations of target contaminants in each organism (for model validation or calibration). This is preferably whole body wet weight analysis. If specific tissues are analyzed (i.e. muscle fillet) then it is preferable to measure tissue-specific lipid content as well as the whole body lipid content, and convert following Appendix E.

Biological data

9. Develop a simplified representation of the local food web to model. This should include about 10 species, typically generalizing primary producers and invertebrates across broad taxonomic categories.
10. Develop a matrix of percent diet for each species in the food web. Depending on data availability, this can be the result of gut surveys, stable isotope analysis or general feeding behaviors (e.g., species X predominantly feeds on species Y and Z which are represented by organisms with the same trophic guilds in the model).
11. Whole body percent lipid for each organism.
12. Whole body wet weight for each organism.
13. A narrative description of the exposure of the organism's gills or respiratory organs to sediments and pore water, as compared to the overlying water column (used to estimate percent of respired water that is pore water).

Optional local input data for model (can be estimated if not available)

Physical data

14. Density of organic carbon in sediment.
15. Dissolved oxygen concentration in the water column.

Contaminant data

16. Freely dissolved water contaminant concentration
17. Pore water contaminant concentration

Sediment Quality Guidelines developed for the National Status and Trends Program

Background and Intended Uses

Through its National Status and Trends (NS&T) Program, NOAA generates considerable amounts of chemical data on sediments. Without national criteria or other widely-applicable numerical tools, NOAA scientists found it difficult to estimate the possible toxicological significance of chemical concentrations in sediments. Thus, numerical sediment quality guidelines (SQGs) were developed as informal, interpretive tools for the NS&T Program.

The SQGs were initially intended for use by NOAA scientists in ranking areas that warranted further detailed study on the actual occurrence of adverse effects such as toxicity. Also, they were intended for use in ranking chemicals that might be of potential concern. In many regional surveys of sediment toxicity performed throughout North America, NOAA has used the guidelines to compare the degree of contamination among sub-regions, and to identify chemicals elevated in concentration above the guidelines that were also associated with measures of adverse effects.

The SQGs were not promulgated as regulatory criteria or standards. They were not intended as cleanup or remediation targets, nor as discharge attainment targets. Nor were they intended as pass-fail criteria for dredged material disposal decisions or any other regulatory purpose. Rather, they were intended as informal (non-regulatory) guidelines for use in interpreting chemical data from analyses of sediments.

Derivation

SQGs were needed relatively quickly for use in interpreting data from the ongoing NS&T Program studies; thus, existing data were used in their derivation, rather than data from tedious and expensive laboratory tests or modeling approaches. SQGs were needed that could be applied nationwide in the NS&T Program; therefore, data from studies performed throughout North America were assembled and compiled into a database to ensure broad applicability of the guidelines. Because guidelines were needed that were based on measures of biological effects associated with toxicants, data were compiled that included both chemical measures and biological effects. SQGs based on a weight of evidence from numerous studies were expected to be more useful nationwide than values based upon only limited amounts of data. SQGs were needed for a variety of different substances commonly measured in the NS&T Program; accordingly, guidelines were developed for as many chemicals as the data would warrant. SQGs were needed that would estimate the “safe” concentrations, i.e.,

concentrations below which effects were not likely. Also, guidelines were needed above which adverse effects were more likely. Therefore, two values were derived for each substance.

SQGs were derived initially using a database compiled from studies performed in both saltwater and freshwater and published in NOAA Technical Memorandum NOS OMA 52 (Long and Morgan 1990). A larger database compiled from many studies performed by numerous investigators in only saltwater was used to revise and update the SQGs (Long et al. 1995). Data from freshwater studies and/or of marginal quality used in 1990 were removed from the database in 1995, and a considerable amount of higher quality data were added to the database. Data from each study were arranged in order of ascending concentrations. Study endpoints in which adverse effects were reported were identified. From the ascending data tables, the 10th percentile and the 50th percentile (median) of the effects database were identified for each substance. The 10th percentile values were named the "Effects Range-Low" (ERL), indicative of concentrations below which adverse effects rarely occur. The 50th percentiles were named the "Effects Range-Median" (ERM) values, representative of concentrations above which effects frequently occur.

An example of the derivation method is shown in **Figure 1** in which the data for phenanthrene are arranged in ascending order. Green symbols indicate study endpoints in which no adverse effects were observed, such as in reference area samples. Red symbols indicate those study endpoints at which an adverse effect was observed. In the case of phenanthrene, there were 53 study endpoints indicating adverse effects. The 10th percentile of this data distribution was the 6th value, equivalent to 240 ppb phenanthrene. The 50th percentile was the 27th value, equivalent to 1500 ppb. As was apparent in the data for phenanthrene, the percentages of study endpoints indicating toxicity increased with increasing concentrations of most chemicals. The measures of reliability discussed below were calculated from the data available within the three concentration ranges defined by the ERL and ERM.

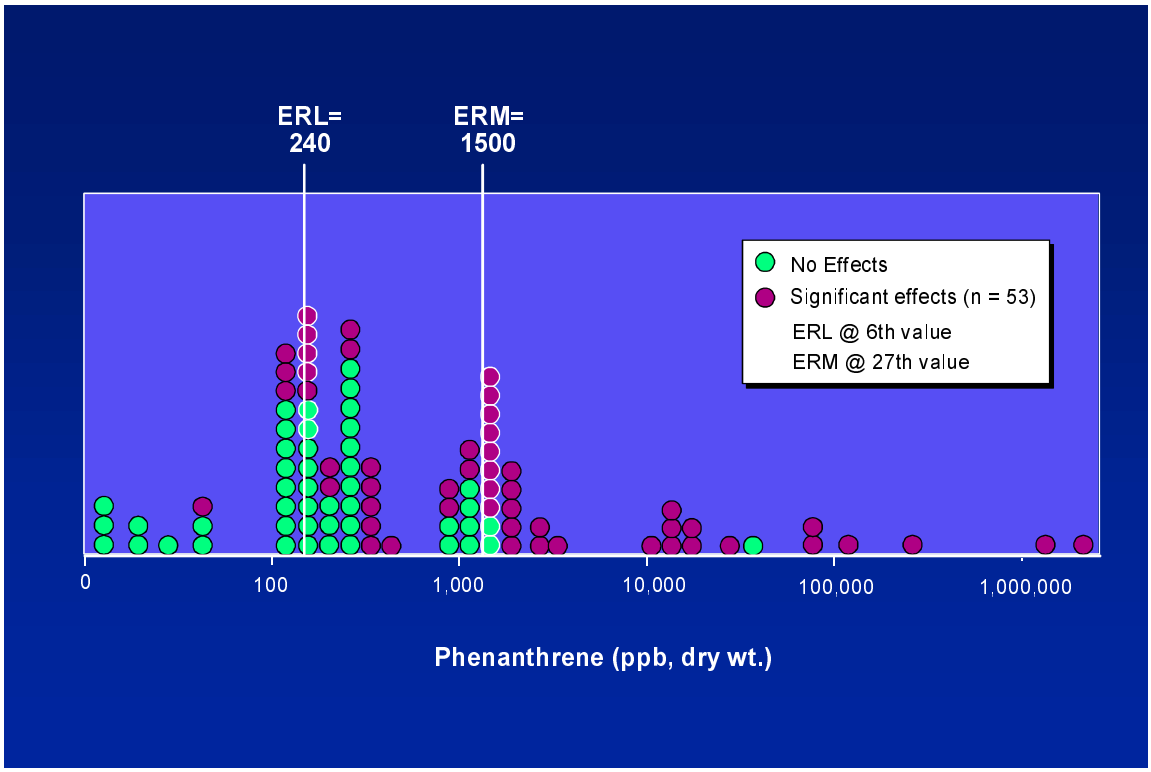

Figure 1. An example of the database used to derive the SQGs. Data for phenanthrene in which no adverse effects were observed are indicated by green symbols and those in which toxicity or some other measure of adverse effects were observed are indicated by red symbols. ERL= Effects Range-Low; ERM= Effects Range-Median.

The sediment quality guidelines

Based on the database assembled by Long et al. (1995), ERL and ERM values were calculated for 9 trace metals, 13 individual PAHs, 3 classes of PAHs, and 3 classes of chlorinated organic hydrocarbons **(Tables 1 and 2)**. There were insufficient amounts of reliable data available to perform similar calculations for other substances, including a few previously reported by Long and Morgan (1990).

The amount and quality of data used to derive the SQGs differed among the substances. Therefore, to provide a measure of the reliability of the SQGs, the percentages of study endpoints indicating adverse effects were calculated for the chemical ranges defined by the ERLs and ERMs **(Tables 1 and 2)**. Because the ERLs were intended to represent concentrations below which effects were rarely observed, low percentages of studies were expected to indicate effects within the ranges below the ERLs. Indeed, for all trace metals the percent of studies indicating adverse effects was less than 10% when concentrations were below the ERL values. For most organics, the incidence of effects was less than 25% when concentrations were below the ERLs.

Table 1. ERL and ERM guideline values for trace metals (ppm, dry wt.) and percent incidence of biological effects in concentration ranges defined by the two values (from Long et al., 1995). ERL= Effects Range-Low; ERM= Effects Range-Median.

	Guidelines		Percent incidence of effects*		
Chemical	ERL	ERM	<ERL	ERL - ERM	>ERM
Arsenic	8.2	70	5.0	11.1	63.0
Cadmium	1.2	9.6	6.6	36.6	65.7
Chromium	81	370	2.9	21.1	95.0
Copper	34	270	9.4	29.1	83.7
Lead	46.7	218	8.0	35.8	90.2
Mercury	0.15	0.71	8.3	23.5	42.3
Nickel	20.9	51.6	1.9	16.7	16.9
Silver	1.0	3.7	2.6	32.3	92.8
Zinc	150	410	6.1	47.0	69.8

*Number of data entries within each concentration range in which biological effects were observed divided by the total number of entries within each range.

The incidence of effects increased to 20% to 30% for most trace metals and 40% to 60% for most organics when concentrations exceeded ERL values but were lower than the ERM values. When concentrations exceeded the ERM values, the incidence of adverse effects increased to 60% to 90% for most trace metals and 80% to 100% for most organics. However, the reliabilities of the ERMs for nickel, mercury, DDE, total DDTs, and total PCBs were much lower than those for other substances. Therefore, the probabilities that the ERM values for these substances would accurately predict adverse effects are much lower than those for most chemicals.

Table 2. ERL and ERM guideline values for organic compounds (ppb, dry wt.) and percent incidence of biological effects in concentration ranges defined by the two values (from Long et al. 1995). ERL= Effects Range-Low; ERM= Effects Range-Median.

	Guidelines		Percent incidence of effects*

Total PCBs	22.7	180	18.5	40.8	51.0

*Number of data entries within each concentration range in which biological effects were observed divided by the total number of entries within each range.

Interpretation

Two guideline values were generated for each chemical: the ERL and the ERM. It is important to understand that these values were not derived as toxicity thresholds. That is, there is no assurance that there will be a total lack of toxicity when chemical concentrations are less than the ERL values. Similarly, there is no assurance that samples in which ERM values are exceeded will be toxic. Toxicity, or a lack thereof, must be confirmed with empirical data from toxicity tests.

The ERL values were not intended as concentrations that are always predictive of toxicity. Rather, they were intended and should be used primarily as estimates of the concentrations below which toxicity is least likely. As shown in Tables 1 and 2, the incidence of effects was usually higher when concentrations exceeded the ERLs than when concentrations were below the ERLs. However, the ERM values are better indicators of concentrations associated with effects than the ERLs.

Uses

The guidelines are commonly used in North America both to rank and prioritize sites of concern and chemicals of concern. That is, samples or study areas in which many chemicals exceed the ERM values and exceed them by a large

degree may be considered as more contaminated than those in which none of the SQGs are exceeded. Samples in which ERL concentrations are exceeded, but no ERM values are exceeded, might be given intermediate ranks. Similarly, chemicals at concentrations well above the ERM values might be given a higher priority than those at concentrations below the ERLs. Chemicals at intermediate concentrations may qualify as a moderate priority. However, caution should be used when prioritizing sites or chemicals where only the concentrations of nickel, mercury, DDE, total DDTs, or total PCBs are elevated.

In studies performed by NOAA of toxicity and contamination of sediments in specific estuaries and bays, the SQGs have been used to rank and prioritize both sites and chemicals of potential concern. In these studies the chemical data were compared with the SQGs to identify spatial patterns in contamination, to estimate the spatial scales in contamination, and to rank sampling sites. The data also were compared with the SQGs to (1) identify which chemicals, if any, exceeded the ERL and ERM values, (2) tally the number of samples in which the SQGs were exceeded, (3) calculate the degrees to which the SQGs were exceeded, and (4) to identify which chemicals were most associated with measures of toxicity. For each regional assessment of bioeffects, the SQGs were used along with the results of toxicity tests to estimate the relative quality of sediments throughout the study area.

Field validation of predictive ability

To provide quantitative information on how well the SQGs correctly predict toxicity in actual field conditions, an analysis was conducted (Long et al. 1998a) with existing data compiled from many regional assessments conducted by NOAA and EPA. Matching chemistry and toxicity data from 1,068 samples from the Atlantic, Gulf of Mexico, and Pacific coasts were compiled into a database. Data were available from acute amphipod survival tests for all 1,068 samples; data from one or two additional tests in which sublethal responses were recorded were available for 437 samples. Several analyses were conducted with the data to investigate the predictive ability of the SQGs.

In the first analysis, the percentages of samples that were highly toxic were determined when individual ERM values were equaled or exceeded. That is, samples were identified in which the ERM value was equaled/exceeded for a particular substance. The percentages of those samples that were highly toxic in either the amphipod survival tests alone or in a battery of 2 to 4 tests (including those with amphipods) were then determined. Statistical analyses were used to classify samples as either non-toxic ($p>0.05$), marginally toxic ($p<0.05$), or highly toxic ($p<0.05$ and sample means exceed minimum significant differences) relative to controls in the laboratory tests. The predictive abilities of 28 sets of ERLs/ERMs were determined.

For most substances, 40% to 60% of samples in which chemical concentrations exceeded individual ERMs were highly toxic in the amphipod tests **(Figure 2)**.

For example, among the samples in which copper concentrations exceeded the ERM value (n=25), 52% were highly toxic in the amphipod survival tests. More than 75% of samples were highly toxic in which the ERMs for lead, 2-methylnaphthalene, and acenaphthylene were exceeded. For most substances, an increase in predictive ability of approximately 20% to 30% occurred when the data from the sublethal tests were included along with the amphipod data. Therefore, for most substances, 80% to 90% of samples were highly toxic in at least one of the tests performed when concentrations exceeded individual ERMs.

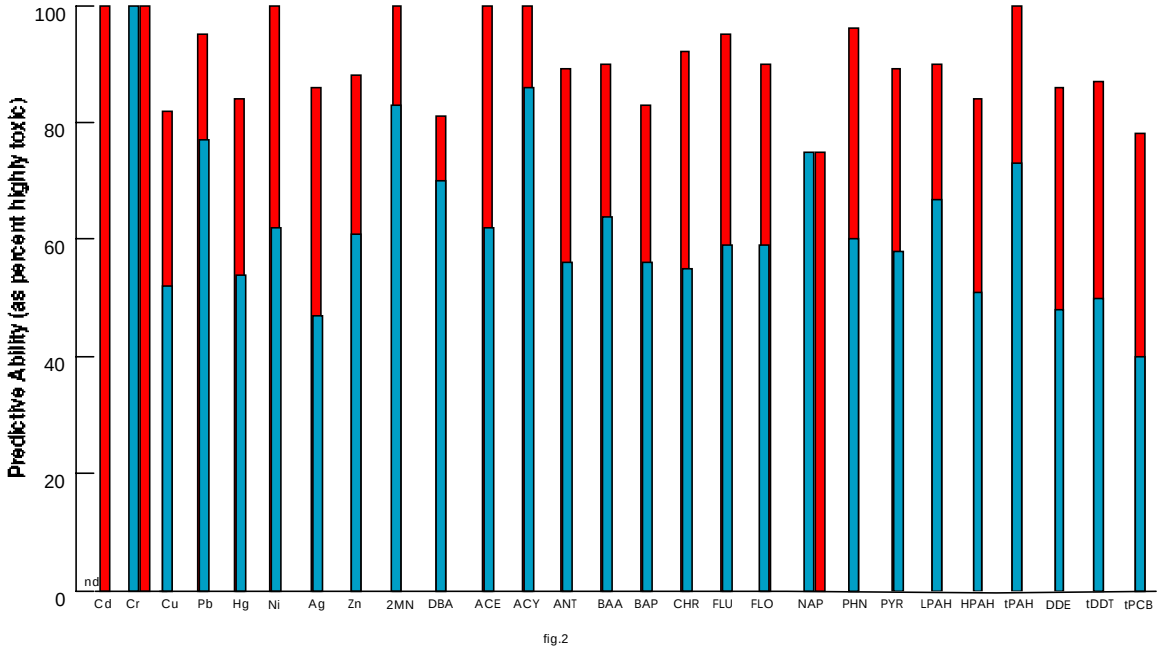

Figure 2. Percent of sediment samples in field validation database in which highly significant toxicity was observed in amphipod survival tests alone (blue bars) and in any of 2 to 4 tests performed (red bars) when chemical concentrations equaled or exceeded individual ERM values (from Long et al., 1998a). ERL= Effects Range-Low; ERM= Effects Range-Median.

These data suggest that individual ERM values were reasonably predictive of toxicity. Given that the ERMs were derived as median values (not toxicity thresholds) in the effects database, predictive abilities of roughly 50% might be expected. Indeed, in the amphipod tests, 40% to 60% of samples were highly toxic when individual ERMs were exceeded. However, chemicals often occur in complex mixtures in environmental samples and toxicity in these tests could not be necessarily attributable to the substance which occurred at concentrations greater than the ERM values.

Therefore, a second series of analyses was conducted to estimate the effects of additivity of toxicants upon measures of toxicity. In these analyses the

percentages of samples were calculated for several categories of samples: (1) no SQGs exceeded, (2) only ERLs exceeded, no ERMs equaled/exceeded, (3) increasing numbers of ERMs exceeded.

Table 3. Percentages of samples in which no significant toxicity, marginal toxicity, and highly significant toxicity was observed in amphipod survival tests (from Long et al., 1998a). ERL= Effects Range-Low; ERM= Effects Range-Median.

Chemical category	Number of samples	Percent not toxic	Percent marginally toxic	Percent highly toxic
no ERLs exceeded	329	68	21	11
1 or more ERLs exceeded	448	63	20	18
1 or more ERMs exceeded	291	48	13	39
1 to 5 ERMs exceeded	225	53	15	32
6 to 10 ERMs exceeded	46	37	11	52
11 to 20 ERMs exceeded	20	10	05	85

Only 11% of the 329 samples were highly toxic in the amphipod tests when none of the ERLs were exceeded **(Table 3)**. In this category, 21% of the samples were marginally toxic and 68% were not significantly toxic in this category. These data suggest that the ERLs were reasonably predictive of non-toxic conditions.

Given that the ERLs were calculated as the 10th percentiles of effects data, roughly equivalent predictive abilities (i.e., about 10%) were expected in this field validation study. The data, however, indicated that 18% of samples in which one or more ERLs (but, no ERMs) were exceeded were highly toxic. The incidence of toxicity increased with increases in the numbers of ERLs exceeded, peaking at 67% when 15 to 19 ERLs were exceeded (Long et al. 1998a; data not shown).

Given that the ERMs were derived as 50th percentile values in the effects databases, roughly equivalent predictive abilities (i.e., about 50%) were expected. There were 291 samples in which at least 1 ERM was exceeded by any amount **(Table 3)**. Among these samples, 13% were marginally toxic and 39% were highly toxic. As the numbers of chemicals exceeding the ERMs increased, there was an increase in the percentages of samples that were highly toxic, peaking at 85% when 11 to 20 ERMs were exceeded.

Mean ERM quotients

Chemicals often occur in saltwater sediments as complex mixtures. To provide a tool useful in assessing the potential toxicological significance of the presence of mixtures, mean ERM quotients were calculated for all 1068 samples used in the field validation study (Long et al. 1998a). These indices were derived as the average of the 25 quotients obtained by dividing the individual chemical concentrations by their respective ERM values. The percentages of samples

that were not toxic, marginally toxic, and highly toxic were determined within ranges in the quotients. The data suggested a relatively consistent dose-response relationship: as the mean ERM quotients increased, the incidence of highly toxic responses increased (Long et al. 1998a). As more experience is gained with this tool, it may be useful in assessing the potential significance of chemical mixtures in sediment samples.

Probabilities of toxicity
