Public Comment
Beneficial Uses and Mercury Objectives
Deadline: 2/17/17 12 noon

The Honorable Felicia Marcus, Chair
and Members of the State Water Resources Control Board
c/o Jeanine Townsend, Clerk to the Board
State Water Resources Control Board
1001 I Street, 24th Floor
Sacramento, CA 95814

Re: Comment Letter – Beneficial Uses and Mercury Objectives

Dear Chair Marcus and Members of the Board,

Today, the Association of California Water Agencies (ACWA), the California Water Association (CWA), and the California Municipal Utilities Association (CMUA) and their member agencies are concurrently and timely submitting by email signed versions of the following documents, which are also set forth on the enclosed flash drive:

- A Letter of Comment; and
- A supporting Technical Evaluation Memorandum prepared by Exponent, Inc. (Technical Report).

In addition, ACWA, CWA and CMUA now also timely submit on the enclosed flash drive some of the key technical documents referenced in the Technical Report. The reference documents set forth on the enclosed flash drive were not submitted by email because the file sizes for the documents are too large to email.

The Letter of Comment, Technical Report, and supporting technical reference documents set forth on the enclosed flash drive constitute the complete comment package submitted on ACWA, CWA, CMUA and its member agencies regarding the proposed amendments to Part 2 of the Water Quality Control Plan for Inland Surface Waters, Enclosed Bays, and Estuaries of California – Tribal and Subsistence Fishing Beneficial Uses and Mercury Provisions, and related Staff Report, including Substitute Environmental Documentation. Thank you and please call or email me if you have any questions regarding this submission.

Sincerely,

Mary Lynn Coffee

Sacramento, CA 95814

Re: Comment Letter - Beneficial Uses and Mercury Objectives

Dear Chair Marcus and Members of the Board:

I. INTRODUCTION.

The Association of California Water Agencies, the California Water Association, and the California Municipal Utilities Association thank you for the opportunity to provide comments on the Draft Staff Report, Including Substitute Environmental Documentation for Part 2 of the Water Quality Control Plan for Inland Surface Waters, Enclosed Bays, and Estuaries of California – Tribal and Subsistence Fishing Beneficial Uses and Mercury Provisions, issued on January 3, 2017 (referred to hereinafter as the "Staff Report").

The Association of California Water Agencies (ACWA) is the largest statewide coalition of public water agencies in the country. Its 430 public agency members collectively are responsible for 90% of the water delivered to cities, farms and businesses in California. ACWA's mission is to assist its members in promoting the development, management and reasonable beneficial use of good quality water at the lowest practical cost in an environmentally balanced manner. ACWA's public agency members are special districts created to perform specific functions and include irrigation districts, municipal water districts, county water agencies, community service districts, flood control districts and others. ACWA's members carry out highly specialized functions to support their communities and protect public health, ranging from water treatment, and delivery, to wastewater treatment, to recycled water production and distribution, to flood control, to groundwater management and a host of others, ACWA member agencies.

The California Water Association (CWA) is a statewide association that represents the interests of more than 100 investor-owned public water utilities that are regulated by, and subject to the jurisdiction of, the California Public Utilities Commission. CWA's member water companies provide the same types of high-quality water utility services as those provided by the public agency members of ACWA to nearly 6 million people in communities throughout California. CWA provides a forum for sharing best management practices, to optimize utility

operations and customer service, and it promotes sound water policy by representing its members and their customers before the Legislature and regulatory agencies. Further, it creates opportunities for educating the public on the efficient use of water resources.

The California Municipal Utilities Association (CMUA) is a statewide association that represents publicly-owned electric utilities that provide 25 percent of the state's power and 40 public water agency members that deliver water to 70 percent of Californians.

ACWA, CWA, CMUA, and their member agencies and utilities support the designation of beneficial uses that protect human health. Our comments are intended to provide the State Water Board with additional information that it may wish to consider in the adoption of this far-reaching rule-making and incorporate into the Staff Report and the regulatory text of the Provisions to provide guidance to the regional boards, which will be responsible for designating new beneficial uses and adopting WQOs into basin plans and implementing the program to attain objectives to protect beneficial uses.

II. SUMMARY.

Consistent with our missions, ACWA, CWA, and CMUA wish to emphasize that our primary concerns arise with respect to the Mercury Provisions that will apply (1) immediately upon adoption of the proposed mercury program by the State Water Board without further hearings or additional due process or public comment opportunities, and (2) that are not associated with the protection of cultural or socioeconomic driven elevated rates of fish consumption. Specifically, these comments focus primarily on the promulgation and immediate application of the "Non-Tribal/Non-Subsistence Related Provisions" of the mercury program, namely:

- A new Sport Fish mercury objective of 0.2 mg/kg for purposes of protecting human health for those consuming a typical level of fish, which is more stringent than the federal law objective, promulgated to protect COMM, WILD, RARE, WARM, COLD, MAR, EST, and SAL;

- Two new very stringent wildlife water quality objectives (WQO), Prey Fish (0.05 mg/kg) and California least tern (CLT) Prey Fish (0.03 mg/kg), promulgated to protect WILD, RARE, WARM, COLD, MAR, EST, and SAL, rather than beneficial uses directly related to fishable/swimmable goals derived from federal Clean Water Act, 33 U.S.C. § 1251; and

- Three new, exceptionally low effluent limitations (EL) for mercury (ranging from 1 ng/L to 12 ng/L) to be applied upon adoption in all non-stormwater individual NPDES permits, including NPDES permits for effluent discharged from groundwater and surface water supply treatment, wastewater treatment, and water purification/recycled water production, as well as other individual permits such as drinking water system discharges, potable water line dewatering, testing, and industrial discharge NPDES permits.

We have raised concerns regarding the effects that the proposed Tribal beneficial uses (T-SUB and CUL) and Subsistence fishing beneficial use (SUB) could have on minimum

instream flow surface water objectives, and flow-related 401 Water Quality Certification and NPDES permit requirements. However, the Water Board Staff Workshop presentations questions, and testimony at the February 7 Hearing gave us the strong impression that flow and water supply consequences are not intended either by the State Water Board nor by the people that the new beneficial use definitions are being developed to protect. Therefore, we believe that our issues regarding the text of the proposed beneficial uses are relatively limited, and effective text revisions to address those issues should not be difficult to develop to allow their adoption.

The technical evaluation commissioned by the water agencies and attached hereto as **Exhibit A** (Technical Report) and the Staff Report both conclude, however, that the WQOs and the ELs of the Non-Tribal/Non-Subsistence Related Provisions— which were first shared with the regulated community on January 4, 2017 (and were not published as a part of the beneficial use outreach process) — are unattainable even in the extremely long term (multiple decades at a minimum) due primarily to:

- Natural background environmental characteristics of all of the hydrographic units under consideration, including naturally occurring and background levels of mercury in soils and waters. *Cf., Wat. Code* § 13241(b) (requiring consideration of environmental characteristics of hydrographic unit, including water quality).

- The water quality conditions that can be reasonably achieved through controllable water quality factors, given the absence of technologies and methods that enable control of mercury in non-point source discharges of sediment or aerial deposition. *Cf., Wat. Code* § 13241(c) (requiring consideration of water quality conditions that could reasonably be achieved through coordinated control of all factors affecting water quality).

- The absence of measures in the implementation program reasonably designed to achieve the new water quality objectives. *Cf., Wat. Code* § 13242 (a) (requiring implementation program to include a description of the nature of actions necessary to achieve water quality objectives).

- The absence of concurrently adopted compliance protections for dischargers.

III. RECOMMENDATIONS.

1. ACWA, CWA, CMUA, and their member agencies and utilities (the "water agencies") request a time extension pursuant to the United States Environmental Protection Agency (USEPA) Consent Decree in *Our Children's Earth Foundation v. USEPA*, paragraph 35A. The time extension is very much need additional time to work with State Board Staff to integrate all the information and analysis necessary to develop compliance protections and additional implementation program measures to ameliorate the many legal, economic, and environmental issues created by the Non-Tribal/Non-Subsistence Related Provisions.

2. Irrespective of the State Board granting a time extension, the water agencies recommend, among others, the following critical changes to the mercury program established by the Provisions:

a) Assure that the proposed water quality objectives (WQO) and effluent limitations (EL) are properly calculated, and established only after taking into account all factors required by law to be considered and balanced;

b) Properly and comprehensively assess the economic burden on ratepayers likely to be imposed by the Provisions;

c) Amend the Provisions to assure extended compliance schedule authority for NPDES permits to avoid a substantial increase in potential enforcement and third party citizen suit liability;

d) Amend the revised Reasonable Potential Process (RPA) process for mercury currently set forth in the Provisions to require consideration during the RPA analysis of all appropriate factors related to mercury exceedances in receiving waters caused primarily by natural water quality and soils conditions, legacy pollutants and uncontrollable water quality factors;

e) Amend the Provisions to eliminate the disproportionate burden of attaining WQOs placed on dischargers subject to individual non-stormwater permits, MS4 permits and industrial stormwater permits;

f) Amend the Provisions to authorize and clarify permit compliance schedule authority, and to allow compliance schedules of longer duration than currently permitted by the *Policy for Implementation of Toxics Standards for Inland Surface Waters, Enclosed Bays, and Estuaries of California* (SWRCB 2005) (SIP) and Resolution 2008-0025.

g) Adopt authority for, and direction to Regional Water Quality Control Boards (Regional Boards) to implement long-term compliance protections for dischargers, including: completion of Use Attainability Analyses (UAAs) to establish temporary water quality objectives for mercury prior to imposition of ELs; authorization for development of mercury site specific objectives (SSOs) for all beneficial uses (not just SUB); general authorization for development and use of variances for NPDES permits and WDRs; and general authorization for use of mixing zones and/or dilutions credits for NPDES permits and WDRs;

h) Bolster the currently insufficient implementation program by adopting additional implementation measures that will lead to meaningful reductions in mercury in the state's water and fish, some of which may be appropriate to offer as alternative compliance pathways for dischargers;

i) Eliminate vague regulations governing wetlands to assure that the Provisions are consistent with and do not impede: the stated intent of the State Water Board, which is not to prevent new wetland projects because of mercury

concerns; requirements of the State Board's "No Net Loss" policy for wetlands and other similar state and federal law requirements;

j) Tailor beneficial uses to eliminate concerns regarding water supply and instream flow objectives; and

k) Provide guidance to Regional Board with respect to designation of the new water quality objectives, compliance protections, and robust implementation measures that should be considered if newly defined beneficial uses and WQOs are considered for designation and adoption by Regional Boards.

IV. DISCUSSION.

A. Request for Time Extension.

A time extension is requested to assure that the mercury program when adopted can achieve the following goals:

- Directs resources toward achieving real, measurable reductions of mercury in fish and the environment, which are caused, as set forth in the Staff Report, primarily by natural background conditions in soils, aerial deposition, and legacy mercury and gold mines;

- Avoids substantial increases in cost for treatment upgrades and development of new technologies, which must be borne by water and wastewater ratepayers, many of whom are socio-economically disadvantaged, without providing measureable reduction in mercury or improvement in human health outcomes;

- Provides clear and permanent compliance protections necessary to avoid substantial costs to ratepayers, many of whom are socio-economically disadvantaged, to fund enforcement penalties, fines and third party citizen suit attorneys' fees since the Staff Report makes it clear that the very low mercury WQOs ranging from 0.2 to as low as 0.03 mg/kg of fish tissue, may never be attainable in most California receiving waters, or at a minimum should be expected to take decades if not centuries to attain;

- Provides additional implementation program control measures, including alternative compliance mechanisms for dischargers as well as additional state programs, to try to attain real and measurable reductions of mercury in fish and the environment; and

- Avoids direction to Regional Boards to regulate wetlands, including wetlands created for natural treatment, water quality polishing, and/or to enhance beneficial uses or avoid net loss of wetlands, without the provision of meaningful guidance and direction as to what types of regulatory controls might be effective and feasible to implement.

Such an extension of the adoption process for at least the Non-Tribal/Non-Subsistence Related Provisions is feasible and should be granted to allow development of additional information,

collaboration among State Water Board Staff, and the regulated community, and development of additional compliance assurances and implementation program measures because:

- While the adoption of new wildlife protection WQOs must be developed pursuant to a United States Environmental Protection Agency (USEPA) Consent Decree in *Our Children's Earth Foundation v. USEPA*, No. 3:13-cv-2857-JSW (2014), paragraph 35A of that Consent Decree enables USEPA to obtain an extension of the due date for adoption of such objectives.

- While we concur that adoption of an implementation program concurrently with the adoption of new, more stringent wildlife water quality WQOs is appropriate and preferable to federal adoption of objectives and a subsequent state process to adopt an implementation program, the implementation program needs considerable work to provide for attainment of the WQOs and to protect dischargers from enforcement for the time period necessary to reach attainment.

- Although the federal Consent Decree is driving the adoption of new WQOs for protection of wildlife, there are no litigation, environmental justice, or other known concerns regarding the protection of human health driving adoption of a new COMM mercury WQO for those Californians eating a typical diet, rather than an elevated amount of fish as a part of their regular diet.

We therefore urge the State Water Board to grant a substantial extension to allow for the development, in coordination with the regulated community, of additional key scientific and regulatory information regarding, at a minimum, the Non-Tribal/Non-Subsistence Related Provisions and detailed and thorough consideration of their regulatory and economic consequences in light of serious attainment challenges.

B. Establishment of Water Quality Objectives.

1. The Wildlife Mercury Water Quality Objectives Will Become Effective Without Any Further Regulatory Action.

The proposed Provisions would amend the Inland Surface Waters, Enclosed Bays and Estuaries Water Quality Control Plan to include new mercury WQOs for Sport Fish, Prey Fish, California Least Tern (CLT) Prey Fish, Tribal Subsistence (T-SUB) and Subsistence (SUB). Of these, the first three would become effective and would apply statewide upon adoption of the Provisions by the State Water Board and approval by the Office of Administrative Law (OAL) and USEPA. This is contrary to the implication – and the understanding of some – at the Staff Workshop and the State Water Board Hearing that the public would have additional opportunity to comment on the proposed Mercury Provisions when Regional Boards designate specific waterbodies with the proposed new beneficial use definitions of T-SUB, SUB, and Tribal, Tradition, and Culture (CUL). Although this is true with regard to the proposed T-SUB and SUB WQOs and the Sport Fish WQO where CUL is designated, it is important to understand that the WQOs for Prey Fish, CLT Prey Fish, and Sport Fish (for all beneficial uses except CUL) will become effective immediately.

The proposed Sport Fish WQO is proposed as a fish tissue concentration of 0.2 mg/kg to protect human health (COMM and CUL) and wildlife, which is lower than the current USEPA-recommended water quality criterion of 0.3 mg/kg. The Sport Fish WQO would apply to all inland surface waters, bay and estuaries, since all such waters with the beneficial use designations COMM, MAR, SAL, EST, WARM, COLD, WILD, and RARE would trigger the Sport Fish objective upon adoption and approval of the Provisions (*see,* Tab. 2.1). The proposed Prey Fish WQO of 0.05 mg/kg was developed specifically to protect wildlife and would also apply to all surface waters, bays and estuaries, with MAR, SAL, EST, WARM, COLD, WILD, and RARE beneficial uses upon adoption and approval of the Provisions; as would the CLT Prey Fish WQO of 0.03 mg/kg (*id.*).

2. The Proposed Water Quality Objectives Are Unattainable – At Least into the Next Century.

The Staff Report acknowledges that the proposed WQOs, particularly the Prey Fish and CLT Prey Fish WQOs, — which will apply immediately without further action by Regional Boards to designate new tribal, subsistence or cultural beneficial uses — are unattainable even in the extreme long term (multiple decades at a minimum): "The legacy of mercury left by historic gold and mercury mining is not easily controlled and may prevent attaining the Mercury Water Quality Objectives for many fish species for the next century in many waters." Staff Report, p. 267; *see also,* p. 266 (recognizing it may take a "significant period of time" to attain WQOs by implementing the Provisions). The Staff Report also notes that mercury from atmospheric emissions may be a significant source of mercury that will "prevent attainment" of the mercury WQOs (pp. 266-267.)

Sections 1 and 2 of the Technical Report also confirm that the proposed mercury WQOs are likely unattainable due primarily to the following:

- Natural background environmental characteristics of all of the hydrographic units under consideration, including naturally occurring and background levels of mercury in soils and waters. *Cf., Wat. Code* § 13241(b) (requiring consideration of environmental characteristics of hydrographic unit when establishing WQOs).

- Human-caused environmental characteristics of the hydrographic units under consideration, including legacy mercury from historic gold and mercury mines and aerial deposition of mercury. *Cf., id.*

- Water quality conditions that can be reasonably achieved through controllable water quality factors, given the absence of technologies and methods that enable control of mercury in non-point source discharges of sediment or aerial deposition. *Cf., Wat. Code* § 13241(c) (requiring consideration of water quality conditions that could reasonably be achieved through coordinated control of all factors affecting water quality when establishing WQOs).

3. The Mercury Water Quality Objectives Are Not Properly Established under Federal Law.

The federal Clean Water Act's implementing regulations require states to adopt WQOs that protect beneficial uses based on sound scientific rationale. 40 CFR § 131.11(a). For toxic pollutants such as mercury, states must "review water quality data and information on discharges to identify specific water bodies" where a toxic pollutant may be adversely affecting water quality or achievement of a beneficial use. *Id.* However, because the Provisions include a mass adoption of WQOs for inland surface waters, enclosed bays, and estuaries throughout the State without regard to site-specific conditions or the discharges affecting specific water bodies, the WQOs do not meet the requirements of 40 CFR section 131.11(a).

Section 10.1.2 of the Staff Report includes a brief discussion of site-specific water quality information (Environmental Characteristics and Water Quality of the Hydrographic Unit under Consideration). However, that section, comprising less than one-half a page in the Staff Report, refers only to the general conditions in the State as a result of legacy and widespread mercury contamination due to mines and atmospheric deposition, respectively. Nor is the section's cross-reference to Appendix D, a "brief description" of the geographic scope and generalized features of the nine regions governed by the Regional Boards, availing.

For example, the State Water Board Staff has indicated that wildlife-protective WQOs, Sport Fish (except for COMM and (future) CUL), Prey Fish and CLT Prey Fish, would apply even in waters where sensitive wildlife species do not occur. This application demonstrates the importance of examining the water quality conditions of specific waterbodies when adopting WQOs: the wildlife WQOs as applied to waterbodies without wildlife species do not serve the purpose of achieving the stated beneficial use. *See Cal. Sportfishing Protection Alliance v. SWRCB* (2008) 160 Cal.App.4th 1625 (site-specific WQO relaxing basin-wide temperature criteria appropriate where substantial evidence supported finding that creek had no viable population of rainbow trout).

Similarly, the Tribal Subsistence WQO was established based on fish consumption information from the Shilling 2014 report. However, no coastal southern California tribes south of Ventura (Chumash) participated in the study; and it is likely that the fish diet of coastal southern California tribal members would differ from that of their northern California counterparts. This underscores the need to look at the species, trophic level, and size of fish consumed at a regional level, not statewide.

The proposed WQOs – particularly the wildlife WQOs of Sport Fish (except COMM and CUL), Prey Fish, and CLT Prey Fish – are not based on nor do they reflect consideration of water quality data and information on discharges with regard to specific water bodies, contrary to the requirements of the federal regulations.

4. The Mercury Water Quality Objectives Are Not Properly Established under State Law.

Water Code section 13241 factors to be considered in establishing WQOs shall include, but not necessarily be limited to, all of the following: (a) Past, present, and probable future beneficial uses of water. (b) Environmental characteristics of the hydrographic unit under consideration, including the quality of water available thereto. (c) Water quality conditions that could reasonably be achieved through the coordinated control of all factors which affect water

quality in the area. (d) Economic considerations. (e) The need for developing housing within the region. (f) The need to develop and use recycled water.

The State Water Board is proposing to implement a mass designation of WQOs throughout inland surface waters, estuaries, and enclosed bays for Sport Fish, Prey Fish, and CLT Prey Fish. This fails to take into consideration the environmental characteristics and water quality at the hydrographic unit level. As discussed above, Staff Report section 10.1.2 and Appendix D do not constitute a review of site specific water quality information or environmental characteristics of any hydrographic unit.

The WQOs, particularly the more stringent WQOs established to protect Prey Fish, CLT Prey Fish, and ultimately, potentially, in the future, T-SUB, fail to take into account the water quality conditions that could reasonably be achieved through coordinated control of the factors or conditions affecting water quality insofar as it is acknowledged that it will take decades, if not a century or more, to achieve WQOs under the proposed Mercury Provisions (Staff Report pp. 266-267). The main sources of mercury – natural background conditions, aerial deposition, and legacy mines – are diffuse throughout the environment and not readily controlled through NPDES/WDR permit conditions.

Finally, as documented in section 3 of the Technical Report and Section II.C.3 of this memorandum, contrary to the requirements of section 13241 of the Water Code, the Staff Report fails to fully consider the economic impacts of the new WQOs.

C. Establishment of Mercury Effluent Limitations.

As documented in Sections 5 and 6 of the Technical Report, the proposed effluent limitations for NPDES non-stormwater discharges are problematic for the following reasons:

- They are likely much more conservative than necessary to protect even the most sensitive fish consumers because they are based on overly conservative fish tissue concentrations;
- They are improperly based on national bioaccumulation factors rather than factors that take local conditions into account; and
- They are not based on the best available science.

For these reasons, we urge the State Water Board not to adopt the effluent limitations proposed in the Staff Report until Staff can work with stakeholders to conduct additional review and incorporate the attached Technical Report comments into the analysis.

D. Implementation Program, Compliance and Enforcement Issues and Recommendations.

1. Implementation Program – Legal Framework.

Contrary to law and effective policy the program of implementation is not reasonably designed to address the quality of water as it pertains to mercury, or to attain the proposed

WQOs for mercury. Under State law, Water boards are instructed to consider "water quality conditions that could reasonably be achieved through coordinated control of all factors which affect water quality in the area" (Wat. Code § 13241(c)). Further, the program of implementation for achieving WQOs is required to include the following: (a) A description of the nature of actions which are necessary to achieve the objectives, including recommendations for appropriate action by any entity, public or private; (b) A time schedule for the actions to be taken; and (c) A description of surveillance to be undertaken to determine compliance with objectives (Wat. Code § 13242).

Additionally, under federal guidance published by EPA in April 2016, states and tribes responsible for implementing the Clean Water Act are directed to address implementation as part of the water quality criteria and standards development process, with a focus on addressing implementation issues early that may impede attainability of water quality standards. Priorities for Water Quality Standards and Criteria Programs, FY 2017-2018 (USEPA Apr. 21, 2016).

2. Compliance/Implementation Issues.

a) The program of implementation does not properly consider water quality conditions that could reasonably be achieved through coordinated control of all factors which affect water quality in the area.

Despite the law and guidance requiring that the implementation program must take into account the water quality conditions that could be reasonably achieved through coordinated control of all factors affecting water quality in the area, the Staff Report recognizes that attainment of the new WQOs across the many waters subject to those objectives may take a century and that the legacy of mercury left by historic gold and mercury mining, absence of original mine owners, diffuse distribution of mercury, and mercury emissions to the atmosphere makes coordinated control of contaminants "extremely challenging" (p. 267). The Staff Report further documents that adoption of stringent ELs for mercury for individual NPDES non-stormwater discharges -- and implementation of source controls and advanced treatment to attempt to achieve such ELs – is unlikely to achieve the WQOs:

> Even if all sources of the contaminants are eliminated, the contaminants are likely to remain high for decades, because either they do not degrade or they degrade very slowly. Much of the mercury in fish today is thought to be from historic mining in the late 19th century and early 20th century. Further, current sources may not be directly regulated by the water boards (e.g., atmospheric emissions, naturally occurring in soils, or geothermal sources).

(Staff Report, p. 108.) Nevertheless, the Provisions propose to establish a suite of unattainable WQOs, three of which (Sport Fish, Prey Fish, and CLT Prey Fish) will apply immediately to essentially all inland surface waters, bays, and estuaries, based on the numerous waterbody beneficial uses designations, any one of which triggers application of one or more of the three objectives.

b) The program of implementation does not include a description of the nature of actions which are necessary to achieve the objectives,

including recommendations for appropriate action by any entity, public or private.

The proposed WQOs are not met in the existing condition for most (if not all) of the inland surface waters, bays and estuaries to which they will apply and the implementation program does not identify any means to attain the new objectives because reasonable means to address the naturally occurring, legacy and aerial deposition sources of mercury as necessary to achieve such stringent WQOs do not exist. Consequently, most inland surface waters, enclosed bays and estuaries will have to be listed under Clean Water Act Section 303(d) as impaired for mercury, requiring the time and resource intensive development of TMDLs by the regional boards for all such waters.

c) *The program of implementation does not include a time schedule for the actions to be taken.*

The Staff Report does not include a time schedule for implementation program actions to be taken, other than to declare that the water boards would determine time schedules for compliance with new discharge regulations on a "discharge-by-discharge basis" (Staff Report, p. 268). Substantial reductions of mercury in fish tissue will have to be achieved to meet the proposed WQOs given the baseline levels measured in the State's fish (Technical Report, section 7). According to the Staff Report, achieving the proposed WQOs may take decades, if not a century, due to legacy mercury from mines, widespread aerial deposition and natural background conditions, and the persistent nature of mercury. Such reductions demand implementation program measures that are not focused on individual NPDES permit discharges or industrial or stormwater runoff, but instead are designed to control aerial deposition, and mercury in nonpoint source runoff, particularly within high mercury open space and former mining areas. *See,* Technical Report §§ 3 and 8. Because the Staff Report does not identify sufficient implementation program measures to attain mercury WQOs, it also fails to identify a time schedule for implementation of program measures and actions designed to achieve proposed WQOs.

d) The Effluent Limitations for NPDES Non-stormwater Discharges Will Not Achieve Water Quality Objectives.

Point source dischargers subject to individual non-stormwater NPDES permits represent a minor source of mercury compared to the other sources (Staff Report, pp. 153-54). As such, the implementation program focuses on the wrong mercury discharges and fails to identify actions that would effectively achieve reductions of mercury in fish or the environment to a level that achieves the established WQOs. *See, e.g.,* Staff Report p. 165 (minor reductions that can be achieved through ELs imposed on wastewater and industrial discharges may not translate to noticeable reductions in mercury concentration); *see also*, Technical Report Section 1. As a result, the actual sources contributing the vast majority of mercury to surface waters are not addressed by the proposed implementation program. *See,* Staff Report, p. 108. Instead, the centerpiece of the implementation program is the promulgation of new, very stringent ELs for inclusion in all individual non-stormwater NPDES permits.

Because the proposed ELs (and other implementation measures addressing industrial and urban stormwater runoff) cannot attain the proposed mercury WQOs, and because such

attainment will not, in most circumstances, effectively contribute to mercury reductions, we urge the State Water Board to further amend the revised Reasonable Potential Process (RPA) process for mercury currently set forth in the Provisions to require appropriate consideration during the RPA analysis of appropriate factors related to mercury exceedances in receiving waters caused primarily by natural water quality and soils conditions, legacy pollutants and uncontrollable water quality factors such as aerial deposition, as well as the relatively minor nature of mercury contributed by specific discharges analyzed to determine the *reasonable* potential for such discharges to contribute to mercury pollution, rather than the most conservatively determined potential contribution to mercury pollution theoretically possible as a result of the discharge. The following amendments to the RPA steps set forth in the Provisions are recommended. The operation of these amendments to the RPA process are also graphically set forth in Technical Report § 3, Figures 2 and 3.

Determining Whether a Discharge Requires an Effluent Limitation for Mercury

1. Reasonable Potential Analysis

Step 3: Replace highest *observed* annual average effluent mercury concentration with the ~~highest~~ representative annual average effluent mercury concentration.
This revision allows the RWQCB discretion to consider if any data are inappropriate or insufficient for use in determining the annual average effluent mercury concentration for purposes of determining whether an effluent limitation is required.

Step 6: Replace Step 6 of the SIP with the following: If the B is less than C and mercury was not detected in any of the effluent samples, effluent monitoring is not required. In all other cases, proceed with *Step 7.*
This revision completes the Reasonable Potential Analysis where the observed maximum ambient background concentration is less than the lowest water quality objective for mercury and mercury was not detected in the effluent. This is consistent with the Staff Report, which provides that where the background mercury level is elevated above the lowest EL "it may not be reasonable to require smaller contributors of mercury to reduce their mercury discharge to levels below background." (p. 154)

Step 7: Add to the list of types of information that may be used to aid in determining whether a water quality-based effluent limitation is required the following: existing ambient water quality in the hydrographic unit, background conditions in soil and water, controllable water quality factors, whether the discharge is a significant source of mercury in the waterbody, and whether ELs are an effective means for reducing mercury in fish and the environment.
This information was added to the types of information properly considered in the determination of whether a water quality-based effluent

limitation is required to reflect natural background conditions and legacy mercury in the environment and recognizes the potential limitations inherent in trying to achieve reductions of mercury in fish and the environment. See Technical Report § 3, Figs. 2 and 3.

Step 8: In addition to low volume discharges, the RWQCB may choose to exempt <u>low threat discharges</u> determined to have no significant adverse impact on water quality from this monitoring requirement.
This addition recognizes that certain discharges permitted under an individual NPDES permit pose a low threat to water quality and as such are not expected to contain mercury; therefore these discharges should be exempted from all monitoring requirements provided for in Step 8 for mercury.

e) *The Effluent Limitations for Individual NPDES Permit Non-stormwater Discharges Will be More Difficult to Achieve and More Expensive than Estimated in the Staff Report.*

The Non-Tribal/Non-Subsistence Related Provisions state in Section IV.D.2. that the water quality objectives shall be implemented by the application of very low ELs, ranging from 1 ng/L to 12 ng/L depending on receiving water body flow conditions and beneficial uses for all individual non-stormwater NPDES Permits, 401 water quality certifications, WDRs, and waivers (pp. A-8 – 10).[1] In addition, in the future, other very stringent ELs for other bioaccumulative pollutants must also be developed (e.g., PCBs) to fully protect new wildlife protection and Tribal, Cultural, and Subsistence Fishing beneficial uses if and when designated. See Staff Report, Appendix T).

Although the Staff Report asserts that the proposed 12 ng/L EL "is achievable" with existing secondary treatment technology (with an adjunct mercury source control/minimization program), consistent with the PowerPoint presentation by Thomas Grovhaoug of Larry Walker Associates at the February 7 Hearing, the Technical Report concludes that some NPDES dischargers will not be able to meet this EL without additional upgrades to tertiary treatment. *See,* Technical Report section 2. This means that secondary treatment facilities must be upgraded to tertiary treatment to meet 12 ng/L consistently enough to avoid enforcement of the EL. However, the Staff Report economic analysis fails to consider the costs of the upgrades,

---

[1] Although there has been some confusion regarding the NPDES permits that the Provisions will apply to, the Provisions clearly require the implementation of effluent limits in, at a minimum, all individual non-stormwater NPDES Permits and WDRs, which encompass many more permits than just permits those issued to POTWs or municipal wastewater plants and individual industrial dischargers. Appendix N defines "municipal wastewater and industrial NPDES permits" as all individual non-stormwater NPDES Permits and WDRs. In addition, the Staff Report indicates that certain General NPDES permits and WDRs already excluded from the SIP or involving low threat discharges should be excluded from the amended SIP analysis and default effluent limits set forth in the Provisions (pp. 145, N-1). However, the regulatory language of the Provisions does not contain express exceptions or clarify whether other General Permits and WDRs, like the Recycled Water WDRs, would also be excluded from the amended SIP analysis and default effluent limitations.

finding instead that for discharges to flowing water bodies that no facility upgrades are required to meet 12 ng/L for the 308 facilities discharging to meet Sport Fish, Prey Fish, and CALT Prey WQOs (*see,* Staff Report, section 7.2.7 and p. 246).

Furthermore, the attached Technical Report § 2 summarizes persuasive evidence that even with tertiary treatment, some facilities will not be able to achieve the 4 ng/L EL consistently, thus requiring additional treatment upgrades to advanced technologies such as RO (*id*.). This analysis is consistent with information presented in testimony and PowerPoint slides presented by Thomas Grovhaoug of Larry Walker Associates at the Hearing. Thus, many tertiary treatment facilities must implement additional treatment upgrades to meet 4 ng/L consistently enough to avoid enforcement. Again, however, the Staff Report fails to consider these costs in their entirety, finding instead that facilities may need, at most, to upgrade to tertiary treatment to assure that discharges to slow moving waters consistently meet Sport Fish, Prey Fish, and CLT Prey WQO and discharges to flowing water bodies consistently meet T-SUB of 4 ng/L *see,* Staff Report, section 7.2.8).

In addition, pursuant to the Technical Report § 2, and as presented in testimony and PowerPoint by Thomas Grovhaoug of Larry Walker Associates at the Hearing, a new, as yet undeveloped treatment technology is required to consistently meet 1 ng/L. The Staff Report concurs with this conclusion, finding discharges to slow moving waters to meet T-SUB and CLT Prey Fish EL of 1 ng/L may require major, but unspecifiable facility upgrades (Staff Report, section 7.2.9). Nevertheless, as documented in Section 2 of the Technical Report, the Staff Report fails to fully consider the costs associated with development and implementation of new technologies necessary to comply with the proposed ELs. Even by the State Water Board's own estimates, the economic impact of compliance is potentially quite high – source control, BMPs, and treatment controls, e.g., RO – and these costs are understated as outlined above.

Further, no known technologies are available to deploy to treat geographically dispersed discharges in compliance with the ELs, *e.g*., discharges pursuant to individual non-stormwater NPDES permits issued for activities such as dewatering, testing, hydrant flushing, groundwater treatment, and remediation. Nevertheless, the Staff Report fails to fully consider the costs associated with invention, development, and deployment of new, as yet undefined technologies necessary for such discharges to comply with the proposed ELs.

Finally, the proposed ELs are well below currently applicable MLs for mercury of 0.5 µg/L and 0.2 µg/L (500 ng/L and 200 ng/L). At a minimum, new and more expensive monitoring methods and equipment must be implemented by dischargers and significant cost and expense to address detection at levels far below existing MLs. Nevertheless, as documented in Section 2 of the Technical Report, the Staff Report fails to fully consider the costs associated with adoption of new monitoring technologies necessary to assure compliance with the proposed ELs.

We urge the State Water Board to consider the substantial evidence provided in the attached Technical Report indicating that treatment technologies for water treatment and wastewater treatment plants alone would cost ratepayers far more than currently estimated in the Staff Report. Further, increased costs of monitoring and upgrades to tertiary treatment, as well as development of new technologies to consistently meet the proposed ELs are not included in the Staff Report economic analysis, but will be expensive. Unfortunately, despite the

significant economic costs of meeting the ELs, all of which must be borne by water and wastewater ratepayers, only a very small reduction in mercury pollution can be anticipated to result because discharges are such a small source of mercury, and the ELs will not result in attainment of the proposed WQOs. Because all available evidence supports a conclusion that the designated uses do not currently exist in terms of compliance of waters with the WQOs, it is unreasonable to require dischargers, and particularly the ratepayers of such dischargers, to incur substantial economic control costs to protect mercury conditions. *Cal. Ass'n of Sanitation Agencies v. State Water Res. Control Bd.* (2012) 208 Cal.App.4th 1438, 1460. The Staff Report fails to articulate why adoption of the WQOs is necessary in these circumstances to assure the reasonable protection of beneficial uses despite the potential adverse economic consequences. *Memorandum of William R. Attwater, Office of Chief Counsel of the State Water Resources Control Board Re: Guidance on Consideration of Economics in the Adoption of Water Quality Objectives or Waste Discharge Requirements,* pp. 1-2 (Jan 4 1994).

f) *The ELs Create Compliance and Enforcement Risk for NPDES Non-stormwater Dischargers.*

The unavailability and cost of treatment technologies that can consistently meet the lowest ELs proposed for adoption raise serious concerns regarding risk of liability for significant fines, penalties, and attorneys' fees as a result of enforcement action or citizens' suit for permittees discharging under individual non-stormwater NPDES permits and WDRs. This disproportionate regulatory impact and risk of liability is noted in the Staff Report, which discusses inevitable enforcement actions by the water boards or via citizens' suits for permit violations that will occur where ELs cannot be achieved, and notes these costs will be borne by point source dischargers with individual non-stormwater NPDES permits, despite the relatively minor source of mercury in those discharges as compared to other sources. *See,* Staff Report p. 153; *see also,* Technical Report, sections 2 and 3; *also as presented* in testimony and PowerPoint at the Hearing by Thomas Grovhaoug of Larry Walker.

This risk of liability is compounded by limitations on NPDES permit compliance schedules. The Staff Report acknowledges that the mercury WQOs cannot be achieved in the short-term, taking multiple decades, if not a century to attain at minimum. The unattainability of WQOs will, in turn, lead to listing of most waterbodies for mercury impairment, and requirements to develop TMDLs. TMDLs, and particularly the data analyses required to support TMDLs, are extremely time intensive to prepare and approve, often taking at least three years, and many times requiring more than 7 years to fully approve per TMDL.

The Provisions do not clearly exempt individual non-stormwater NPDES permits from the SIP, including its limitations on compliance schedules. The SIP allows only up to five (5) years from the date of issuance, reissuance, or modification of an NPDES permit to complete actions necessary to comply with ELs and no longer than 10 years from the effective date of the SIP (2006) – which is past (2016).[2] Due to the fact that the Provisions immediately require

[2] Even if the USEPA had not disapproved longer timeframes, 15 years, and an additional five years, from the effective date of the SIP to develop and adopt a TMDL, and to comply with WQBELs – which it did – they are similarly not of sufficient duration given the nature of, and the limited measures available to reduce mercury in, the environment. *See,* Letter: California SIP; compliance schedule provisions from USEPA to SWRCB dated Oct. 23, 2006

application of ELs in individual non-stormwater NPDES permits to implement the Non-Tribal/Non-Subsistence-related WQOs, facilities will be required to begin upgrades to treatment processes and/or facilities soon after adoption of the Provisions.[3] *See, e.g.,* Staff Report, pp. 177-180; Technical Report § 2. It is unlikely that dischargers can plan, design, engineer, environmentally review, permit, fund, and construct the necessary upgrades within a five year permit term or the (maximum) five year compliance schedule period available under the SIP. However, the Staff Report does not identify interim actions or compliance schedule authority that individual NPDES non-stormwater dischargers can rely on to assure compliance before TMDLs can be fully adopted. The maximum compliance schedule limitations of the SIP also preclude post-TMDL compliance schedules for individual non-stormwater NPDES permits of sufficient length to provide dischargers compliance assurance, but the Staff Report fails to identify actions to implement to remain in compliance with NPDES permits over the course of the decades it will take to achieve the proposed WQOs.

For these reasons, we recommend the Provisions expressly exempt from the SIP all individual non-stormwater NPDES permits regulated under the Provisions to allow sufficient permit compliance schedules before, during, and after development of mercury TMDLs. Such exemption may be intended since Section 10.2 of the Staff Report appears to indicate that timelines for permit compliance schedules should be established pursuant to the State Water Board's Resolution 2008-0025, *Policy for Compliance Schedules in NPDES Permits.*

However, Resolution 2008-0025 also limits the duration of permit time schedules. Specifically, section 6(b) of Resolution 2008-0025 caps compliance schedules at a maximum of 10 years absent the development of a TMDL. Given the large number of TMDLs that will be required to address the very low WQOs and the typical length of time required to prepare and fully approve a TMDL, it is unlikely that 10 years will be sufficient permit compliance schedule protection during the development of all TMDLs as necessary to protect dischargers and their ratepayers from liability risk associated with enforcement actions and citizen suits.

Federal regulations require that a State must authorize the use of schedules of compliance for water quality based effluent limits in NPDES permits if they plan to allow such schedules. 40 CFR § 131.11(j)(1). Therefore, we urge the State Water Board to modify the Provisions to provide clear permit compliance schedule authority and to allow compliance schedules of longer duration than currently permitted by Resolution 2008-0025.

3. Additional Recommended Compliance Protections for Dischargers.

While compliance schedule authority is critical to protecting dischargers subject to individual non-stormwater NPDES permits from the disproportionate risk of enforcement and third party citizen suit liability that they face under the current Provisions, dischargers also need long-term compliance protections due to the substantial period of time that the Staff Report states will be necessary to achieve meaningful reductions in mercury in receiving waters. Accordingly, it is incumbent on the State Water Board that it include in its order adopting the Provisions an implementation program that offers compliance protections that are real and

---

[3] The Staff Report acknowledges that mercury reduction measures without treatment process modifications are unlikely to reduce mercury to the point of compliance with the Provisions' bioaccumulative- based effluent limitation (Staff Report p. 165).

implementable statewide. The Water Agencies propose to work in coordination with the State Board to explore appropriate development of the following long-term compliance protections for dischargers: completion of Use Attainability Analyses (UAAs) to establish temporary water quality objectives for mercury prior to imposition of ELs; authorization for development of mercury site specific objectives (SSO) for all beneficial uses (not just SUB); general authorization for development and use of variances for NPDES permits and WDRs; and general authorization for use of dilutions credits for NPDES permits and WDRs.

a) Use Attainability Analyses.

According to staff in the January 9 Workshop and EPA surveys, UAAs[4] are rarely (if ever) approved in California. However, it is not clear why UAAs are not used in California given that the federal Clean Water Act provides for preparation of a UAA most importantly for this case when a use is not an existing use because the water quality standards necessary to support it are not attained, and attainment of the use and WQO is infeasible. 40 CFR §§ 131.3(e), 131.10(d); 131.10(g). More specifically, federal regulations state that that states may permanently or temporarily remove or relax water quality standards if the state can demonstrate that attaining the designated use is not feasible because:

> (1) Naturally occurring pollutant concentrations prevent the attainment of the use; or
>
> ***
>
> (3) Human caused conditions or sources of pollution prevent the attainment of the use and cannot be remedied…; or
>
> ***
>
> (5) Physical conditions related to the natural features of the waterbody…unrelated to water quality, preclude attainment of aquatic life protection uses; or
>
> (6) Controls more stringent than those required by section 301(b) and 306 of the Act would result in substantial and widespread economic and social impact. 40 CFR § 131.10(g).

Further, 40 CFR § 131.10(j) provides that states are actually required to conduct UAAs when designating uses not included in the fishable/swimmable uses specified in CWA

[4] A use attainability analysis demonstrates that attaining the use is not feasible due to the following: naturally occurring pollutant concentrations that prevent the attainment of the use; natural, ephemeral, intermittent or low flow conditions or water levels prevent the attainment of the use; human caused conditions or sources of pollution prevent the attainment of the use; dams, diversions or other types of hydrologic modifications preclude the attainment of the use; physical conditions related to the natural features of the water body and unrelated to water quality preclude attainment of aquatic life protection uses; or controls more stringent than those required by Clean Water Act sections 301(b) and 306 would result in substantial and widespread economic and social impact. 40 CFR § 131.10(g).

section 101(a)(2)). Prey Fish and CLT Prey Fish uses are not fishable/swimmable uses, but are instead wildlife protection related uses.

USEPA guidance provides that when waters do not meet water quality standards promulgated under the Clean Water Act, and the problems have been produced over many years and it may take many years and substantial changes in resource management to implement desired water quality standards, UAAs are an appropriate tool, conducted alone or in conjunction with the TMDL process, to allow for use attainability over time. *UAAs and Other Tools for Managing Designated Uses*, Preface p. iv (USEPA March 2006) (UAA Guidance). UAAs are appropriate not only to remove a use that is not an existing use, but perhaps more importantly for this situation, UAAs are appropriate for establishing temporary water quality standards, including WQOs, where the goal of the temporary water quality standards is to ultimately, over time, improve water quality to the point where designated uses are fully supported. UAA Guidance, Montana's Temporary Water Quality Standards, at p. ix. As such, temporary WQOs play a key role in the remediation of damaged water resources. *Id.* The duration of temporary standards is set based on an estimate of the time needed to remediate water resources, and, because clean-up of legacy pollutants takes time, temporary standards can be and are issued for multiple years. *Id.*, p. x. States need only to authorize UAAs to use them to set temporary water quality standards as part of a long program of resource management actions designed to improve water quality. *Id.*, p. ix.

Pursuant to the Staff Report, all of the conditions required by regulation to allow, and even to require, conducting UAAs to establish temporary mercury WQOs are satisfied. Accordingly, we urge the State Board to adopt authorization for water boards to conduct such UAAs, and to include in the Provisions a requirement that regional boards shall conduct such UAAs prior to conducting an RPA for mercury or applying ELs in individual non-stormwater discharge Permits. Adopting authority and directing Regional Boards to develop, consider, and where appropriate, to approve UAAs to establish temporary WQO is particularly important given the "mass designation" approach that the State Water Board is following, and the adoption of very low WQOs for all water bodies without considering the natural background conditions applicable to each waterbody or hydrological unit, and without considering the degree to which water quality factors leading to exceedances of the proposed objectives in that hydrographic unit are, or are not controllable. If those factors are not considered now, when adopting WQOs, the only vehicle for consideration of those factors is via a UAA once it is demonstrated the water body cannot comply for the reasons set forth in federal law. A UAA is also the only vehicle available for long-term relief from WQOs and ELs for the entire duration it may take to attain WQOs.

b) Site-Specific Objectives.

Federal regulations (40 CFR § 131.11), Cal. Wat. Code § 13241, and Section 5.2 of the SIP authorize the development of SSOs based on scientifically defensible methods appropriate to the situation and circumstances found in particular regions and waterbodies. The Provisions and Staff Report currently support and authorize regional boards to develop SSOs for the protection of Subsistence Fishing uses because SSOs will more effectively take into account natural conditions and controllable versus uncontrollable water quality factors in the waterbodies for which they are developed, as well as local and regional fish consumption patterns. In fact, this rationale supports authorization and direction to consider mercury SSOs for the protection

of all beneficial uses, including, COMM, WARM, COLD, WILD, RARE, EST, MAR, and SAL. We therefore urge the State Water Board to consider amending the Provisions to advise Regional Boards that it is appropriate to consider adoption of SSOs to replace all the WQOs in light of all the different beneficial uses they are designed to protect in order to better account for local ambient conditions for mercury in each region, subregion or waterbody.

c) Variances.

On August 21, 2015, the EPA published its water quality standards regulation (80 FR 51020), including water quality standards variances (40 CFR § 131.14). The rule explicitly authorizes the use of water quality standards variances pursuant to Clean Water Act sections 101(a) and 303(c)(2) in the same circumstances as those discussed above for UAAs. The federal regulations specify that variances are appropriate when pollutants are persistent in the environment and lack economically feasible control options (80 FR 51020, p. 25).

Like UAAs establishing temporary WQO, variances allow a state to retain the designated use for a waterbody, but to temporarily relax WQOs or ELs as specified in the variance so long as the variance reflects the highest attainable condition identified at the time of the adoption of the WQS variance. 40 CFR § 131.14(b)(ii) and (iii). The relaxed WQOs may then be used for purposes of establishing interim uses and interim WQOs, as well as for purposes of developing NPDES permit limits and requirements, as well as 401 Water Quality Certification requirements. 40 CFR § 131.14(a). Unlike UAAs establishing temporary WQOs, variances with a term greater than five (5) years must be re-evaluated no less than every 5 years, providing less assurance of long-time compliance protection for dischargers. Nevertheless, if any waterbodies may be close to meeting the proposed WQOs, variances may be an appropriate mechanism to use to allow compliance protection for dischargers until new treatment technologies, and particularly those that have yet to be developed, can be identified, planned, designed, environmentally reviewed, permitted, funded and implemented.

However, currently, no consistent statewide mechanism for establishing water quality standards and NPDES permit variances exists; only the Central Valley RWQCB has adopted a variance for salinity (*see, Public Scoping Meeting for the Proposed Statewide Water Quality Standards Variance Policy* (Jan. 23, 2017); Resolution No. R5-2014-0074). Adoption of a general variance policy consistent with federal regulations the State Water Board would provide necessary State implementation authority, establish a consistent procedure for adopting variances across the Regional Boards, and alleviate the burden associated with each regional board having to conduct a public outreach and hearing process to amend their respective water quality control plans to provide such implementing authority.

d) Mixing Zones and Dilution Credits.

The Staff Report notes in several places that water boards have the discretion to allow mixing zones and dilutions credits where appropriate. *See, e.g.,* Staff Report p. 10. However, Staff comments at the January 9, 2017 workshop indicated that the Provisions are not intended to allow regional boards to permit mixing zones and dilution credits, and this position is confirmed by a number of statements in the Staff Report indicating that dilution credits and mixing zones "would be allowed but would not be recommended in most situations since mercury is a bioaccumulative compound …" (p. 156), and shall be prohibited if the mercury

concentration in fish tissue from fish in the receiving water exceeds the applicable WQOs. Staff Report Appendix A, p. A-11. As a matter of practice, mixing zones and dilution credits are not available statewide; they are never applied, at least in Southern California, despite Precedential Order 2001-006, which provides that mixing zones are allowed even in water bodies listed as impaired. *Cf.*, Staff Report pp. 176, 179, 182, 184 (water boards have the discretion to allow dilution credits in waters that currently meet applicable water quality standards). Pursuant to Order 2001-06, a key consideration in determining to establish a mixing zone and/or dilution credit, even for a listed water body, should be a determination of whether even the elimination of a bioaccumulative pollutant from discharges would have had no effect on pollutant concentrations in the waterbody or in fish.

With respect to mercury, the Staff Report and the Technical Report establish that even if all individual non-stormwater NPDES permit discharges were eliminated, reductions in mercury sufficient to attain waterbody compliance with WQOs would not result. Therefore, we urge the State Board to amend the Provisions to expressly authorize the application of mixing zones and dilution credits in circumstances such as those analyzed in Order 2001-06.

4. Recommended Additional Implementation Program Measures.

We also recommend bolstering the currently insufficient implementation program by considering and adopting additional implementation measures that will lead to meaningful reduction in mercury in the state's waters and fish, and some of which may be appropriate to offer as alternative compliance pathways for dischargers. The additional measures should be specifically focused on measures and the development of information and technologies capable of addressing mercury in the environment. We recommend for additional study and consideration six possible additions to the implementation program that the water organizations and member agencies would like to work with Staff to explore:

1. New or more effective control methods for historic mines and tailings;

2. Regional solutions and programs particularly for nonpoint source implementation measures, and which may involve the engagement of other state agencies;

3. Trading/offset programs to allow funding of measures to address actual sources of mercury;

4. A "water funds" approach to support development of studies and pilot projects for design, testing and evaluation of new technologies and control measures that would better target mercury in the environment, including nonpoint source runoff from open space and areas of elevated mercury, wetlands, and sediment;

5. Coordinated development of state funded control programs among the State Board, local agencies, and CARB to address aerial deposition; and

6. Interventions to protect human health developed in other nations dependent upon subsistence fishing, such as Brazil (Passos *et al*. 2007).

E. Insufficiency of Certain Proposed Implementation Measures.

The Staff Report and Mercury Provisions fail to identify and analyze certain reasonably foreseeable compliance methods/management measures, including those imposed on stormwater and wetlands discharges at the discretion of water boards in areas of elevated mercury.

1. Stormwater Implementation Program Measures.

The Provisions impose new requirements as a part of the implementation program on both MS4 and industrial stormwater discharges. Certain mercury control BMPs are specified for inclusion in MS4 permits, and new, much lower action levels are imposed on industrial stormwater permit discharges. However, the Staff Report fails to evaluate the likelihood that the additional MS4 Permit measures specified may reasonably lead to reductions of mercury in receiving waters. Further, the Staff Report fails to identify any treatment technologies that might be available to implement on a geographically dispersed basis to control urban runoff in a manner that would effectively reduce mercury in receiving waters. Because no treatment technologies are identified or evaluated for assuring that industrial stormwater permits meet the new mercury action levels, the Staff Report's substitute environmental analysis of potential impacts of such technologies is missing contrary to the requirements of CEQA that environmental impacts of all reasonably foreseeable pollution control technologies required by mandate must be analyzed. Cal. Code Regs. tit. 14, § 15126.2.

Further, the new implementation program's regulatory requirements applicable to MS4 and industrial stormwater permits raise serious risk of enforcement and third party citizen suit liability for stormwater permittees. Upon adoption, the new, stringent, and unattainable WQOs will become MS4 permit and industrial stormwater permit "receiving water limitations." As a result, any MS4 or industrial stormwater discharges that "cause or contribute to an exceedance of the mercury WQOs" would create a receiving water limits violation for permittees. The vast majority, if not all inland surface waters, enclosed bays and estuaries will exceed the new WQOs for mercury, creating the risk of liability under industrial and MS4 stormwater permit receiving water limitations, regardless of the significance (or relative insignificance) of mercury contributions associated with those discharges.

To attempt to maintain compliance in light of such receiving water limitations, MS4s and industrial dischargers will be required to expand the reasonable assurance analysis mandated by the permits to attempt to show what the Staff Report could not—that the BMPs deployed to control mercury are reasonably likely to bring receiving waters into compliance with the WQOs. In addition, costs of watershed management plans (WMPs) and industrial stormwater pollution prevention plans (SWPPPs) will increase to attempt to control mercury as required by new mercury "receiving water limitations." As WMPs and SWPPPs are modified, new control measures for mercury in urban and industrial stormwater will have to be implemented, even though there are no effective treatment practices or technologies, thus imposing costs for invention, development and implementation of new mercury stormwater control technologies, despite the fact that stormwater discharges are very small sources of mercury. The Provisions should be modified to clarify that mercury WQOs should be excluded from receiving water limitations in both MS4 permits and the Industrial General Stormwater permit.

2. Wetland Mercury Control Measures.

The draft Provisions address wetlands by providing discretionary control to water boards to use existing law to implement mercury controls in areas with elevated mercury concentrations. The draft Provisions include examples of design features and management measures to reduce the production of methylmercury in the wetland that water boards "should consider requiring." Staff Report § 6.10.3. Yet the Staff Report, including the Wetlands Appendix Q, emphasizes that the science on mercury/methylmercury controls is not advanced enough to provide BMPs that will clearly reduce mercury or methylmercury in most situations. Further, the relative importance of the many factors that can influence mercury chemistry can vary from site to site. *See,* Technical Report section 8. This is why the Staff Report states that the science on mercury/ methylmercury controls is not advanced enough to provide BMPs that will clearly reduce mercury or methylmercury in most situations.

The Staff Report provides, "New wetland projects (creation or restoration of wetlands) should not be prevented because of mercury concerns. However, wetland projects should be done in [a] manner to reduce unintended impacts. If practicable, new wetlands should not be created in areas with high levels of mercury." (p. 136)

As an initial matter, this potentially conflicts with State's no net loss of wetlands policy (E.O. W-59-93). Wetland projects are a cost-effective manner to improve water quality by removing contaminants, including sediments to which mercury binds, before entering receiving waters, and they play an important role in the implementation of TMDLs. Wetlands provide an environmentally sound way to address the pollution caused by urban runoff before the runoff reaches sensitive receiving waters. Wetlands provide a cost effective alternative that can be used to address runoff from existing communities that can't easily be retrofitted.

The challenge for wetlands is that this understanding is not translated into the Provisions regulatory language. The regulatory language, which is what will ultimately survive this rulemaking and drive water boards' future actions, does not reflect the State Water Board's position with regard to the scientific uncertainty of the process of methylation and wetlands. Absent revisions, the text implies (a) the listed measures are necessary and appropriate to incorporate into permit conditions for wetlands development [which they are not]; and (b) the listed measures will achieve mercury reductions from wetlands projects [which they may not] – leaving a cloud of regulatory uncertainty over future wetlands projects.

The Staff Report and regulatory language should be amended to reflect the current knowledge of the effectiveness of control measures as it relates to wetlands and other bodies. We believe the regulatory language should clarify that the listed measures are not BMPs and may or may not be appropriate depending on site specific factors. Alternatively, the listed management measures could be eliminated altogether from the regulatory text at section IV.D.7 [Wetland Projects]. Such amendments would ensure that the Provisions are consistent with the stated intent of the State Water Board, which is not to prevent new wetland projects because of mercury concerns. Otherwise, a cloud of regulation on wetland creation/restoration will have the regulated community looking for alternatives to wetland creation, often to the detriment of water quality and other environmental outcomes.

3. Further Analysis of Stormwater and Wetlands Mercury Control Measures is required under the Water Code and CEQA.

Failure to identify and properly analyze mercury stormwater controls and wetlands implementation measures is a violation of Water Code sections 13241(c) and 13242(a). Delete the limitations or properly identify and analyze such controls consistent with the requirements of the Water Code.

Failure to identify and assess environmental impacts of stormwater controls and wetlands implementation measures is a CEQA violation. Delete the limitations or properly identify and analyze such controls.

F. New Beneficial Uses.

1. The New Beneficial Uses Will Likely Result in Further Water Quality Regulations for Pollutants Other than Mercury.

As recognized in the Workshops and at the Board Hearing, the new beneficial use categories of T-SUB, SUB, and CUL will pave the way for listing, WQOs, ELs, and TMDLs for other constituents. See, Beneficial Use handout, p. 5 (stating that the subsistence beneficial uses may require regulation of other bioaccumulatives). Wastewater and industrial facility upgrades may be needed to comply with multiple future statewide or region wide WQOs for other pollutants regulated in association with new beneficial use categories (facility upgrades likely to involve adding nitrification and denitrification steps or adding additional filtration) (see p. 177).

2. The Staff Report and the Regulatory Text Should Include Direction Regarding the Adoption of Flow and Fish Population Objectives.

It is likely that without specific direction in the Staff Report and the Provisions the new CUL beneficial use will result in flow and fish quantity objectives. See, Workshop Beneficial Use handout, p. 2, (stating that the State Board may develop a flow objective to protect the new CUL beneficial use, although “it is not anticipated.”)

For example, in 2011 the Oregon Department of Environmental Quality adopted the strictest standard for toxic water pollution in the United States to protect tribal members and others who eat large amounts of contaminated fish. The human health water quality criteria have been adopted for 113 pollutants, including mercury, flame retardants, PCBs, dioxins, plasticizers and pesticides. However, the new rule could end up costing millions and improvements in water quality are expected to take years, if not decades; yet it's not clear how much the rules will actually reduce pollution.

Similarly, the State of Washington was thereby restricted from developing and operating infrastructure that would hinder fish passage and thereby diminish the number of fish that would otherwise be available for Tribal harvest. *United States v. Washington*, 20 F. Supp. 3d 986, 1000, 1022 (W.D. Wash. 2013). A Florida tribe challenged the State of Florida’s implementation of new water quality criteria for 39 chemical components not currently regulated by the state and revisions to standards for 43 more were for failing to account for the higher levels of fish

consumption by tribe members who subsist on fish and doesn't include sufficient protections for tribe members who subsist on fish and other seafood. *Seminole Tribe of Florida v. Dep't of Envt'l Protection,* No. 2D16-4305.

3. The Staff Report Does Not Properly Document Consideration of Water Code Section 13241 in the Adoption of the New Beneficial Uses.

Contrary to CWC § 13241 the Staff Report fails to consider the relevant factors in establishing the new B/U categories by failing to consider information about background conditions in specific water bodies or regionally, by failing to identify water quality conditions that can reasonably be achieved through the coordinated control of factors that affect water quality, and by failing to properly consider the full scope of economic impacts associated with treatment plan upgrades and associated mitigation measures.

4. The Staff Report Should Include Policy Guidance and Criteria in the Designation of Beneficial Uses to Avoid Unintended Consequences.

In order to provide consistent application of the Mercury Provisions and the designation of beneficial uses throughout the State and to avoid misapplication of the implementation program, we recommend the State Water Board include guidance for the Regional Boards in the Staff Report as follows:

1. State that with respect to the tribal (T-SUB, CUL) and subsistence (SUB) beneficial uses and WQOs flow and fish quantity criteria/objectives shall not be established.

2. Prohibit the designation of tribal (T-SUB, CUL) and subsistence (SUB) beneficial uses where the use is wholly in the past (*i.e.*, not existing and not probable future use). *See,* Staff Report at Appendix T-4 (stating that regional water boards do no designate waters with beneficial uses that occurred solely in the past).

3. Prohibit the designation of tribal (T-SUB, CUL) and subsistence (SUB) beneficial uses where the water quality does not support the use.

For already designated beneficial uses that will immediately trigger the Mercury Provisions, e.g., COMM and RARE, we strongly recommend conducting a UAA to determine whether the use is attainable. *See, Cal. Ass'n of Sanitation Agencies v. State Water Res. Control Bd.* (2012) 208 Cal.App.4th 1438, 1460 (finding that where a water board has evidence that a designated use does not exist and likely cannot be feasibly attained it is unreasonable to require dischargers to incur control costs to protect that use). Alternatively, regional boards could conduct a UAA prior to imposing ELs in NPDES permits.

G. Adoption of the Mercury Provisions is an Unfunded Mandate.

Section 6 of Article XIII B of the California Constitution provides, in relevant part: "Whenever the Legislature or any state agency mandates a new program or higher level of service on any local government, the State shall provide a subvention of funds to reimburse that

local government for the costs of the program or higher level of service." Where a subvention is not provided, the new program – or in this case, regulation – is an unfunded mandate.

The Mercury Provisions are an unfunded mandate because they mandate a higher level of protection (more stringent WQOs) than required under federal law.

First, the proposed Sport Fish WQO of 0.2 mg/kg, which applies to COMM and is protective of human health, is slightly lower the federal Fish Contaminant Goal of 0.22 mg/kg developed by OEHHA (Klasing and Brodberg 2008). While the federal OEHHA value is not enforceable, it is the contaminant goal for mercury in fish, concentrations above which the federal agency has determined warrant advisories to those consuming the fish. Further, the 0.22 mg/kg value has been used by the State since 2012 for water quality assessment purposes in the state, according to the Staff Report (p. 31).

Second, the proposed Sport Fish WQO of 0.2 mg/kg is also more stringent than the federal EPA national water quality criterion and the USEPA federal regulatory objective for fish tissue of 0.3 mg/kg. The USEPA fish tissue criterion has been used to fulfill the narrative toxicity objective in regards to mercury (*id.*).

Third, the proposed Sport Fish WQO of 0.2 mg/kg is also more stringent than the fish tissue concentration for mercury of 0.37 mg/kg used to derive the currently applicable federal USEPA CTR water criterion for protection of human health (*id.*).

All told, even the least protective human health mercury WQO of 0.2 mg/kg – which would apply immediately upon adoption and approval of the proposed Provisions – provides a higher level of protection as compared to all applicable federal limits, therefore constituting an unfunded State mandate.

In addition, the wildlife beneficial uses (Sport Fish (except COMM, CUL), Prey Fish, CLT Prey Fish) are not supported under federal law if the use is not an existing or probable future use or water quality does not support the use because the federal act authorizes designation of only existing or probable future beneficial uses. Where WQOs are already exceeded, it is highly likely that wildlife uses have not been occurring since 1975 given the legacy nature of mercury pollution. Thus, where a designation is based on a wholly past use, and therefore protected under Porter Cologne, but not the federal act it is an unfunded State mandate.

H. CEQA Comments.

1. Failure to Include the Reservoir Program in the Project Description is Piecemealing.

The Staff Report provides, "Many methods of compliance for the Provisions could be similar to those required for the Reservoir Program, including sediment controls, possible wastewater treatment plant upgrades, and mercury monitoring . . . . Reservoir Management Actions [i.e., methods to manage mercury in reservoirs] are different methods of compliance not required by the Provisions, but some of the impacts could be similar as the impacts of the Provisions." (p. 255) This rulemaking's WQOs will be used to determine which waters are impaired and will therefore drive the Reservoir Program – for water districts with multiple

discharges and operations that will be regulated for mercury, it is important to understand how the Reservoir Program, which is under development, will work in conjunction with the Provisions as a comprehensive statewide mercury program.

2. The Project Objectives are Improperly Narrow and Violate CEQA.

CEQA Guidelines § 15124(b) requires a clearly written statement of objectives, including the underlying purpose of the project, which will help the lead agency to develop a reasonable range of alternatives and aid decision makers in preparing findings or a statement of overriding considerations. The process of selecting the alternatives to be included in the EIR begins with the establishment of project objectives by the lead agency. "A clearly written statement of objectives will help the lead agency develop a reasonable range of alternatives to evaluate in the EIR and will aid the decision makers in preparing findings . . . . The statement of objectives should include the underlying purpose of the project." Cal. Code Regs., tit. 14, § 15124, subd. (b).

However, the Mercury Provisions project objectives are simply listed in the Staff Report and not discussed or explained. CEQA and the State Water Board's implementing regulations require an analysis of reasonable alternatives to the project and mitigation measures to avoid or reduce any significant or potentially significant adverse environmental impacts. Cal. Code Regs., tit. 23, § 3777. Failure to include a meaningful discussion of project objectives undercuts CEQA's requirement to analyze reasonable alternatives.

3. The Staff Report Does Not Evaluate a Reasonable Range of Alternatives.

The SED improperly eliminates alternatives for failing to meet one of a list of five project objectives, where the project objectives are not discussed or explained and no project purpose is identified in the project description (CEQA Guidelines 15126.6(b) [An EIR should not exclude an alternative from detailed consideration merely because it "would impede to some degree the attainment of the project objectives."] Although a lead agency may not give a project's purpose an artificially narrow definition, a lead agency may structure its EIR alternative analysis around a reasonable definition of underlying purpose and need not study alternatives that cannot achieve that basic goal. *In re Bay-Delta etc.,* (2008) 43 Cal. 4th 1143, 1165-66.

However, the Staff Report's project description does not identify a project purpose. For this reason, eliminating alternatives for failing to meet one of five project objectives – particularly where the Staff Report only lists and does not discuss the rationale behind the project objectives – does not comply with the requirement to consider a reasonable range of alternatives.

4. Environmental Impacts Are Not Properly Considered or Analyzed in the Staff Report.

a) *Treatment Facility Upgrades Required to Comply with Effluent Limitations Will Effect Water Supply.*

As a result of planned activities and emergencies, water purveyors have discharges from their drinking water systems, such as line testing. Planned discharges may be scheduled or unscheduled and are due to development and maintenance activities mandated by statutory requirements under the federal Safe Drinking Water Act and the California Safe Drinking Water Act (Health and Saf. Code, division 104, part 12, chapter 4.) Emergency discharges are due to system leaks, facility failures, and catastrophic events.

Drinking water system discharges under the scope of the proposed Mercury Provisions ELs for individual non-stormwater NPDES permits would include both planned and emergency discharges. As discussed above and in Section 2 of the attached Technical Report, added costs to upgrade treatment technologies to meet new ELs as low as 1 ng/L, the lack of treatment technologies to reduce discharges to meet ELs, new listings and associated TMDLs, and the lack of realistic time schedules to comply with the new mercury program pose a significant risk of increased compliance costs, permit violations and penalties, and citizen suit enforcement and attorneys' fees – all of which will increase the cost of water service. While the exemption for small disadvantaged communities will provide some protection, increased cost of service must be passed on to ratepayers or be paid for by eliminating other programs – both of which would adversely affect water purveyors' ability to provide clean, safe and affordable drinking water to their customers.

b) Treatment Facility Upgrades Such as Reverse Osmosis, Necessary to Meet 1 ng/L May Result in Significant Energy Use and Air and GHG Emissions.

As documented in Section 2 of the Technical Report, wastewater treatment facilities with tertiary treatment may need to introduce advanced treatment to meet the proposed 1 ng/L EL for slow-moving waterbodies designated T-SUB. The Staff Report does not offer examples of such treatment options to comply with the 1 ng/L standard; however, the Technical Report indicates that RO could be used. Operation costs for this treatment would require up to twice as much power consumption as tertiary treatment alone. Air quality and climate change effects associated with the concomitant air and greenhouse gas emissions must be evaluated in the Staff Report so that the public and decision makers may understand the scope of potential environmental impacts associated with adoption of the Mercury Provisions.

c) *Sediment Controls to Reduce Mercury May Result in Hydromodification Impacts*

The Provisions recommend water boards impose sediment controls at mine sites and for nonpoint sources in areas of elevated mercury (pp. 171-172). Sediment controls are designed to keep or reduce the amount of sediment from entering into waterbodies. The reduction of sediment in natural stream channels can create "hungry water," resulting in erosion and downcutting of the natural streambed. *See, e.g., Hydromodification Management Plan: County of San Diego* § 6.4.7 (Brown and Caldwell 2011). The Staff Report does not address this potential for hydromodification effects resulting from implementation of sediment control measures as imposed by regional boards.

II. CONCLUSION.

The water agencies appreciate this opportunity to provide comments on the proposed beneficial uses and Mercury Provisions. We support protection of public health, and our comments are focused primarily on concerns with the Non-Tribal/Non-Subsistence provisions. We would very much appreciate the opportunity and time to work with you and your staff to address those concerns.

Sincerely,

Rebecca Franklin

DATE: February 17, 2017

PROJECT: 1608830.000

SUBJECT: Technical comments on proposed California Mercury Provisions

This technical memorandum summarizes Exponent's comments on the State Water Resources Control Board's (SWRCB's) proposed "Part 2 of the Water Quality Control Plan for Inland Surface Waters, Enclosed Bays, and Estuaries of California—Tribal and Subsistence Fishing Beneficial Uses and Mercury Provisions" (Mercury Provisions), which was released for public review on January 3, 2017.[1] Our comments focus on concerns that the proposal will not produce reductions in mercury concentrations in fish because it fails to address the primary sources of mercury to the State's water bodies and fish. The proposal also contains a number of technical shortcomings that should be addressed before adoption. Our comments fall into seven primary categories, summarized as follows:

1. Point source discharges subject to individual National Pollutant Discharge Elimination System (NPDES) permits (e.g., water treatment plants, wastewater treatment plants, and industrial discharges) are small relative to other mercury sources. Imposing stringent numeric effluent limitations on those sources will have little effect on mercury concentrations in fish and the environment. Stringent numeric effluent limits are inappropriate for most point sources, and alternative implementation mechanisms should be explored and developed by the SWRCB.

QAID 1608830.000 - 3640

2. The proposed effluent limitations for non-stormwater individual NPDES dischargers may be unattainable (especially 1 ng/L), and treatment upgrades to meet the proposed limits will be more costly than disclosed by the SWRCB.
3. The implementation program in the State's proposed policy should be modified to focus on actions that will lead to meaningful reductions in mercury in the state's waters and fish.
4. The Staff Report's position on dilution credits and mixing zones for NPDES discharges containing mercury is inconsistent with SWRCB precedential orders. The appropriateness of mixing zones and dilution credits should be evaluated on a site-specific basis.
5. The fish tissue objectives proposed to protect wildlife are likely to be overly conservative and should be revised to address this limitation.
6. The water concentration targets derived from the proposed fish tissue water quality objectives are fundamentally flawed and should not be implemented at this time.
7. The proposed human health objectives may be too conservative.
8. The proposed action to address dredging, wetlands, and nonpoint sources of mercury is vague and does not prescribe or prevent any specific actions.

Details of these comments are included below.

1. Point source discharges subject to individual NPDES permits (e.g., water treatment plants, wastewater treatment plants, and industrial discharges) are small relative to other mercury sources. Imposing stringent numeric effluent limitations on those sources will have little effect on mercury concentrations in fish and the environment. Stringent numeric effluent limits are inappropriate for most point sources, and alternative implementation mechanisms should be explored and developed by the SWRCB.

In Appendix N of the Mercury Provisions, SWRCB presents source analysis data for the 14 existing mercury-related TMDLs in the state; these TMDLs are listed in Table 1.[2] Only three of the mercury TMDLs for these water bodies list wastewater and industrial discharges as sources of mercury.[3] As reproduced in Figure 1, Table N-11 from Appendix N indicates that wastewater and industrial discharges constitute 4% of methylmercury discharged to the Delta and 1.5% of total mercury discharged to San Francisco Bay. (The third TMDL, for Calleguas Creek/Mugu Lagoon, lacks a quantitative source analysis.) Sources related to historical mining (tributaries

[2] Appendix N. Wastewater and Industrial Discharges. pp. N-14 to N-15. Note that Figure 3-1 (p. 33) of the Staff Report shows a map of mercury impaired waters on the 2012 303(d) list, which includes many more water bodies than those for which mercury TMDLs have already been developed.

[3] Appendix N, p. N-14.

QAID 1608830.000 - 3640

and water body sediments) account for 93% and 82% of mercury in the Delta and San Francisco Bay, respectively, while atmospheric deposition (direct deposition and urban stormwater generated by mercury-laden precipitation) accounts for 15% of mercury in San Francisco Bay. Thus, data from these two TMDLs indicate wastewater and industrial NPDES dischargers contribute little mercury to affected water bodies relative to other sources, suggesting tight limitations on mercury from such dischargers will not result in significant reductions in environmental mercury concentrations.

Table 1. Waterbodies in California subject to a mercury-related TMDL

Water body	Individual NPDES permit dischargers listed as source?
Sacramento-San Joaquin Delta	Yes
San Francisco Bay	Yes
Calleguas Creek/Mugu Lagoon	Yes
Guadalupe River Watershed	No
Walker Creek	No
Clear Creek and Hernandez Reservoir	No
Las Tablas Creek and Lake Nacimiento	No
El Dorado Park Lakes	No
Puddingstone Reservoir	No
Lake Sherwood	No
Consolidated Slip and Fish Harbor, Los Angeles-Long Beach Harbor	No
Cache Creek	No
Clear Lake	No
Rhine Channel, Newport Bay	No

Table N-11. Estimated Mercury Loadings from the Sacramento-San Joaquin Delta TMDL (Delta) and the San Francisco Bay TMDL.

Sources	Delta *Methylmercury* (g/day)	San Francisco Bay *Total Mercury* (g/day)	Delta (% total)	San Francisco Bay (% total)
Tributaries (Central Valley)	8.2	1205	57	36
Guadalupe River Watershed (Historic mining, San Francisco Bay only)	-	252	-	8
Sediments in water body (Delta: open water, wetlands. San Francisco Bay: Bed erosion)	5.1	1260	36	38
Atmospheric deposition (San Francisco Bay: direct deposition only. Delta: direct and indirect, so includes atmospheric mercury carried by nonpoint source storm water, but not urban storm water)	0.06	74	0.4	2
Non-urban storm water (San Francisco Bay only: includes mercury enriched sediments and atmospheric mercury. Delta: Atmospheric mercury from non-urban storm water is included in 'atmospheric deposition')	-	68	-	2.0
Urban runoff (Caltrans, MS4s, Construction, Industrial)	0.05	438	0.3	13
Municipal wastewater and **Industrial discharges** (Delta had only municipal wastewater)	0.6	49	4	1.5
Agricultural return flows (Delta only)	0.3	-	2	-
Total	14.31	3348	100	100

Figure 1. Table N-11 from Appendix N of the Mercury Provisions. Source: Appendix N, p. N-15 of "Part 2 of the Water Quality Control Plan for Inland Surface Waters, Enclosed Bays, and Estuaries of California—Tribal and Subsistence Fishing Beneficial Uses and Mercury Provisions." Accessed February 7, 2017, at http://www.swrcb.ca.gov/water_issues/programs/mercury/docs/staff_report/hg_apndx_n.pdf.

Appendix N states:

> *From the [mercury TMDL source] estimates in Table N-11, atmospheric deposition is not a major source of mercury. In the Sacramento-San Joaquin Delta TMDL, municipal wastewater is more significant than atmospheric deposition. If this information is used to extrapolate relative source contribution to the state as a whole, then for any watershed without historic [sic] gold or mercury mining, wastewater and industrial dischargers can be a significant source of mercury.*[4]

[4] Appendix N, p. N-14.

QAID 1608830.000 - 3640

However, a finding that atmospheric deposition is small does not lead directly to the conclusion that NPDES discharger contributions "can be a significant source of mercury"—instead, the Staff Report should consider the possibility that *neither* source might be significant. Appendix N also suggests NPDES discharges can be significant in "any watershed without historic [sic] gold or mercury mining,"[5] but this assertion is not supported by data or information in the Staff Report, and no evidence is provided to suggest extrapolating data from the Delta or San Francisco Bay to the entire state is appropriate.

In contrast to the proposal's focus on NPDES discharges, the Staff Report indicates that historical mining, natural soils, and direct deposition are "significant" and "major" sources of mercury.[6] The Staff Report notes that "the median and average mercury concentrations in rain in California were 6 ng/L and 12 ng/L" and "the 99.8th percentile of mercury concentrations in rain in the United States was 174 ng/L."[7,8] Thus, a significant fraction of rain samples in California would have concentrations higher than these values, which, as discussed below, are equivalent to the proposed effluent limitations for point source discharges. The Staff Report also indicates that "[m]ercury deposition from atmospheric emissions is thought to be the major source of mercury in some Southern California lakes and reservoirs (U.S. EPA 2012, Tetra Tech 2008)."[9]

Finally, the Staff Report states, "[m]unicipal wastewater treatment plants are generally a relatively minor source of mercury to the environment compared to other sources. Wastewater

---

5 Ibid.

6 The Staff Report notes that "elevated mercury concentrations in present-day mine impacted waters and sediments indicate that hundreds to thousands of pounds of mercury remain at each of the many sites affected by hydraulic mining" (Staff Report at p. 47). The Staff Report also notes, "The Coast Ranges are naturally high in mercury… The soils in these areas that are naturally enriched with mercury erode, contributing to the mercury load in waterways… The mercury from mine waste, naturally enriched soils, and geothermal springs is a major source of mercury in the Coast Ranges, the Sierra Nevada Mountains, and also downstream in the Sacramento/San Joaquin Delta and San Francisco Bay" (Staff Report at p. 49). Finally, the Staff Report finds that "direct deposition of mercury to water bodies (vs. deposition on land upstream) has been found to be very important in determining mercury levels in fish. Harris and colleagues applied isotopically labeled mercury (as $HgNO_3$) to a lake and the surrounding watershed. Essentially all of the increase in methylmercury in fish after 3 years was due to the mercury deposited directly to the lake surface… Furthermore, the results could suggest that controlling emissions that are deposited directly on the water surface may have a rapid effect (few years) on mercury level in fish (Harris et al. 2007)" (Staff Report at p. 50).

7 Staff Report at p. 140.

8 It has been widely demonstrated that precipitation in California has significant concentrations of mercury linked to coal-based Asian industrial emissions. For example, Steding and Flegal conclude that their study "demonstrates the impact of Asian industrial emissions on Hg concentrations in rain in western North America. The analyses substantiate previous reports on the influence of those emissions on Hg deposition in the North Pacific." (Steding, D.J. and A.R. Flegel. 2002. Mercury concentrations in coastal California precipitation: evidence of local and trans-Pacific fluxes of mercury to North America. J. Geophys. Res., 107 (2002):D24, p. 11-6.) They estimate mercury deposition via rainfall at approximately 25–50 nmol/year/m^2, which, if applied over the area of San Francisco Bay (approximated as 2,500 km^2), is roughly the same rate reported in the San Francisco Bay mercury TMDL for atmospheric deposition (74 g/day, from Table N-11).

9 Staff Report at p. 49.

QAID 1608830.000 - 3640

treatment plants already remove most of the mercury from the effluent."[10] Because mercury sources attributable to NPDES dischargers are small compared to the dominant sources in the state, imposing stringent effluent limitations on NPDES dischargers such as those proposed in the Mercury Provisions will not result in a significant reduction in water body or fish concentrations. The Staff Report acknowledges this, noting that bioaccumulative pollutants, including mercury, are "generally very persistent in the environment," concluding that:

> *Even if all sources of the contaminants are eliminated, the contaminants are likely to remain high for decades, because either they do not degrade or they degrade very slowly. Much of the mercury in fish today is thought to be from historic mining in the late 19th century and early 20th century. Further, current sources may not be directly regulated by the water boards (e.g., atmospheric emissions, naturally occurring in soils, or geothermal sources).*[11]

In summary, the Staff Report establishes clearly that sources other than NPDES discharges are the primary sources of mercury to the state's water bodies and that imposing controls on NPDES discharges will have little or no effect on ambient mercury concentrations. This information should lead the SWRCB to develop a program to address those major sources.

2. The proposed effluent limitations for non-stormwater individual NPDES dischargers may be unattainable (especially 1 ng/L), and treatment upgrades to meet the proposed limits will be more costly than disclosed by the SWRCB.

As discussed in Section 2 of the Staff Report, the proposed water quality objectives for mercury are expressed as fish tissue concentrations. These fish tissue concentrations are "translated" into water column concentrations proposed to be used to evaluate "reasonable potential" (RP) and to derive effluent limitations applicable to point source discharges. The water column concentrations and their proposed applicability to various water quality objectives (WQOs) and kinds of water bodies are summarized in

[10] Staff Report at p. 151.

Table 2. Proposed water column mercury concentrations for NPDES discharges and their applicability to various kinds of water bodies

Total Hg water column concentrations	Water quality objectives (WQOs) and water bodies to which water column concentration applies
12 ng/L	Sport Fish and Wildlife WQOs in flowing water bodies
4 ng/L	Sport Fish and Wildlife WQOs in slow-moving water bodies; Tribal Subsistence Fishing (T-SUB) WQOs in flowing water bodies
1 ng/L	Tribal Subsistence Fishing (T-SUB) WQOs in slow-moving water bodies
Case-by-case determination	Subsistence Fishing (SUB) WQOs in any water body; Any WQOs in lakes and reservoirs

Source: SWRCB. 2016. Draft Staff Report, Including Substitute Environmental Documentation, for Part 2 of the Water Quality Control Plan for Inland Surface Waters, Enclosed Bays, and Estuaries of California—Tribal and Subsistence Fishing Beneficial Uses and Mercury Provisions. State Water Resources Control Board January 3. pp. 173–183. Accessed February 7, 2017, at http://www.swrcb.ca.gov/water_issues/programs/mercury/docs/staff_report/hg_staff_report.pdf.

The Staff Report asserts the proposed 12 ng/L effluent limitation "is achievable" with existing secondary treatment technology and (possibly) a mercury source control/minimization program.[12] However, according to a recent study by HDR, typical mercury concentrations after secondary treatment range from 3.0 to 50 ng/L in Publicly Owned Treatment Works (POTWs) and from 10 to 50 ng/L in industrial discharges.[13] The report does not examine the factors responsible for the variability in mercury concentrations in treated effluent, though it likely depends in part on plant influent mercury concentrations. HDR's data suggest some NPDES dischargers will *not* be able to meet the 12 ng/L effluent limitation with secondary treatment and/or a source control/minimization program.

The Staff Report also asserts the proposed 4 ng/L effluent limitation is achievable with tertiary treatment that includes nitrification/denitrification but not with secondary treatment.[14] Data from the Central Valley Regional Board indicate that tertiary treatment can reduce mercury concentrations to 4 ng/L or below in at least some cases but not in every case. On average, the San Jose/Santa Clara Waste Water Treatment Plant (WWTP) achieves a mercury concentration of 4 ng/L limitation using tertiary treatment,[15] while the Onondaga County WWTP does not.[16] Thus, it is likely some plants already employing tertiary treatment will not be able to meet the 4 ng/L water column concentration.

QAID 1608830.000 - 3640

In contrast with the 12 ng/L and 4 ng/L effluent limitations, the 1 ng/L effluent limitation proposed for slow-moving water bodies with a Tribal Subsistence Fishing designation is likely unachievable without extraordinary treatment upgrades and expenditures for most NPDES dischargers. The treatment processes that would be needed to meet a concentration limit of 1 ng/L are not disclosed in the Staff Report. The Staff Report indicates the 1 ng/L effluent limitation may be unachievable for NPDES dischargers not already achieving it (i.e., 73% of such dischargers according to Staff Report data).[17] The Staff Report suggests no treatment methods for NPDES dischargers to meet the 1 ng/L effluent limitation. Instead, the Staff Report states, "the Water Boards may use compliance schedules, site-specific objectives (with extended compliance schedules), TMDLs, or variances if the [1 ng/L] effluent limitation is unachievable."[18]

HDR's review of treatment technologies states, "[t]here is limited information available about achieving ultralow effluent mercury concentrations near the 5 ng/L range."[19] The treatment process that appears most likely to meet the proposed 1 ng/L effluent limitation is advanced treatment employing microfiltration and reverse osmosis (MF/RO), and then under optimal conditions where input concentrations are low.[20] Under these circumstances, HDR found dischargers could achieve mercury effluent concentration in the range of 1.2 to 3 ng/L.[21] However, this level of treatment exceeds tertiary treatment and requires substantial additional expenditures (see below), and the Staff Report does not disclose or examine the costs of this level of treatment.

Appendix R of the Staff Report estimates the cost of upgrades from secondary to tertiary treatment that would be required by the policy to be in the range of $9–15 million/year over 20 years. Exponent believes this range significantly underestimates upgrade costs. For example, Sacramento Regional San—a POTW with a design flow rate of 181 million gallons per day (mgd)—is currently upgrading from secondary to tertiary treatment at a capital cost of approximately $2 billion and $50 million/year in operation and maintenance (O&M) thereafter.[22] These estimates for a single plant surpass the Appendix R total estimate for all plant upgrades in the state.

---

17 Staff Report at p. 178: "Based on statewide monitoring data for all facilities that may be impacted by the Provisions, it is estimated that eight facilities would not meet the new effluent limits for the [T-SUB] water quality objective in flowing water bodies and will have to undergo a major treatment plant upgrade if they are designated with the T-SUB beneficial use in the future." And from the Staff Report at p. 180: "Recent data from discharger self-monitoring reports indicates [sic] that about 73 percent of all discharges to waters included in the geographic scope of the Provisions exceeded 1 ng/L, based on 2009-2015 data."

18 Staff Report at p. 180.

QAID 1608830.000 - 3640

Given advanced treatment (e.g., MF/RO) will be necessary to achieve the 1 ng/L limitation, costs will be far higher. HDR suggests that the capital cost of upgrading a plant from secondary to advanced treatment (MF/RO) would be about $15–$162 per gallon per day (gpd) of treatment capacity, depending on the size of the plant to be upgraded.[23] This range is 13–142 times higher than the Appendix R estimate of $1.14 per gpd to upgrade to tertiary treatment[24] and would cost $1.5–$16.2 *trillion* for a plant that treats 100 mgd. Clearly, the costs required to upgrade a treatment plant to advanced treatment will exceed the costs to upgrade to tertiary treatment, such that the costs of implementing the SWRCB's proposal will be far greater than disclosed in the Staff Report.

In addition to capital and O&M costs, upgrading POTW treatment to advanced treatment would increase power consumption. For POTW dischargers, HDR estimates advanced treatment would require 50–100% more power than tertiary treatment.[25] Increased power consumption produces increased greenhouse gas emissions. This impact is not considered in the Environmental Document associated with the Mercury Provisions, and no mitigation measures are offered for this potentially permanent, long-term additional source of greenhouse gases.[26]

3. The implementation program in the State's proposed policy should be modified to focus on actions that will lead to meaningful reductions in mercury in the state's waters and fish.

Issue L in the Staff Report addresses the question, "What procedure should be used to determine which municipal wastewater and industrial dischargers would need effluent limitations?"[27] Two options are considered: (1) use a mercury concentration in water; (2) use mercury concentrations in fish tissue. Both options would result in effluent limitations for discharges to most of the state's water bodies, despite the fact that point source discharges are minor contributors to mercury in the state's water bodies; as detailed throughout these comments, such effluent limitations are not likely to result in reductions in ambient mercury concentrations. Although the proposed Mercury Provisions include language stating that the permitting authority is authorized to exempt certain dischargers from some or all of the provisions of the policy if the discharge is found to be "insignificant [de minimis],"[28] it appears that this exemption would be highly limited and unavailable for most dischargers. For this reason, Exponent recommends that the flow charts for both options be modified to consider additional factors and implementation options before concluding that effluent limits are required. Only if the policy is modified to include alternative implementation options will the policy be likely to lead to meaningful reductions in mercury concentrations in the state's waters and fish.

QAID 1608830.000 - 3640

As shown in Figure 2 and Figure 3, Exponent recommends the addition of decision points based on the relative importance of point sources to mercury loads in the water body, and the consideration of alternative implementation measures. First, if point source discharges are not significant contributors to mercury in the water body, effluent limitations should not be required. The second query recognizes that effluent limitations on point sources may not be the most effective method for reducing mercury concentrations in receiving waters and fish, and indicates that alternative implementation measures (as discussed below) should be required in lieu of effluent limitations. And finally, when effluent limitations are found to be necessary because point source discharges are an important source of mercury, the policy should require consideration of dilution credits, compliance schedules, and variances, particularly for effluent limitations that are infeasible to achieve, or that will require time and resources to implement.

A second concern relates to the Staff Report's recommendation that water column targets be used to determine reasonable potential and to calculate effluent limitations for point source discharges. As detailed in comment 6, the water column concentration targets calculated using nationwide average BAFs fail to consider the behavior of mercury, which is highly site-specific and complex. As a result, the recommendation to use water column targets calculated using BAFs as the basis for RP and effluent limitations is not scientifically appropriate. Exponent therefore recommends that a modified version of the second option, i.e., the use of mercury concentrations in fish tissue, be used to determine the need for effluent limitations, as shown in Figure 3.

Since, in most cases, the point source implementation measures that are the focus of the proposed Mercury Provisions are unlikely to appreciably reduce environmental mercury concentrations due to the dominance of non-point sources, alternative measures offer the best—and perhaps the only—chance to achieve meaningful reductions in mercury concentrations in the environment. Alternative measures should be investigated and discussed in public workshops prior to adoption of the proposed Provisions. Alternative implementation measures that should be considered include, but are not limited to the following:

- A program for trading or offsets
- A "water funds" approach to regional or watershed-based mercury control measures
- Engaging other state agencies in efforts to control non-point sources (e.g., engaging the Air Resources Board in efforts to control atmospheric sources of mercury)
- Programs to address non-point sources.

QAID 1608830.000 - 3640

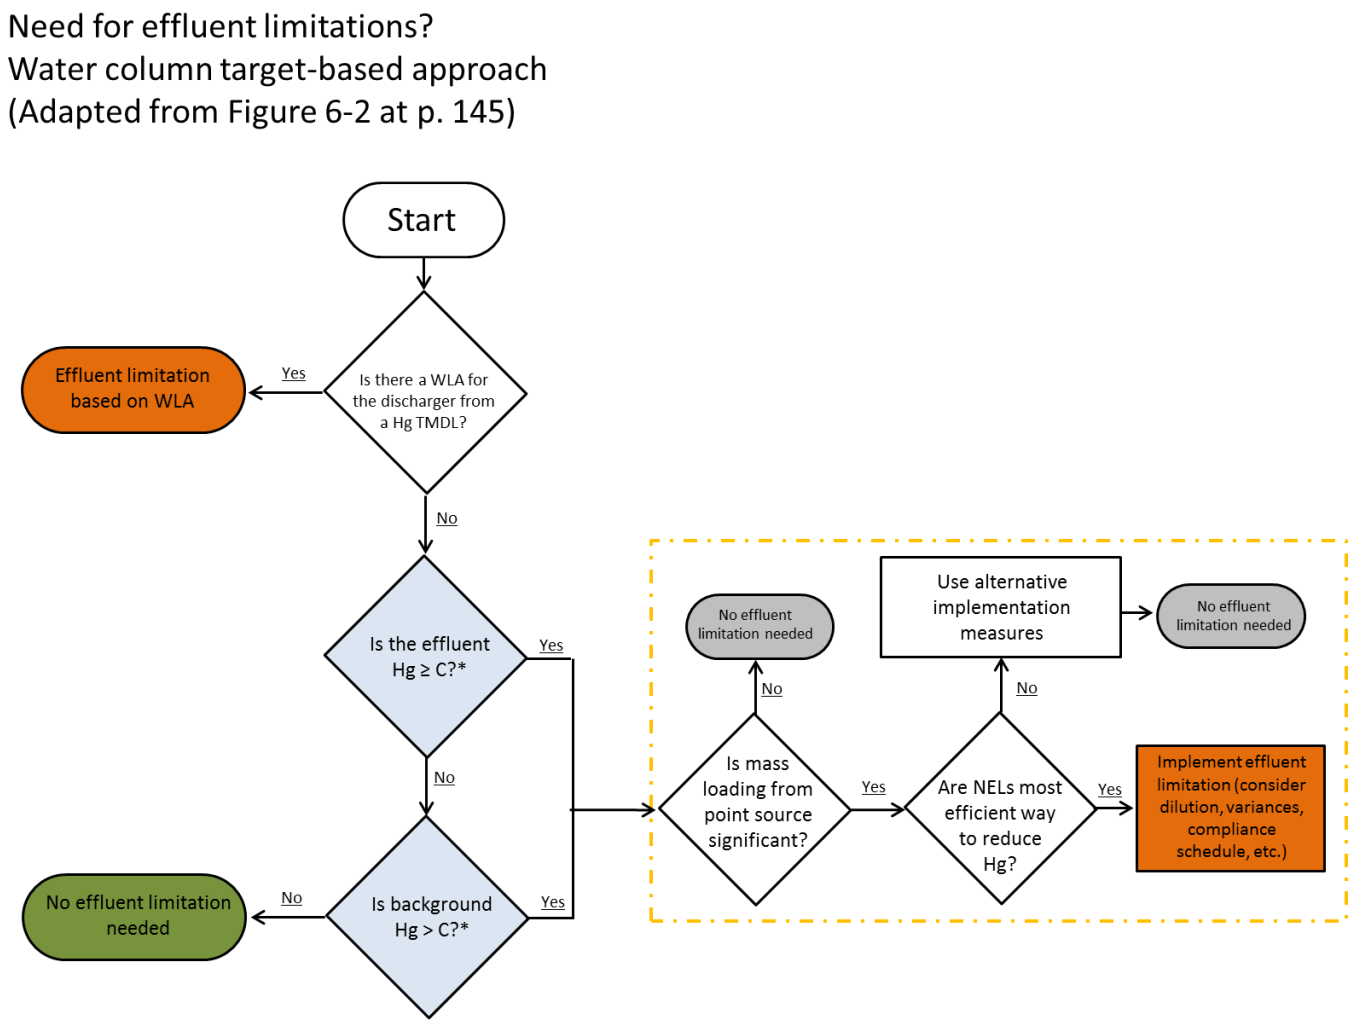

Figure 2. Adapted flow chart for Option 1, a water column concentration-based approach to determining the need for effluent limitations. Only the part of the figure within the dashed orange line has been added. The rest of the figure is identical to Figure 6-2 of the Staff Report (p. 145).

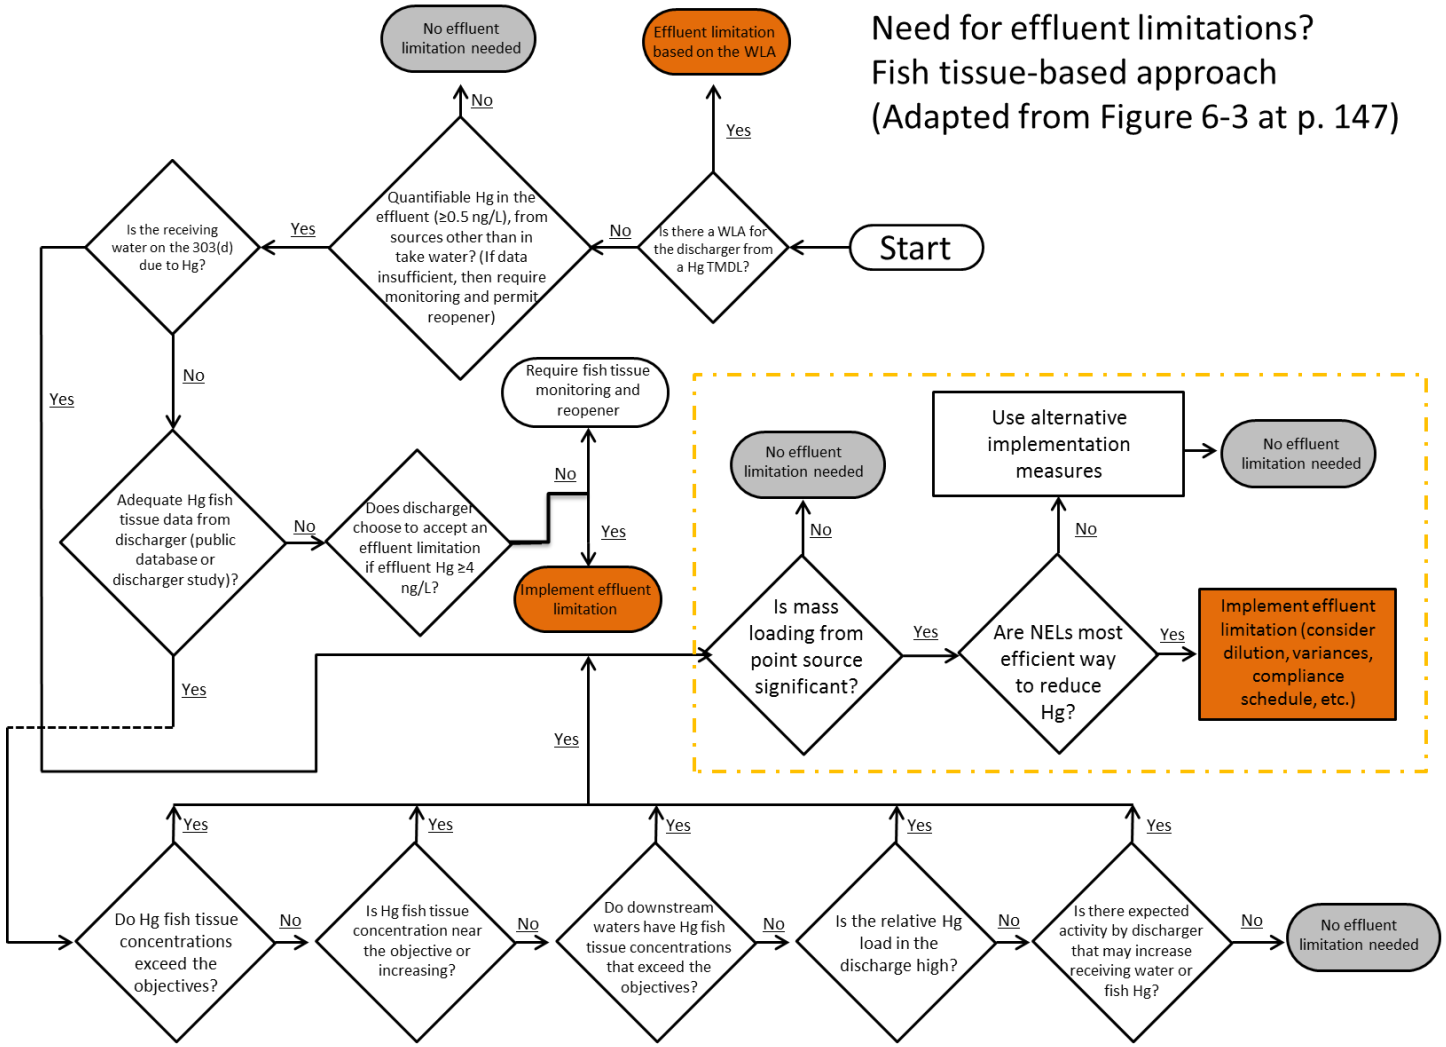

Figure 3. Adapted flow chart for Option 2, a fish tissue-based approach to determining the need for effluent limitations. Only the part of the figure within the dashed orange line has been added. The rest of the figure is identical to Figure 6-3 of the Staff Report (p. 147).

The most effective approaches to mercury control will be those that identify implementation actions for the primary sources of mercury. The implementation measures currently identified in the proposed Mercury Provisions do not effectively target these primary sources. The State's proposed Mercury Provisions should be revised accordingly.

4. The Staff Report's position on dilution credits and mixing zones for NPDES discharges containing mercury is inconsistent with SWRCB precedential orders. The appropriateness of mixing zones and dilution credits should be evaluated on a site-specific basis.

The Staff Report states in several places, "Water Boards have the discretion to allow dilution credits where appropriate."[29] For example, in discussion of the difficulty of meeting the proposed 1 ng/L effluent limitation, the Staff Report states, "if the Water Board exercises its discretion to allow dilution credits, the objective would be much more achievable."[30] The Staff Report also states,

> *Dilution credits would be allowed but would not be recommended in most situations since mercury is a bioaccumulative compound, and the SIP (Section 1.4.2.2.B) and the [U.S. Environmental Protection Agency] recommends limiting dilution for bioaccumulative compounds (U.S. EPA 2010, section 5.3.2). The U.S. EPA explains, "While fish tissue contamination tends to be a far field problem affecting entire water bodies, rather than a narrow scale problem confined to mixing zones, the U.S. EPA's guidance recommends restricting or eliminating mixing zones for bioaccumulative pollutants such as mercury so that they do not encroach on areas often used for fish harvesting (particularly for stationary species such as shellfish). Restriction or elimination might also be used to compensate for uncertainties regarding the ability of aquatic life or the aquatic system to tolerate excursions above the criteria, uncertainties inherent in estimating bioaccumulation, or uncertainties in the assimilative capacity of the water body*."[31]

However, at other points the Staff Report indicates dilution credits would *not* be allowed. For example, the Staff Report indicates the following language would be included in Chapter IV of the Water Quality Control Plan for Inland Surface Waters, Enclosed Bays, and Estuaries (ISWEBE Plan) (the Implementation Chapter): "Dilution shall be prohibited if the mercury concentration in fish tissue from fish in the receiving water exceeds the applicable MERCURY WATER QUALITY OBJECTIVES."[32] Presumably, this prohibition would apply regardless of whether a water body is on the 303(d) list of impaired waters for mercury. SWRCB Staff also indicated at the January 9, 2017, workshop that dilution credits and mixing zones would not be allowed in NPDES permits for water bodies that are impaired for mercury.

QAID 1608830.000 - 3640

Disallowing the use of dilution credits would contradict precedential SWRCB orders. For example, the summary for Order 2001-06 states that "A Regional Water Quality Control Board (Regional Water Board) cannot rely solely on a Section 303(d) listing as the basis for concluding that a receiving water lacks assimilative capacity for an impairing pollutant. Rather, the Regional Water Board must base assimilative capacity determinations on the relevant water quality-related data."[33] The facts before the SWRCB in Order 2001-06 included a water body listed as impaired for bioaccumulative pollutants but where the dilution achieved by individual discharges was so great that even the elimination of those discharges would have had no effect on pollutant concentrations in the water body or in fish. Such facts would have to be established on a site-specific basis but appear to be supported for many water bodies given the information provided in the Staff Report for the proposed mercury provisions.

The Staff Report should be amended to clearly indicate, consistent with SWRCB precedential orders, that dilution credits and mixing zones must be considered on a site-specific basis, such that if the proposed effluent limitation (without dilution) would have no discernible impact on mercury concentrations in receiving waters or in fish, dilution must be allowed.

5. The fish tissue objectives proposed to protect wildlife are likely to be overly conservative and should be revised to address this limitation.

The fish tissue objectives proposed for wildlife protection are generally in the range of values commonly used by United States Fish and Wildlife Service (USFWS) and are generally based on peer-reviewed literature. However, in many instances the information for key species is generated using surrogates of mammals or avian species with numerous assumptions. For example, the wildlife value is based on a mallard duck reference dose of 0.021 mg/kg/day, and assumptions regarding the life histories of other avian species, body weight, etc., are used to extrapolate to a wildlife value for all other birds (presented in Appendix K Table K-1).[34] It appears a similar treatment is applied to mammals, using a reference dose of 0.018 mg/kg/day; however, the species used for the determination of this reference dose is not provided (a generic citation of USFWS 2003 appears in the text without any reference to a mammal species). We recommend the mammalian reference dose [p. K-4 and Table K-1] cite the source.

The avian reference dose derived from the mallard duck study by Heinz (1979)[35] appears to be superseded by a later study by the same author.[36] Heinz (1979) identified the lowest dosage of 0.5 mg/kg in diet as the lowest-observed-adverse-effect concentration (LOAEL), whereas a dietary toxicity threshold ranging from approximately 3 mg/kg to 9 mg/kg was found in more

recent studies (Figure 4).[37] In addition, USFWS applied interspecies and NOAEL-to-LOAEL[38] uncertainty factors to derive the avian reference dose of 0.021 mg/kg/day.[39] A critical review paper by Fuchsman et al. suggests the reference dose of 0.021 mg/kg/day may be too conservative.[40] Based on the current literature, Fuchsman et al. identify/propose ranges of toxicity reference values suitable for risk assessment applications between 0.05 mg/kg/day to 0.5 mg/kg/day on a dose basis, which are a factor of 2–20 higher than the proposed reference dose. This overly conservative approach employing an artificially lower reference dose translates into a lower fish tissue concentration. While we understand this recently published information became available after the Staff Report was released for public review, SWRCB should consider the critical evaluation by Fuchsman et al. (2017) of avian threshold values in their evaluation and revise the reference dose and tissue objectives accordingly.

QAID 1608830.000 - 3640

Trophic level (TL) values were used in the Staff Report to protect wildlife that consumes prey from more than one trophic level. Clarification on 'statewide' TL values is needed. The 'statewide' values for some species were derived from site-specific data from only one region (i.e., Guadalupe River for Great blue heron and Forster's tern, Clear Lake for common loon; Table K-2, Table K-3, and text on pages K-9 through K-13), and this limitation needs to be consistently documented throughout the Staff Report.[41] Knowing 'statewide' data are derived from a data set that does not truly represent the whole state or given area would allow additional site-specific data to be used preferentially over the default value, when site-specific data become available.

The proposed water quality objective tissue concentrations for protection of wildlife—0.03 mg/kg in TL3 fish less than 50 mm, 0.05 mg/kg in TL3 fish less than 150 mm, and 0.2 mg/kg for TL4 fish 150–500 mm—are similar to or lower than background mercury concentrations in forage (TL3) and predatory fish (TL4). As presented in Figure H-1 of the Staff Report, mercury concentrations in largemouth bass, a common TL4 fish, are 0.4 mg/kg on average, equivalent to 2 times the wildlife value for the same TL, with concentrations that range up to approximately 0.73 mg/kg. For TL3 fish, average concentrations of mercury in rainbow trout and Chinook salmon are approximately 0.1 mg/kg, as shown Figure H-1 of the Staff Report, which are 2–3.3 times the fish concentration target calculated for this TL. A recent review by Fuchsman et al. (2016) indicated average naturally occurring Hg concentrations in forage (TL3) and predatory (TL4) fish are roughly 0.03–0.1 mg/kg and 0.1–0.3 mg/kg, respectively.[42] Given most of the mercury already in the system is from nonpoint sources, it is unlikely the proposed wildlife values of 0.03, 0.05, and 0.2 mg/kg could be attained.

The California least tern prey fish water quality objective should be applied only to water bodies where the species commonly forages. Table K-5 of Appendix K lists 8 counties where this objective is to be applied.[43] However, the map shown in the January 9, 2017 Staff presentation (Slide 20) includes Monterey County, which is not listed in Table K-5, and does not include Alameda or San Mateo County, which are listed in Table K-5. Because there have been very few historical regular breeding colonies between the City of Santa Barbara and Monterey Bay[44] the objective to protect the California least tern should not be applied in Monterey County. Also, as noted in Table K-5, the spatial application of the objective should be limited to areas within a reasonable foraging distance from known breeding colonies. However, slide 20 of the Staff presentation seems to indicate that application of the objective will be applied county-wide, without regard to distance from known breeding colonies. The Staff Report should be

revised to clarify that objectives to protect the California least tern should be limited to areas within a reasonable foraging distance from known breeding colonies.

6. The water concentration targets derived from the proposed fish tissue water quality objectives are fundamentally flawed and should not be implemented at this time.

The Staff Report derives water column concentrations based on fish tissue bioaccumulation factors (BAF)[45] and translators.[46] Proposed targets of 12 ng/L and 4 ng/L are based on the Sport Fish WQO (0.2 mg/kg in TL4 fish, 150–500 mm; see Table 3). The Staff Report uses an EPA-derived national BAF for rivers and streams to derive a water column target concentration of 12 ng/L total mercury for flowing water bodies, including rivers, creeks, and streams. The target concentration of 4 ng/L total mercury for slow-moving water bodies, such as estuaries and bays, was derived from the combined national BAF for lakes and rivers. Water target concentrations of 4 ng/L and 1 ng/L were derived for flowing waters and slow-moving waters, respectively, based on the Tribal Subsistence mercury objective (0.06 mg/kg in TL4 fish)[47] and the same national BAFs.

Table 3. Water column concentrations based on water body type and beneficial use. From Staff Report. COMM: Commercial and Sport Fishing, T-SUB: Tribal Subsistence Fishing, SUB: Subsistence Fishing by other communities or individuals, CUL Tribal Tradition and Culture, WILD: Wildlife Habitat RARE: Rare, Threatened, or Endangered Species, MAR: Marine Habitat.

Beneficial Use of the Receiving Water	**COMM, CUL, WILD, MAR, RARE**	**COMM, CUL, WILD, MAR, RARE**	**COMM, CUL, WILD, MAR, RARE, T-SUB**	**T-SUB**	**T-SUB**	**SUB**
Water body type	Flowing water bodies (generally, rivers, creeks and streams)	Slow moving water bodies (generally, lagoons and marshes)	Lakes and reservoirs	Flowing water bodies (generally, rivers, creeks and streams)	Slow-moving water bodies (generally, lagoons and marshes)	Any
Value for "C"	12 ng/L total mercury	4 ng/L total mercury	Case-by-case	4 ng/L total mercury	1 ng/L total mercury	Case-by-case

[45] The bioaccumulation factor (BAF) is the ratio between the dissolved methylmercury concentration in water and the concentration of methylmercury in fish tissue.

[46] Staff Report, Appendix I. p. I-1.

[47] The default value is 0.04 mg/kg based on 30% TL4 and 70% TL3 diet, which is equivalent to 0.03 mg/kg in TL3 fish and 0.06 mg/kg TL4 fish (Staff Report, Appendix H, p. H-12). BAF and fish tissue targets in TL4 fish were used to derive water column targets (Staff Report, Appendix I, p. I-1).

QAID 1608830.000 - 3640

There are several problems with SWRCB's approach to calculating water concentration targets from the proposed fish tissue water quality objectives. First, and most importantly, application of two national BAFs to calculate mercury water concentration targets for every water body in California is inappropriate. National BAFs, California statewide BAFs, and translation factors for mercury are highly variable and uncertain.[48] National BAFs are calculated as the geometric mean of field-measured BAFs obtained from published literature.[49] As illustrated in Figure 5, national BAFs range over two to three orders of magnitude due to variability between the many different regions and water bodies reflected in the 90 percent confidence-interval range (i.e., between the 5th and 95th percentiles). The Staff Report also discusses the potential use of an available California-wide BAF, but because this value is based on a limited dataset, the Staff Report proposes to use the EPA national BAFs instead.[50] However, the use of nation-wide BAFs oversimplifies the very complex process of mercury bioaccumulation and ignores site-specific conditions. A BAF is a site-specific value and is affected by numerous physical, chemical, and biological factors including among others pH, dissolved organic carbon (DOC), salinity, water flow, temperature, redox potential, sulfide and sulfate, suspended solids, nutrient loading, fish size and age, and concentration-dependent demethylation.[51,52,53,54,55,56,57,58] There is potential for mercury methylation and bioaccumulation to vary significantly from location to location and over time (seasonally). Even within California, conditions vary considerably

QAID 1608830.000 - 3640

between regions. As a result, national or statewide default values are likely to be inaccurate on a site-specific basis. As the Staff Report states, the water concentration targets based on national BAFs can be over- or under-protective in different water bodies.[59] Because of this likely possibility, EPA recommends the use of site-specific data over default national values such as those used in developing the mercury water concentration targets.[60,61] The use of site-specific data allows the development of BAFs that are more realistic.

Second, the Staff Report lacks clear guidance on the classification of the receiving water body type as either "flowing" or "slow-moving." The Report refers to "Table 1" for guidance, but there is no Table 1 in the document.[62] The Board expects individual permit writers at the Regional Boards to apply site specific information and "professional judgment" to determine which category fits best for a given water body. However, this approach seems highly subjective and open to arbitrary determinations, despite its importance given the significant difference between the two water concentration targets (12 ng/L versus 4 ng/L) and the potentially significant costs to NPDES dischargers that could result from this choice.

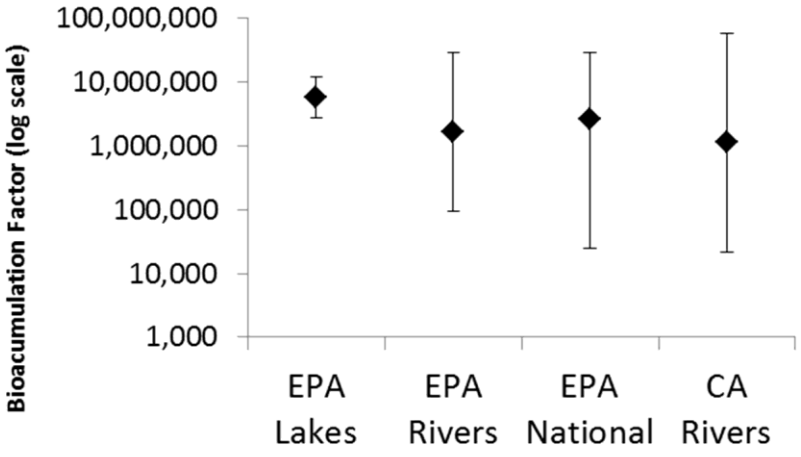

Figure 5. Comparison of National and California Bioaccumulation Factors. Data points (diamond symbols) are geometric means. Vertical bars extend from the 5th to the 95th percentile of the log-normal distribution. (From Staff Report, Appendix I. p. I-2, Figure I-1.)

Third, it is unclear whether estuaries should be understood as "slow-moving" water bodies, and thus whether a BAF applicable to lakes should be applied in calculating water concentration

[59] Staff Report, p. 91.

[62] Staff Report, pp. 155.

QAID 1608830.000 - 3640

targets for estuaries. Unlike lakes, most estuaries are actively flowing water bodies containing a wide distribution of many different TL fishes. Our experience indicates that in some estuaries, waters are not "slow-moving"; for example, in Carquinez Strait in San Francisco Bay, water velocities routinely exceed the velocities measured in most rivers, such that it is wholly inappropriate to assume estuaries are "slow-moving."[63] The proposal should be revised to provide clear guidance for distinguishing the two types of water bodies.

Fourth, as noted above, the Staff Report uses a BAF for rivers and streams to derive a water column target concentration of 12 ng/L for flowing water bodies and a BAF for lakes and rivers to derive a water column target concentration of 4 ng/L for slow-moving water bodies, such as estuaries and bays. Thus, the BAFs used to calculate concentration targets for flowing water bodies and slow-flowing water bodies *both* rely on data from rivers. This double use suggests that one or both BAFs may be inappropriate to the flow categories they were used to represent.

Fifth, the method of calculating water concentration targets from BAFs is flawed. A recent study by Dutton and Fisher (2014) shows that methylmercury concentrations in fish are driven by food exposure and not by water column exposure.[64] The BAF approach does not address potentially wide variability in water concentrations and assumes all compartments (water, sediment, and biota) are in equilibrium with each other. In fact, in most cases the water compartment is *not* in equilibrium with the lower portions of the food chain—thus, one of the most basic assumptions behind the use of a BAF is violated.

Sixth, the use of translators adds to the already considerable degree of uncertainty associated with the water concentration targets. Different forms of mercury and methylmercury, such as dissolved/filtered and total/unfiltered, are measured in the water column. Translators are applied to convert dissolved methylmercury concentration (obtained via the BAF method) to total mercury and to total methylmercury concentrations, which are the forms in which mercury water concentration targets are typically expressed. The Staff Report proposes water column target concentrations expressed as total mercury concentrations. Underlying the use of any type of mercury translator is the assumption that mercury levels in fish tissue will respond in a linear manner to reductions in mercury loading. Evidence indicates this relationship between fish tissue levels and loadings is much more complex and influenced by a number of interacting biogeochemical factors that are highly variable in time and space.[65] In addition, relationships used to derive the translation factors are very weak (Figure 6). The translation factor between dissolved and total mercury in a given waterbody can be highly variable, changing spatially and temporally. The Staff Report should be revised to include a detailed discussion of the variability of the translators employed in their methodology.

---

[63] During high flow periods of the tidal cycle, flow velocity in Carquinez Strait is routinely higher than three feet per second (fps). See Warner, J., D. Schoellhamer, J. Burau, G. Schladow. 2002. Effects of tidal current phase at the junction of two straits. Continental Shelf Res. 22:1629-1642. Figure 2, p. 1632.

QAID 1608830.000 - 3640

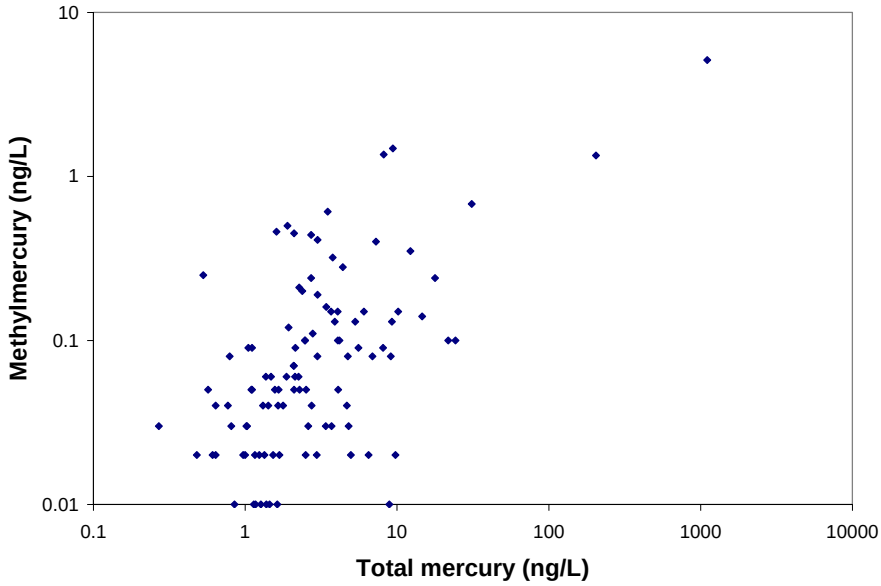

Figure 6. Total Mercury versus methylmercury in stream water samples collected throughout the U.S. as Part of the National Water-Quality Assessment Program (from Krabbenhoft et al. 1999)

In short, there are multiple problems with the Staff Report's approach to calculating water concentration targets in the Mercury Provisions. The use of national BAFs rather than local site-specific BAFs, and the use of mercury translators, introduces enormous uncertainty into the proposed values. In addition, given the lack of clarity about what constitutes "flowing" and "slow-moving waters," it is unclear whether the Staff Report used BAFs for the correct water body categories in calculating the concentration targets. Moreover, the use of BAFs is flawed given the faulty assumptions upon which the methodology is based, such as the assumption of equilibrium between the water, sediment, and biota compartments. Given these problems, and the potentially huge costs that NPDES dischargers would likely incur to comply with the water concentration targets if they are imposed as effluent limitations, SWRCB should revise the proposed targets and should not implement them at this time.

7. The proposed human health objectives may be too conservative.

We share the state's concern about protection of human health but would request that the Staff Report be revised to confirm that specific assumptions are appropriate. The Staff Report describes numerical fish tissue levels for two human health objectives: Commercial and Sport Fishing (COMM) and Tribal Subsistence (T-SUB) (Table 4).[66]

[66] Table 5.1, p. 80 of the Staff Report.

QAID 1608830.000 - 3640

Table 4. Summary of numerical mercury water quality objectives for human health in the Mercury Provisions

Human Health Objective	Beneficial Uses	Numerical Fish Tissue Level
Commercial and Sport Fishing (COMM)	Commercial and Sport Fishing; Wildlife Habitat[a]; Marine Habitat[a]	0.2 mg methylmercury/kg in Trophic level 4 fish
Tribal Subsistence (T-SUB)	Tribal subsistence fishing	0.04 mg methylmercury/kg in 70% Trophic Level 3 fish and 30% Trophic Level 4 fish

[a] According to the Mercury Provisions, the objectives supporting Wildlife Habitat and Marine Habitat may also be applied to Warm Freshwater Habitat, Cold Freshwater Habitat, Estuarine Habitat, and Inland Saline Water Habitat because each of those includes protection of wildlife habitat.

The proposed fish tissue concentration for COMM is 0.2 mg methylmercury/kg in highest TL fish (TL4, e.g., largemouth bass; fishes in this trophic level contain the highest concentrations of mercury). This value is similar to the Fish Contaminant Goal (FCG) of 0.22 mg methylmercury/kg developed by the Office of Environmental Health Hazard Assessment (OEHHA).[67] The difference between the two fish tissue concentrations (the proposed COMM and OEHHA FCG) arises from the use of a Relative Source Contribution value (see the next comment) in the proposed COMM fish tissue concentration but not in the OEHHA FCG. The OEHHA FCG of 0.22 mg/kg is non-enforceable but has been used since 2012 for water quality assessment purposes in the State, according to the Mercury Provisions.[68] EPA developed a national criterion for fish tissue of 0.3 mg methylmercury/kg in 2001,[69] but the Staff Report did not adopt that value.

Currently, the only enforceable concentration for mercury is for water as established in the California Toxics Rule (CTR) to protect people from consuming mercury from fish caught recreationally; the fish tissue concentration for mercury used to derive the CTR water criterion was 0.37 mg/kg.[70] There is no statewide criterion that addresses subsistence fishers.

The proposed fish tissue concentration for the T-SUB is 0.04 mg methylmercury/kg, assuming a diet comprised of 70% TL3 fish and 30% TL4 fish. This proposed concentration is similar to EPA's national criterion for subsistence fishing of 0.05 mg methylmercury/kg[71] and matches the

QAID 1608830.000 - 3640

fish concentration of 0.04 mg methylmercury/kg developed for Oregon's Columbia River Tribes.[72] EPA has proposed even lower fish concentrations for subsistence fishing in Washington (0.033 mg methylmercury/kg)[73] and Maine (0.02 mg methylmercury/kg).[74] While EPA has promulgated a fish concentration of 0.03 mg methylmercury/kg for Washington,[75] the state of Maine is contesting EPA's proposal of 0.02 mg methylmercury/kg.

The Staff Report and appendices[76] describe the assumptions and values used in the calculations of the human health objectives (COMM and T-SUB), which are fish tissue concentrations. The equation used to calculate the proposed fish tissue concentrations for COMM and T-SUB is:

$$FTC = \frac{BW * (RfD - RSC)}{FI}$$

FTC = a fish tissue concentration in milligrams (mg) methylmercury per kilogram (kg wet weight) fish. The FTC value is the methylmercury WQO.

BW = average human body weight; a value of 70 kg was used.

RfD = reference dose of 0.0001 mg methylmercury/kg body weight/day was used. This value is EPA's Rfd for oral exposure of methylmercury.

RSC = relative source contribution, estimated at 2.7×10^{-5} mg methylmercury/kg body weight/day. This value is subtracted from the reference dose to account for other sources (e.g., store bought marine fish).

FI = fish intake rate or fish consumption rate (kg fish wet weight/day). A value of 0.032 kg/day (32 g/day) is used for COMM, and a value of 0.142 kg/day (142 g/day) is used for T-SUB.

While the assumptions and values used are EPA default values or specifically based on California data where available, there may be a compounding effect of conservatism, which may result in lower fish tissue concentrations for the objectives than necessary. In other words, the combined impact of the multiple conservative assumptions about exposure and toxicity may lead to the compounding of uncertainty factors only in one direction (i.e., toward worst case) and may result in target fish tissue concentrations that may not be representative of the actual dose and exposure and that may be lower than necessary . For instance,

QAID 1608830.000 - 3640

- The RfD is EPA's maximum acceptable oral dose of a chemical; it is defined as "an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime." While EPA's RfD of 0.0001 mg/kg/day for methylmercury is the standard toxicity value commonly used, EPA applied uncertainty factors to derive the value. While uncertainty factors are intended to provide protection in the face of uncertainty, the compounding of several or many uncertainty estimates can result in overprotective values. In this case, if the RfD is lower than necessary, the fish tissue concentration also will be lower than necessary.

- The RSC is the mean daily exposure estimate of methylmercury from other sources, in this case from store-bought marine fish; EPA developed a default value of 2.7×10^{-5} mg/kg/day in their 2001 water quality criteria for methylmercury.[77] Applying an RSC value of 2.7×10^{-5} mg/kg/day to the RfD drives down the RfD to 0.000073 mg/kg/day, which in turn lowers the calculated fish tissue concentration. While EPA's default RSC value for methylmercury was used by SWRCB to calculate fish tissue levels, other states such as Oregon have decided not to apply that value, acknowledging that their consumption rates already account for the other sources (e.g., store bought marine fish).

- The proposed fish tissue concentrations for COMM and T-SUB were derived using EPA's old default average body weight value (70 kg)[78] rather than the revised default average body weight (80 kg) used in a later document.[79] Using the previously reported lower body weight (70 kg) rather than the revised default weight (80 kg) also results in lower calculated fish tissue concentrations (e.g., the COMM fish tissue concentration would be 0.18 mg/kg instead of 0.16 mg/kg, before rounding). EPA has used the new default body weight (80 kg) to revise human health criteria for several chemicals[80] but not methylmercury.

- The fish consumption rates used in these calculations are 32 g wet weight/day (approximately one and half 5-oz. meals per week) for COMM and 142 g wet weight/day (approximately seven 5-oz. meals per week) for the T-SUB and are based on

QAID 1608830.000 - 3640

> California surveys.[81] EPA's default value for the general population, which was developed under the Clean Water Act, Section 304(a), is 17.5 g wet weight/day (approximately one 5-oz. meal per week).[82] While EPA updated the default fish consumption rate for the general population to 22 g/day (approximately one 6-oz. meal per week),[83] EPA has not updated its methylmercury criteria for human health to reflect this newer rate.

Although applying these assumptions and values may not individually drive down the proposed fish tissue concentrations by a substantial amount, applying them collectively may artificially lower the fish tissue concentrations. Therefore, we recommend the Board review the assumptions and values in the proposed human health objectives for COMM and T-SUB in the Mercury Provisions.

A further concern is that the proposed fish tissue concentrations for human health objectives (COMM and T-SUB) in the Mercury Provisions are likely unattainable. The mercury concentration in fish for T-SUB is 0.04 mg/kg, assuming a diet of 70% TL3 fish and 30% TL4 fish. As shown in Figure H-1 of the Mercury Provisions (reproduced below as Figure 7), mercury concentrations in largemouth bass, a common TL4 fish, are on average 0.4 mg/kg, ten times higher than the proposed objective, with concentrations up to approximately 0.73 mg/kg. Average concentrations of mercury in rainbow trout and Chinook salmon (TL 3 fish) are approximately 0.1 mg/kg (Figure H-1), which are approximately 2.5 times the fish concentration calculated for T-SUB.

Figure H-1. Mercury concentrations in largemouth bass, rainbow trout, anadromous chinook salmon in California. Largemouth bass and trout were 150-500 mm. Chinook were 500-1000 mm. Data from ceden.org.

Figure 7. Figure H-1 from Appendix H (p. H-6) of the Mercury Provisions. Accessed February 9, 2017, at http://www.swrcb.ca.gov/water_issues/programs/mercury/docs/staff_report/hg_apndx_h.pdf.

Given most of the mercury already in the system is from nonpoint sources, it is unlikely the proposed human health-based values of 0.2 and 0.04 mg/kg for COMM and T-SUB, respectively, could be attained. In addition, salmon largely accumulate mercury during the long time spent in the ocean, not in inland waters and estuaries where the proposed objectives would be applied. In California, freshwater fisheries currently capable of sustaining subsistence fishing tend to be limited to anadromous species such as salmon, which are largely limited to rivers of coastal northern California and tributaries of the Sacramento River. As such, WQOs for other regions of California may be inappropriate.

Finally, alternative implementation measures to protect human health should be considered, particularly since reduction in environmental mercury concentrations is expected to take decades or longer. There are alternatives for lowering mercury exposure in populations of subsistence fishers other than reduction of mercury concentrations in the environment. Extensive experience has been gained in recent decades in balancing public health risks and mercury exposure in indigenous populations in the Canadian Arctic and the Brazilian Amazon that are dependent on fish consumption. This experience has led to several strategies to maintain fish consumption while reducing mercury exposure; these strategies can be implemented where it is impossible to reduce environmental mercury concentrations. These interventions through public health education include:

QAID 1608830.000 - 3640

- Guidance on mercury status of fish species to encourage consumption of less contaminated species
- Guidance on which waters contain higher mercury levels so that they can be avoided
- Encouraging greater fruit consumption, which may be protective against the bioaccumulation of mercury in human populations exposed via dietary intake of fish.[84]

This section of the Mercury Provisions also contains several significant typographical errors that require correction. On page H-9 of Appendix H (Section H.3.3), the report states "Two example trophic level specific objectives were derived that would protect consumption of one fish meal per week (0.016 mg/kg in fish tissue on average, from Table H-2A)." The value 0.016 mg/kg appears to be a typo. Based on Table H-2A, the value should be 0.16 mg/kg.

8. The proposed action to address dredging, wetlands, and nonpoint sources of mercury is vague and does not prescribe or prevent any specific actions.

The Mercury Provisions present three options to "control mercury discharges from dredging, wetlands and nonpoint source discharges (other than legacy mines… and current NPDES permitted discharges)"[85]:

Option 1. No Action.
Option 2. Emphasize that under existing law the Water Boards have discretion to address nonpoint source discharges of mercury and methylmercury production in wetlands and the Water Boards should consider such implementation measures in areas with elevated mercury concentrations.
Option 3. Establish new requirements for mercury and methylmercury and continue to use existing programs.

Of the three options presented to reduce mercury impact from wetlands, the Staff Report recommends Option 2, which allows for the use of existing law to implement mercury controls where warranted and seeks to emphasize their use in areas of "elevated" mercury. Specifically, the Staff Report identifies areas of "elevated" mercury as locations with mercury of 1 ppm or higher or areas with a history of mercury or gold mining.[86] However, this recommendation is vague and does not prescribe (or prevent) any specific action. It is unclear how this is different from Option 1, "No Action."

It is also unclear how Option 2 is intended to be implemented. In the discussion of wetlands management in Appendix Q, the Staff Report identifies several factors which may be used to minimize mercury transport or methylmercury production, but all of these are areas of active

[84] Passos, C.J.S., D. Mergler, M. Fillion, M. Lemire, F. Mertens, J.R.D. Guimarães, and A. Philibert. 2007. Epidemiologic confirmation that fruit consumption influences mercury exposure in riparian communities in the Brazilian Amazon. Environmental Research 105(2):183–193.

[86] Staff Report, p. 133.

QAID 1608830.000 - 3640

research rather than established management procedures.[87] The science to determine which environmental factors are important in controlling the production of methylmercury in wetlands is still evolving, and the relative importance of the many factors which can influence mercury chemistry can vary from site to site.[88]

There are no established best management practices to reduce the production or transport of methylmercury in wetlands. The Staff Report acknowledges this in Appendix Q but describes wetland studies with "potential" methods to control mercury transport and methylation. Some of the potential management procedures described in Appendix Q are relatively untested, and their possible utility for mercury control on a wide scale is unknown, while others are more applicable and/or straightforward to implement.

For example, settling ponds to reduce sediment load (and potential mercury transport) to other water bodies is a reasonable approach, but care must be taken to minimize potential methylation and/or bioaccumulation in such a system, as the slow-moving conditions required for settling to occur may also be conducive to anoxic conditions that favor mercury methylation. Similarly, wetting/drying cycles, especially in areas with significant organic matter, have been shown to contribute to the production of methylmercury.[89] Managing water flow to minimize wetting/drying cycles caused by water level fluctuation is a reasonable management approach for agricultural or other managed wetlands, but it is not possible at this time to quantify the predicted effect that this would have in any specific system.[90]

In contrast, the recommended use of coagulants for mercury removal in settling ponds is based on a single paper, which used experimental coagulants to attempt to minimize methylmercury bioaccumulation and transport.[91] This study used a single environmental site and a limited time frame (approximately 1 year). The practicality of treating a large wetland or agricultural system using a similar approach is not discussed. There would likely be issues with mercury accumulation in the pond and with the potential to re-methylate mercury in new locations if the coagulated mercury is transported to locations with different chemistry. This is not addressed in either the Staff Report or the cited paper. Additionally, while both experimental treatments reduced the amount of methylmercury produced, only one of the two chemical coagulants

reduced the amount of methylmercury accumulated in biota, consistent with other publications reporting that the total mercury concentration is not always the controlling factor in mercury bioaccumulation.[92] The suggested use of coagulants as a management practice in California wetlands is premature.

CALIFORNIA LEAST TERN RECOVERY PLAN

EXECUTIVE SUMMARY

1. Point or condition when subspecies is considered recovered?

The annual breeding population in California must increase to at least 1200 pairs distributed in at least 20 secure coastal management areas throughout their 1982 breeding range before delisting can be considered. Each of the 20 secure management areas must have a miminum of 20 breeding pairs with a 5-year mean reproductive rate of at least 1.0 young fledged/per breeding pair. Of these 20 secure management areas San Francisco Bay, Mission Bay and San Diego Bay must have a minimum of 4, 6 and 6 secure colonies, respectively. If 1,200 breeding pairs in California occur in 15 secure management areas with a 3-year mean reproduction rate of 1.0, the California least tern may be considered for threatened status. When additional information is available on the extent of nesting in Baja California, the Mexican colonies may be considered in the recovery goal for both threatened status and delisting.

2. What must be done to reach recovery?

Properly managed, suitable habitat of sufficient size must be available for nesting purposes; foraging, roosting, and wintering habitat must be preserved and properly managed. The status of least tern in Baja California, Mexico must be determined and the role of such colonies in the overall recovery must be assessed.

3. What specifically must be done to meet needs of 2?

Various site specific management plans must be developed and implemented; nesting habitat must be preserved and properly managed; colonies must be protected against certain predation pressures and other disturbances; management techniques must be further refined through additional research; a conservation education program should be developed; laws and regulations protecting the tern and its habitat must be enforced. The range, distribution, and population status of California least terns in Baja California, Mexico during the nesting season must be determined; and the range, distribution and status of wintering birds should be adequately identified.

4. What management/maintenance needs have been identified to keep the subspecies recovered?

Implementation of site specific management programs which address future needs of the terns to protect and properly manage tern habitat; periodic review and update of such plans; a continuing effort to inform the public regarding conservation issues to heighten public support.

PART I

INTRODUCTION

Brief Overview

Once the beaches of southern California teemed with California least terns [Sterna antillarum (=albifrons) browni]. Today, least tern numbers are so depleted that both the U.S. Fish and Wildlife Service (Federal Register 35:16047, October 13, 1970; Federal Register 35:8495, December, June 2, 1970) and California Fish and Game Commission (California Department of Fish and Game 1980) consider the subspecies in danger of extinction and classify it as an endangered species.

The goals of this recovery plan are to prevent extinction and return the California least tern population to a stable, nonendangered status. The plan summarizes available biological information on the terns, identifies their ecologic needs, and proposes orderly and comprehensive actions to restore them to a viable population, and ultimately to delist the species.

Nomenclature

The least tern (Sterna antillarum) of the New World was described by Lesson (1847) as distinct from the cosmopolitan, polytypic species of the Old World (little tern), Sterna albifrons Pallas.

Although known and studied at an early date (Holterhoff 1884, McCormick

1899), the California least tern was not recognized as a separate subspecies until Mearns (1916) published the description. In 1921, Hartert combined antillarum under albifrons, but the common name was kept as least tern (Hartert 1921). The California least tern was then one of 12 recognized subspecies of the least (or little) tern (Brodkorb 1940, Burleigh and Lowery 1942, Peters 1934, Van Rossem and Hachisuka 1937), three of which inhabited the United States (AOU 1957). In 1982, however, the least tern was split from S. albifrons of the Old World and returned to the status of a full species, S. antillarum (AOU 1982, 1983), based upon research by Massey (1976) that documented differences in vocalizations and morphology. The subspecific status of the California least tern has no bearing on its endangered species listing because distinct population segments of a vertebrate species may be listed under the Endangered Species Act of 1973, as amended.

Description

Least terns are the smallest members of the subfamily Sterninae (family Laridae), measuring about nine inches long with a 50.8 cm (20 inch) wingspread. Sexes look alike, being characterized by a black cap, gray wings with black wingtips, orange legs, and black-tipped yellow bill. Immature birds have darker plumage and a dark bill, and their white heads with dark eye stripes are quite distinctive. The California least tern cannot be reliably differentiated from other races of the least tern on the basis of plumage characteristics alone (Burleigh and Lowery 1942).

Distribution

The California least tern is migratory, usually arriving in its breeding area by the last week of April and departing again in August (Davis 1968, Massey 1974, Swickard 1971). However, terns have been recorded in the breeding range as early as 13 March and as late as 31 October (Sibley 1952) and 24 November (San Diego Natural History Museum specimen records).

The historical breeding range of this subspecies has usually been described as extending along the Pacific Coast from Moss Landing, Monterey County, California, to San Jose del Cabo, southern Baja California, Mexico (AOU 1957, Dawson 1924, Grinnell 1928, Grinnell and Miller 1944). However, least terns were nesting several miles north of Moss Landing at the mouth of the Pajaro River, Santa Cruz County, California, at least from 1939 (W.E. Unglish, Western Foundation of Vertebrate Zoology egg collection) to 1954 (Pray 1954). Also, although nesting at San Francisco Bay was not confirmed until 1967 (Chandik and Baldridge 1967), there are numerous spring and summer records for the area, so nesting may have occurred previously (Allen 1934, Chase and Paxton 1965, De Benedictis and Chase 1963, Grinnell and Wythe 1927, Sibley 1952). Since 1970, nesting sites have been recorded from San Francisco Bay to Bahía de San Quintín, Baja California (Figure 1). The nesting range in California has apparently always been widely discontinuous, with the majority of birds nesting in southern California from Santa Barbara County south through San Diego County. Between the

city of Santa Barbara and Monterey Bay, a distance of over 322 km (200 miles), the only known regularly used breeding locations are within 16.1 km (10 miles) of the mouths of the Santa Ynez and Santa Maria rivers in Santa Barbara County. Local sources have also reported least terns once nesting at Morro Bay, San Luis Obispo County, and in 1980 a small nesting colony was present near Oso Flaco Lake, San Luis Obispo County. While San Francisco Bay appears to be the usual northern limit of the least tern's range, there are four records of single birds at Humboldt Bay (Yocom and Harris 1975, P. Springer[1] pers. comm.), two specimens collected at Fort Stevens, Clatsop County, Oregon (Walker 1972), and a single bird observed at Ocean Shores, Washington (Hunn and Mattocks 1979). These extra-limital records probably represent misoriented, migrating individuals.

In Baja California, two nest sites are identified in the literature: Scammons Lagoon (Bancroft 1927, Grinnell 1928), and San Jose del Cabo (Grinnell 1928, Lamb 1927). In 1975, a nesting colony was found near Ensanada (Massey 1977) and in 1976, a small colony was discovered at Bahía de San Quintín (Wilbur [2] pers. comm.). Several other nesting areas in Baja California, including Magdelena Bay, San Felipe, and Bahía del Los Angeles are suspected.

Life History

Night Roosting--Early in the breeding season, California least terns display rather stereotyped night roosting behavior. Prior to incubation terns sleep during the night at varying distances from the actual nesting sites. In natural breeding sites consisting of open sandy beaches, birds generally roost on the beach within 0.4 km (¼ mile) of the locality where eggs are eventually laid. Birds inhabiting colonies in more unnatural areas such as small islands constructed in estuarine areas, land fills, etc. may travel early in the season up to 16.1 km (10) miles from the colonies to nocturnal roosting sites on open sandy beaches.

Once incubation begins, birds roost at night on the actual nesting site. Such nocturnal roosting continues at the colonies through the remainder of the season, except where late season nocturnal predators pressure the family units to return to roosting sites used during the early, pre-incubation period.

The use of roosting sites away from breeding colonies prior to egg laying appears to be related to predator avoidance. By not sleeping on the colony until eggs are laid, the terns delay by 2-3 weeks the time at which the colony might be discovered by nocturnal predators. The usual difference in nesting success between early and late nesting terns, with late-nesters showing decidedly reduced nesting success as the result of predation, suggests that this 2-3 week delay in advertisement by early-nesting birds, may be an important reproductive strategy.

Breeding Biology--Least terns arrive in the vicinity of the nesting areas from mid-April to early May. Some pair bonds may form before arrival in the nesting areas, others begin to form within the group almost immediately, and active courtship may be observed within the first few days after arrival (Davis 1968, Swickard 1971, Massey 1974).

Courtship follows a well-defined pattern, beginning with "fish flights" wherein a male carrying a fish is joined by one or two other terns in high flying aerial display. Aerial glides (pairs flying in unison) follow. Posturing and parading on the ground occur in the late stage of courtship with the male holding a small fish in his beak as he courts the female. During copulation, the female takes the fish from the male and eats it (Wolk 1954, Hardy 1957, Davis 1968, Massey 1974).

Nest Location and Construction--The least tern usually chooses nesting locations in an open expanse of light-colored sand, dirt, or dried mud close to a lagoon or estuary with a dependable food supply (Craig 1971, Swickard 1971, Massey 1974). Formerly, sandy ocean beaches regularly were used, but increased human activity on most beaches has made many of them uninhabitable. As a result, terns have been forced to nest on mud and sand flats back from the ocean, and on man-made "habitats" such as airports and land fills (Longhurst 1969, Craig 1971). Least terns are colonial but do not nest in as dense concentrations as other tern species. Although nests have been found as close together as 0.8 m (2.5 feet) (Davis 1968), usual minimum distances between nests are 3.0m-4.6m (10-15 feet), with averages usually much greater (Wolk 1954, Hardy 1957, Massey 1974). At one site, Swickard (1971) found nest densities

to be 40-45 per ha (16-18 per acre). In other instances, colonies are widely dispersed with over 91 m (300 feet) between nests. In northern Santa Barbara County, where nesting occurs in almost limitless expanses of coastal dune habitat, as few as 15 nesting pairs can be widely scattered in colonies with a 1.6 km (1 mile) perimeter or more. Thus, nesting densities are highly variable and seem to be related to amount of available habitat. In general, nesting colonies are located near coastal lagoons and estuaries.

The nest is a small depression in which the eggs are laid. In sand, it is scooped out by the bird (Davis 1968, Swickard 1971, Massey 1974), but in hard soil, it may be any kind of natural or artificial depression - for example, a dried boot print (Swickard 1971). After the eggs are laid, nests are often lined with shell fragments and small pebbles. Swickard found a nest depression completely lined with small twigs.

Eggs and Duration of Nesting Season--Least tern eggs measure approximately 31 x 24 mm (1.2 x 0.9 in.), and are buffy with various brownish and purplish streaks and speckles (Bent 1921, Davis 1968, Hardy 1957, Massey 1974). One to four eggs are laid, with two to three-egg clutches being reported most often (Anderson 1970, Massey 1974). Egg laying usually occurs in the morning, with the eggs laid on consecutive days (Davis 1968, Massey 1974).

The nesting season extends from approximately 15 May into early August, with the majority of nests completed by mid-June (Bent 1921, Grinnell 1898, Swickard 1971). A second wave of nesting occurs from mid-June

to early August. These are mainly renests after initial failures and second year birds nesting for the first time (Massey and Atwood 1981a). Most authorities agree that least terns are capable of successfully raising only one brood per pair in a season.

Incubation--Incubation, which begins with the laying of the first egg, is irregular at first but becomes steady after the clutch is completed (Davis 1968, Massey 1974, Swickard 1971).

Both parents participate, but the female initially takes a much greater part than the male (Davis 1968, Hagar 1937, Hardy 1957, Massey 1974, Swickard 1971). Extremes of from 17 to 28 days have been documented. The usual incubation period is 20-25 days (Massey 1972), with an approximate mean of 21 days (Massey[1], Pers. comm.)

Nest Success and Survival of Young--Most California least tern colonies suffer some losses of eggs and young to predators or unfavorable weather conditions during the course of a normal nesting season. Despite this, hatching success is usually high (especially compared to fledging success--see below). Eighty to 90 percent hatching success of eggs was reported by both Massey (1974) and Swickard (1971) during the 1970-72 period. Infertility appears to be a minor cause of least tern egg failure. For example, Massey found only six infertile or addled eggs out of 157 laid in her study area. Predators have been implicated in

---

[1] Ms. Barbara Massey, Research Associate, California State University, Long Beach, CA.

a number of egg losses and colony failures, with coyote (Canis latrans), Norway rat (Rattus norvegicus), striped skunk (Mephitis mephitis), long-tailed weasel (Mustela frenata), common raven (Corvus corax) and American crow (Corvus brachyrhynchos) often named as the known or suspected predators. Dogs (Canis familiaris), gulls and other less commonly implicated species also destroy eggs.

Fledging rates vary greatly from colony to colony and from year to year (Swickard 1971, Massey 1974). The maximum overall success rate (percent of eggs laid resulting in flying young) yet observed in a major colony is about 70 percent (Massey and Atwood 1979). Since 1978, fledging rate (number of young fledged per number of breeding pairs) has varied from an estimated low of 0.46 in 1982 to an estimated high of 0.86 in 1981 (Table 1). Because of its large number of nesting colonies, San Diego County usually contributes the highest percentage of fledglings produced (among counties) in the state. Statewide data from specific nesting colony sites are given in Table 2.

Post-hatching Period Including Predation--Eggs usually hatch on consecutive days, and the chicks, although precocial, are initially weak and helpless. The adults brood continuously during the first day (Davis 1968), but by the second day, the chicks are stronger and make short walking trips from the nest. From the third day on, they are increasingly mobile and active (Davis 1968, Massey 1974). Flightless young have been seen as late as the first week of September (Tijuana

[1] The prime objective specifies that a minimum of 20 distinctive management areas (MA) are necessary for the tern to qualify for delisting. See objectives for other details. San Francisco Bay, (MA a), Mission Bay (MA u), and San Diego Bay (MA v) must have a minimum of 4, 6, and 6 secure colonies, respectively, before each can qualify toward the goal of 20 secure, distinct management areas. Colonies with the same letter indicate that they are considered representative of a management area.

* Not included as site counted toward 20 secure management locations.

River mouth, R. G. McCaskie[1] and J. M. Sheppard[2], pers. comm.).

Flight stage is reached at approximately 20 days of age, but the young birds do not become fully proficient fishers until after they migrate from the breeding grounds. Consequently, parents continue to feed their young even after they are strong fliers (Massey 1974, Swickard 1971, Tompkins 1959).

Loss of tern chicks has been attributed to American kestrels (Falco sparverius) (Craig 1971), loggerhead shrikes (Lanius ludovicianus) and American crows (Atwood et al. 1977, Bender[3] pers. comm.), house cats (Felis cattus) (Edwards 1919) and dogs (Pentis 1972); to cold, wet weather (Pentis 1972) and to extreme heat spells (CDFG 1981); and to dehydration and starvation (Massey 1972). Burrowing owls (Athene cunicularia) have been known to feed on nesting adult least terns and young (Jorgensen[4] and Collins[5], pers. comm.). Common ravens and red foxes (Vulpes vulpes) are also reported predators. Human disturbance is a perennial problem at some colonies (i.e., Tijuana River Mouth, Delta Beach, and Santa Maria River).

---

1 Mr. Guy McCaskie, San Diego, CA.
2 Mr. Jay Sheperd, Office of Endangered Species, U.S. Fish and Wildlife Service, Washington, D.C.
3 Ms. Kristen Bender, past California Least Tern Recovery Team member.
4 Mr. Paul Jorgensen, Biologist, California Department of Parks and Recreation, San Diego, CA.
5 Dr. Charles Collins, Department of Biology, California State University, Long Beach, CA.

In the past, high tides washed away many California least tern eggs (Sechrist 1915, Shepardson 1909); however, most California least terns nest in situations where flooding is not a normal factor. Summer rains sometimes cause losses where nests occur on soils less permeable than beach sands (Swickard 1971).

Post-breeding Dispersal--Fledglings accompanied by adults are often observed at various shallow-water, freshwater, and estuarine marshes prior to migrating south. Post-breeding dispersal to such areas probably affords juveniles the opportunity to develop foraging skills prior to the demands of migration. Most known post-breeding, foraging and roosting areas appear to be characterized by (1) suitable food resources, (2) proximity to active breeding colonies, and (3) relatively protected loafing and nesting sites. The known post-breeding dispersal sites include: Oso Flaco and Dunes Lakes, Santa Ynez River mouth, Mugu Lagoon, Harbor Lake, Guajome Lake, Lake Val Sereno, Whelan Lake, various stretches of the Santa Margarita and San Luis Rey Rivers and O'Neill Lake, Buena Vista, Batiquitos and San Dieguito Lagoons, San Diego River Flood Control Channel, Delta Beach, and the Dairy Mart Ponds.

Migration and Wintering Grounds--Least terns usually arrive along the California coast in mid-April to early May and head south by September. Little is known about where the remaining 8 months of each year are spent.

Up to 78 least terns have been observed during the winter as far north as

Colima, Mexico (A. Craig[1] unpubl. rpt.) but subspecfic identify could not be determined. There are only a few reports from the Pacific Coast in Honduras and Guatemala. Small numbers of birds (2-3 individuals) have been reported from the Pacific Coast of Panama, but other investigators have checked suitable locations in Panama and not found wintering least terns. The winter range is still in great need of documentation.

Nothing is known about actual migration routes, but the terns presumably move along the west coast of Baja California, to the west coast of Mexico and further south.

Longevity and Breeding Age--Banded least terns (including all three North American subspecies) have been recovered at up to 21 years of age, and 31 of 61 banded individuals were 5 years old or older (Massey and Atwood 1978). A 15 year old bird has been documented to breed in San Diego (B. Massey and E. Copper[2] pers. comm.). This suggests a relatively long life for individuals of this species.

Banding studies have demonstrated that the usual age of first breeding is 3 years, but that least terns occasionally do breed at age two (Massey and Atwood 1981a,b). One-year old birds occur rarely in breeding areas during the nesting season; they do not participate in breeding activities nor are they in breeding plumage (Massey and Atwood 1978).

---

1 Mr. Allan Craig, Biologist, California Department of Fish and Game.
2 Ms. Elizabeth Copper, Tern Biologist, San Diego, CA

Food and Feeding Habits--The California least tern obtains most of its food from shallow estuaries and lagoons, and nearshore ocean waters. Feeding activity at the few sites that have been studied occurs mostly within 3.2 km (2 miles) of breeding colonies, and at many sites foraging is primarily in nearshore ocean waters less than 18.3 m (60 feet) deep. Colonies located near productive estuarine habitats appear to utilize such areas heavily but data regarding the relative value of estuaries to feeding least terns are scarce. The increased use of freshwater marsh systems, lakes, lagoons, and estuarine areas during post-breeding dispersal suggests the special importance of such habitats during the breeding cycle when juveniles are learning to fish for themselves.

The California least tern has not been observed eating anything but fish (Massey 1974). Most fish taken are apparently younger than 1 year old. General size characteristics of the fish eaten are a maximum body depth of less than 1.2 cm and a maximum body length of about 8 cm. The main food items are variable from colony to colony, but usually include northern anchovy (Engraulis mordax) and topsmelt (Atherinops affinis). In San Diego County, deepbody and slough anchovies (Anchoa spp.) are relatively important. Other locally or temporally important species include shiner surfperch (Cymatogaster aggregata), several gobies [notably the yellowfin goby (Acanthogobius flavimanus)], the longjaw mudsucker (Gillichthys mirabilis), California killifish (Fundulus parvipinnis), jacksmelt (Atherinopsis californiensis), and mosquitofish (Gambusia affinis) plus other species (Atwood, Minsky, and Massey, pers. comm). At least 50 species of forage fish have been identified from fish dropped at colony sites (Massey and Atwood 1981b).

Past Conservation Efforts

Past efforts to conserve the California least tern have involved monitoring breeding colonies to determine distribution and location of colonies, pairs, number of fledglings, reproductive rate, and predation problems. Fencing of colonies has been effective in some cases in minimizing human disturbance. Predator control through judicious use and placement of electric fences and other barriers as well as by trapping efforts have reduced losses of adults, eggs, and/or young.

The number of nesting pairs has increased throughout recent years largely because of the result of the above conservation efforts. Unfortunately preliminary data for 1984 indicate a 25-30% reduction of nesting adults (Massey, pers. comm.). As yet, causes for this unexpected decline have not been determined.

A non-inclusive list of actions that have been undertaken on behalf of the least tern include the installation of an electric fence on NASA Island (Seal Beach National Wildlife Refuge) in addition to marsh restoration efforts to increase tidal action. The U.S. Marines-Camp Pendleton and the California Department of Parks and Recreation routinely maintain a fence around nesting colonies and post admonitory signs to minimize human disturbance. This is especially important because Venice Beach and Huntington Beach are two of the largest colonies in the state. Local concerns, other agencies, and the Fish and Wildlife Service cooperate in an effort to manage the Santa Margarita colonies, another essential site.

The U.S. Navy at Point Mugu instituted a research project to evaluate the impacts of predation on terns by the introduced red fox. As indicated by the above, the scope and complexity of recovery actions for least terns has been varied and has involved a host of various agencies.

California Department of Fish and Game (CDFG) has created nesting islands in Bolsa Chica, one of which now supports a large breeding tern colony. CDFG has also attempted to abate the sedimentation problem in Upper Newport Bay in addition to creating nesting sites and protecting existing birds.

The U.S. Navy has fenced Delta Beach to prevent disturbance to the site. Site preparation to enhance the suitability of the area for terns has been undertaken.

Reasons for Decline

No reliable estimates are available on historical numbers of California least terns, but they once were abundant and well-distributed along the southern California coast. Shepardson (1909) describes a colony of about 600 pairs along a 4.8 km (three-mile) stretch of beach in San Diego County. "Good-sized" colonies were located in Los Angeles County (Grinnell 1898).

Reduction in numbers was gradual. This subspecies appears to have escaped the slaughter inflicted on the East Coast populations by the millinery trade of the late 1800's (Bent 1921, Hagar 1937), although there were some early local losses to shooting (Holterhoff 1884) and egg collecting (McCormick 1899). It is doubtful these activities were widespread enough

to adversely influence the population. Although certain least tern colonies were still thriving in the early 1900's, others were already beginning to feel the pressure of human influence.

The Pacific Coast Highway was constructed early this century along previously undisturbed beach, and summer cottages and beach homes were built in many areas. Soon children, dogs and cats were being blamed for disrupting tern nesting (Chambers 1908, Edwards 1919, Massey 1974). The buildup of human use of the beaches displaced more and more colonies at the same time their bay feeding areas were being developed, filled in, and polluted. By the 1940's, most terns were gone from the beaches of Orange and Los Angeles counties (Cogswell 1947), and they were considered sparse everywhere (Grinnell and Miller 1944). Continuing loss of both nesting and feeding habitat and high levels of human disturbance at remaining colonies have been responsible for the continued decline to the present time (Craig 1971).

Current Status

The least tern breeding population in California was approximately 890-1215, 963-1171, 1015-1245, and 1180-1299 pairs in 1980, 1981, 1982, and 1983, respectively (Table 3).

Earlier apparent increases were partly attributable to more thorough surveys of colony locations resulting from experience gained in previous years. Subsequent increases have resulted from colony management and protection efforts. The number of terns nesting in Baja California is

unknown. Additional information is needed to assess the importance of least terns nesting in Baja California to the overall recovery effort. Security and management of Mexican colonies must be evaluated to assess the impact of these colonies on recovery goals. Those factors that have contributed to the decline of the California least tern - loss of nesting and feeding habitat, and continued disturbance of nesting colonies - continue to operate, and the bird's status continues to be precarious. There is potential, however, for creating or restoring nesting and feeding habitat in the vicinity of most existing colonies, and in areas that have not been used in the recent past.

PART II

RECOVERY

Objectives

The primary objective of this recovery plan is to restore and subsequently maintain the breeding population of California least terns at a secure level so that delisting can be considered. To achieve this level, the annual breeding population in California must increase to at least 1,200 pairs distributed among secure colonies in at least 20 secure coastal management areas throughout their breeding range. Concurrently, efforts should be directed toward protecting the existing breeding population in Baja California, Mexico. Data from California least tern populations in Baja California are insufficient to incorporate population numbers and necessary fledging rates into the prime objective for reclassification. When these data become available the prime objective will be modified accordingly. Because of current Mexican land use practices, remoteness of areas, and minimal monitoring of land uses, it appears unlikely that the Mexican colonies will contribute substantially to the recovery effort. However, this situation requires clearer definition.

If the 1,200 pair population level is achieved, delisting of the species can be considered, with these provisions: 1) sufficient habitat to support at least one viable tern colony (defined as consisting of a minimum of 20 breeding pairs with a 5-year mean reproductive rate of at least 1.0 young fledged per year per breeding pair) at each of the 20 coastal

management areas (see Table 2) (including San Francisco Bay, Mission Bay and San Diego Bay, which should have 4, 6 and 6 secure colonies, respectively), that are managed to conserve least terns; and 2) land ownership and management objectives are such that future habitat management for the benefit of least terns at those locations can be assured. The security and status of Baja California colonies must be assessed; if any such colonies are estimated to be secure and will be managed in perpetuity to benefit least terns, such colonies will also be incorporated into the quantified prime objective.

Interim reclassification to threatened status can be considered when: 1) the 1,200 pair population level is achieved; 2) 15 coastal management areas (including San Francisco Bay, Mission Bay and San Diego Bay, which should have 3, 5 and 4 secure colonies, respectively) support viable least tern colonies and are managed to conserve least terns; and 3) a 3-year mean reproductive rate of at least 1.0 young/breeding pair is achieved. Once additional information on the Baja California colonies is available, possibly one or two secure sites of the above 15 may be located in Baja. Because of possible non-security of Baja California habitats, it appears unlikely that the Mexican populations will contribute significantly to tern recovery. However, this must be more thoroughly investigated. As additional data become available, the prime objective may be modified to reflect current information.

The chief limiting factor influencing the number of least tern breeding pairs is the availability of undisturbed suitable habitat on the breeding grounds. Therefore, many tasks outlined in this plan include preservation

and management of existing nesting, foraging and roosting habitat, restoration of former nesting habitat and degraded coastal wetlands, creation of nesting islands, and protection of nesting and roosting areas from excessive human disturbance and predation. Research is needed to refine and direct a number of these management actions. Recovery will depend upon a continuing cooperative effort by the U.S. Fish and Wildlife Service, California Department of Fish and Game, California Department of Parks and Recreation, U.S. Army Corps of Engineers, U.S. Navy, U.S. Marine Corps, U.S. Air Force, Federal Aviation Administration, numerous city, county and other local government agencies, private conservation organizations, and the governments of Mexico and other countries within the range of this subspecies.

Step-down Outline

Primary Objective: In order to consider delisting, increase the least tern breeding population in California to a secure level of at least 1,200 pairs distributed in viable colonies in at least 20 coastal management areas distributed throughout its current breeding range with at least a 1.0 reproductive rate as a 5-year average for the total population within the 20 management areas while encouraging the preservation of the existing breeding population in Baja California. Reclassification to threatened status may be considered when there are 1,200 breeding pairs in 15 secure coastal management areas, with an overall-mean productive rate of 1.0 for a consecutive 3-year period.

1. Preserve and manage nesting habitat.

    11. Preserve and manage nesting areas of existing colonies.

111. Develop and implement least tern management plans/programs for secure[1] nesting habitat in Alameda, San Mateo, Santa Barbara, Ventura, and Los Angeles counties.

1111. Alameda Naval Air Station.

1112. Bair Island.

1113. San Antonio Creek.

1114. Purisima Point.

1115. Santa Clara River Mouth.

1116. Mugu Lagoon.

1117. Venice Beach.

112. Develop and implement least tern management plans/programs for secure nesting habitat in Orange County.

1121. Anaheim Bay (Seal Beach National Wildlife Refuge, Naval Weapons Center-Seal Beach).

1122. Huntington State Beach Least Tern Natural Area.

1123. Bolsa Chica Ecological Reserve.

1124. Upper Newport Bay Ecological Reserve.

113. Develop and implement least tern management plans/programs for secure nesting habitat in San Diego County.

1131. San Mateo Creek.

1132. Aliso Creek.

1133. Santa Margarita River Mouth.

---

[1] Secure land is defined as being in public ownership or control and is actively managed for its resource values emphasizing endangered species.

1134. Buena Vista Lagoon.

1135. San Elijo Lagoon.

1136. Delta Beach.

1137. San Diego Bay salt pond dikes.

1138. Tijuana River Estuary.

114. Preserve and manage nesting areas for currently insecure colonies.

1141. Protect/secure nesting habitat now in private ownership (San Diego County unless otherwise stated).

11411. Agua Hedionda Lagoon (eastern part).

11412. Los Penasquitos Lagoon.

11413. Playa del Rey (Los Angeles County).

11414. Bayfront end of "D" Street Fill", Sweetwater Marsh.

11415. Oakland Airport (Alameda County).

1142. Manage when, and if, secured.

11421. Agua Hedionda Lagoon (eastern part).

11422. Los Penasquitos Lagoon.

11423. Playa del Rey.

1143. Develop and implement management plans to establish secure nesting areas for colonies on public lands (San Diego County unless otherwise stated).

11431. North Island Naval Air Station.

11432. Chula Vista Wildlife Reserve.

11433. Oso Flaco Lake (San Luis Obispo County).

115. Secure and manage a minimum of six least tern nesting sites in Mission Bay (San Diego County).

1151. Establish an interagency coordinating team to annually maintain least tern colonies.

1152. Annually maintain Crown Point Sanctuary.

1153. Annually maintain FAA Island site.

1154. Annually maintain and protect North Fiesta Island breeding area.

1155. Annually maintain and protect Stoney Point nesting site.

1156. Establish and manage at least two additional breeding sites at the Cloverleaf and South Sea World Drive, or at other potential sites.

116. Develop management plans/programs that identify special site protection problems of certain insecure colonies and implement corrective action as needed in Ventura, Los Angeles, and Alameda counties.

1161. Coyote Hills (Alameda County).

1162. Ormond Beach (Ventura County).

1163. Santa Clara River Mouth (Ventura County).

1164. Cerritos Lagoon (Los Angeles County).

1165. Playa del Ray (Los Angeles County).

1166. Terminal Island--Reeves Field and the land-fill site (Los Angeles County).

117. Develop management plans/programs that identify special site protection problems of certain insecure colonies and implement corrective action as needed in San Diego County.

1171. San Diego International Airport.

1172. Grand Caribe Island, Coronado Cays.

1173. D Street Fill.

12. Provide adequate nesting habitat in former, potential, or newly identified breeding areas.

121. Develop and implement management plans to construct and manage new nesting sites in protected areas.

1211. Anaheim Bay (Seal Beach National Wildlife Refuge, Naval Weapons Station Seal Beach)

1212. Sunset Aquatic Park.

1213. Bolsa Chica Ecological Reserve.

1214. Upper Newport Bay Ecological Reserve.

1215. Silver Strand, south end of San Diego Bay

1216. Naval Training Center, San Diego.

1217. Marine Corps Recruiting Depot-San Diego

122. Manage newly identified sites.

123. Develop and implement least tern management plans/programs for currently non-secure habitats with emphasis on construction of adequate breeding sites.

1231. Protect and manage San Dieguito Lagoon.

1232. Protect and manage mouth of Santa Ana River (southeast area).

2. Protect and manage non-nesting habitat.

21. Maintain adequate feeding habitat for colonies.

211. Protect existing coastal feeding grounds of colonies.

2111. Mugu Lagoon.

2112. Bolsa Chica Bay.

2113. Terminal Island.

2114. Anaheim Bay.

2115. Los Penasquitos Lagoon.

2116. Tijuana River Estuary.

212. Investigate and implement actions needed to increase populations of fish eaten by terns in degraded or potential tern feeding areas.

2121. Mouth of Santa Ana River, southeast area.

2122. San Elijo Lagoon.

2123. Batiquitos Lagoon.

2124. Other areas as needed.

213. Identify major feeding areas.

22. Protect important[1] non-nesting, feeding, and roosting habitats from detrimental land or water use changes in San Luis Obispo, Santa Barbara and Los Angeles Counties.

221. Oso Flaco and Dune Lakes (San Luis Obispo County).

222. Santa Ynez River Mouth (Santa Barbara County).

223. Harbor Lake (Los Angeles County).

224. Belmont Shores (Los Angeles County).

---

[1] "Important" = used more than on merely a casual basis.

225. Identify and protect other habitats as needed.

23. Protect important non-nesting, feeding, and roosting habitats from detrimental land or water use changes in San Diego County.

231. Guajome Lake.

232. Lake Val Sereno.

233. Whelan Lake.

234. Santa Margarita River-O'Neil Lake.

235. San Luis Rey River.

236. Dairy Mart Ponds.

237. San Dieguito Lagoon.

238. Buena Vista Lagoon.

239. San Diego River Flood Control Channel.

3. Monitor least tern population to determine status, distribution and progress of management during the breeding season.

31. Determine breeding success.[1]

311. Determine colony locations.

312. Estimate breeding population size.

313. Conduct annual breeding colony surveys.

32. Investigate population dynamics, life history, and movement of terns by banding and marking.

4. Conduct research on California least tern to provide additional necessary information for tern management.

41. Determine effects of environmental pollutants on least terns.

---

[1] "Breeding success" = number of young that fledge per number of least tern pairs.

42. Determine factors affecting the choice of location for roosting, loafing, and feeding areas used during the breeding and post-breeding seasons.

43. Determine amount of habitat that is necessary to maintain the current population and the prime recovery objective.

44. Identify potentially suitable nesting sites, including beach, landfill, salt pond, and estuarine areas.

45. Identify factors causing colony disruption and nest site abandonment.

46. Develop or refine management techniques for providing adequate nesting sites and implement techniques where needed.

461. Investigate nest site requirements of colonies.

462. Investigate methods of enhancing nesting sites of existing colonies.

463. Investigate methods of constructing adequate nesting sites in potential breeding habitat.

5. Encourage the protection of population outside the United States.

51. Protect least tern population and habitats in Baja California.

511. Determine colony locations and population size.

512. Identify least tern population and habitat protection problems.

513. Develop cooperative programs between the United States and Mexican governments for least tern protection and habitat preservation.

52. Identify and protect key migration and winter habitats outside the United States.

6. Utilize existing laws and regulations protecting California least tern and its habitat.

   61. Evaluate success of law enforcement.

   62. Propose appropriate new regulations or revisions.

7. Develop and implement a conservation education program.

Narrative

1. Preserve and manage nesting habitat.

California least tern conservation and recovery depends upon the adequate protection and management of habitat for nesting, feeding, roosting, post-breeding dispersal and wintering. It is particularly important that nesting habitat be properly managed to maximize tern productivity. Human disturbance must be minimized. This may entail posting admonitory signs, erecting fences, providing adequate patrols and law enforcement, and undertaking an energetic conservation education program.

Predation of adult terns, eggs, or young and prevention of colony abandonment may be attempted by judiciously monitoring colonies to detect potential or actual predation problems. Control of problem predators by trapping, shooting, use of electric fences, and other means is required and has been successful at increasing tern nesting and reproductive success. Emergency procedures may need to be implemented to maximize tern survival and reproduction.

11. Preserve and manage nesting areas of existing colonies.

In California, least terns have nested in about 20 coastal ecosystems since 1969. The numbers of colonies and their nest site locations in many of these areas have varied from year to year. At least two more nesting areas exist in Baja California, Mexico. If

colonies are to continue in these areas, their nesting and feeding habitats must be preserved.

At some breeding sites, habitat management actions are needed annually to provide suitable nesting substrates. Growth of vegetation, wind, rain, tidal action, vehicle or human foot traffic, and other factors contribute to the deterioration of the quality of nesting substrates. Generally, site preparation actions are needed between February 1 to April 15 (no later than the start of the nesting season). Pre-breeding season management actions may include site inspections to evaluate management needs, removal of vegetation, deposition of sand or other substrate material, disking and leveling of substrates, prevention of rain or tidal water flooding, and placement of clay, concrete or other artificial shelters in or near nesting sites to provide shade for chicks and use of decoys to attract adults. Schedules for annual nest site enhancement actions on State or Federal management areas must be incorporated in management plans for those areas.

Where potential nesting sites are created and adequately prepared, annual nest site enhancement actions and experimentation should continue for at least five years to entice breeding pairs to establish new colonies. If, after this 5 year period, a colony has not become established, the site should be re-evaluated as a potential nesting area.

In some areas, recommended management actions include the

construction of alternate nesting sites where currently used sites are highly vulnerable to disturbance or are jeopardized by habitat loss. In some instances where land development plans would cause the destruction of a nesting site, construction of an alternate nest site may be the only feasible alternative to avoid detrimental impacts.

In areas where nesting sites and/or feeding areas are protected under public ownership or jurisdiction, this plan recommends that responsible agencies develop and implement least tern management plans. Coordination of plans is the responsibility of the California Department of Fish and Game and the U.S. Fish and Wildlife Service.

111. Develop and implement least tern management plans/programs in Alameda, San Mateo, Santa Barbara, Ventura, and Los Angeles Counties.

For most existing colonies, the nesting area is the habitat element most in need of preservation. In California, not all currently used colony nesting sites are protected under State, Federal or other public ownership or jurisdiction. Protected sites are reasonably secure from adverse habitat alteration or are located where human access can be controlled. The remaining active colony nesting sites are located in areas where human disturbance is a recurrent problem, where needed management programs are now difficult or nearly impossible to implement,

or where land use changes threaten the suitability of the site for breeding. For a few of these sites, construction and protection of nearby alternate nesting areas, where possible, would be preferable to the protection of those currently used, but always vulnerable nesting sites. For the remaining areas, however, efforts are now needed to preserve essential nesting habitat through acquisition, zoning or other actions.

1111. Alameda Naval Air Station.

The most effective means of tern conservation in this area is through development and implementation of a least tern management plan. The Navy is currently formulating such a plan; it has constructed and maintains a protective fence around the nesting colony. Monitoring of the colony and predator control is routinely undertaken.

1112. Bair Island.

The most effective means of tern conservation in this area is through development and implementation of a least tern management plan. CDFG is currently working on such a plan.

1113. San Antonio Creek.

The most effective means of tern conservation in this area is through development and implementation of a least tern

management plan.

1114. Purisima Point.

1115. Santa Clara River Mouth.

See item 113.

1116. Mugu Lagoon.

See item 1113.

1117. Venice Beach

See item 1113.

112. Develop and implement least tern management plans/programs for secure nesting habitat in Orange County.

For most existing colonies, the nesting area is the habitat element most in need of preservation. In California, not all currently used colony nesting sites are now protected under State, Federal or other public ownership or jurisdiction. These protected sites are reasonably secure from adverse habitat alteration or are located where human access can be

controlled. The remaining active colony nesting sites are located in areas where human disturbance is a recurrent problem, where needed management programs are now difficult or nearly impossible to implement, or where land use changes threaten the suitability of the site for breeding. For a few of these sites, construction and protection of nearby alternate nesting areas, where possible, would be preferable to the protection of those currently used, but always vulnerable nesting sites. For the remaining areas, however, efforts are now needed to preserve essential nesting habitat through acquisition, zoning or other actions.

1121. Anaheim Bay (Seal Beach National Wildlife Refuge, Naval Weapons Center-Seal Beach).

The most effective means of tern conservation in this area is through development and implementation of a least tern management plan. Construction of an alternate nesting site is planned. Site enhancement, monitoring, and predator control is ongoing.

1122. Huntington State Beach Least Tern Natural Area.

Effective tern recovery depends upon the development and implementation of a suitable mamagement plan. Monitoring and control of predators is an ongoing process.

1123. Bolsa Chica Ecological Reserve.

See item 1122.

1124. Upper Newport Bay Ecological Reserve.

See item 1122.

113. Develop and implement least tern management plans/programs for secure nesting habitat in San Diego County.

For most existing colonies, the nesting area is the habitat element most in need of preservation. In California, not all currently used colony nesting sites are now protected under State, Federal or other public ownership or jurisdiction. Protected sites are reasonably secure from adverse habitat alteration or are located where human access can be controlled. The remaining active colony nesting sites are located in areas where human disturbance is a recurrent problem, where needed management programs are now difficult or nearly impossible to implement, or where land use changes threaten the suitability of the site for breeding. For a few of these sites, construction and protection of nearby alternate nesting areas, where possible, would be preferable to the protection of those currently used, but always vulnerable nesting sites. For the remaining areas, however, efforts are now needed to preserve essential nesting habitat through acquisition, zoning or other actions.

1131. San Mateo Creek.

See item 1122.

1132. Aliso Creek.

See item 1122.

1133. Santa Margarita River Mouth.

See item 1122.

1134. Buena Vista Lagoon.

See item 1122.

1135. San Elijo Lagoon.

See item 1122.

1136. Delta Beach.

This beach was recently fenced to prevent human disturbance. Vegetation was removed to enhance the site's suitability for tern use. It has been used as a roosting site by large numbers of post-breeding terns. It is anticipated that terns will increase their use of the area and may nest there. The beach

is managed by the Naval Amphibious Base-Coronado.

1137. San Diego Bay Salt Pond Dikes.

See item 1122.

1138. Tijuana River Estuary.

Presently this site does not provide suitable conditions to support a secure least tern colony. A management plan is needed to control human disturbance (primarily horseback riding), minimize the effects of flooding and high tides (may require moving nesting areas to higher ground), and to limit vegetation encroachment. A management plan, once implemented, would be an effective tool to enhance tern reproduction in this location.

114. Preserve and manage nesting areas for currently insecure colonies.

Numerous least tern nesting colonies are located on land that is not managed to benefit least tern. The status of terns is such that their recovery necessitates adequately protecting currently insecure nesting colonies.

1141. Protect/secure nesting habitat now in private ownership (San Diego County unless otherwise stated).

Certain colony sites have the potential to provide good nesting and/or feeding habitat if properly managed. Securing such sites either by acquisition, conservation easements, memoranda of understanding, or other means is necessary to insure their protection; otherwise future habitat modification may make the areas unsuitable for terns. Any habitat that Fish and Wildlife Service may be involved directly in securing will require the preparation of a Land Protection Plan. Such a plan delineates the possible methods of securing a given site.

11411. Agua Hedionda Lagoon (eastern part).

This site is now in private ownership. Proper management to conserve and recover least terns is essential. Considering the pressures to develop the area, acquisition may be the best method to insure the continued use by least tern.

11412. Los Penasquitos Lagoon.

See item 11411.

11413. Playa del Rey (Los Angeles County).

See item 11411.

11414. Bayfront end of "D Street Fill", Sweetwater Marsh.

See item 11411.

11415. Oakland Airport (Alameda County).

See item 11411.

1142. Manage when, and if, secured.

Once areas are secured, active management will be necessary to provide the best habitat conditions for least tern.

11421. Agua Hedionda Lagoon (eastern part).

After this area has been secured, intensive management to conserve and enhance California least terns will be required to maximize the reproductive potential of terns using the site.

11422. Los Penasquitos Lagoon.

After this area has been secured, intensive management to conserve and enhance California least terns will be required to maximize the reproductive potential of terns using the site.

11423. Playa del Rey.

See item 11422.

1143. Develop and implement management plans to establish secure nesting areas for colonies on public lands (San Diego County unless otherwise stated).

Several areas in public ownership provide nesting sites for terns but need additional efforts to improve tern nesting success. Specific management plans should be developed for each area. Enhancing these sites will increase productivity and state-wide population levels.

11431. North Island Naval Air Station.

An existing management plan is being revised in response to development planned on the nesting site. Intensive management of the remaining nesting area and alternate nesting sites is necessary to enhance reproduction.

11432. Chula Vista Wildlife Reserve.

Presently this site does not provide suitable conditions to support a secure least tern colony. A management plan, once implemented, would be an effective tool to enhance tern reproduction in this location.

11433. Oso Flaco Lake (San Luis Obispo County).

See item 11432.

115. Secure and manage a minimum of six least tern nesting sites in Mission Bay (San Diego County).

Twelve different sites around Mission Bay have supported tern nesting colonies since 1960. As recently as 1975, eight of these sites were in use, and in 1982 five areas were used. At least six sites that have been used in the past still possess the potential, if managed, to support viable tern colonies. Controlling vegetation, human disturbance and predation is the key to fostering successful tern colonies around Mission Bay.

1151. Establish an interagency coordinating team to annually maintain least tern colonies.

Several agencies are involved in managing Mission Bay. A coordinated, focused effort is needed to ensure that breeding areas are maintained and properly protected.

1152. Annually maintain Crown Point Sanctuary.

This area could support far more terns than it now does. Annual maintenance (e.g., vegetation removal) is required to maintain habitat quality. Other forms of maintenance may also be required to maximize the reproductive potential of this site.

1153. Annually maintain FAA Island Site.

For its size, this area has supported more nesting terns than any other colony in California. Annual maintenance (e.g., vegetation removal) is required to maintain habitat quality. Effective predator control is required to maximize the reproductive potential of this site.

1154. Annually maintain and protect North Fiesta Island breeding area.

This area could support far more terns than it now does. Annual maintenance (e.g., vegetation removal) is required to maintain habitat quality. Predator control is also required to maximize the reproductive potential of this site.

1155. Annually maintain and protect Stoney Point colony site.

This area could support far more terns that it now does. Annual maintenance (e.g., vegetation removal) is required to maintain habitat quality. Predator control is also required to maximize the reproductive potential of this site.

1156. Establish and manage two additional breeding sites at the Cloverleaf and South Sea World Drive.

These two colony sites in Mission Bay plus the above four sites, if adequately managed (including predator control and fencing),

could substantially increase the reproductive output of least terns in San Diego County.

116. Develop management plans/programs that identify special site protection problems of certain insecure colonies and implement corrective action as needed in Ventura, Los Angeles, and Alameda counties.

Success of insecure (and also secure) colonies may be enhanced by first determining what site specific problems exist. Needed actions may involve signing, fencing, and/or patrolling to control unwarranted human intrusion. Site enhancement (i.e., vegetation removal or thinning) and predator control also may be necessary.

1161. Coyote Hills (Alameda County).

Management actions which deal directly with site specific problems affecting tern survival and reproductive success at this colony site are required. The exact problems of the colony must first be ascertained so that protective strategies can be developed and implemented.

1162. Ormond Beach (Ventura County).

Management actions which deal directly with site specific problems affecting tern survival and reproductive success are required. Disturbance from heavy ORV use appeared to be a major problem at this site but has been prohibited since 1982.

1163. Santa Clara River Mouth (Ventura County).

The major problem at this site is flooding of the nesting area caused by closure of the river mouth by drifting sand in the summer. Opening the mouth is required several times during an average nesting season. Encroaching vegetation and disturbance from ORV's are the other problems that need attention.

1164. Cerritos Lagoon (Los Angeles County).

Management actions which deal directly with site specific problems affecting tern survival and reproductive success are required. There are major people-trespass and predator problems that should be examined in greater detail and alleviated. Problems within the colony must be evaluated so that protective strategies can be developed and implemented.

1165. Playa del Rey (Los Angeles County).

Management actions which deal directly with site specific problems affecting tern survival and reproductive success are required. The exact problems of the colony such as human disturbance and predation must first be identified in greater detail so that protective strategies can be developed and implemented.

1166. Terminal Island--Reeves Field and the land-fill site (Los Angeles County).

Management actions which deal directly with site specific problems affecting tern survival and reproductive success are required. The exact problems of the colony must first be ascertained so that protective strategies can be developed and implemented to secure a permanent nesting location.

117. Develop management plans/programs that identify special site protection problems of certain insecurecolonies and implement corrective action as needed in San Diego County.

Success of insecure colonies may be enhanced by first determining what site specific problems exist. Needed actions may involve signing and/or fencing the important nesting areas or patrolling to control unwarranted human intrusion. Site enhancement (i.e., vegetation removal or thinning) and predator control may be necessary.

1171. San Diego International Airport.

Management actions which deal directly with site specific problems affecting tern survival and reproductive success are required. Problems with airport operations need resolution.

1172. Grand Caribe Island, Coronado Cays.

Because colony site characteristics have been destroyed, a management plan should be developed and implemented that will provide a replacement site.

1173. D Street Fill.

Management actions which deal directly with site specific problems affecting tern survival and reproductive success at this colony site are required. The exact problems of the colony such as human intrusion and predation must first be evaluated so that protective strategies can be developed and implemented. The time required for colony reestablishment needs to be determined once human disturbance has been curtailed. Continued monitoring of human disturbance and predator-related problems will be necessary so that appropriate actions can be taken to alleviate them.

12. Provide adequate nesting habitat in former, potential, or newly identified breeding areas.

A number of areas if properly managed could support nesting colonies of least terns. One important management tool is the creation of additional or alternative nesting habitat. We have achieved some success in determining how sites should be prepared to be attractive to terns. Prevention of unnecessary human

intrusion and an active predator control program may be part of managing these areas.

Least terns readily accept artificial bare ground areas as nesting sites. This is evidenced by the fact that from 1969 to 1977, terns have chosen nest sites on at least 23 human-made land fills or other earthen structures in coastal wetland areas. In 1975 and 1976, 60 percent of known breeding pairs nested on man-made substrates. Experience at the Camp Pendleton (Swickard 1971) and Bair Island colony sites demonstrates that specially constructed nest sites can be acceptable to breeding least terns. Further research and experimentation are needed to refine this management technique. Construction of new nesting sites, restoration of abandoned nesting areas and restoration of feeding areas are recommended actions at many coastal wetlands. These actions are necessary to encourage new colonies to form in potential breeding habitats and to enhance conditions that will allow existing colonies to increase in size.

121. Develop and implement management programs/plans to construct and manage new nesting sites in protected areas.

If new colony sites can be prepared and adequately managed, terns may recolonize certain areas. This could result in an increase in overall number of nesting pairs and reproductive success. It is particularly advantageous to encourage additional nesting in secure habitat since the birds usually have a greater probability of success.

1211. Anaheim Bay (Seal Beach National Wildlife Refuge, Naval Weapons Station-Seal Beach)

Anaheim Bay lies within the Seal Beach National Wildlife Refuge which occupies land owned by the Naval Weapons Station, Seal Beach. The entire colony site at NASA Island may have to be fenced to alleviate predation problems. Because of these predation problems, additional nesting sites may be needed to improve reproductive success. Nesting sites should be created in areas where predators and other disturbance can be effectively controlled.

1212. Sunset Aquatic Park.

In this area, additional nesting sites (preferably adjacent to the National Wildlife Refuge), including an appropriate available nearby food supply, are needed to help augment the numbers of nesting least terns. Nesting sites should be created in the best potential habitat such as areas that are relatively predator-free or could be managed to minimize loss because of predation; areas that are not prone to human intrusion or where access could be properly controlled, and sites near the necessary food supplies.

1213. Bolsa Chica Ecological Reserve.

Additional nesting sites may be desirable to augment the two

created nesting islands. Nesting sites should be created in the best potential habitat such as areas that are relatively predator-free or could be managed to minimize loss because of predation; areas that are not prone to human intrusion or where access could be properly controlled, and sites near adequate food supplies.

1214. Upper Newport Bay Ecological Reserve.

In this area additional nesting sites are needed to help augment the numbers of nesting least terns. Nesting sites should be created in the best potential habitat such as areas that are relatively predator-free or could be managed to minimize loss because of predation; areas that are not prone to human intrusion or where access could be properly controlled, and sites near the necessary food supplies. It appears to be necessary to increase the elevation of the newly created nesting island at the upper end of the bay, and possibly provide additional nesting habitat at an alternate site.

1215. Silver Strand, south end of San Diego Bay (Naval Radio Receiving Facility

The feasibility of establishing a nesting site, such as at the Naval Radio Station, should be investigated. Nesting sites should be created in the best potential habitat such as areas that are relatively predator-free or could be managed to minimize

loss because of predation; areas that are not prone to human intrusion or where access could be properly controlled, and sites near adequate food supplies. In November 1983, the down-coast end of the Silver Strand State Beach was designated as a Natural Preserve. The California Department of Parks and Recreation plans on reestablishing native plants and a least tern nesting colony.

1216. Naval Training Center, San Diego.

Since terns last nested at the site here in 1978, the area has become over-grown with vegetation. Intensive site enhancement is necessary if terns are to nest here again. A management plan, developed and implemented by the Navy, is needed to recreate a colony site.

1217. Marine Corps Recruiting Depot-San Diego

The site should be examined to assess its potential as a future tern nesting colony.

122. Manage newly Identified Sites.

Ten or 12 pairs of California least terns nested in the Santa Ynez River Mouth last year. Fledglings were observed, however no census was undertaken (Farley[1], pers. comm.). The possibility

---

1 Commander Earl Farley, Vandenberg Air Force Base

of enhancing tern nesting in the area should be investigated.

123. Develop and implement tern management plans with emphasis on construction of adequate breeding sites in non-secure habitats.

Least tern breeding habitat has been drastically reduced from historical levels. Additional habitat needs to be restored or developed to increase overall nesting numbers. Potential habitat should thus be secured through acquisition, easements, or other means, if necessary, and restored as per a management plan designed specifically for each potential site.

1231. Protect and manage San Dieguito Lagoon.

Part of San Diequito Lagoon is in private ownership. To adequately protect this area, acquisition may be necessary although this is only one possible alternative to secure the site. A management plan should be prepared that stresses preparation of nesting habitat and protection from predators and human beings on the private acreage. The San Dieguito Lagoon Resource Enhancement Program has been approved and is currently being implemented by the City of Del Mar. This includes the construction of a tern nesting island of over 15 ha (6 acres). The California Department of Fish and Game is in the process of designating San Dieguito Lagoon as a state ecological reserve.

1232. Mouth of Santa Ana River, southeast area.

To adequately protect this area, acquisition, conservation easement or other alternatives, may be necessary. A management plan should be prepared that stresses preparation of breeding habitat.

2. Protect and manage non-nesting habitat.

Non-nesting habitat such as that used for roosting, loafing, or feeding must also be protected to enhance tern survivability and the recovery effort.

21. Maintain adequate feeding habitat for colonies.

An ideal nesting substrate will not attract and support least tern breeding pairs if suitable feeding conditions do not exist within a reasonable distance. With few exceptions, colonies form adjacent to estuaries, lagoons, bays or channels where food supplies are readily available. If efforts to preserve colonies are to be successful, the associated feeding areas also must be preserved. Yearlong habitat preservation efforts are needed in major least tern foraging areas. Especially important are feeding areas where least tern adults and fledglings roost after the nesting season ends and before migration south begins.

Least tern colonies need dependable supplies of small fish to sustain the adults and young throughout the breeding season. Several southern California coastal wetlands are now in a degraded condition (e.g., Mudie et al. 1974, 1976). This plan recommends that responsible management agencies investigate and implement actions that are needed to improve feeding conditions for least terns in wetland ecosystems which lack adequate fish populations. In some wetlands restoring tidal circulation is essential to restoring estuarine fish populations. Sedimentation and pollution are other factors that affect forage supplies.

211. Protect existing coastal feeding grounds of colonies.

Existing coastal foraging habitat must be protected by maintaining high water quality, minimizing tideland fill and drainage projects and by restoring or improving tidal flow in wetlands to enhance feeding habitat. If water quality is reduced, fish populations upon which least terns feed could diminish or be locally extirpated, resulting in adverse impacts to tern nesting success. If tidelands are filled or drained, fish habitat will be lost thus reducing the tern's prey base. This also may affect tern nest site selection and reproductive rate.

If the quality of nearby feeding grounds can be improved, the probability that a local nesting colony can be successful may be increased. It is also very important that high quality feeding grounds adjacent to highly productive colonies be

maintained. Improving tidal flow to wetlands can be a very effective means of increasing wetland production.

2111. Mugu Lagoon.

The possibility of improving tidal actions should be explored. Any additional actions that appear feasible should be initiated.

2112. Bolsa Chica Bay.

Foraging conditions for least terns could be improved by reestablishing tidal action to restorable wetlands.

2113. Terminal Island.

Within Los Angeles Harbor, shallow water feeding habitat appears very important to the foraging needs of this tern colony. Maintaining this habitat and providing acceptable water quality are undoubtedly important to conserving Los Angeles Harbor as acceptable breeding habitat.

2114. Anaheim Bay.

Foraging conditions for least terns could be improved by enhancing tidal action in some areas of the estuary.

2115. Los Penasquitos Lagoon.

Tidal action must be restored to this area to improve foraging conditions for least terns.

2116. Tijuana River Estuary.

Least tern foraging habitat could be expanded and enhanced by restoring tidal influence in portions of the north and south reaches of the estuary that have been cutoff from tidal waters in recent years. Agricultural runoff and sewage effluent pose threats to water quality in the Tijuana River Valley. Estuarine waters should be periodically analyzed to identify potential problems and provide a basis for recommending management actions. Flooding and high tides can destroy least tern nests. The possibility of moving the colony site to higher ground should be evaluated and, if deemed feasible, the site should be relocated or modified as needed.

212. Investigate and implement actions needed to increase populations of fish eaten by terns in degraded or potential tern feeding areas.

Tern use of a particular area is partly dependent upon food resources. Sufficient populations of fish of the appropriate size must be available. If sites with low fish numbers could be restored with a concomitant increase in forage availability,

it is anticipated that terns may begin to use the area, or their current use will increase. Thus, additional individuals could be supported.

2121. Mouth of Santa Ana River, southeast area.

This is a prime area to increase the fish forage supply for least terns. A study is needed to determine the best method to enhance fish populations.

2122. San Elijo Lagoon.

This area appears to have significant potential for increasing forage supplies for least terns. Necessary actions must be determined so that efficient strategies to increase fish numbers can be developed.

2123. Batiquitos Lagoon.

See item 2121.

2124. Other areas as needed.

See item 2121.

213. Identify major feeding areas.

Providing suitable fish resources for tern foraging is essential to enhance tern survivorship.

22. Protect important non-nesting, feeding, and roosting habitats from detrimental land or water use changes in San Luis Obispo, Santa Barbara and Los Angeles Counties.

Tern habitat has been drastically reduced from what was historically available. What remains should be protected so that further potential declines in tern numbers can be arrested. Terns must be provided suitable non-nesting habitat for roosting and feeding.

221. Oso Flaco and Dune Lakes (San Luis Obispo County).

California least terns use this area for a variety of non-nesting activities. It is important that the birds can continue to use these areas without adverse disturbance. Undue stress or disturbance may affect their survivability, success at obtaining sufficient food supplies, and predator avoidance; and thus, may influence the probability of tern recovery.

222. Santa Ynez River Mouth (Santa Barbara County).

This is a traditional feeding and roosting site used during

post-breeding dispersal. Management needs should be devised to protect these values.

223. Harbor Lake (Los Angeles County).

Terns are known to roost, feed, or loaf in this area. This is a particulary important post-breeding area where young of the year congregate in substantial numbers. These birds should not be disturbed.

224. Belmont Shores (Los Angeles County).

See item 221.

225. Identify and protect other habitats as needed.

Other areas may need protective measures. Once these areas are identified, site-specific actions may be proposed.

23. Protect important non-nesting, feeding and roosting habitats from detrimental land or water use changes in San Diego County.

Tern habitat has been drastically reduced from what was historically available. What remains should be protected so that further potential declines in tern numbers can be arrested. Terns must be provided suitable non-nesting habitat for roosting and feeding.

231. Guajome Lake.

239. San Diego River Flood Control Channel.

See item 221.

3. Monitor least tern population to determine status, distribution and progress of species management during the breeding season by conducting annual breeding colony surveys.

Population monitoring is necessary to evaluate the success of management actions and to modify such actions or implement new ones, if necessary.

31. Determine Breeding Success.

The only way to determine whether the prime objective has been obtained is to assess the number of breeding pairs, their distribution, and reproductive success. Surveys indicate when a colony is having difficulty and can provide an opportunity for biologists to quickly try to resolve problems that may arise (e.g., removal of predators). Breeding population surveys are needed annually in California and in Baja California. These

surveys will identify active colony sites, determine colony size and evaluate breeding success. This information is necessary for evaluating management and protection efforts. There is also a need to refine census techniques to reduce the time and costs involved in data collection, yet not sacrifice the quality of data.

311. Determine colony locations.

The location of individual colony sites must be determined before a comprehensive survey can be conducted.

312. Estimate breeding population size.

The size of the breeding population usually varies throughout the nesting season. Therefore censusing during the entire season is needed to arrive at a reasonable estimate of the number of pairs. Such information is beneficial in assessing the status of the recovery effort.

313. Conduct annual breeding colony surveys.

Even if many least terns are nesting, recovery will still only be achieved if reproductive success is sufficiently high to compensate for mortality losses and provide for a long-term tern stability. Breeding success is determined by the number of young that fledge per number of least tern pairs (or nesting attempts

in the case of renesting) which is ascertained during annual breeding colony surveys.

32. Investigate population dynamics, life history, and movement of terns.

Banding and marking least tern chicks can provide information on age-class structure, mortality rates, and estimates of longevity. These factors can be used to predict long-range stability of tern populations. Such information will include the degree of colony fidelity (i.e., the extent to which birds return to the same breeding area year after year), the degree of shifts between breeding colonies or the establishment of new ones, the age at first breeding, techniques for aging young birds in colonies, life expectancy, factors affecting clutch size, renesting attempts, and breeding success.

4. Conduct research on California least tern to provide additional necessary information for tern management.

Studies are needed to provide information to make appropriate management decisions. Many of these studies will entail banding and color marking large numbers of least tern chicks.

41. Determine effects of environmental pollutants on least terns.

Adverse effects from pollutants may affect terns' egg producing

abilities, the viability of eggs, and the fish food supply on which both the adults and young depend. The recovery effort could be thwarted by environmental contaminants. More information on this aspect of tern biology is needed. A substantial pesticide threat may occur from chemicals used for mosquito larvicide control. These may have high invertebrate toxicities. It is conceivable that pesticides could alter the benthic communities to such an extent that fish production or availability could be changed drastically. Agricultural fields near estuaries could also be affected (Faatz[1], pers. comm.).

42. Determine factors affecting the choice of location for roosting, loafing, and feeding areas used during the breeding season and during post-breeding dispersal.

Because such areas need to be protected against adverse land and water uses, factors that determine site selection by the birds should be assessed.

43. Determine how much habitat is necessary to maintain the current population and the prime recovery objective.

This information will provide a more concise estimate of the amount of habitat needed to ensure recovery. Components of

---

1 Dr. Wayne C. Faatz, Wildlife Biologist, Ecological Effects Branch, Environmental Protection Agency, Washington, D.C.

this determination include the number of hectares with the associated biomass of small fish being regularly used by the terns, the food requirements for a nesting pair, the minimum density of appropriate fish, and the amount of lagoons, bays etc. required to support a given number of terns through the nesting period (e.g., 100 pairs/40 ha of minimum fish density waters).

44. Identify potentially suitable nesting sites, including beach, landfill, salt pond and estuarine areas.

Wildlife biologists need additional information regarding what constitutes suitable nesting habitat so that they can concentrate management efforts (i.e. enhancement of potential nest sites) in such areas.

45. Identify factors causing colony disruption and nest site abandonment.

It is unfortunate that terns fairly frequently abandon nesting colonies. This tendency is especially prevalent early in the nesting season and has tentatively been correlated to disruption (mainly by predators). Early in the nesting season initial colony surveys should be done from a distance to minimize disturbance. A more detailed appraisal on the causes of disruption and abandonment of colony sites is needed so that remedial measures may be implemented.

46. Develop or refine management techniques for providing adequate nesting sites and implement techniques where needed.

Additional information is required on nest site management so that reproductive success can be enhanced.

461. Investigate nest site requirements of colonies.

If tern nest site requirements are thoroughly understood, appropriate nest enhancement procedures can be implemented.

462. Investigate methods of enhancing nesting sites of existing colonies.

Various types of nest enhancement procedures should be undertaken and evaluated so the most effective means of habitat improvement can be determined.

463. Investigate methods of constructing adequate nesting sites in potential breeding habitat.

Some areas of potential habitat will require rehabilitation. Construction techniques need to be refined so that they are economical and efficient.

5. Encourage the protection of breeding population outside the United States

Recovery of California least terns will be partly dependent on successful protection and management of those terns nesting in Baja California. Once the status, including distribution, numbers, and threats, has been determined, the importance of Mexican populations to overall least tern recovery can be ascertained.

51. Protect least tern population and habitats in Baja California.

California least terns are known to nest in Baja California. Suitable protection measures must be undertaken to ensure the terns' continued reproductive success in this area, thus aiding the recovery effort.

511. Determine colony locations and population size.

The first step in managing the Baja least terns is to determine the size and location of each colony. The number of breeding terns in Baja California is unknown, hence their potential contribution to the recovery effort can not be assessed at this time.

512. Identify least tern population and habitatprotection problems.

Each colony should be monitored and evaluated to determine what, if any, problems exist. Once the problems have been described then measures to counteract them can be developed and initiated. The security and future management plans for specific sites must be considered in the evaluation of the impact of Baja California's least terns on recovery.

513. Develop cooperative programs between the United States and Mexican governments for least tern protection and habitat preservation.

A cooperative program is necessary to coordinate the recovery effort for this subspecies and to ensure that appropriate conservation actions are taken by both parties.

52. Identify and protect key migration and winter habitats outside the United States.

Preliminary surveys have been conducted to identify wintering habitat of the California least tern. Additional work is needed to further define key migration and wintering habitat so it can be adequately protected and managed. This is particularly important because of a recent drastic (25% or more) decline in the number of terns returning from the wintering grounds to breed in the U.S. Without more precise

information on the location(s) and conditions on the wintering grounds, it is difficult to delineate the specific problems that are causing the decline in population numbers. Clearly, obtaining data on wintering birds is thus becoming increasingly important and crucial to tern conservation. The population cannot tolerate a yearly loss of such a large proportion of the adults.

6. Utilize existing laws and regulations protecting least tern and their habitat.

Recovery is dependent upon the judicious enforcement of rules and regulations designed to prevent losses of birds and to enhance population status.

61. Evaluate success of law enforcement.

To maximize least tern protection, an appraisal of the law enforcement strategy should be routinely conducted. Modifications in the strategy to increase efficiency can then be recommended.

62. Propose appropriate new regulations or revisions.

If it becomes evident that additional regulations or a modification of existing provisions are necessary to adequately protect terns, such changes should be expeditiously proposed.

7. Develop and implement a conservation education program regarding recovery of California least tern.

Public support is generally enhanced when the public is informed of the conditions of an endangered species and the steps necessary to conserve it. This may be accomplished through a series of pamphlets, informational signs posted near selected habitats and audio-visual programs for local schools.

PART III

IMPLEMENTATION SCHEDULE

The schedule that follows is a summary of actions and costs for the California least tern recovery program. It is a guide to meet the objectives of the Recovery Plan, as elaborated upon in Part II, Action Narrative Section. This table indicates the general category for implementation, recovery plan tasks, corresponding step-down outline number, task priorities, duration of the tasks, which agencies are responsible to perform the tasks, and the estimated costs to perform the tasks. General categories and priority numbers are defined on the following page. Note that priority 3 tasks, contrary to the usual format of recovery plans, are included because recovery of this subspecies is well underway and few priority 1 items remain to be done. Implementing Part III is the action of the recovery plan, that when accomplished, will bring about the recovery of this endangered species.

GENERAL CATEGORIES FOR IMPLEMENTATION SCHEDULES

Information Gathering - I or R (research)

1. Population status
2. Habitat status
3. Habitat requirements
4. Management techniques
5. Taxonomic studies
6. Demographic studies
7. Propagation
8. Migration
9. Predation
10. Competition
11. Disease
12. Environmental contaminant
13. Reintroduction
14. Other information

Acquisition - A

1. Lease
2. Easement
3. Management Agreement
4. Exchange
5. Withdrawal
6. Fee title
7. Other

Management - M

1. Propagation
2. Reintroduction
3. Habitat maintenance and manipulation
4. Predator and competitor control
5. Depredation control
6. Disease control
7. Other management

Other - O

1. Information and education
2. Law enforcement
3. Regulations
4. Administration

RECOVERY ACTION PRIORITIES

1 = An action that must be taken to prevent extinction or to prevent the species from declining irreversibly.
2 = An action that must be taken to prevent a significant decline in species population/habitat quality, or some other significant negative impact short of extinction.
3 = All other actions necessary to provide for full recovery of the species.

[1] Continuous - once a task is begun it will continue.

Ongoing = currently underway.

[2] Agency abbreviations:

AF - U.S. Air Force

BCDC - San Francisco Bay Conservation and Development Commission

CDFG - California Department of Fish and Game

CDPR - California Department of Parks and Recreation

CE - Corps of Engineers

EPA - Environmental Protection Agency

FAA - Federal Aviation Administration

FS - Fauna Silvestre (Mexico)

LA City - Los Angeles City

LE - Law Enforcement (U.S. Fish and Wildlife Service)

NABC - Naval Amphibious Base, Coronado

OCHPBD - Orange County Harbor, Beaches and Park Department

RE - Refuges (U.S. Fish and Wildlife Service)

SDCPR - San Diego County Department of Parks and Recreation

SDGE - San Diego Gas and Electric

SDUPD - San Diego Unified Port District

SE - Endangered Species (U.S. Fish and Wildlife Service)

SLC - State Lands Commission

SWRCB - State Water Resources Control Board

USM - U.S. Marine Corps

USN - U.S. Navy

[3] TBD = to be determined

ACKNOWLEDGEMENTS

We would like to acknowledge Darcy Jones, State Water Resources Control Board (SWRCB), and Diane Fleck, U.S. Environmental Protection Agency Region 9, for information and discussion on bioaccumulation factors, translators, and implementing the methylmercury criterion. We would also like to acknowledge Lauren Petruzzi and Eloise Castillo, Science Applications International Corporation (SAIC) for providing additional information on the database containing California water and fish data compiled by SAIC for the SWRCB (referred to as the SWRCB database in this report). We would like to thank Bruce Hope and Diane Fleck for comments on the draft report.

EXECUTIVE SUMMARY

The U.S. Environmental Protection Agency (U.S. EPA) has established an ambient water quality criterion for methylmercury in fish tissue of 0.3 ppm, for the protection of human health (U.S. EPA, 2001). A criterion based on fish tissue was considered appropriate for methylmercury, in part, because fish consumption is the major route of human exposure to this contaminant (U.S. EPA, 2001). As effluent standards are necessarily water-based, and must also account for the bioaccumulation of mercury in the aquatic environment, U.S. EPA drafted a report, National Bioaccumulation Factors for Methylmercury, (U.S. EPA, 2000) describing the derivation of national bioaccumulation factors[1] (BAFs) that can be used to convert between methylmercury tissue concentrations in various fish species and water concentrations for regulatory applications. The State Water Resources Control Board (SWRCB) funded the Office of Environmental Health Hazard Assessment to evaluate these national default bioaccumulation factors, as well as translators used to convert between different forms of mercury in water, and bioaccumulation factors derived from California data for mercury in fish and water compiled by Science Applications International Corporation (SAIC) for SWRCB into a SWRCB database.

OEHHA reviewed U.S. EPA's methods and results as presented in their report and describes their methodology, results, strengths and weaknesses of their approach, and its application to California water bodies in this report. OEHHA also reviewed the SWRCB database and BAF values, and developed alternate BAFs and translators based on California data that are analogous to those of U.S. EPA. OEHHA compared the U.S. EPA BAFs and translators to those based on California data and also tested the U.S. EPA values to determine how well they predicted fish tissue concentrations in California water bodies.

OEHHA found that U.S. EPA's methods and results met their goal of developing BAFs and translators that were broadly applicable, especially for lentic and lotic water bodies. U.S. EPA made a careful effort to compile available data and ensure quality control for the data they used. Despite their efforts, they were not able to compile data representative of all of the categories of aquatic environments and organisms. In particular, they were unable to develop BAFs for estuarine environments due to gaps in available data. U.S. EPA included some data from California in their database, but most of their data came from the Midwest United States and other areas where the source of mercury in water bodies was atmospheric deposition.

Examining data exclusively from California water bodies was an important step in evaluating whether BAFs and translators were applicable to California since the source of mercury in much of California has been legacy mercury and gold mining, and because environmental conditions in California water bodies may be different than in other areas in the U.S. EPA database. OEHHA recalculated California BAFs using the SWRCB California database. OEHHA also calculated translators for some forms of mercury using data available in this database. There were gaps in available data in the SWRCB database that prevented OEHHA from developing BAFs for some water body types (*e.g.* lentic) or trophic levels and translators for some forms of mercury in water. OEHHA developed BAFs for organisms in lotic environments and demonstrated that they

[1]A bioaccumulation factor is the ratio between the concentration of a chemical measured in an organism and the concentration of the same chemical in water. This ratio is derived from field-collected samples of organisms and water.

were very similar to the U.S. EPA BAFs. OEHHA also developed California estuarine BAFs for some trophic levels but there are no national values for comparison. OEHHA's estuarine values, however, were also similar to the national default values. Translators developed from the SWRCB California data were also similar to the U.S. EPA translators.

U.S. EPA developed translators and BAFs but did not test them to determine how accurately they predicted fish tissue mercury concentrations from water concentrations. OEHHA was able to test the U.S. EPA national translators and BAFs to see if they accurately predicted mercury levels in fish for several California lotic water bodies by using the SWRCB California database. OEHHA found that the national values predicted California values very well (*i.e.*, no statistical difference between measured and predicted mercury concentration) except for some water bodies where mercury concentrations in water were statistically higher. It was not possible to perform similar tests for fish in other types of water bodies because data were not available in the SWRCB database.

OEHHA has identified three alternatives for consideration by SWRCB when selecting BAFs and translators to use for California water bodies in order to implement the U.S. EPA ambient water quality criterion for methylmercury: 1) use the U.S. EPA BAFs and translators as developed by U.S. EPA; 2) use some BAF (*i.e.*, lotic BAFs) and translator values developed from the California database, and others developed by U.S. EPA; 3) before using BAFs and translators for a methylmercury criterion, institute a program of data gathering that would supplement existing data in the SWRCB California database and enable development and testing of additional BAFs and translators using California data from different types of water bodies throughout the state. Alternative 1 is a practical solution that could be implemented without collecting additional data and would be consistent with national implementation. Based on OEHHA's evaluation using available data, it will also yield predictions that are similar to measured concentrations of mercury in fish for many, but not all, lotic water bodies. It is unknown how well this alternative will work for other California water bodies. Alternative 2 is appealing because it would incorporate California data and values for lotic water bodies, but due to gaps in the data available in the current SWRCB database it would also require using national values for lentic water bodies and some translators. However, since OEHHA's evaluation found no significant difference between U.S. EPA and California values based on the existing database, there is no scientific basis to support this alternative over Alternative 1. Alternative 3 would require collecting additional data on mercury concentrations in water and biota before full implementation and should include establishing standards for sampling, analytical methods, and Quality Assurance/Quality Control before data collection begins. Additional data collection is important to consider because OEHHA was not able to test Alternative 1 for California lentic and estuarine water bodies using the current datasets and because some water bodies were identified where Alternative 1 did not work well.

SWRCB could consider using Alternative 1 on an immediate basis while collecting additional California data for mercury concentrations in fish and water to fill gaps in available data, help identify biogeochemical factors with the greatest impact on methylmercury production and bioaccumulation, and better characterize how these factors affect variability in BAFs and translators in a longer term effort to develop better BAFs and translators for California. In

particular more fish and water data are needed to fill gaps in available data for: 1) developing lentic BAFs and translators; 2) for developing estuarine translators and BAFs for estuarine Trophic Level 3 biota; and 3) to collect enough data to test lentic and estuarine BAFs and translators. SWRCB should consider prioritizing data collection based on which type(s) of water bodies are most impacted by regulatory implementation.

Collecting data that represent a broader geological and ecological coverage of water bodies is recommended to verify, explain, and expand OEHHA's observation that the U.S. EPA BAFs did not work well for water bodies with higher mercury concentrations (approximately $2x10^{-7}$ mg/L or more). The concentration of mercury from these water bodies was found to be more than one standard deviate from the mean for data used in testing from the SWRCB dataset. This concentration and level of variation should not be considered as screening points for outlier water bodies. Rather this observation suggests that there are water bodies and conditions in California for which the U.S. EPA BAFs and translators may not work well or be appropriate. Additional data are needed to identify these water bodies and conditions (*e.g.,* salinity or mercury source) so that the national BAFs are not applied to them and so that better translators and BAFs are developed for them.

Collecting additional California data is also recommended to better characterize variability in mercury concentration in California water bodies and biota. Natural variability in mercury concentrations will occur in water and fish from any water body. Statistical tests, such as those used by OEHHA to test BAF predictions, will account for this variability when testing for true differences among water bodies. But statistical testing is not typically used in regulatory applications and permits. One way to recognize variability in a regulatory setting would be to collect more data to separate variablility due to environmental differences from variablility common to all environments and use this to further verify predictions and set regulatory limits.

Further data and testing would put BAFs and translators on a more sound scientific footing in California and provide data to determine whether the mining source of much of the mercury in California water bodies (at least in the Central Valley, northern California, and the Coast Ranges) lead to significant differences in BAFs and translators for some parts of the state.

1. INTRODUCTION

The U.S. Environmental Protection Agency (U.S. EPA) has established an ambient water quality criterion for methylmercury in fish tissue of 0.3 ppm, for the protection of human health (U.S. EPA, 2001). This is the first ambient water quality criterion established in tissue rather than in water. A criterion based on fish tissue was considered appropriate for methylmercury, in part, because fish consumption is the major route of human exposure to this contaminant (U.S. EPA, 2001). As effluent standards are necessarily water-based, and must also account for the bioaccumulation of mercury in the aquatic environment, U.S. EPA drafted a report, National Bioaccumulation Factors for Methylmercury, (U.S. EPA, 2000) describing the derivation of national bioaccumulation factors[2] (BAFs) that can be used to convert between methylmercury tissue concentrations in various fish species and water concentrations for regulatory applications. This draft report has not been finalized, but a draft implementation plan is being developed that explains a national policy to use methylmercury bioaccumulation factors in water quality regulations and permit writing (personal communication, Diane Fleck, U.S. EPA Region 9). Although the U.S. EPA report and related policies have not been adopted, the California State Water Resource Control Board (SWRCB) has begun consideration of the national bioaccumulation factors and an implementation policy to use such factors for regulation of methylmercury in ambient waters in California.

As bioaccumulation factors for different fish species may differ significantly based on environmental pH, redox potential, temperature, alkalinity, buffering capacity, suspended sediment load, and geomorphology in individual water bodies (Andren and Nriagu, 1979; Berlin, 1986; WHO, 1989), the SWRCB funded the Office of Environmental Health Hazard Assessment (OEHHA) to evaluate the derivation of national bioaccumulation factors for methylmercury and the potential for using these factors, or alternate factors based on California data, for California water bodies. OEHHA has organized this evaluation into three parts: 1) a description and critique of the national bioaccumulation factors; 2) a description and critique of California bioaccumulation factors calculated from a database of California water and tissue concentrations (referred to in this report as the SWRCB database) compiled by Science Applications International Corporation (SAIC) for SWRCB; and 3) a description and critique of a simulation in which national and California bioaccumulation factors are used to predict tissue levels from water concentrations in sample California water bodies. As part of this report, OEHHA also describes and critiques national and California translators[3] for mercury and methylmercury where possible.

[2] A bioaccumulation factor is the ratio between the concentration of a chemical measured in an organism and the concentration of the same chemical in water. This ratio is derived from field-collected samples of organisms and water.

[3] Translators are ratios between one form of a chemical and another form in the same media. In this case, the translators are for different forms of mercury in water and are based on field-collected samples.

2. U.S. EPA'S DEVELOPMENT OF BAFs FOR LENTIC AND LOTIC ENVIRONMENTS

U.S. EPA's BAF report (U.S. EPA, 2000) served as the primary source of information on U.S. EPA's derivation of national bioaccumulation factors and translators for OEHHA's evaluation. A brief description of the national values for BAFs and translators was also included in the final document establishing the methylmercury tissue criterion (U.S. EPA, 2001). U.S. EPA has subsequently published a final technical support document describing methods to develop bioaccumulation factors for a variety of chemicals (U.S. EPA, 2003). U.S. EPA stated that the goals for developing national methylmercury BAFs were to "represent the long-term [central tendency] bioaccumulation potential of methylmercury in aquatic biota that are commonly consumed by humans throughout the United States," and "to be applicable under as many circumstances and to as many water bodies as possible" (U.S. EPA, 2000). The national methylmercury BAFs would serve as default values that could be used when regional or other local values are not available.

U.S. EPA selected studies containing empirical field-collected data for co-located mercury or methylmercury concentrations in fish and water from a literature search and created a database that they used to calculate BAFs for aquatic organisms in Trophic Level 2, 3, and 4 (*i.e.*, the trophic levels[4] used to set the tissue criterion). Studies of lotic, lentic, and estuarine water bodies were included in the database. Study data had to meet certain standardized criteria for analytical chemistry data (*e.g.*, be reproducible, have a low detection limit, minimal matrix interferences, and use appropriate analytical techniques) to be included in the database. In most cases, methylmercury results collected prior to 1990 were not used because they did not meet these criteria. A cutoff was set for the literature review and studies published after April 1999 were not included in the literature search or resulting database. The database itself was not available for OEHHA to review, so it was not possible to determine exactly which data were used by U.S. EPA, or to carry out calculations using the raw database data. Instead, it was necessary to use the summary information in the draft U.S. EPA document (U.S. EPA, 2000) to describe the U.S. EPA data and carry out comparative calculations.

U.S. EPA used methodology from the Ambient Water Quality Criteria Derivation Methodology Human Health Technical Support Document, Final Draft (U.S. EPA, 1998) and the Mercury Study Report to Congress (U.S. EPA, 1997a) to derive their national BAF and translator values. Fish were assigned to trophic levels based on U.S. EPA guidance (U.S. EPA, 1995) and information from the selected studies. There were some exceptions to these methods and guidelines. In some cases, zooplankton, which are not consumed by humans, were used to calculate Trophic Level 2 BAFs. And in other cases, mercury concentration data in Trophic Level 3 and 4 fish were based on whole body data or tissue samples not clearly identified as

[4] Trophic means eating. Trophic levels are steps in a food chain characterized by feeding interactions. Energy moves up the food chain from lower to higher trophic levels as a result of organisms in one level feeding on those in a lower level. Organisms in Trophic Level 1 are primary producers that fix energy in an ecosystem (*e.g.*, plants and other organisms that fix energy. Trophic Level 2 organisms are herbivorous and feed on the primary producers. In aquatic ecosystems Trophic Level 3 organisms eat the herbivores and are forage fish for the next level. Trophic Level 4 organisms are carnivorous and eat primarily Trophic Level 3 organisms. In aquatic ecosystems these are the top predatory fish. Humans mostly eat fish and other aquatic organisms from Trophic Level 3 and 4.

fillet, muscle, whole body, or other tissue types. U.S. EPA attempted to treat all samples equally when deriving trophic level BAFs by first calculating individual mean BAFs for species in Trophic Level 3 and 4 within studies and then calculating a mean for all species in the same trophic level. This was not always possible for Trophic Level 2 because zooplankton collections contain a mix of species. It is not possible to describe the treatment of data and samples in detail without the full database and associated information. U.S. EPA expressed both species and trophic level BAFs as unweighted geometric means. The U.S. EPA BAF report does not discuss statistical testing of the distributions of individual studies or the database data at the species or trophic level, but states that geometric means were used primarily because the factors underlying BAF variability were believed to be multiplicative rather than additive, and also in part for convenience (U.S. EPA, 2000).

U.S. EPA derived BAFs using the ratio of methylmercury in field-collected data from biota and water as shown in Equation 1. Mercury in biota was most often measured and reported as total mercury (which can include inorganic and methylmercury). When only total mercury was reported in studies, U.S. EPA made assumptions about the percent of total mercury that was methylmercury for organisms at Trophic Levels 2, 3, and 4 in different environments. Equation 1 is a simple empirical model estimating the magnitude of accumulation of methylmercury from water into biota (*e.g.*, zooplankton and fish). BAFs calculated using this equation only require two parameters (a tissue concentration and a water concentration) and have units of L/kg because generally mercury concentrations in water are reported in mg/L and concentrations in biota are reported in mg/kg (wet weight). More complex mechanistic models that use multiple parameters to model individual steps in methylmercury production, uptake, and accumulation have also been used to estimate the relationship between methylmercury in water and biota (Hope, 2003; Kamman, *et al.*, 2003). More complex models would require a great deal more data than was available in most studies in the U.S. EPA database.

Equation 1.

$$\text{BAF, L/kg} = \frac{\text{mercury in biota, mg/kg}}{\text{dissolved methylmercury in water, mg/L}}$$

Using Equation 1 and data in their database, U.S. EPA calculated BAFs for organisms in lentic (*e.g.*, lakes) and lotic (*e.g.*, rivers) water bodies for the trophic levels used to establish the ambient water criterion (Trophic Levels 2, 3, and 4) for methylmercury (U.S. EPA, 2001). U.S. EPA chose to combine the BAFs at the same trophic level for lentic and lotic water bodies into one national BAF for each trophic level. U.S. EPA did not derive BAFs for the estuarine environment because of insufficient data.

U.S. EPA suggests that the national BAFs are functional default values that can be used when more representative regional, local or site-specific BAFs are not available (U.S. EPA, 2003). BAFs can be used to solve for the numerator or denominator in the above equation when the other is known, *i.e.*, by using the appropriate BAF, a concentration of methylmercury in biota can be calculated from known dissolved methylmercury concentrations in water, or a water

concentration of dissolved methylmercury can be calculated from known biota methylmercury concentrations.

U.S. EPA also used data from their database to calculate national translator values to convert between various forms of mercury in water (*e.g.*, between total mercury and dissolved methylmercury). Their translator values were calculated as simple ratios between one mercury form and another. U.S EPA calculated separate geometric mean national translators for lentic and lotic environments (U.S. EPA, 2000). U.S. EPA did not discuss why they did not combine translators as they had done for national BAFs. Translators were essential to the U.S. EPA's derivation of BAFs because many measurements of water mercury concentrations in studies included in the U.S. EPA database were for a form other than dissolved methylmercury. Initially, U.S. EPA calculated BAFs based on studies that had directly measured dissolved methylmercury in water; these were "directly estimated" BAFs. U.S. EPA then used the national translators to convert water measurements from other studies into dissolved methylmercury to calculate additional BAFs. These were termed "converted" BAFs, and using them increased the number of studies and data in the U.S. EPA database. U.S. EPA combined directly estimated and converted BAFs to derive the national values. U.S. EPA's derivation of the national BAFs for Trophic Levels 2, 3, and 4 is discussed in more detail below. U.S. EPA did not develop BAFs for Trophic Level 1 as these primary consumers are not normally eaten by humans.

Directly estimated BAFs for lentic or lotic environments are those from studies where dissolved methylmercury was measured in water and then used in the calculation of the BAF. U.S. EPA defined the directly estimated BAF for each trophic level as the average methylmercury concentration (often measure as total mercury) accumulated by all possible routes of exposure in organisms of that trophic level, divided by the average directly measured dissolved methylmercury concentration in water.

Converted BAFs for lentic or lotic environments, on the other hand, were defined as the average methylmercury concentration in each trophic level (often measured as total mercury) accumulated by all possible routes of exposure, divided by the dissolved methylmercury concentration in water obtained from conversion of measured total mercury to dissolved methylmercury using the appropriate translator determined from other studies.

2.1 U.S. EPA BAFs FOR LENTIC ENVIRONMENTS

2.1.1 Directly Estimated Trophic Level 2 BAFs, Lentic Environments

The BAFs for zooplankton in lentic environments for Trophic Level 2 are listed in Table 3-1 in the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). Two studies were used to develop the BAFs: one, which evaluated 15 lakes in Wisconsin (Watras *et al.*, 1998), and another, which surveyed 12 lakes in northeast Minnesota (Monson and Brezonick, 1998). As noted above, total mercury, rather than methylmercury, was measured in zooplankton and Trophic Level 2 organisms in many studies. In order to calculate BAFs for these and other studies in their database, U.S. EPA assumed that 44 percent of the measured total mercury in biota in lentic environments for this trophic level was methylmercury. U.S. EPA calculated

geometric mean BAF values for the Wisconsin and Minnesota studies of 42,400 L/kg and 172, 764 L/kg, respectively, and a combined geometric mean BAF of 85,600 L/kg.

2.1.2 Directly Estimated Trophic Level 3 BAFs, Lentic Environments

The U.S. EPA assumed that 100 percent of the mercury measured as total mercury in this trophic level was methylmercury. BAFs for this trophic level (forage fish) were developed from five studies and are listed in Table 3-2 in the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). U.S. EPA derived a combined BAF of 504,000 L/kg for shiner and yellow perch in 15 Wisconsin lakes using data from Watras *et al.*, (1998). Using data from Becker and Bigham (1995), U.S. EPA derived a BAF of 666,666 L/kg for gizzard shad from Lake Onondaga, New York. A BAF of 1,460,000 L/kg for yellow perch at Lake Iso Valkjarvi, Finland, was generated from Rask and Verta (1995), while a combined BAF of 1,530,000 L/kg was established for silversides and juvenile bass in Clear Lake, California, using data from Suchanek *et al.* (1993). The Suchanek data include silversides, a fish not usually consumed by humans. It is, nevertheless, a species that probably falls in this trophic level. Finally, U.S. EPA used data from Mason and Sullivan (1997) to develop a BAF of 4,170,000 L/kg for bloater in Lake Michigan. The geometric mean BAF values for these five studies ranged from 504,000 L/kg to 4,170,000 L/kg, a difference of less than 10-fold despite the wide geographic distribution of these studies (United States and Finland). The overall combined geometric mean BAF determined by U.S. EPA for this trophic level was 1,260,000 L/kg.

2.1.3 Directly Estimated Trophic Level 4 BAFs, Lentic Environments

Fish in Trophic Level 4 are predatory and feed predominantly on other fish. U.S. EPA assumed that the measured total mercury in these species was 100 percent methylmercury. Four North American studies were used in the BAF calculations; results are summarized in Table 3-3 in the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). U.S. EPA derived a combined BAF of 4,000,000 L/kg for smallmouth bass and walleye from Lake Onondaga, New York based on data in Becker and Bigham (1995), and an overall BAF of 5,860,000 L/kg for northern pike and walleye in four lakes in Manitoba, Canada, studied by Jackson (1991). Using data from Suchanek, *et al.*, (1993) from Clear Lake, California, U.S. EPA derived a BAF of 8,060,000 L/kg for largemouth bass. And finally, U.S. EPA used data from Mason and Sullivan (1997) to derive a BAF of 11,400,000 L/kg for lake trout from Lake Michigan. The BAFs for these studies ranged from 4,000,000 L/kg to 11,400,000 L/kg, a difference of less than three-fold. The geometric mean BAF for these studies was 6,800,000 L/kg.

2.1.4 Converted Trophic Level 2 BAFs, Lentic Environments

When mercury was measured as total mercury, U.S. EPA assumed that 44 percent was methylmercury for this trophic level. Five studies, all from North America, were used in these BAF calculations. The study results are summarized in Table 5-4 in the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). U.S. EPA derived an aggregate BAF of 61,757 L/kg, for zooplankton from 15 Wisconsin lakes using data from Watras *et al,* (1998). A BAF of 104,405 L/kg for zooplankton collected on an 80 μm filter in several lakes in the Experimental Lakes Region in NW Ontario, Canada, was derived from Paterson *et al.* (1998). A second BAF of 283,850 L/kg for zooplankton collected on a 400 μm filter was also derived

from Paterson *et al.*, (1998). An aggregate BAF for zooplankton (filter size >300 μm) from 12 lakes in Minnesota of 127,000 L/kg was developed from Monson and Brezonick (1998); a second BAF of 326,264 L/kg for plankton (filter size[1] not reported) from Tamarack Lake, Minnesota, was derived from data from the same study. The BAFs from these studies ranged from 61,757 to 326,264 L/kg, a difference of slightly more than six-fold. The unweighted BAF geometric mean for these studies was 149,960 L/kg.

2.1.5 Converted Trophic Level 3 BAFs, Lentic Environments

U.S. EPA assumed that measured total mercury was 100 percent methylmercury for this trophic level. Data from the four studies used to derive BAFs for this trophic level are summarized in Table 5-5 in the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). All studies were from the Midwestern United States. An aggregate BAF of 734,095 L/kg for shiner and yellow perch from 15 Wisconsin lakes was derived from Watras *et al.* (1998). Data from Glass *et al.* (1992) were used to derive a BAF of 1,022,326 L/kg for yellow perch from Sand Point Lake, Minnesota, and a BAF of 1,297,052 L/kg for yellow perch from Crane Lake, Minnesota. Finally, a BAF of 3,262,643 L/kg was derived for young-of-the-year bluegill (*i.e.*, fish in the same age cohort that were less than one year old) at Tamarack Lake, Minnesota, based on data from Monson and Brezonick, (1998). These immature bluegill had the highest BAF in the reported studies, although they are too small for human consumption. BAFs in this age class of fish might reflect high intake prior to subsequent growth dilution. Some unknown amount of variation will be introduced when studies using fish of different ages and sizes are combined because mercury levels in fish are known to vary with age and size (Wiener, *et al.*, 2003). The geometric mean BAF value for these studies was 1,330,000 L/kg, with values ranging from 734,095 to 3,262,643 L/kg. This less than five-fold range, while still broad, is smaller than the approximately 10-fold range for directly measured BAFs in Trophic Level 3 fish. The closer geographic proximity of these studies and similarities in species used to derive BAFs might account, in part, for the tighter range. However, the results also show that there remains a broad range in BAFs from different lakes even when the lakes are from a more restricted geographic area.

2.1.6 Converted Trophic Level 4 BAFs, Lentic Environments

U.S. EPA assumed that 100 percent of measured total mercury was methylmercury for this trophic level. BAF values from two studies are summarized in Table 5-6 in the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). A BAF of 3,954,284 L/kg for walleye from various unspecified Lakes in Minnesota was derived from Glass *et al*. (1999), and a BAF of 4,203,000 L/kg was derived for pike from the same study. The geometric mean for these data was 4,100,000 L/kg.

[1] The US EPA did not regularly report filter sizes for each study. When they were reported, they are noted. Different size filters will capture different sizes and kinds of planktonic organisms. This introduces an unknown amount of variability in BAFs for this trophic level.

2.1.7 Combined Direct and Converted BAFs, Lentic Environments

The U.S. EPA combined the direct and converted BAFs for Trophic Levels 2, 3, and 4 for lentic ecosystems to obtain the values presented in Table 1 of this report. U.S. EPA stated that it was justified to combine the direct and converted data into a composite value because, when graphically displayed, the data appeared to be in the same range. U.S. EPA did not statistically test for differences in the means between direct and converted BAFs for each trophic level. Statistical testing may have been limited by the available small dataset.

The differences between the geometric mean direct and converted BAFs in Trophic Levels 2, 3, and 4 were less than two-fold for each trophic level. For Trophic Levels 2 and 3, the converted BAF is higher than the directly measured BAF. For Trophic Level 4, the directly measured BAF was higher than the converted BAF. The combined geometric mean for direct and converted BAFs shows that the BAF for Trophic Level 3 is about 10-fold greater than that for Trophic Level 2 (1,115,000 vs. 127,000 L/kg), and the BAF for Trophic Level 4 is about five-fold greater than the BAF for Trophic Level 3 (5,740,000 vs. 1,115,000 L/kg).

Table 1. Direct and converted Bioaccumulation Factors (L/kg) for trophic levels in the lentic environment*

Trophic level	**2**		**3**		**4**	
BAF	Direct	Converted	Direct	Converted	Direct	Converted
GM[1/]	85,600	150,000	1,260,000	1,330,000	6,800,000	4,080,000
Combined GM[2/]	127,800		1,115,000		5,740,000	

1 GM: Geometric Mean
2 Geometric Mean (GM) after combining direct and converted BAFs for the lentic environment

. *Summarized from Tables 5-12, 5-14 (U.S. EPA, 2000)

2.2 U.S. EPA BAFs FOR LOTIC ENVIRONMENTS

2.2.1 Directly Estimated Trophic Level 2 BAFs, Lotic Environments

U.S. EPA assumed that 49 percent of the total mercury measured in organisms in lotic environments at this trophic level was methylmercury. U.S. EPA used data from three studies to derive these BAFs. Data from a study in the North Florida Everglades reported by Cleckner *et al.*, (1998) for whole body fish samples from three species (*Gambusia sp*., *Heterandia formosa*, and *Lucanian goodie*) were combined to obtain a BAF of 34,474 L/kg. Another study by Miles and Fink, (1998), also in the North Florida Everglades, was used to derive a BAF of 271,831 L/kg. Finally, a BAF of 608,728 L/kg for stonerollers, which are zooplankton, was derived from a study in East Popular Creek, Tennessee (Hill *et al.*, 1996). The unweighted geometric mean for these studies was 178,678 L/kg. Since only three studies met U.S. EPA's criteria, fish and zooplankton were used for derivation of the BAF for this trophic level. These data are listed in Table 5-7 of the National Bioaccumulation Factors for Methylmercury U.S. EPA, (2000).

2.2.2 Directly Estimated Trophic Level 3 BAFs, Lotic Environments

U.S. EPA assumed that 100 percent of the measured total mercury was methylmercury for this trophic level (forage fish). Studies by Lores *et al.* (1998) in South Florida canals provided data for the following BAFs: spotted tilapia: 334,325 L/kg; bluegill: 1,286,156 L/kg; and spotted sunfish: 1,472,669 L/kg. Data for bluegills from a study in the North Florida Everglades (Miles and Fink, 1998) yielded a BAF of 577,465 L/kg. Data from studies on creeks in Tennessee yielded a BAF of 2,026,609 for shiner (Hill *et al.*, 1996) and 4,863,263 L/kg for redbreast (DOE, 1997). A second BAF for redbreast of 11,250,000 L/kg was also derived (DOE, 1997). The geometric mean for these data was 1,636, 298 L/Kg, with a substantial range of about 34-fold. These data are presented in Table 4-2 in the National Bioaccumulation Factors for Methylmercury U.S. EPA, (2000).

2.2.3 Directly Estimated Trophic Level 4 BAFs, Lotic Environments

U.S. EPA assumed that 100 percent of the measured total mercury was methylmercury for this trophic level (piscivorous fish). Two studies were used to estimate the BAF for this trophic level. One study of largemouth bass in the Florida Everglades yielded a BAF of 985,915 L/kg (Miles and Fink, 1998). Another study of largemouth bass in some South Florida Canals yielded a BAF of 6,464,028 L/kg (Lores *et al.*, 1998). The geometric mean for these data is 2,524,477 L/kg. These data are presented in Table 4-3 in the National Bioaccumulation Factors for Methylmercury U.S. EPA, (2000).

2.2.4 Converted Trophic Level 2 BAFs, Lotic Environments

U.S. EPA assumed that 49 percent of the measured total mercury was methylmercury for this trophic level. U.S. EPA used three studies to derive the BAF for this trophic level. Data from a study in the Tom River in Siberia (Papina, *et al.*, 1995) yielded a BAF of 8,661 L/kg for zooplankton. Data from Stober *et al*. (1995) yielded a BAF of 105,128 L/kg for mosquitofish in South Florida Everglade canals. Finally, data from Miles and Fink, (1998) from the north Florida Everglades yielded a BAF of 260,811 L/kg, also for mosquito fish. The unweighted geometric mean for these data was 62,000 L/kg, with a nearly 30-fold difference in converted BAF values for this trophic level. Data are listed in Table 5-8 in the National Bioaccumulation Factors for Methylmercury U.S. EPA, (2000). The small number of studies available and wide geographic range may have contributed to the difference in the BAFs between the studies.

2.2.5 Converted Trophic Level 3 BAFs, Lotic Environments

U.S. EPA assumed that 100 percent of the measured total mercury was methylmercury for this trophic level. Acceptable data from seventeen studies were used from various geographic regions for this BAF. Six studies in the Tom River in Siberia, Papina *et al.*, (1995) yielded the following BAFs for six different species: grayling: 35,238 L/kg; carp: 52,857 L/kg; roach: 70,476 L/kg; perch: 79,286 L/kg; dace: 132,143 L/kg; and bream: 211,429 L/kg. Data from Glass *et al.* (1992), for St. Louis River in Minnesota yielded the following BAFs for five different species: yellow perch: 345,622 L/kg; Johnny darter: 391,705 L/kg: log perch: 460,829 L/kg; spottail shiner: 691,244 L/kg; and emerald shiner: 921,659 L/kg. Studies in South Florida Canals by Lores *et al* (1998) yielded data to derive BAFs for spotted sunfish (524,381 L/kg),

bluegill (933,810 L/kg), spotted tilapia (1,132,656 L/kg), and mayan cichlid (1,326,049 L/kg). Data from Miles and Fink (1998) were used to derive a BAF for bluegill in the North Florida everglades of 1,130,723 L/kg. Lastly, a BAF of 1,499,688 L/kg for a perch/roach mix from the Kokenmaenjoki River Estuary, Finland, was derived from Schultz *et al.* (1995). This data set is the largest of all those used for either direct or converted estimation of BAF values and the data were listed in Table 5-9 in the National Bioaccumulation Factors for Methylmercury U.S. EPA, (2000). Although additional data might yield a more representative overall BAF, the studies do include the broadest geographic distribution of water bodies of any trophic level category. BAFs range more than 40-fold from the grayling (35,238 L/kg) in the Tom River in Siberia to 1,499,688 L/kg for the perch/roach found in the Kokenmaenjoki River Estuary, Finland. The broad geographic distribution and related environmental differences may contribute to this wide range. The geometric mean for these data is 346,613 L/kg.

2.2.6 Converted Trophic Level 4 BAFs, Lotic Environments

U.S. EPA assumed that 100 percent of the measured total mercury was methylmercury for this trophic level. Data from studies in the Tom River, Siberia (Papina *et al.*, 1995) yielded BAF values for burbot and pike of 96,905 and 352,381 L/kg, respectively. A BAF for bass from North Florida Everglades of 1,930,502 L/kg was derived based on data in Miles and Fink (1998), while a BAF value of 7,308,573 L/kg for pike from the Kokenmaenjoki River Estuary, Finland, was derived from the data of Schultz *et al*. (1995). Finally, a BAF of 10,401,681 L/kg for largemouth bass was derived from Lores *et al*., (1998). The unweighted geometric mean for these data was 1,380,361 L/kg, and the data were listed in Table 5-10 in the National Bioaccumulation Factors for Methylmercury U.S. EPA, (2000).

2.3 COMBINED DIRECT AND CONVERTED BAFs FOR LOTIC ENVIRONMENTS

The U.S. EPA combined the direct and converted data for BAFs for Trophic Levels 2, 3 and 4, respectively, in lotic ecosystems to obtain the values presented in Table 2 in this report. The rationale expressed by the U.S. EPA for the combination of the direct and converted data into a composite value for this ecosystem is that the data, when graphically displayed, appeared to be in the same range. When the direct and converted BAFs are compared for these trophic levels, all converted values are less than directly measured values with the differences ranging from about two- to four-fold. For example, the direct and converted BAFs for Trophic Level 2 are 179,000 and 61,900 L/kg, respectively, a difference of slightly less than three-fold. The combination of the direct and converted BAFs for Trophic Level 2, 3, and 4 are 105,000, 517,000 and 1,240,000 L/kg, respectively.

Table 2. Direct and converted Bioaccumulation Factors (L/kg) for trophic levels in the lotic environment*

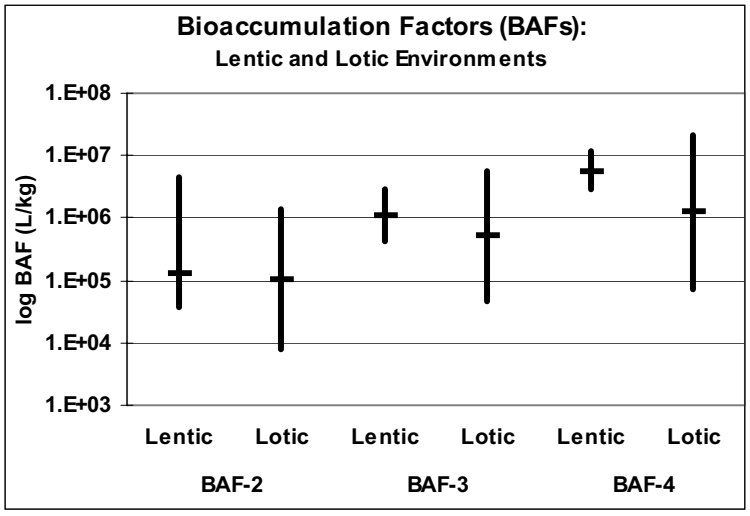
* Summarized from Tables 5-13 and 5-14 (U.S. EPA, 2000)

2.4 COMBINATION OF LENTIC AND LOTIC BAFs TO DERIVE NATIONAL BIOACCUMULATION FACTORS

The U.S. EPA, after examining the data for the combined lentic and lotic BAFs at each trophic level, decided that it was appropriate to combine lentic and lotic BAFs. The primary reason given by the U.S. EPA for combining BAFs for lentic and lotic environments was that there was no difference between these BAFs when tested statistically ($p > 0.05$). Figure 1 shows the overlap at the lower and upper bounds (5^{th} and 95^{th} percentiles) of the distributions of lentic and lotic BAFs at each trophic level for the U.S. EPA geometric mean BAFs.

Figure 1



BAF-2, BAF 3, and BAF-4 are for Trophic Level 2, 3, and 4 biota, respectively.
The mean values used to construct this figure above are from U.S. EPA (2000) as shown in the Table 3.
The horizontal bar is the geometric mean.
Vertical bar is the 5^{th} to 95^{th} percentile.

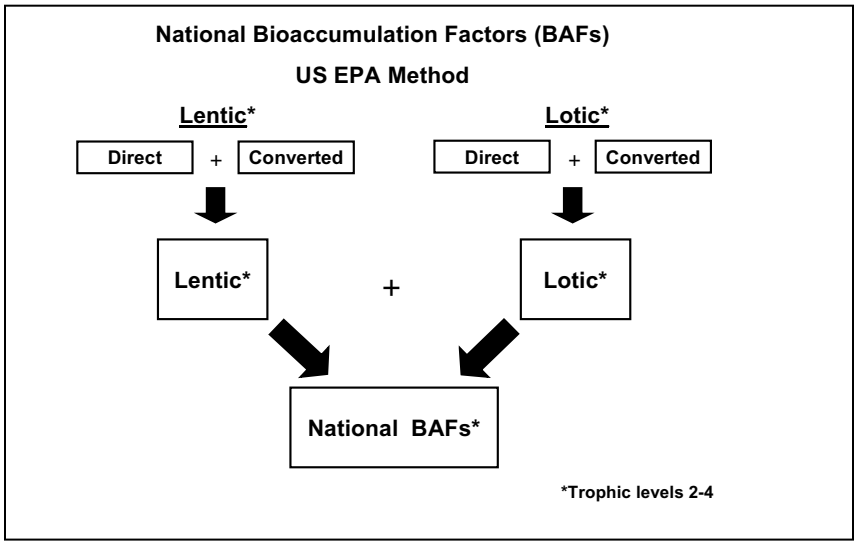
GM[1/]	127,800	105,000	1,115,000	517,000	5,740,000	1,240,000
Combined GM[2/]	117,000		680,000		2,670,000	

1 GM: Geometric Mean for each environment
2 Geometric Mean (GM) after combining lentic and lotic BAFs for both environment

Figure 2 diagrams the process that U.S. EPA utilized to derive the national BAFs for Trophic Levels 2, 3 and 4. The national BAFs are applicable to both lotic and lentic aquatic environments (U.S. EPA, 2000). U.S. EPA did not develop estuarine BAFs because their data set contained insufficient data of adequate quality.

Figure 2



2.5 U.S. EPA's DEVELOPMENT OF TRANSLATORS

Mercury, like other metals in water, can occur in a number of physical and chemical forms. Physically, mercury can be freely dissolved or bound to organic matter or particles suspended in water. And chemically, mercury can be found as elemental mercury, inorganic ionic mercury, or organic mercury (*e.g.*, methylmercury or dimethylmercury). Thus, mercury in water can be separately characterized physically (*e.g.*, total suspended mercury including all chemical forms) or chemically (total methylmercury including all physical forms). In most cases "total mercury" refers to a measured total concentration of all physical and chemical forms in water. U.S. EPA determined that dissolved methylmercury was the most relevant form of mercury for bioaccumulation and calculating BAFs (U.S. EPA, 2000 and 2003). But dissolved methylmercury was not always the form measured in the studies U.S. EPA identified for

inclusion in their database. Hence, translators were necessary to convert between other forms of mercury measured in water and dissolved methylmercury for BAF calculations. In addition, U.S. EPA intends to use translators for similar conversions for regulatory purposes to "convert the dissolved criteria back to a total metal concentration for use in the waste limit calculations. The translator is the fraction of the total recoverable metal in the downstream water that is dissolved, f_d. The translator is used to estimate the concentration of the total recoverable metal in the effluent discharge that equates to the criterion concentration [methylmercury] in the receiving water body."[5]

U.S. EPA used a general equation for calculating fractional translators (f_d s) for metals. This is the ratio between the total measurable concentration (C_t) of a metal in water and the dissolved concentration (C_d) of the metal in water: $f_d = C_d/C_t$. U.S. EPA was most interested in translators that would yield the dissolved fraction of methylmercury (f_{dmHg}). These translators would always be based on a measured concentration of dissolved methylmercury (C_{dmHg}) and either a total concentration in water based on measured total mercury (C_{tHg}) or measured total methylmercury (C_{tmHg}). The best way to estimate dissolved mercury forms (either methylmercury or inorganic) is by passing the water through filters with micron-sized pores and collecting the water and the filter. The dissolved concentration of one or more mercury species is measured in the water that passes through the filter. The total concentration of the same species is the sum of the concentrations of those species measured on the filter and those in the water that passes through.

U.S. EPA used measured values for C_d and C_t determined for the mercury species of interest from studies in their database. They used data criteria to select studies for the development of translators that were similar to the data requirements for the development of BAFs. Briefly, the studies must use clean techniques, have adequate Quality Assurance/Quality Control (QA/QC) and the methods must have a detection limit that unambiguously allows the quantitation of low (10^{-7} to 10^{-9} mg/L) concentration of species such as dissolved methylmercury. The low detection requirement is especially critical for dissolved methylmercury, which may be less than 10 percent of total mercury (*i.e.*, the concentration of all physical and chemical forms) in an aquatic environment.

U.S. EPA calculated the geometric mean of the ratio, $f_d = C_d/C_t$ for several measurements in several water bodies as a measure of central tendency for deriving national translators. U.S. EPA did not specifically discuss the rationale for the selection of a geometric mean over an arithmetic mean for the estimate of mercury f_ds (translators). Using geometric means for translators was consistent with their approach for BAFs. U.S. EPA developed translators for the lentic and lotic environments but did not combine them as they did for BAFs.

The following discussion summarizes the studies that U.S. EPA utilized to derive water translators for lentic and lotic aquatic systems.

[5] Section II: Default chemical translator for mercury and methylmercury., (U.S. EPA 2000), p2

2.5.1 Translator For Conversion Of Total Mercury To Dissolved Methylmercury ($MeHg_d/Hg_t$), Lentic Environments

U.S. EPA used nine studies to derive a translator representing the fractional relationship between dissolved methylmercury and total mercury in water. Table 4 lists the studies and is based on the data in Table 2 in Appendix B of the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). Geographically, the studies were widely distributed: two were from Europe (France and Finland); the rest were from the United States, including one in California at Clear Lake, California. The data range was about 70-fold (0.002 - 0.139). The geometric mean was 0.032. This indicates that dissolved methylmercury was about 3.2 percent of total mercury, *i.e.*, physical and chemical mercury, in these water bodies.

2.5.2 Translator For Conversion Of Total Mercury To Dissolved Methylmercury (MeHgd/Hgt), Lotic Environments

U.S. EPA selected 13 studies for the derivation of the translator for conversion between dissolved methylmercury and total mercury in lotic environments. Table 5 lists the studies utilized by the U.S. EPA. These data were taken from Table 7 in Appendix B of the National Bioaccumulation Factors for Methylmercury U.S. EPA (2000). There were no acceptable studies in the U.S. EPA database for this translator using data from California water bodies. The closest geographically to California was the study by Bonzongo *et al*., (1998) from the Carson River, Nevada. Two studies were for water bodies outside of the U.S. The translator values ranged from 0.002 to 0.051, or about 25-fold. The geometric mean for these data is 0.014, which means that 1.4 percent of total mercury (all physical and chemical forms) in these lotic systems is dissolved methylmercury.

Comparison of the lentic and lotic translators for dissolved methylmercury and total mercury in water suggests that there is more dissolved methylmercury in lentic than lotic water bodies. U.S. EPA speculated that the higher titer of organic matter in lentic systems compared to lotic environments may play some role in increasing dissolved methylmercury in lentic systems. U.S. EPA did not discuss whether they considered combining the translators for the two environments as they had done for the BAFs. OEHHA compared the data sets for the lentic and lotic environments using a two-tail t-test assuming unequal variance and calculated a statistical value of $p = 0.06$, which is just over a standard level of statistical significance ($p < 0.05$). This is not a clear reason to combine or separate lentic and lotic translators.

2.5.3 Translator For Conversion Of Total Methylmercury To Dissolved Methylmercury (MeHgd/Hgt), Lentic Environments

The 13 studies U.S. EPA used to derive the translator for lentic environments are listed in Table 6. They were taken from Table 3 in the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). The translator values for water bodies in the table range from 0.303 to 1.02 with an unweighted geometric mean value of 0.613. This is only about a three-fold difference between values even though several water bodies were in Europe. Data from two studies conducted at Clear Lake, California are included. One study in the upper arm of Clear Lake found that the dissolved methylmercury was about 43 percent of the total methylmercury, while the other study observed that dissolved methylmercury and total mercury were nearly equivalent (*i.e.* dissolved methylmercury was 102 percent of total mercury), a difference of about two-fold. The high value might be related to conditions at Clear Lake associated with drainage from a

mercury mine. While mine drainage (from either mercury or gold mining using mercury) may be unusual source of mercury in most states it is a common source in California. These data show that, in some lakes, dissolved methylmercury in water can be nearly equivalent to total methylmercury.

2.5.4 Translator For Conversion Of Total Methylmercury To Dissolved Methylmercury (MeHgd/Hgt), Lotic Environments

The data and studies used by U.S. EPA for this translator are from Table 8 in Appendix B in the National Bioaccumulation Factors for Methylmercury (U.S. EPA 2000) and are presented in Table 7 in this report. Detailed discussions about each study for this table are not presented in the U.S. EPA document. The values in Table 7 ranged about five-fold (0.17 - 0.83). None of the studies took place in California; the closest study geographically was in the Carson River, Nevada (Bonzongo *et al.*, 1998). The geometric mean was 0.49, (a value similar to that found in lentic environments), indicating that about one-half of the total methylmercury is in the dissolved form in lotic environments. Filters of different pore size were used (*e.g.*, 0.20 and 0.8 μm) in some studies, which may have affected data variability. U.S. EPA (2000) did not discuss the impact of pore size on measurement of the concentration of dissolved methylmercury.

2.5.5 Translators For Conversion Of Total Mercury To Dissolved Mercury (Hgd/Hgt), Lotic And Lentic Environments

U.S. EPA developed translators in both lentic and lotic environments for the relationship of dissolved mercury to total (physical and chemical) mercury (Hg_d/Hg_t) of 0.60 and 0.37, respectively. U.S. EPA (2000) did not discuss how these translators might be used in the implementation plan for mercury in ambient water. It appears that this ratio may be ancillary information from the analysis for total methylmercury and dissolved methylmercury in a water sample, so it will not be discussed here in further detail.

2.5.6 Translators For Estuarine Environments

U.S. EPA developed translators for this environment from very small data sets. In two cases, the ratio of dissolved methylmercury to total (physical and chemical) mercury ($MeHg_d/Hg_t$) and dissolved methylmercury to total methylmercury ($MeHg_d/MeHg_t$) data came from only two studies. Data will not be discussed individually for translators for these relationships due to small sample size. There were sufficient data in the literature to allow a derivation of the relationship between dissolved mercury and total mercury (Hg_d/Hg_t), but this translator is less useful. Table 8 lists the studies U.S. EPA used for this translator and the location where the studies occurred. Data are summarized from Appendix B Table 11 of the National Bioaccumulation Factors for Methylmercury U.S. EPA (2000). The translators from different studies range from 0.08 to 0.881, a difference of a slightly more than 10-fold. The geometric mean was 0.35, which indicates that about 35 percent of the total mercury (physical and

chemical) in estuarine environments in is in the form of dissolved total mercury. These data are primarily from studies outside the United States; eight of 11 studies were of water bodies in other locations in the world. One study supplied data from San Francisco Bay in California. However, the U.S. EPA (2000) has not proposed using this translator for regulatory of other purposes.

∇ 0.7 μm filtration

OEHHA's review noted some concerns regarding data from the estuarine environment because in several studies, it was uncertain as to whether "clean techniques" were used in the sample work-up and analysis. Another concern was that micron filters of different porosities were used in the studies. As noted above, the impact of the filter size on the magnitude of the translator values was not discussed in the U.S. EPA's summary of these values. Apparently the filter size used by the individual investigators has not been standardized for these analyses. Standardization could make the results from the studies more comparable.

2.5.7 Summary Of Translators For Lentic, Lotic And Estuarine Environments

The translators derived by the U.S. EPA for three aquatic environments are shown in Table 9. These data are summarized from Appendix B Table 15 of the National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). The translator data for estuaries for the relationships between dissolved methylmercury and total mercury and between dissolved methylmercury and total methylmercury are less robust because each was derived from only two studies, as noted above. The translator data set for estuaries for the relationship of dissolved mercury and total mercury uses 11 studies so there is some confidence in the geometric mean value of 0.35.

Table 9. Summary of U.S. EPA translators for lakes, rivers and estuaries

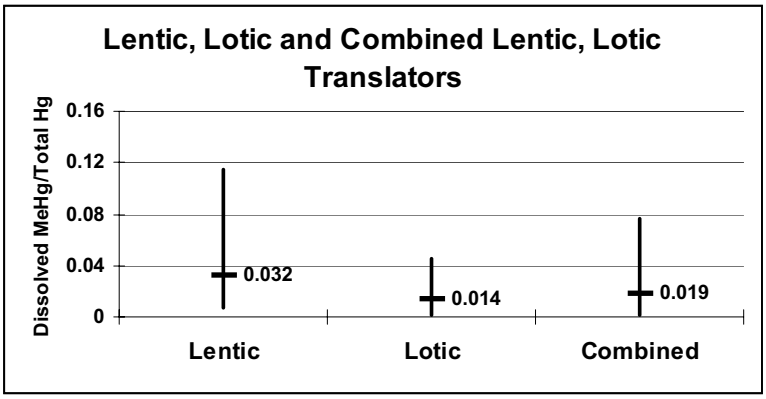
Mercury Species and Ratios	Lentic (Lake)	Lotic (River)	Estuary
f_d Hg (Hg_d/Hg_t)	0.60	0.37	0.35
f_d $MeHg_d/Hg_t$	0.032	0.014	0.19*
f_d $MeHg_d/MeHg_t$	0.61	0.49	0.61*

f_d Dissolved fraction
* These translators were developed from two sites

Examination of the summary values in Table 9 shows that, on average, the translator between dissolved methylmercury and total mercury for lakes (lentic) is slightly more than two-fold (0.032 vs. 0.014) greater than the same translator for rivers (lotic), and that the same translator for estuaries is very similar to the lotic translator. The similarity between the estuary and lotic values might be expected because rivers form a part of estuary systems. The translators between dissolved total mercury and total mercury for lotic and lentic environments, which are 0.37 and 0.60, respectively, exhibit a difference of less than two-fold, and the difference between the translators for dissolved methylmercury and total methylmercury in water for lentic (0.61) and lotic (0.49) was also less than two-fold. This is somewhat unexpected given the large variability among values from individual water bodies in the database. It may be that this is a result, in part, of the reduction in variation that occurs when one uses means of means to derive a value.

In the previous discussions of bioaccumulation factors, U.S. EPA combined lotic and lentic BAFs for three trophic levels to derive national default values that could be used if local values did not exist. It seems consistent with U.S. EPA BAF methodology that the summarized translators for the relationship of dissolved mercury species to total mercury species for lotic and lentic water body types (shown in Table 9) could be combined to provide a single value for each of the three relationships. Also, the differences are not great (geometric means less than two-fold apart) and it is likely that the distributions of the translators from lotic and lentic water bodies overlap. Through combining the data for the lentic and lotic aquatic environments, the dataset would be larger and perhaps more representative of a translator for both lentic and lotic environments. Figure 3 below shows an example of combining the U.S. EPA lentic and lotic translators for conversion between dissolved methylmercury and total mercury. The bars above and below the geometric mean are the 95^{th} and 5^{th} percentiles of the data, respectively. This shows the high degree of overlap between values for this translator in both ecosystems. However, it should be noted that there is considerably more variability in lentic water bodies.

Figure 3



The horizontal bar is the geometric mean.
Vertical bar is the 5^{th} to 95^{th} percentile.
The mean values that were used to construct the figure above are shown in the Table 9.

2.6 CRITIQUE OF U.S. EPA MERCURY BAFs AND TRANSLATORS

U.S. EPA's stated goal for deriving national BAFs values was that they would represent long-term bioaccumulation and be applicable for as many circumstances and for as many water bodies as possible (U.S. EPA, 2000). Presumably, national translators were also intended to be as broadly applicable as BAFs. However, U.S. EPA did not test the methylmercury BAF and translator values that they derived in an effort to determine whether they met this goal. The document describing how U.S. EPA derived the national values was a draft that has not been revised or finalized as a separate document. However, U.S. EPA did include peer review comments in the document (U.S. EPA, 2000) and they did use and publish the national BAFs, including peer review comments, with the final methylmercury water quality criterion (U.S. EPA, 2001). Apparently, the national BAFs and translators met U.S. EPA's goals well enough to be used in this criterion document without any changes.

A key step in evaluating whether and how to develop regional, local, or site-specific BAFs and translators for California water bodies, and whether or when to use the national BAFs and translators in California, is to understand the limitations of the methodology and data used by U.S. EPA as well as limitations or strengths of the resulting BAF and translator values. A number of strengths, weaknesses, and limitations are described below. These include observations from the original peer reviewers, OEHHA, and other authors commenting on the U.S. EPA methylmercury criterion, BAFs, and translators.

2.6.1 Comments On The U.S. EPA Methodology To Derive BAFs

2.6.1.1 BAF Equation:

U.S. EPA used a simple ratio, equivalent to a single box model, to calculate BAFs. Theoretically, the mercury concentrations in water and fish in this model should be at steady state. There are other, more complex, models that incorporate the effects of biological, environmental, and ecological factors to estimate the accumulation of methylmercury in biota (Hope, 2003; and Kamman, *et al.*, 2003); however, these models require more information than is needed for the BAF ratio calculation. These information requirements would have further restricted the number of studies that could have been used by U.S. EPA, limiting the scope of application of the national BAFs and translators. Whether or not more complex models can be used in California will depend on data readily available for California water bodies or on designing studies that would provide these data.

The theoretical basis for the BAF equation and model has been criticized by some reviewers (AMEC-ENVIRON, 2003, and Grovhoug *et al.*, 2003). Grovhoug *et al.* (2003) used data from two sampling sites on the Sacramento River and found no significant correlation between mercury in water and methylmercury in Trophic Level 3 and 4 biota, at the same site. This lack of correlation may be due, in part, to their treatment of sites as opposed to water bodies. Grovhaoug *et al.* (2003) looked for correlations between water and tissue concentration within single sites on this large water body. The studies used by U.S. EPA to derive BAFs averaged data across whole water bodies. In practice, no correlation is expected between a water sample and a Trophic Level 3 or 4 fish collected at the same site and time because the samples themselves represent different spatial and temporal scales. The water sample is a snapshot representation of daily conditions and single grab samples may fail to capture diurnal or hourly variation of dissolved methylmercury. The fish samples integrate conditions over a much longer period (months to years) and over a much greater space (everywhere the mobile fish has been exposed to mercury through water or food in its lifetime to date), so they cannot reflect differences in conditions for the time at which the water sample is taken. It would be more appropriate to look for correlations between mercury in water and fish across sites showing different tissue and water concentrations of mercury within a water body to see if the fish have integrated the differences in water concentrations. Some comparisons on a broader scale have shown a correlation between methylmercury in water and fish (Krabbenhoft, 1999).

2.6.1.2 Dissolved Methylmercury In Water:

Overall using the dissolved methylmercury fraction in water to derive BAFs was a good choice by U.S. EPA as methylmercury is the form of mercury that bioaccumulates in the aquatic food web. Methylmercury is also the form of mercury of human health concern following fish consumption. The production, availability, and accumulation of methylmercury in aquatic food webs can be affected by a number of factors including pH, alkalinity, water temperature, sulfate concentration, dissolved oxygen, organic matter, dissolved organic carbon, landscape characteristic (*e.g.*, wetlands), and trophic structure (Brumbaugh *et al.*, 2001; Greenfield *et al.*, 2001; Harris and Bodaly, 1998; Wiener *et al.*, 2003), but clearly the amount of the dissolved

methylmercury is a potentially limiting factor at an early step in food web bioaccumulation (Kelly *et al.*, 1997; Paterson *et al.*, 1998). The chief problem U.S. EPA encountered with dissolved methylmercury to derive BAFs was that data from many studies did not measure methylmercury in water and it was necessary to convert measurements of total mercury to methylmercury using national translators.

2.6.1.3 Methylmercury In Biota:

This is the best measurement to use for mercury in biota to calculate BAFs. It is the form used in the U.S. EPA tissue criterion because it is the most relevant form for human exposure via fish consumption and it is clearly associated with neurotoxicity in humans (U.S. EPA, 2001). The main problem with calculating BAFs based on methylmercury in biota is that most studies measure total mercury in this medium. This made it necessary for U.S. EPA to convert total mercury measurements in tissue to methylmercury values in tissue for various trophic levels.

2.6.1.4 Trophic Levels:

U.S. EPA apparently developed BAFs for Trophic Levels 2, 3, and 4 because this is part of their general strategy for developing BAFs for use in water quality criteria (U.S. EPA, 2003). U.S. EPA first developed BAFs for individual species and then combined them into trophic level BAFs. The reliability of the trophic level BAFs thus depends, in part, on accuracy in assigning species to the appropriate trophic level, as is discussed further below. While it is reasonable to calculate various trophic level BAFs because methylmercury does bioaccumulate up the food web through all trophic levels (Wiener *et al.* 2003), the role of the Trophic Level 2 BAF is unclear since no information is presented in the methylmercury tissue criterion (U.S. EPA, 2001) to show that people are consuming organisms from Trophic Level 2. The BAFs for Trophic Levels 3 and 4 are most relevant for fish species consumed by humans.

2.6.1.5 Classification Scheme (Lotic/Lentic/Estuarine):

U.S. EPA did not state how they assigned the studies they used to lotic, lentic, and estuarine water body classifications. Some of the peer reviewers suggested that these classifications were too broad, and that there should be more categories based on physical, chemical, and ecological differences and similarities. One reviewer suggested the following categories: oligotrophic, mesotrophic, eutrophic lakes; estuarine (deep and shallow); open ocean; streams and rivers (high and low dissolved organic carbon); and wetlands/everglades. Using additional categories could help determine whether the national BAFs are not representative of specific environments and conditions, and identify those that fall at the extremes for bioaccumulation. However, U.S. EPA's database did not contain appropriate studies to break out categories representing all of the water body types suggested by the reviewers. Also, reclassifying water bodies into more categories would further reduce the representative data for each category. Although this was a scientifically sound idea, it would have little effect if the BAFs from all environments were still combined.

2.6.1.6 Statistical Methods:

U.S. EPA used geometric means throughout their calculations of BAFs to represent the central tendency of data from studies that sometime included multiple water bodies. U.S. EPA did not discuss their choice of the geometric mean in detail. They state that geometric means were used for convenience and because the factors underlying BAF variability were believed to be multiplicative and the data sets log normally distributed (U.S. EPA, 2000). However, they did not present the distributions of the data they used or show statistical tests demonstrating that these data were log normal. One reviewer suggested that they provide a more detailed explanation of their rationale and provided some possible language. Another suggested that means could have been calculated for individual water bodies rather than using a single mean for all water bodies in the same study.

Arithmetic means could be used rather than geometric means to represent the central tendency of data when calculating BAFs. Arithmetic means generally yield higher values than geometric means. OEHHA favors using arithmetic means in human health assessments and fish consumption advisories because they are more health protective. Using arithmetic means to calculate the data summaries for methylmercury concentrations in biota and water that are used to calculate BAFs from individual studies might have little effect on the BAF values at this level. However, using arithmetic means to calculate means from studies and means after merging lentic and lotic BAFs would likely result in higher final national BAF values. BAFs based on arithmetic means are likely to yield higher tissue concentrations from the same water concentration than BAFs based on geometric means. Conversely, if BAF values are used to convert back to water concentrations, BAFs based on arithmetic means are likely to yield lower water concentrations from the same tissue concentration than BAFs based on geometric means.

Ideally, the distribution of the data sets used in BAF calculations should be tested to determine whether they are log normally distributed before choosing to use geometric means. This cannot be done for the national BAFs without the entire database, but it is recommended for any attempts to derive BAFs based on data from California water bodies.

2.6.1.7 Combining Lotic And Lentic Classifications Into Single National BAFs For Trophic Levels:

U.S. EPA based merging lentic and lotic BAFs on a qualitative rather than quantitative comparison of BAF values. They combined BAFs because the data ranges overlapped. As a result, the variability within each BAF was very large. The merging of lotic and lentic datasets to derive a single national BAF generated considerable discussion by the peer reviewers. Reviewers suggested that, instead of merging the lentic and lotic datasets for the calculation of BAFs, lentic and lotic environments should be split into more ecological categories that better reflect the aquatic chemistry of each environment. Although peer reviewers recognized U.S. EPA's purpose in deriving a single BAF, most disagreed with combining BAFs and advocated for developing separate BAFs for more environments, especially at the regional or local level. Developing specific BAFs for various categories of California water bodies (*e.g.*, lentic, lotic, and estuarine) would be consistent with this recommendation. It would also provide an

opportunity to compare the California values with the national values to see if they are really different and to look for water body characteristics associated with very different BAF values.

2.6.1.8 Standard Techniques:

Standard techniques were not used in the retrospective database compiled by U.S. EPA. Many of the peer reviewers suggested that using standard methods and uniform protocols would improve the study design and resulting data quality. This is especially true for determination of dissolved methylmercury. Different filter pore sizes were used by different researchers to separate the dissolved fraction of mercury or methylmercury in some of the studies used by U.S. EPA. As a result, some of the data for dissolved mercury or methylmercury could include some mercury bound to organic carbon or colloids. Standard sampling periods for water samples and standard ranges for fish lengths or edible sizes were not used and differences in these methods could also contribute to variation in the resulting BAFs. Standardized techniques would be essential for water and tissue measurements used in regulations.

2.6.2 Comments On The U.S. EPA Methodology To Derive Translators

2.6.2.1 Translators For Water:

U.S. EPA derived translators to convert other forms of mercury in water to dissolved methylmercury in order to calculate BAFs in a consistent manner. Again, U.S. EPA used a simple ratio between forms to calculate each translator. The translator conversion factors for water assume that there is a linear relationship between the various forms of mercury in water. This may be an over-simplification, especially of the relationship between total mercury and methylmercury in water. Methylmercury concentrations, in particular, are affected by other factors, *e.g.*, microbial communities, temperature, sulfide, and redox conditions (Ullrich *et al.* 2001), and high or low methylmercury values may not correlate well with total mercury values (Monson and Brezonik 1998; Gilmour *et al.* 1998). Many peer reviewers expressed reservations about using translators between total and methylmercury in water, and suggested that these be developed on a more local or site-specific basis. As noted in the discussion of the BAF method, the lack of standardized methods, especially standard pore sizes for determining dissolved mercury forms, may affect the variability in data used to calculate translators, as well as BAFs.

2.6.2.2 Translators For Biota:

U.S. EPA derived translators for biota to convert total mercury measurements in tissue to methylmercury values in tissue. This was fairly straightforward for higher trophic level fish (Trophic Level 3 and 4) where the conversion based on the assumption that nearly 100 percent of total mercury is methylmercury is well accepted, health protective, and consistent with most monitoring programs. U.S. EPA derived additional conversion factors for Trophic Level 2 organisms in lentic and lotic water bodies. The reliability of the Trophic Level 2 translators depends on whether the organisms used are representative of all Trophic Level 2 organisms, and whether U.S. EPA accurately assigned species to Trophic Level 2. This is discussed further below.

2.6.2.3 Separating Water Body Types:

U.S. EPA developed and retained separate translator values for lentic, lotic and estuarine water bodies. They did not explain why they did this but later combined the BAFs derived from them. Peer reviewers were in favor of separate lentic and lotic translators, and suggested that some of the water bodies in these separate classifications were actually at environmental or ecological extremes and should not be combined with other data to derive translators.

2.6.2.4 Other:

As noted in the BAF methodology discussion, U.S. EPA used geometric means to calculate translators because environmental variables tend to be log normally distributed. However, they did not show that the underlying data were log normally distributed or discuss their rationale in detail. The reviewers commented on this and one also suggested that means could have been calculated for individual water bodies rather than using a single mean for all water bodies in the same study.

2.6.3 Comments On The Data U.S. EPA Used To Derive BAFs

2.6.3.1 Representativeness Of Water Bodies In The Database:

It is not clear whether the water bodies from the studies used by U.S. EPA are representative of the range of water body types in the United States. U.S. EPA did not include specific physical and chemical information on the water bodies that might be useful in categorizing them. Many of the studies used are for seepage lakes in the Midwestern United States, whose primary source of mercury is atmospheric deposition. Conditions and BAFs from these water bodies may be different than in California water bodies where the primary source of mercury, in most cases, is gold or mercury mining. In fact, some of the peer reviewers recommended not using the data from Clear Lake, California because this site was not "typical" and had an unusual BAF. They felt that Clear Lake was not typical at the national level because its main source of mercury was runoff from a former mercury mine instead of atmospheric mercury. But legacy mining is a typical mercury source in California so these data may be especially relevant for California water bodies. Reviewers also questioned using data from other areas with unique conditions or high contamination, and they questioned U.S. EPA's inclusion of wetland data as a lotic ecosystem. U.S. EPA used international data but did not explain why they were merged with U.S. data. Using these data did broaden their database on which BAF calculations were based, however, it might also have introduced data from water bodies with variations in abiotic and biotic factors very different than those in the United States. The Papina *et al.* (1995) study from Russian was one of the studies the peer reviewers suggested had questionable data. In retrospect some reviewers were focused more on potential water body differences in physical, chemical, or ecological conditions than on U.S. EPA's attempt to derive broadly representative BAF values. These differences in perspective can only be resolved by deriving better local or regional BAFs.

2.6.3.1 Quality Assurance:

One problem with the study data was that standard collection and analytical techniques were not used. The peer reviewers commented on this and the necessity of using well-defined techniques in particular for the assessment of methylmercury in water because it is difficult to measure due to its low concentrations in water (*e.g.*, from 10^{-6} to 10^{-9} mg/L). U.S. EPA dealt with the non-standard analytical techniques, in part, by applying a set of analytical QA criteria to the chemistry data from the studies they selected. Using QA criteria increased the precision and reproducibility of the chemistry results, but had the effect of excluding studies relying on methylmercury data in water analyzed before 1990, although some studies containing total mercury results in water were included. This did not solve all problems associated with the lack of standard techniques. The peer reviewers pointed out some water data that U.S. EPA used that they felt were unreliable. Among the studies mentioned were data from Papina *et al.* (1995) where the methylmercury concentration was unusually high; data of Glass *et al.* (1990 and 1992) where the measured concentrations were very low; data from Jackson *et al.* (1991) that included data from the early 1980's using non-contemporary methods; data from Mason and Sullivan (1997) who reported values at the detection limit of the analytical method; data from Monson and Brezonik (1998 and 1999) who used a different method to measure mercury forms; and the study by Stober *et al.* (1995) where QA/QC issues were discovered after its inclusion in the U.S. EPA set. The peer reviewers felt that using data from these studies might affect the overall quality of BAF values calculated from them.

The peer reviewers also raised issues concerning the collection and interpretation of plankton and seston data noting that some samples were potentially a mixture of trophic levels (Trophic Level 1 and 2) and phylogenetically different organisms. These problems would impact the BAFs for Trophic Level 2.

2.6.3.3 Trophic Level Classification:

It is not clear if the number and kind of species from the studies used to derive each trophic BAF are representative of species in water bodies across the U.S. and those in California. Furthermore, the functional trophic level of a species can vary between water bodies and regions and this could lead to misclassifications of data assigned to a trophic level (*e.g.*, in lakes King salmon eat like Trophic Level 4 organisms, but in rivers they eat like Trophic Level 3 organisms). Trophic Level 2 organisms from the U.S. EPA studies included phytoplankton, zooplankton, microseston, mosquito fish, and stone rollers (see Table 10). Phytoplankton are Tropic Level 1 organisms, and microseston might include some primary producers, but it can be hard to separate these from zooplankton. Similar organisms are likely to be found in California. However, none of the studies included potential Trophic Level 2 organisms such as clams, mussels, crayfish, or crabs that might be harvested and eaten from water bodies in California. Although U.S. EPA has included Trophic Level 2 organisms in their water quality criteria it is not clear whether organisms at this level contribute significantly to human exposures in California. Peer reviewers questioned the assignment of mosquito fish to Trophic Level 2 rather than Trophic Level 3. Trophic Level 3 organisms from the U.S. EPA studies included shiner, perch, carp, shad, silversides, bluegill, sunfish, and juvenile bass species, which might also be found at this trophic level in California. The U.S. EPA studies did not include any trout, salmon

or catfish species in this trophic level. In California, some species of these fish are likely to be at this trophic level and these are also important game fish (*i.e.*, fish that anglers catch and consume). Trophic Level 4 organisms from the U.S. EPA studies included largemouth bass and other bass species, lake trout, walleye, northern pike, and burbot. In California, largemouth bass and other bass species are likely to be at this trophic level and some brown trout, catfish, or lake salmon may be as well. Including a more complete cross-section of data for species relevant to California consumers would improve the relevance of the trophic level BAFs. California data should be investigated to see if this is possible.

Table 10: Biota used by U.S. EPA to calculate BAFs for Trophic Level 2, 3, & 4

Trophic Level 2	Trophic Level 3	Trophic Level 4
Microseston	bass (juvenile)	bass
Mosquito fish	bloater	largemouth bass
Phytoplankton	bluegill	smallmouth bass
Stone roller	bream	burbot
Zooplankton	carp	lake trout
	dace	northern pike
	gizzard shad	pike
	grayling	walleye
	Johnny darter	
	Mayan cichlid	
	perch	
	perch/roach mix	
	log perch	
	yellow perch	
	redbreast	
	roach	
	shiner	
	spottail shiner	
	emerald shiner	
	spotted shiner	
	silversides	
	spotted sunfish	
	spotted tilapia	

Species lists from U.S. EPA (2000).

2.6.3.4 Standard Techniques:

The lack of standardized methods increases variability and decreases reproducibility of the water and fish data compiled by U.S. EPA. Sampling periods, fish age and size, and analytical preparation techniques (*e.g.* whole fish vs. fillet) differed among studies. For example, in some cases, water data were based on single grab samples while seasonal composite samples were taken in others. Thus some sampling incorporated seasonal variation while other sampling excluded it.

2.6.3.5 Compiled Data:

It is not possible to determine the actual sample size for fish and water measurements in the database compiled by U.S. EPA because the sections of the report (U.S. EPA, 2000) available to OEHHA only include summaries of the studies from which data were entered into the database. The existing database compiled by U.S. EPA is acceptable for developing broad-based BAFs despite the limitations discussed. However, as noted by the peer reviewers, the underlying spread of data may not yield BAFs that are practically very useful. The peer reviewers unanimously supported collecting more and better quality data, especially on the local and regional level. These data would be more applicable for local or regional conditions and would likely be less variable than the broad-based national data.

2.6.3.6 Other Studies:

The peer reviewers compiled lists of additional studies that they suggested U.S. EPA consider including to derive BAFs. Some of these studies were for California water bodies, and additional studies have been published in the past several years. These studies could potentially be used to derive BAFs based on California specific data.

2.6.4 Comments On The Data U.S. EPA Used To Derive Translators

2.6.4.1 Quality Assurance:

As discussed above, the lack of standard techniques (*e.g.*, using different pore size filters) to separate the dissolved fraction of mercury increases the variability and decreases the reproducibility of derived translators. Some of the study data could include mercury bound to dissolved organic carbon or colloids, while others do not. Since mercury in water can vary seasonally, non-standard sampling could also increase variation if data from different seasons were used to derive translators.

Also as noted above, reviewers suggested that data from some water bodies (*e.g.* Clear Lake, California, and others) be excluded from the U.S. EPA database because of the high total mercury, but low methylmercury concentrations in water. These studies also yielded high translator relationships, which may bias the current translator values. These studies, however, may be relevant in California where total mercury concentrations in water bodies may be higher due to mining sources.

The general comments above on the BAF data concerning representativeness of water bodies in the database, standard techniques, compiled data, and other studies are also applicable to the translator data.

2.6.5 Comments On The U.S. EPA National BAF Values

2.6.5.1 Gaps in Available Data

There were not enough good data available to U.S. EPA at the time they compiled their database to develop estuarine BAFs. This is a significant data gap for California because the San Francisco Bay-Delta is a huge estuary draining about 60-70 percent of the runoff from the Sierra Nevada Mountains. SWRCB should investigate compiling data from this estuary and/or other California estuaries to develop water body specific or a California default BAF for estuaries.

2.6.5.2 Variability

Table 11 shows the direct, converted, and combined BAFs developed by U.S. EPA for different trophic levels and water body types. The minimum, maximum, and geometric means for the studies compiled by U.S. EPA are given in the table. In order to get some measure of the data variation within each category, the maximum value is divided by the minimum value and shown in the table as the "fold variation." Standard deviation or the coefficient of variation would be better measures of variability but these cannot be calculated without the complete database. These simple calculations give some idea of the inherent variability in the BAF values.

Table 11: Relative variability in BAFs for lentic and lotic Trophic Level 2, 3, & 4

	BAF Trophic Level 2		**BAF Trophic Level 3**		**BAF Trophic Level 4**	
Direct BAFs	Lentic	Lotic	Lentic	Lotic	Lentic	Lotic
minimum	42,400	34,474	504,000	334,325	4,000,000	985,915
mean	85,600	178,678	1,260,000	1,636,298	6,800,000	2,524,477
maximum	172,764	608,728	4,170,000	11,250,000	11,400,000	6,464,028
Fold variation	4	18	8	34	3	7
Converted BAFs						
minimum	61,757	8,661	734,095	35,238	3,954,284	96,905
mean	149,960	62,000	1,330,000	346,613	4,100,000	1,380,361
maximum	326,264	260,811	3,262,643	1,499,688	4,203,000	10,401,681
Fold variation	5	30	4	43	1	107
Combined BAFs						
minimum	34,474		35,238		96,905	
mean	117,000		680,000		2,670,000	
maximum	608,728		11,250,000		11,400,000	
Fold variation	18		319		118	

Minimum and maximum values are the mean values for the species with the lowest and highest BAF, respectively, for each water body type and indicated trophic level.
Mean values are geometric means from U.S. EPA (2000).

Examination of direct BAFs in the table showed that, for Trophic Level 2, the lotic mean and maximum are higher than the lentic mean and maximum values, but the lotic minimum was less than the lentic. This same pattern was seen for Trophic Level 3. However, for Trophic Level 4 the lentic mean and maximum values were higher than the same lotic values, and the lentic minimum was also higher than the lotic minimum. Although the trophic level pattern of BAF values was not consistent, the lotic BAFs at all trophic levels were consistently more variable based on the ratio of the maximum and minimum values. All of the lentic values show less than an order of magnitude difference, while the values for Trophic Levels 2 and 3 in lotic water bodies show greater than an order of magnitude difference.

Examination of the converted BAFs show a different pattern of high and low values for trophic levels in lentic and lotic water bodies, but a similar pattern for variation. In this case, for Trophic Level 2, the lentic mean, maximum, and minimum values are greater than the corresponding lotic values. The same pattern is seen in Trophic Level 3. In Trophic Level 4, the mean and minimum values are higher than the lotic, but the maximum value is lower. Some of the differences between direct and converted BAFs are likely to be due to effects of using translators to convert measured values. But, in all cases, the lotic BAF values are again more variable; all show more than an order of magnitude variation, and all show more variation than for direct BAFs. Lentic values, however, all show less than an order of magnitude variation, and the level of variation is similar to that seen for direct BAFs.

As seen in Table 11, combining the direct and converted BAFs for lentic and lotic water bodies to derive the national default values either retains or increases the variability from the underlying data. U.S. EPA calculated the 5^{th} and 95^{th} percentile ranges for BAFs at each trophic level in lentic and lotic water bodies and for the combined national BAFs. The lower and upper bounds also show the same pattern of variability demonstrated above: lotic BAFs are more variable than lentic, and lotic BAFs show greater than an order of magnitude difference between upper and lower bounds.

One way to decrease the inherent variability when using BAFs would be to use the direct BAFs for each trophic level and water body type, rather than using the U.S. EPA default values. SWRCB should investigate compiling data to derive California specific direct BAFs for lentic, lotic and estuarine water bodies, and other water body types of potential interest. This could be especially important because the primary source of mercury in most California water bodies is different than the atmospheric source in most of the studies U.S. EPA used to derive BAFs.

2.6.6 Comments On The U.S. EPA National Translator Values

2.6.6.1 Gaps in Available Data

U.S. EPA did develop three translators for estuarine water bodies. However, the translators between dissolved methylmercury and total mercury and dissolved methylmercury and total methylmercury were based on a relatively small sample size. Good estuarine translators are important in California because of the San Francisco Bay. SWRCB should investigate compiling

data to derive translators for San Francisco Bay and/or other California estuaries and water body types.

2.6.6.2 Variability

Table 12 shows national translator values for lentic and lotic water bodies and one based on more data for estuarine water bodies. The minimum, maximum, and geometric means for the studies compiled by U.S. EPA are given in the table. In order to get some measure of the data variation within each category the maximum value is divided by the minimum value and shown in the table as the "fold variation." Standard deviation or the coefficient of variation would be better measures of variability but these cannot be calculated without the complete database. These simple calculations give some idea of the inherent variability in the translator values.

Table 12: Relative variability in lentic, lotic, and estuarine translators

Translator	**MeHgd/Hgt**		**MeHgd/MeHgt**		**Hgd/Hgt**
Water body	Lentic	Lotic	Lentic	Lotic	Estuarine
Minimum	0.002	0.002	0.303	0.17	0.08
Mean	0.032	0.014	0.613	0.49	0.353
Maximum	0.139	0.051	1.02	0.83	0.881
Fold variation	70	26	3	5	11

MeHgd = dissolved methylmercury; MeHgt = total methylmercury; Hgd = dissolved inorganic mercury; Hgt = total mercury
Mean values are geometric means from U.S. EPA (2000).

Examination of this table shows that lotic translators have lower minimum, mean, and maximum values than translators for lentic environments. Estuarine values are similar to lotic, but are not directly comparable because they are not for the same forms of mercury as the lentic and lotic translators. The greatest variability, based on the ratio of maximum and minimum values, is seen for the translator between dissolved methylmercury and total mercury. Variability for this translator is more than an order of magnitude, similar to the variability for the estuarine translator between dissolved mercury and total mercury. Variability for the translator between dissolved methylmercury and total methylmercury is less than an order of magnitude.

Using translators to convert other mercury forms to dissolved methylmercury increases the variability in BAF calculations. Analytical methods to measure methylmercury have improved so future studies would be wise to always measure dissolved methylmercury directly, reducing the need to use translators. SWRCB should investigate compiling data or conducting new studies to derive default translators for a variety of California water bodies. This is especially important because the primary source of mercury in most California water bodies is legacy mercury or gold mining, which is different than the atmospheric source in most of the studies in the U.S. EPA database used to derive translators.

2.7 CONCLUSIONS CONCERNING U.S. EPA's DEVELOPMENT OF BAFs AND TRANSLATORS

National BAFs and translators have a number of flaws, owing largely to their derivation from a database that was compiled retrospectively from available studies. A well-designed, prospective study using standardized methods and stratified random sampling of specific types of water bodies might generate data that is less variable and possibly more useful for examining factors affecting mercury bioaccumulation for a broad scale of water bodies. Generating data using standard protocols would remove the influence of variation due to study methodology so that the effects of limnological and environmental variables could be determined. It would also require years to plan and complete but potentially yield information that could be practically applied. The external peer reviewers for the U.S. EPA document (U.S. EPA, 2000) were strongly in favor of collecting additional, higher quality data to use for BAFs and translators. To develop standard methods, factors such as the optimal sampling period for water and fish need to be determined, as well as where samples should be collected in the water column, and whether to do grab or composite samples. Standardized size or age ranges for fish or specific species to be collected for each trophic level should also be developed. The spatial relationship between fish and water samples also needs to be established for water bodies or "sites." In fact, the concept of "site-specific BAFs" should be examined. It is unlikely that BAFs for a specific site, such as a marina dock, or a specific latitude and longitude determined by GPS can be developed. Data can be collected to develop BAFs for larger water bodies (*e.g.*, Clear Lake, or Cache Creek) or perhaps segments of longer rivers (*e.g.*, the Sacramento River above Lake Shasta). The BAFs U.S. EPA developed were essentially for water bodies, not sites.

Despite these problems, the national default values for BAFs and translators were developed in a methodical manner using the best available data. These values were not tested by U.S. EPA to see how well they would predict tissue or water concentrations. This should be done to demonstrate and test their practical application, prior to using them in a policy to implement the methylmercury tissue criterion, using some criterion for goodness of fit to empirical data. Using the directly calculated BAFs (those based on measured dissolved methylmercury in water) for lentic and lotic water bodies separately can be considered as an alternative to the combined national default values. These values are less variable than the combined national values, and do not include the additional uncertainty added by using water translators and combining water body types. However, they are based on a smaller dataset. As another alternative, the California SWRCB could compile data on concentrations of mercury in fish and water for California water bodies to see if regional or local BAFs and translators could be derived that have less variability than the national values. Ideally, information on other factors known to affect methylmercury bioaccumulation (*e.g.*, pH, alkalinity, water temperature, sulfate concentration, dissolved oxygen, organic matter, dissolved organic carbon, landscape characteristic, and trophic structure) could be collected for these water bodies to aid in future classification of differences in BAFs in different types of California water bodies.

3 DERIVATION OF CALIFORNIA-SPECIFIC BAFs AND TRANSLATORS FROM THE SWRCB DATABASE

The State Water Resources Control Board (SWCRB) contracted with Science Applications International Corporation (SAIC) to compile water and biota mercury concentration data for California water bodies in an Access database titled "California Mercury Ambient Water Quality Criteria." This database contains information on water and biota data for lentic, lotic and estuarine environments. OEHHA used an Excel file version of this database[6] (refered to as the SWRCB database in this report) for this evaluation. For each of these environments, BAFs were calculated for three trophic levels in three aquatic environments, hence nine BAFs were reported in the database.
The discussion that follows will:

1) compare U.S. EPA and SAIC methods for calculating BAFs. This will include a brief discussion of the data in the SWRCB and U.S. EPA databases that were used to calculate BAFs.

2) describe an alternate method to calculate BAFs from the California data in the SWRCB database. This method will be used to make the California calculations as similar to those by U.S. EPA as possible within limits of the California data collection method. These alternative California-specific BAFs will be compared to BAFs derived by U.S. EPA.

3) investigate the SWRCB database for California water bodies to determine whether it is possible to develop translators for some aquatic environments. These California-based translators will be compared to translators derived by U.S. EPA.

3.1 U.S. EPA DATABASE FOR CALCULATION OF BIOACCUMULATION FACTORS

As previously noted, U.S. EPA carefully selected studies for inclusion in the database it used to calculate lentic and lotic BAFs. Studies had to meet certain standardized criteria for analytical chemistry data (*e.g.*, be reproducible and have a low detection limit and minimal matrix interferences) as specified in National Bioaccumulation Factors for Methylmercury (U.S. EPA, 2000). These rigorous criteria selected for high quality data, but only a limited number of studies met them and were thus included in the U.S. EPA database. In addition, U.S. EPA only included data from studies in which the same author or authors collected and measured some form of mercury in both biota and water in the same water body as part of the same investigation. These measurements, while for the same water body, were not necessarily collected at the same time or at the same site as defined by GPS coordinates. Sometimes data for water and/or biota mercury concentrations were aggregated over several years for the same water body or site by authors in the selected studies. Table 13 shows the number of studies from which U.S. EPA extracted the data entered in their database. U.S. EPA's calculations of BAFs and translators from this database have already been discussed.

[6] The database referenced in this document is dated March 2004 and referred to as the SWRCB database.

The U.S. EPA database was not available for OEHHA to determine the true number of samples and measurements included in it. Far more samples were included in the database than shown by the number of studies because some of the studies involved many water bodies and/or used data from multiple replicate measurements of mercury in biota and water in each water body. For example, Watras *et al*., (1998) studied 15 lakes in Wisconsin that were entered in the U.S. EPA database and used to calculate the BAFs. The replicate measurements within and among water bodies from each study are not evident because U.S. EPA first reduced the water and biota measurements to a single BAF for each trophic level in a study and then to a single BAF for each environment.

Table 13. Number of studies in the U.S. EPA database used to derive national BAFs[+]

Trophic Level:	**2**	**3**	**4**
Environment			
Lentic			
Direct	2	5	4
Converted	5	4	2
Total	**7**	**9**	**6**

Direct	3	6	2
Converted	3	15	5
Total	**6**	**21**	**7**

[+] Data from Tables 5-1 (lentic) and 5-2 (lotic), U.S. EPA, 2000
Direct: dissolved methylmercury concentration was measured in study;
Converted: the mercury form measured in water was converted into dissolved methylmercury by using the national translators derived by U.S. EPA (2000).

3.2 CALIFORNIA SWRCB DATABASE AND METHOD FOR CALCULATION OF BAFs

Table 14 summarizes information on California biota and water data contained in the Excel file used by OEHHA that contained the SWRCB dataset. SAIC entered mercury measurements for water and biota collected in California by various researchers but did not use the same criteria that U.S. EPA did when compiling their database (see Appendix 1 for criteria for SWRCB database). Unlike the U.S. EPA database data entries were not restricted to studies in which water and biota from the same water body were measured in the same study. The dataset for the lotic environment contained the most entries for both water and biota, with more than 100 entries (see Table 14) for each trophic level. The lentic environment had the fewest entries for water measurements and these were all from one water body, Standish Dam, which did not include any measurements of mercury in biota. The lentic environment also had the fewest entries for Trophic Level 2 biota, but contained a large number of Trophic Level 3 and 4 biota data.

Table 14. Number of data entries in the SWRCB database#

	Water Entries	Biota Entries		
Environment	Water*	Trophic Level 2	Trophic Level 3	Trophic Level 4
Lentic	11	9	345	814
Lotic	474	110	622	1224
Estuarine	306	211	25	240

* Data were reported for various forms of mercury. They were converted to dissolved methylmercury (DMeHg) for the purpose of calculating BAFs. The conversion to dissolved methylmercury was accomplished by using the national translators developed by the U.S. EPA.

The March 2004 version of the SWRCB database was used.

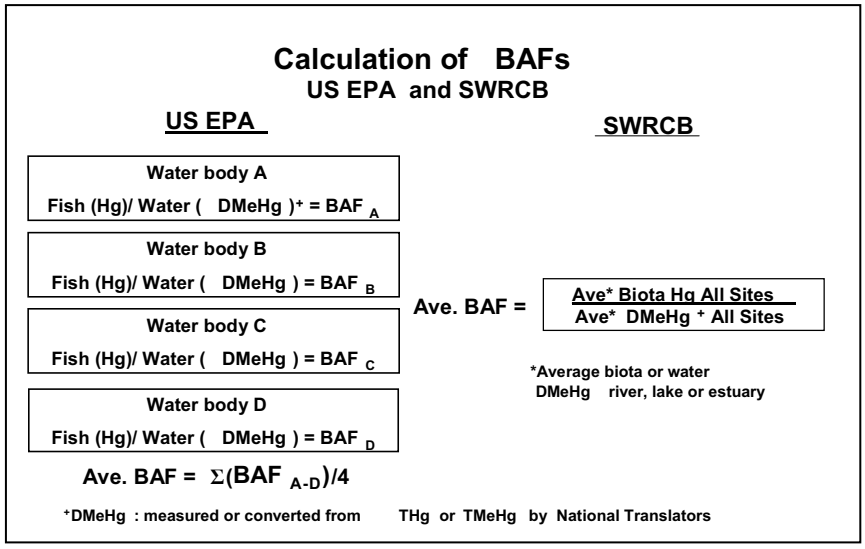
The SWRCB database was a compilation of studies for California water bodies that were reported by different investigators. Because, as noted above, the SWRCB California database was not restricted to matching biota and water samples from the same study and investigators, the compiled data, even when from the same water body, might be more variable than that in the U.S. EPA database due to differences in analytical methods or data quality. This might be expected to lead to differences between BAFs calculated from the SWRCB California and U.S. EPA databases.

SAIC used the standard BAF equation to calculate BAFs from the SWRCB California database. A concentration for methylmercury in biota was divided by a concentration for dissolved methylmercury in water. SAIC also used the national translators developed by U.S. EPA to convert water data reported as total mercury or total methylmercury to dissolved methylmercury when calculating BAFs. SAIC calculated nine statewide BAFs (three environments and three tropic levels) using the data they compiled. However, SAIC calculated BAFs from the SWRCB California database somewhat differently than that used by U.S. EPA to calculate the national BAFs.

In the Excel file SAIC used all biota and water data for each aquatic environmental type (*e.g.*, lentic) and trophic level entered in the SWRCB California database to calculate a statewide arithmetic mean value for biota and water, respectively, and then calculated a corresponding BAF from these overall means for each trophic level and environment. This process is not mathematically equivalent to the method employed by U.S. EPA. U.S. EPA first calculated mean biota and water concentrations of mercury for individual water bodies and/or studies and then calculated a BAF for the water body and/or study at each trophic level. The BAFs from multiple water bodies were averaged by U.S. EPA to derive single national values for each trophic level and aquatic environment. The SAIC method yields a point estimate for each BAF (*i.e.*, the BAF is based on one mean value in the numerator and denominator, not a sum of means from each). Consequently, it is not possible to derive information on the variability (standard deviation, etc.) of their California statewide-BAFs. In contrast, it is possible to calculate variability using the U.S. EPA method. Without repeated measures and estimates of variability it is not possible to statistically compare the SAIC BAFs with those derived by U.S. EPA. Figure 4

illustrates the methods used by the U.S. EPA and in the Excel file of the SWRCB dataset for calculation of BAFs.

Figure 4. Comparison of U.S. EPA and SAIC methods for calculation of BAFs from U.S. EPA and SWRCB datasets



U.S. EPA used fish and water data from one water body at a time to calculate a BAF for each water body (*e.g.*, water bodies A, B, C, and D). Then U.S. EPA summed these BAFs and averaged them. U.S. EPA initially did this for all three trophic levels in each type of water body. In the SWRCB Excel file dataset, SAIC summed all of data for mercury in fish from all of the water bodies of one kind in the California database they compiled and averaged the mercury concentrations. Next, they summed all of data for mercury in water from all of the water bodies of one kind in the California database they compiled and averaged the mercury concentrations. They then calculated a BAF from these grand averages. This was done for all three trophic levels in each type of water body.

3.3 ALTERNATIVE METHOD FOR THE CALCULATION OF BAFs IN CALIFORNIA

An alternative method was investigated for calculation of BAFs using the SWRCB California database. This method is similar to that used by U.S. EPA and allows for calculation of water body-specific BAFs. A preliminary survey of the three aquatic environments in this database indicated that the lotic environment contained sufficient water and biota data to use this method to calculate water body-specific BAFs. U.S. EPA used geometric means to calculate BAFs, but arithmetic means will be used for the alternate California method. Arithmetic means were used because they are more health protective than geometric means (*i.e.*, they are higher numerically) and because, in many cases, the available samples size from an individual water body was too small to test the statistical form of the data distribution. In order to use this alternative method for estimation of BAFs for California water bodies, the following unweighted arithmetic means were calculated:

1) **Numerator:** arithmetic mean mercury concentrations in biota from a water body (*e.g.*, San Joaquin River, Sacramento River, etc.) were calculated for each trophic level (2-4). Most mercury concentrations in biota (Trophic Levels 3, 4) were derived from measurements of

wet tissue samples. Since a few samples in Trophic Level 2 were dried prior to analysis, these data were converted to wet-weight mercury concentrations by using U.S. EPA translators (U.S. EPA, 2000).

2) **Denominator:** arithmetic mean mercury concentrations of dissolved methylmercury were calculated for a water body (*e.g.,* San Joaquin River, Sacramento River, etc.) matching the biota data. Measured dissolved methylmercury and concentrations converted from total mercury or methylmercury were used in this calculation. The U.S. EPA's national translators were used for the conversion of these data to dissolved methylmercury concentrations.

This alternative BAF methodology applied to data selected from the SWRCB California database aggregates biota and dissolved methylmercury concentrations, respectively, from a water body to calculate a BAF for one water body at a time. This aggregation is logical since dissolved methylmercury levels from the same water body are more likely to be similar than those from geographically separated water bodies (*e.g.*, for lakes in northern and southern California). And the same is true of aggregated biota concentrations for the same water body.

3.3.1 Application of the Alternate Method to Calculate BAFs from Data in the SWRCB California Database

This section describes the mercury levels in biota and dissolved methylmercury in water in ten rivers in California from the SWRCB California database and derives BAFs based on these data. These rivers will be used because they are the only rivers in the database that have both measurements of mercury in water and in fish. It should be noted that the ten rivers in the database are not a random sample of California rivers; they fall predominantly in the Sacramento-San Joaquin-San Francisco Bay Delta watershed.

3.3.1.1 Biota Data For Ten Rivers In California

Table 15 contains available information on the concentrations of mercury in Trophic Level 2 biota from the SWRCB California database found in four out of the ten rivers for this trophic level. Concentrations range from a low of 0.013 mg/kg in Putah Creek to a high of 0.018 mg/kg in the Sacramento River, a less than two-fold variation. The values of the arithmetic mean and the median concentrations are similar for the data, suggesting that they may be normally distributed, but the sample size is too small to test this for individual water bodies. Although data for individual water bodies are not very variable (*e.g.*, the standard deviation in all cases is less than the mean), the sample sizes are low (5-11 samples per water body) and additional data for all rivers would need to be collected to have more representative samples of mercury concentrations in Trophic Level 2 organisms in California rivers.

Table 15. Concentrations of methylmercury (mg/kg) in Trophic Level 2 biota[+]

Water Body	Arithmetic Mean	Standard Deviation	Median
Sacramento River (6)*	0.018	0.013	0.011
Mokelumne River (0)	-	-	-
Putah Creek (5)	0.013	0.004	0.013
San Joaquin River (0)	-	-	-
Napa River (11)	0.015	0.006	0.014
Bear River (0)	-	-	-
Coyote Creek (0)	-	-	-
Guadalupe River (0)	-	-	-
Alamo River (0)	-	-	-
Redwood Creek (9)	0.015	0.008	0.013

+ Methylmercury was assumed to be 49 percent of total mercury in Trophic Level 2 biota
* Number of samples collected

These data are from the SWRCB database, March 2004.

Table 16 summarizes the available mercury concentrations for Trophic Level 3 biota from nine rivers in the SWRCB California database. There are no available data for Redwood Creek. Only the Sacramento and San Joaquin River had more than ten samples. The mercury concentrations range from a low of 0.06 mg/kg in the Alamo River biota to a high of 0.53 mg/kg in fish from the Guadalupe River. The arithmetic mean and the median concentrations are similar in six out of nine cases suggesting that the data may be normally distributed for these rivers, but the sample sizes are too low to test this for individual water bodies. The mean and median are dissimilar in three cases (Sacramento, Bear, and Guadalupe River); however, the sample size for the Bear and Guadalupe Rivers is small, so this should not be over-interpreted. In seven out of nine cases, biota concentrations for individual water bodies are not very variable (*e.g.*, the standard deviation is less than the mean). But the sample sizes are low (2-10 samples per water body, and 32 for the San Joaquin River). The Sacramento River, which has the most samples, also has the greatest standard deviation. Based on these limited data, more differences in mercury bioaccumulation are shown by Trophic Level 3 biota in the Sacramento River. This is not surprising given the changes in the river ecosystem between the beginning and end of the Sacramento River. Overall, additional data for all rivers would need to be collected to have more representative samples of mercury in Trophic Level 3 organisms in California rivers.

Table 16. Concentrations of methylmercury (mg/kg) in Trophic Level 3 biota[+]

Water Body	Arithmetic Mean	Standard Deviation	Median
Sacramento River (45)*	0.34	0.45	0.17
Mokelumne River (9)	0.31	0.14	0.31
Putah Creek (10)	0.13	0.04	0.13
San Joaquin River (32)	0.14	0.07	0.12
Napa River (6)	0.26	0.09	0.26
Bear River (2)	0.21	0.21	.0.04
Coyote Creek (5)	0.14	0.06	0.11
Guadalupe River (5)	0.53	0.48	0.20
Alamo River (5)	0.06	0.02	0.06
Redwood Creek (0)	-	-	-

+ Methylmercury was assumed to be 100 percent of total mercury in Trophic Level 3 biota
* Number of samples collected

These data are from the SWRCB database, March 2004.

Table 17 summarizes the available data on mercury concentrations in Trophic Level 4 biota from seven rivers in the California database. No data were available for Trophic Level 4 for Napa River, Coyote Creek or Redwood Creek. Compared to Tropic Levels 2 and 3, the number of samples collected for Trophic Level 4 is significantly larger. Of the rivers with data, only the Alamo River had fewer than ten samples. The data range from a low of 0.04 mg/kg mercury from the Alamo River to a high of 0.98 mg/kg from the Guadalupe River.

The arithmetic mean and the median concentrations are similar in six out of seven cases, suggesting that the data may be normally distributed for these rivers. In many cases, sample sizes are great enough to test the distribution of the biota data for normality in individual water bodies. Although the mean and median values are similar for the Alamo River, the sample size for this water body is lower than for many of the others, so this should not be over-interpreted. In all cases, data for individual water bodies are not very variable (*e.g.*, the standard deviation is less than the mean). Additional collections in the rivers that lack samples and the Bear and Alamo rivers would lead to a more representative database for mercury in Trophic Level 4 organisms in California rivers. Since most of the water bodies have a similar mean concentration of mercury, it could be useful to collect enough data to determine whether bioaccumulation levels in the rivers with the lowest (Alamo and Bear rivers) and the highest (Guadalupe River) concentrations are really different from the other water bodies.

Table 17. Concentrations of methylmercury (mg/kg) in Trophic Level 4 biota[+]

Water Body	Arithmetic Mean	Standard Deviation	Median
Sacramento River (125)*	0.46	0.34	0.35
Mokelumne River (39)	0.69	0.37	0.69
Putah Creek (28)	0.38	0.19	0.34
San Joaquin River (261)	0.48	0.30	0.42
Napa River (0)	-	-	-
Bear River (15)	0.17	0.13	0.10

Alamo River (6)	0.04	0.02	0.04
Redwood Creek (0)	-	-	-

+ Methylmercury was assumed to be 100 percent of total mercury in Trophic Level 4 biota
* Number of samples collected

These data are from the SWRCB database, March 2004.

3.3.1.2 Water Data For Dissolved Methylmercury In Ten Rivers In California

The discussion that follows characterizes the dissolved methylmercury in the same ten California rivers where biota were collected. Table 18 summarizes the available dissolved methylmercury data for these rivers taken from the SWRCB California database. These mean dissolved methylmercury values for each river were derived from measured dissolved methylmercury and measurements of other forms of mercury that were converted into dissolved methylmercury. Overall, there was about three-fold greater number of converted values (223) compared to measured values (78). The total number of water samples collected (combined measured and converted) ranged from a high of 98 from the Bear River to a low of seven for the Alamo River. The standard deviations of the arithmetic means of these data were less than the means in six out of the ten rivers, indicating low variability for environmental data. The average mean value of dissolved methylmercury ranged from a low of 7.06×10^{-08} mg/L for samples collected from Putah Creek to a high of 3.78×10^{-06} mg/L for the Alamo River, a difference of slightly less than 200-fold. In eight out of ten cases, the mean and median were similar indicating that the data could be normally distributed, but statistical tests of normality were limited by the sample size. The mean and median were most dissimilar for the Guadalupe River, which had few samples, and the Bear River, which had the most samples. The source of these differences is not known.

For most water bodies, the mean dissolved methylmercury concentration was influenced by the greater number of converted values in the database. More measured dissolved methylmercury concentrations than converted concentrations were only available for the Mokelumne River and Putah Creek. Data from the Sacramento, San Joaquin and Bear rivers were selected to compare the concentration of measured vs. converted dissolved methylmercury. These rivers were selected because each had at least ten measured and ten converted values. When measured and converted concentration values in the Sacramento, San Joaquin and Bear rivers were compared (data not shown), the converted values were 2.3, 1.8, and 2.8-fold greater, respectively, than the

measured values. This indicates that using converted values can add two to three-fold to the concentration and perhaps contribute to greater variability and uncertainty in dissolved methylmercury concentrations. In order to reduce this variability and uncertainty, water samples of directly measured dissolved methylmercury should be collected in these water bodies, especially those with fewer measured values (Napa, Guadalupe, and Alamo rivers; and Coyote and Redwood creeks). Adding data for water bodies from other geographic areas of California would also improve the statewide coverage and representativeness of data for the lotic environment.

Table 18. Water dissolved methylmercury (DMeHg) concentrations for 10 rivers in California

	Sample Type[+]		**DMeHg (mg/L)**		
Location	Measured.	Converted	Mean[▽]	Standard Deviation	Median

Total	78	223			

\+ DMeHg measured (Meas.) or converted (Conv.) to DMeHg from total mercury or total methylmercury
* Total number of samples collected (sum of measured and converted)
▽ Arithmetic mean of measured dissolved methylmercury concentrations and converted concentrations to dissolved methylmercury from total methylmercury or total mercury

These data are from the SWRCB database, March 2004.

Table 19 shows the BAFs for Trophic Level 2 biota calculated from dissolved methylmercury in biota and methylmercury in water from the SWRCB California database. Four of the rivers or creeks have biota methylmercury concentrations that allow the calculation of a BAF for this trophic level. The mean biota and water methylmercury concentrations are from all sites and all times of sampling. The BAFs range from high of $2.01x10^{+05}$ L/kg in the Sacramento River to a low of $5.76x10^{+04}$ L/kg in the Napa River. These individual BAFs differ by less than four-fold and the standard deviation of the overall mean ($6.41x10^{+04}$ L/kg) is less than the mean BAF of all water bodies combined ($1.52x^{+05}$ L/kg). It is clear from Table 19 that more data are necessary to attain a more representative database for Trophic Level 2 biota so that additional BAFs for this trophic level for more California water bodies can be calculated.

Table 19. Concentrations of dissolved methylmercury in water, biota mercury concentrations and BAFs for Trophic Level 2

Water Body	**Water** DMeHg (mg/L)	**Biota** MeHg (mg/kg)	**BAF** (L/kg)[+]
Sacramento River (48,6)*	$9.00x10^{-08}$	0.018	$2.01x10^{+05}$

* Number of samples (water, biota)

\+ BAF = Biota MeHg (mg/kg)/Water DMeHg (mg/L)

These data are from the SWRCB database, March 2004.

Table 20 shows the BAFs for Trophic Level 3 biota calculated from dissolved methylmercury in biota and methylmercury in water from the SWRCB California database. It was not possible to develop a BAF for Redwood Creek because Trophic Level 3 biota were not collected from this water body. The BAFs range from a low of $1.59x10^{+04}$ L/kg in the Alamo River to a high $3.82x10^{+06}$ L/kg in the Sacramento River, which is a difference of about 240-fold. The standard deviation of the overall Trophic Level 3 BAF is again about as large as the mean itself ($1.36x10^{+06}$ and $1.42x10^{+06}$ L/kg, respectively), and is larger than the variation in biota or water concentrations. This variation could be due to the range of environments and biota with differing mercury levels used in these calculations. Although there are biota data for more water bodies for Trophic Level 3, as noted earlier, in many cases the biota results are based on fewer than ten samples (eight out of the ten rivers). Most of the samples in the current data set are from northern California rivers affected by mercury and gold mining. Collecting a larger database of biota samples from more lotic environments throughout the state could be useful to better characterize the range of bioaccumulation in this important trophic level that contains many fish that people catch and eat. If additional sampling takes place, it is suggested that collection of water and biota could be better coordinated to make the results more similar to the studies used by U.S. EPA in their development of BAFs.

Table 20. Concentrations of dissolved methylmercury in water, biota mercury concentrations and BAFs for Trophic Level 3

Water Body	**Water** DMeHg (mg/L)	**Biota** MeHg (mg/kg)	**BAF** (L/kg)$^{+}$
Sacramento River (48,45)*	9.00×10^{-08}	0.34	$3.82 \times 10^{+06}$
Mokelumne River 18,9)	9.62×10^{-08}	0.31	$3.25 \times 10^{+06}$

* Number of samples (water, biota)
\+ BAF = Biota Me Hg (mg/kg)/Water DMeHg (mg/L)
These data are from the SWRCB database, March 2004.

Table 21 shows the BAFs for Trophic Level 4 biota calculated from dissolved methylmercury in biota and methylmercury in water from the SWRCB California database. BAFs for two of the water bodies, Napa River and Coyote Creek, could not be calculated because Trophic Level 4 biota were not collected. The BAFs range from a low of $1.06E^{+04}$ L/kg in the Alamo River to a high of $7.14E^{+06}$ L/kg in the Mokelumne River, which is a difference of about 670-fold. The overall mean and standard deviation for the BAFs for Trophic Level 4 biota in these rivers are $3.49E^{+06}$ and $3.07E^{+06}$ L/kg, respectively. Again there is more variation in bioaccumulation between water bodies than variation in the underlying biota and water concentrations. This variation is important to note because most of these water bodies have in common that they are in northern California in areas affected by past mercury and gold mining. Of course, there may be many environmental differences within this area, but if there is this much variation for similar water bodies, then the overall variation for a database that includes water bodies from southern California could be greater. Although the Trophic Level 4 dataset includes the highest sample sizes for biota, collecting a larger database of biota samples from more lotic environments throughout the state could be useful to better characterize the range of bioaccumulation in this important trophic level that typically shows the highest methylmercury bioaccumulation.

* Number of samples (water, biota)
\+ BAF = Biota MeHg (mg/kg)/Water DMeHg (mg/L)

These data are from the SWRCB database, March 2004.

Table 22 summarizes the BAFs for lotic environments in California calculated from the SWRCB California database using the alternative method. An unweighted arithmetic mean BAF was calculated for each trophic level from these data for the ten rivers. This is consistent with the U.S. EPA calculation, which also did not factor the number of replicates in a study into their calculations of mean BAFs. Some lotic environments have a larger dataset than others, so the BAF values from them are likely to be statistically more representative. The Bear River is an example of a dataset that is not very robust with respect to both water and biota data. In this river there were 98 water samples, and 0, 2 and 15 biota samples collected in Trophic Levels 2, 3 and 4, respectively. Other water bodies show similar data gaps especially for Trophic Level 2.

Table 22. Summary of bioaccumulation factors (BAFs) for lotic environments in California

Redwood Creek (22;9,0,0)	$1.70x10^{+05}$	-	-
Arithmetic mean	$1.52x10^{+05}$	$1.42x10^{+06}$	$3.49x10^{+06}$
Standard Deviation	$6.41x10^{+04}$	$1.36x10^{+06}$	$3.07x10^{+06}$

* n_w, n_b-sample size for water and biota (3 trophic level values), respectively

These data are from the SWRCB database, March 2004.

The BAFs for the Trophic Levels 3 and 4 differ by slightly more than two-fold (1.42-3.49x10^{+06}), but the difference between Trophic Level 2 and 3 is about 10-fold and between Trophic Level 2 and 4 about 20-fold. A pair-wise t-test (two-tail, unequal variance) was used to test whether the BAFs for these trophic levels were statistically different. The p-values are shown in Table 23. The BAFs for Trophic Levels 3 and 4 were not different (p=0.14), but the BAF for Trophic Level 2 was different than that for Trophic Level 3 (p=0.02) and Level 4 (p=0.03).

A similar pair-wise t-test comparison was performed for the U.S. EPA BAF data for the lotic environment. BAFs from U.S. EPA data were recalculated as arithmetic means for this statistical evaluation. The results of this evaluation are also shown in Table 23. Again, Trophic Level 3 and 4 BAFs are not statistically different, which might be expected since there are not consistent separations between all fish in these trophic levels. But Trophic Level 2 BAFs are different from both Trophic Level 3 and 4, showing the clearer separation between feeding behavior and bioaccumulation at these levels.

Table 23. Comparison of alternate California BAFs and recalculated arithmetic mean U.S. EPA BAFs among trophic levels for the lotic environment

	Trophic level (n)	**Trophic level comparison**	**p statistic+**
Alternate CA BAFs			
1.52x10^{+05}	2 (4)	2 vs. 3	0.02
1.42x10^{+06}	3 (9)	2 vs. 4	0.03
3.49x10^{+06}	4 (7)	3 vs 4	0.14
Recalculated* U.S. EPA BAFs			
2.15x10^{+05}	2 (6)	2 vs. 3	0.02
1.32x10^{+06}	3 (26)	2 vs. 4	0.05
3.93x10^{+06}	4 (7)	3 vs 4	0.15
(n) = number of studies or water bodies included to derive mean BAF			
*recalculated as arithmetic means			
+ two-tail, unequal variance			

Alternate CA BAFs are from Table 22. U.S. EPA BAFs are recalculated from U.S. EPA (2000).

3.4 COMPARISON OF CALIFORNIA ALTERNATIVE BAFs AND U.S. EPA BAFs RECALCULATED AS ARITHMETIC MEANS FOR THE LOTIC ENVIRONMENT

The proceeding discussion demonstrated that California water body-specific BAFs could be derived from the SWRCB California database using an alternate methodology. A statistical comparison of the California and national BAFs was done in order to provide some basis for consideration of the difference between the alternatively calculated California BAFs and the U.S. EPA BAFs. Table 24 shows the results of a two tail pair-wise t-test of the mean California and

U.S. EPA BAF values for each trophic level. This statistical evaluation indicates that the mean BAFs for lotic environments from the U.S. EPA and California river-specific values do not differ ($p>0.05$) for any of the trophic levels. Figure 5 shows this overall similarity graphically.

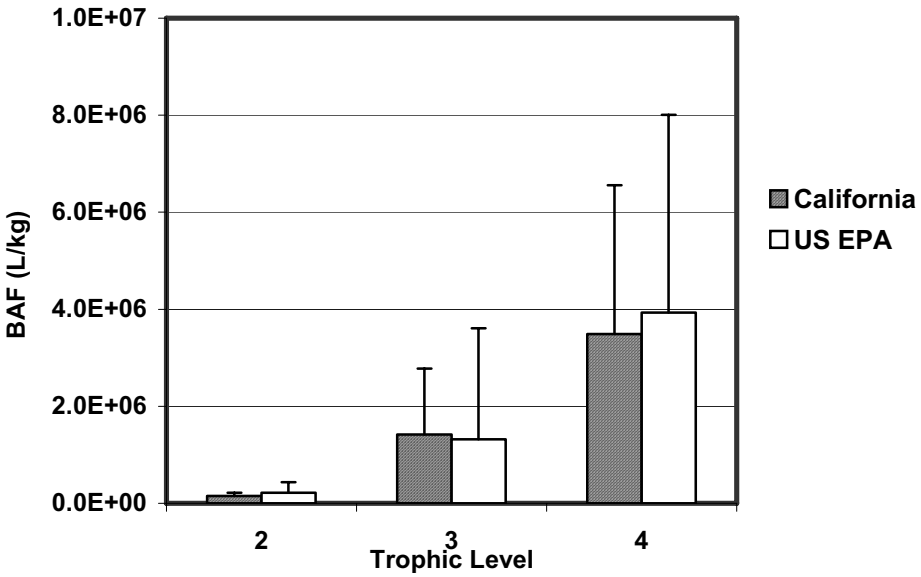
Table 24. Statistical Evaluation of California and U.S. EPA BAFs for the Lotic Environment

Trophic Level	P Statistic*
2	0.34
3	0.89
4	0.82

* Two-tail test for unequal variance

Data for comparisons are from Table 24.

Figure 5: California - U.S. EPA BAFs
Lotic Environment



Whiskers – standard deviation
Plot of data from Table 23.

3.4.1 California Lentic Environment

It is not possible to calculate an alternative BAF for the lentic environment because only a single water body (Standish Dam) had any measurements of forms of mercury in water. As was

mentioned previously, biota were not collected for the analysis of mercury concentration from this water body. Consequently, the alternate method used to calculate BAFs for the lentic environment cannot be used with the data presently compiled in the SWRCB database. In contrast to the water data, there is a large dataset for mercury concentrations in biota in the lentic environment that could be used to calculate BAFs if corresponding water measurements were available.

3.4.2 California Estuarine Environment

The estuarine dataset in the SWRCB California database contains a sufficient number of fish-water combinations to enable recalculation of BAFs for this aquatic environment, but all data are from collection sites in the San Francisco Bay-Delta Estuary. The available biota and water data for the estuary are summarized below prior to calculating BAFs. Only data for Trophic Levels 2 and 4 are presently compiled in the SWRCB California database for this estuary.

Table 25 contains biota mercury concentrations for Trophic Level 2 biota collected from nine sites around San Francisco Bay. Most sites, with the exception of the South Bay, had Trophic Level 2 biota collected. Only four sites had ten or more samples collected. The mean values for methylmercury for this tropic level span a relatively narrow range from 0.010- 0.012 mg/kg. All of the standard deviations are less than the mean values. All of the medians are less than or equal to the mean values. This suggests that the data are normally distributed but the samples sizes are too small to adequately test the distribution. Additional biota samples should be collected to create a more representative database for this trophic level.

Table 25. Summary of methylmercury in Trophic Level 2 biota[+] collected from the San Francisco estuarine environment

Location (n_b)*	**Biota** MeHg (mg/kg)		
	Mean	Standard Deviation	Median
Alameda (10))	0.010	0.003	0.010
Davis Pt (9)	0.012	0.004	0.012

Yerba Buena (7)	0.012	0.002	0.011

\+ Methylmercury was assumed to be 44 percent of total mercury in Trophic Level 2 biota
* Sample number of biota samples collected
These data are from the SWRCB database, March 2004

Trophic Level 3 biota were not collected from the San Francisco Bay estuary so it will not be possible to summarize the data for these biota with respect to mercury concentrations nor to calculate a BAF.

Summary information on Trophic Level 4 biota collected for mercury analyses are presented in Table 26. The SWRCB California database contained only four collections of Trophic Level 4 biota. Two of these collections contained ten or fewer samples, but larger sample sizes were available at two sites, San Pablo Bay (n=47) and South Bay (n=48). The mercury concentrations in these biota ranged from a low of 0.12 mg/kg at the Dumbarton Bridge to a high of 0.60 mg/kg at South Bay, a difference of five-fold. The standard deviations were less than the means, and the medians were similar to the means for collections with few samples. However, for the two collections with a larger sample size, the means and medians were more dissimilar. In order to achieve a more representative estimate of the mercury levels and BAFs for this tropic level, additional sampling should be considered.

Table 26. Summary of methylmercury in Trophic Level 4 biota[+] collected from the San Francisco estuarine environment

Location (n_b)*	**Biota** MeHg (mg/kg)		
	Mean	Standard Deviation	Median

\+ Methylmercury was assumed to be 100 percent of total mercury in Trophic Level 4 biota
* Sample size of biota collected.
These data are from the SWRCB database, March 2004

Table 27 summarizes water data for measured and converted dissolved methylmercury for the San Francisco Bay estuarine environment. The mean values are averaged over all times that a site was monitored and may include both measured and converted values. Measured values were only available for four sites and, in these cases, only one or two measured samples were taken. Out of 185 water samples only eight (<5 percent) were for directly measured dissolved methylmercury concentration. In contrast, for the lotic environment, nearly 25 percent of water values were directly measured dissolved methylmercury. A comparison of the measured and converted values in the estuarine environment suggests that this reliance on converting other measurements to dissolved methylmercury may have biased these results. The mean concentration based on measured and converted dissolved methylmercury was 2.37×10^{-06} mg/L, but the mean concentration based on measured dissolved methylmercury only was 4.99×10^{-08} mg/L. This is about a 500-fold difference. Other reported concentrations for directly measured dissolved methylmercury in water from San Francisco Bay in the literature are more similar to the limited number of measured values in the SWRCB California database. The mean concentration from Conaway *et al.* (2003) was 4.47×10^{-08} mg/L and that from California Regional Water Quality Control Board (2000) was 3.21×10^{-08} mg/L.

The converted values for the estuarine environment based on the SWRCB California database will be discussed here and used to calculate BAFs. However, it should be noted that using just the measure concentrations of dissolved methylmercury might yield different results. And it would be important to collect additional data for measured dissolved methylmercury in the San Francisco estuary.

Nine sites had sample sizes of 17 or more in the SWRCB California database with converted water concentrations for dissolved methylmercury. The values for mean dissolved methylmercury (combining measured and converted concentrations) range from a low of $5.51x10^{-07}$mg/L at Yerba Buena to a high of $3.75x10^{-06}$ mg/L at San Pablo Bay, which is a difference of about seven-fold. In three of the nine locations, Davis Point, Dumbarton Bridge and San Pablo Bay, the standard deviation exceeded the mean suggesting that, at these sites, the data were somewhat more variable than at the other six sites. The reason for this is unknown. The overall mean dissolved methylmercury concentration was $2.37x10^{-06}$ mg/L.

Table 27. Summary of water dissolved methylmercury (DMeHg) concentration for locations in the San Francisco Estuary

	Water Samples:		**DMeHg (mg/L)**		
Location (n*)	Meas.	Conv.	Mean+	Standard Deviation	Median
Alameda (20)	2	18	$5.59x10^{-07}$	$3.95x10^{-07}$	$4.66x10^{-07}$

Sum	8	178			
		Arithmetic mean	$2.37x10^{-06}$		

* Total number of samples (Measured + Converted)

\+ Arithmetic mean of measured DMeHg and converted (DMeHg from THg and DMeHg from TMeHg)

These data are from the SWRCB database, March 2004

The BAFs calculated from the biota data in Tables 25 and 26, and the dissolved methylmercury data in Table 27, are shown in Table 28. The BAFs for Trophic Level 2 range from $2.43x10^{+03}$ L/kg at San Pablo Bay to a high of $1.85x10^{+04}$ L/kg at Alameda, a difference of about eight-fold. The arithmetic mean value for Trophic Level 2 is $8.71x10^{+03}$ L/kg. The standard deviation ($7.67x10^{+03}$) is slightly less than the mean. The BAFs for Trophic Level 4 ranged from a low of 3.73 $x10^{+04}$ L/kg at Dumbarton Bridge to a high of $2.11x10^{+05}$ a South Bay, a difference of about six-fold. The arithmetic mean value for Trophic Level 4 is $1.3x10^{+05}$ L/kg and the standard deviation ($7.64x10^{+04}$) is slightly less than the mean. The BAF for Trophic Level 4 is about 15-fold greater than the Trophic Level 2 BAF. Statistical evaluation of these data using a two-tailed t-test with unequal variance shows that they were of borderline significance ($p = 0.051$). BAFs recalculated using just directly measured dissolved methylmercury (to improve data quality) are

also show in Table 28. Additional biota, especially Trophic Level 3 and 4, and water samples, especially measured dissolved methylmercury, should be considered for future collections in San Francisco Bay and other California estuarine environments. This would yield a more representative database of values. If additional biota and water sampling were to occur, it would be best to coordinate water and biota sampling to increase similarity with the methodology used by U.S. EPA.

Table 28. Summary BAFs for the Estuarine Environment

		Biota MeHg (mg/kg)		**BAF(L/kg)$^{+}$**	
Location(n*)	Water (mg/L)	TL 2	TL 4	TL 2	TL 4

3.5 COMPARISON OF U.S. EPA AND CALIFORNIA TRANSLATORS

The discussion that follows compares translators derived from the SWRCB California database to the U.S. EPA translators. Only lotic translators can be directly compared because these were the only translators for which national and California data were available. Both sets of lotic translators are shown in Table 29. U.S. EPA used multiple studies that met specific analytical criteria to derive national translators. Like the studies used by U.S. EPA for BAFs, many of these studies contained replicates, so the number of U.S. EPA studies in Table 29 are not directly comparable to the number of entries from the SWRCB California database. The major difference between the U.S. EPA translators is that they came from individual studies by the same investigators, whereas, in order to calculate translators from the SWRCB California database, data from different investigators for the same water bodies were used. U.S. EPA translators have been recalculated as arithmetic means to allow comparison with the SWRCB California database translators. The differences and similarities between the U.S. EPA and translators calculated using the data compiled by SAIC in the SWRCB database will be discussed for each translator.

3.5.1 Lotic Environment

Table 29 shows the translators for lotic environment derived from the SWRCB California database and the translators from U.S. EPA for this aquatic environment.

Table 29. Translators for the Lotic Environment: California and U.S. EPA

Source	Translator:	DHg/THg		
	n*	Mean (Standard Deviation)		Range

* Number of samples (U.S. EPA number of studies; California number of entries in the SWRCB database)
These data are from the SWRCB database, March 2004

3.5.1.1 Translator for DHg/THg

The arithmetic mean value for DHg/THg from U.S. EPA (0.44) is higher than the value of 0.31 derived from the SWRCB California database. The California data range is 0.01-6.88 compared to the U.S. EPA's data range of 0.10-0.90. The standard deviations for the U.S. EPA and California arithmetic means are and 0.24 and 0.86, respectively. The U.S. EPA, through its quality assurance and quality control, did not include studies that reported ratios of DHg/THg that were greater than one (unity) as it is not possible for the concentration of dissolved mercury to exceed the concentration of total mercury. Therefore, the range of values in the California dataset is unreasonable and includes some analytically invalid data. These invalid data can be eliminated by censoring (*i.e.*, deleting) any data with a ratio greater than one when calculating a translator mean. When values greater than one are removed from the DHg/THg SWRCB California dataset, the arithmetic mean becomes 0.18, which is 2.4-fold below the arithmetic mean for the U.S. EPA dataset. One reason for the lower mean value for this translator in California compared to the U.S. EPA value may be related to the absence of data less than 0.10 in the U.S. EPA dataset. In the California dataset, 28 percent of values for the ratio DHg/THg range from 0.01-0.09. This may indicate some unique environmental conditions in California lotic environments or additional problems with data quality. Statistical evaluation of the U.S. EPA and California arithmetic mean values using a two-tail t-test with unequal variance indicates that they are not different ($p = 0.17$).

3.5.1.2 Translator for DMeHg/THg

The arithmetic mean value for DMeHg/THg for U.S. EPA's translator (0.020) is higher than the value (0.015) derived from the SWRCB California dataset. The range of the values for the U.S. EPA dataset is 0.002-0.051 and the range for the California dataset is 0.003-0.042. The standard deviations for the U.S. EPA and California arithmetic means are 0.016 and 0.012, respectively. In both cases, the standard deviation is lower than but similar to the mean. Statistical evaluation of U.S. EPA and California arithmetic mean values using a two-tail t-test for unequal variance indicates that they are not different ($p = 0.29$). Given the similarity of the means for the data from California and U.S. EPA and the observation that the dataset from California contains a reasonable range of values (none greater than one), either translator would yield a similar value when converting a total mercury concentration into a dissolved methylmercury concentration.

3.5.1.3 Translator for DMeHg/TMeHg

The arithmetic mean values for this translator from U.S. EPA and SWRCB California datasets are 0.53 and 0.51, respectively. The data ranges for U.S. EPA and California are 0.17-0.83 and 0.04-1.04, respectively. The minimum values from the SWRCB California dataset are approximately four-fold lower (0.04 vs. 0.17) than the U.S. EPA dataset. The standard deviations for these data are 0.20 (U.S. EPA) and 0.26 (California). Also, there are two values in the California dataset that exceed one, suggesting that the quality of the SWRCB California dataset should be examined. Comparison of the U.S. EPA and California mean values with a two-tail t-test for unequal variance indicates that they are not different ($p = 0.70$). When the two data points in the dataset for DMeHg/TMeHg with values greater then one are removed, then the mean value for this translator becomes of 0.49, which is an insignificant change in this relationship. After censoring the values above one in the SWRCB California dataset, there is no clear reason to recommend either the California or U.S. EPA translator for TMeHg to DMeHg.

3.5.2 Lentic Environment

It is not possible to derive translators for the lentic environment because only data for one water body, Standish Dam, are compiled in the SWRCB California database. Other data exist for the lentic environment in, for example, Clear Lake and Lake Berryessa, but they were not included in the SWRCB California database as currently evaluated. If adequate values for concentrations of all forms of mercury in water in lentic environments can be compiled from other sites in California, then it may be possible to calculate these translators.

3.5.3 Estuarine Environment

3.5.3.1 Translator for DHg/THg

Sufficient data exist for derivation of a translator for DHg/THg in the estuarine environment. Table 30 summarizes these data for eight sites in the San Francisco Bay-Delta Estuary. This table contains the arithmetic mean and standard deviations for data from these sites within San Francisco Bay. The number of water samples available to calculate this translator range from a high of 19 in Grizzly Bay to a low of 12 in Alameda. The translators ranged from a low of 0.12 in two locations, Davis Point and Grizzly Bay, to a high of 0.30 in Alameda. The arithmetic

mean for these data is 0.15. The U.S. EPA reports a geometric mean translator value of 0.35 for DHg/THg in the estuarine environment. The raw U.S. EPA data for this translator are not readily available so it was not possible to recalculate the U.S. EPA value as an arithmetic mean to compare it statistically with the California-based translator.

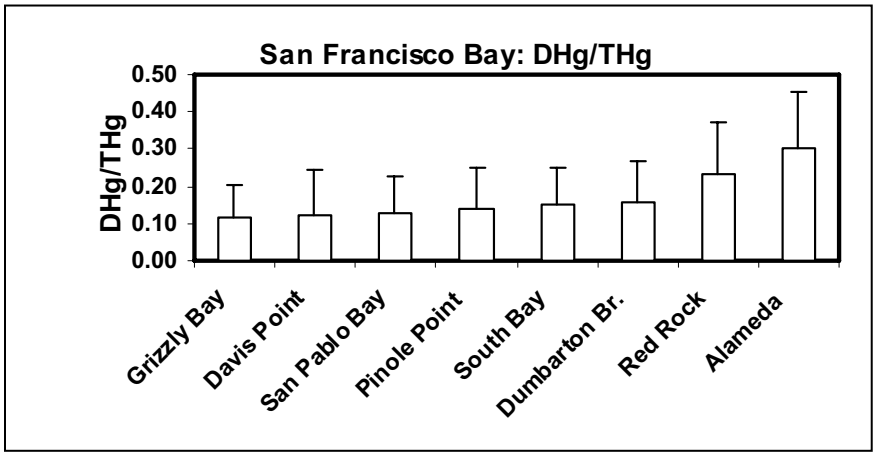
Table 30. Translator (DHg/THg) for sites in San Francisco Bay

Site (n)*	Arithmetic Mean	Standard Deviation
Alameda (12)	0.30	0.15
Davis Point (16)	0.12	0.12
Dumbarton Bridge (18)	0.16	0.11
Grizzly Bay (19)	0.12	0.09
Pinole Point (16)	0.14	0.11
Red Rock (15)	0.23	0.14
San Pablo Bay (15)	0.13	0.10
South Bay (18)	0.15	0.10
Arithmetic Mean	0.15	
n Number of samples		

These data are from the SWRCB database, March 2004

Comparison of these data using a pair-wise t-test for unequal variance showed that mean values for Alameda and Grizzly Bay or Davis Point (the two extremes of the dataset) are different ($p = 0.0012$), while the mean values for Alameda and Red Rock are not different ($p = 0.22$). The mean values of Alameda and Dumbarton are different ($p = 0.009$), while the mean values for Red Rock and Dumbarton are not different ($p = 0.11$). Therefore, the translator for Alameda is statistically greater than all other sites except for Red Rock. This can be seen graphically in Figure 6, which displays the translator mean at each site in the San Francisco Bay along with the standard deviations (whiskers) of the mean for each site. The reason for this difference at Alameda is not known.

Figure 6. DHg/THg at several sites in the San Francisco Bay



The data plotted in this figure are from the SWRCB database, March 2004, as shown in Table 30.

A San Francisco Estuary-wide translator of 0.15 for DHg/THg can be derived using data from all of the sampling sites. Even though it has been demonstrated that statistical differences exist between sites, it is consistent with the U.S. EPA translator approach to derive an estuary-wide translator. U.S. EPA combined data over broader geographic areas (*e.g.*, the United States, Europe and Siberia) than San Francisco Bay without regard to potential differences between sites for the derivation of BAFs and translators. Regardless, this California translator is of limited use because it does not yield a translator to dissolved methylmercury.

3.5.3.2 Translator for DMeHg/THg

It is not possible to develop a California-specific translator for DMeHg/THg in the estuarine environment because only eight values of measured dissolved methylmercury (DMeHg) are compiled in the SWRCB California database. Also, when DMeHg was measured, no corresponding values for THg were measured.

3.5.3.3 Translator for DMeHg/TMeHg

There are less than ten entries in the SWRCB California dataset that could be used to develop an estuarine California-specific translator for DMeHg/TMeHg. Further, the data quality in these measurements was poor, as dissolved mercury forms sometimes exceeded total mercury. Additional data could be collected to so that this translator can be derived.

3.6 CONCLUSIONS CONCERNING DERIVING BAFs AND TRANSLATORS FROM THE SWRCB CALIFORNIA DATABASE

3.6.1 Conclusions concerning California BAFs

OEHHA found a number of differences between the database and methodology used by SAIC to derive BAFs and the U.S. EPA database and methodology. Both databases used the best quality data that could be identified at the time but the U.S. EPA criteria could be more stringent due to its broader geographic scope. Some specific instances were noted in the discussion above where the values in the SWRCB database were unrealistic. Some of these problems can be overcome by censoring such data. Also, OEHHA found that, while the U.S. EPA based individual BAF calculations on water and biota data collected and measured in the same study, the water and biota data compiled in the SWRCB California database, even when collected from the same water body, were from different studies. This potentially increases data variability due to different analytical techniques and quality control measures between study researchers. Coordinating biota and water sampling in California and standardizing analytical techniques and quality control measures would help to reduce variability for future data added to this database. OEHHA also found that the method SAIC used to calculate BAFs was different than that used by U.S. EPA.

Despite these differences, OEHHA demonstrated that California-specific BAFs could be calculated using the data in the SWRCB California database by an alternative method for lotic and estuarine environments. This alternate method is very similar to the U.S. EPA method. OEHHA calculated arithmetic mean values for the alternate California-specific BAFs. U.S. EPA's national BAFs were calculated as geometric means. The U.S. EPA and California-specific BAFs are shown in Table 31. OEHHA used arithmetic means because they are more health protective and because in most cases the sample size for data for individual water bodies was insufficient to determine the form of the distribution. The alternate California-specific BAFs calculated by OEHHA were shown to be similar to U.S. EPA's BAFs, especially U.S. EPA values recalculated as arithmetic means. The alternate California-specific BAFs calculated by OEHHA and the U.S. EPA BAFs re-calculated as arithmetic means were not statistically different. This suggests that the current SWRCB California database can be used to calculate some California-specific BAFs. OEHHA also calculated estuarine BAFs although U.S. EPA could not. These BAFs when calculated using only directly measured methylmercury in water (to improve data quality) are also similar to the national default values (see values in Table 31).

OEHHA found "gaps" in the available data for the SWRCB California database that limited the aquatic environments and trophic levels for which California-specific BAFs could be calculated. Filling these data gaps could improve the application of the database. The following are some of the consequences of these gaps in data availablility:

- California-specific BAFs could not be calculated for any trophic level in lentic environments due to insufficient data. Biota data were available for one water body, but there were no corresponding water data. Water data and additional corresponding biota

data are needed from lentic water bodies throughout California in order to calculate California-specific BAFs for the lentic environment.

- A combined lentic/lotic California-specific BAF equivalent to the U.S. EPA national BAF cannot be calculated because of the lack of lentic data for California.

- California-specific BAFs could not be calculated for Trophic Level 3 in the estuarine environments due to insufficient data. Trophic Level 3 biota data are needed from San Francisco Bay in order to calculate California-specific BAFs for Trophic Level 3 in this estuarine environment. Data for dissolved methylmercury measured in water and mercury measurements in Trophic Level 2, 3, and 4 biota in other estuarine water bodies in California would also useful to develop estuarine BAFs representative of a range of California estuaries. However, a complete dataset for San Francisco Bay is especially important because of the size and importance of this water body.

- OEHHA found that the sample size for biota and water data entered into the SWRCB California database was often low. BAFs based on more samples will be more accurate than those based on fewer samples. Larger samples sizes of water and biota data are needed from water bodies throughout California in order to calculate more accurate California-specific BAFs.

- OEHHA found that the geographic range of lotic, lentic, and estuarine water bodies in California compiled in the SWRCB California database was very limited. The available water bodies are not representative of the range of California environmental conditions. Data for the lotic environment was primarily from northern California and the Sacramento-San Joaquin River watersheds. Data for the estuarine environment were exclusively from the San Francisco Bay-Delta estuary. Both of these areas are heavily impacted by runoff and deposition from mercury and gold mining. Data from Standish Dam were the only data for the lentic environment in the SWRCB California database. Additional water and biota data (for all trophic levels) are needed from water bodies throughout California in order to calculate California-specific BAFs that are representative of a range of California water bodies.

SWRCB should attempt to fill these data gaps to develop a complete spectrum of California-specific BAFs for each trophic level in lentic, lotic, and estuarine environments. Some additional new data may be available in recent literature. For example, several new studies for the San Francisco Bay Estuary are available in which multiple forms of mercury in water have been measured (Conway, *et al.*, 2003; Choe *et al.,* 2003a; b). Data from these and other studies that may become available in the future could be added to the SWRCB California database.

Based on these comparisons there is not a clear-cut scientific basis that shows that either the national or California-specific BAFs will yield more accurate results if used in a methylmercury implementation policy. California-specific BAFs calculated as arithmetic means will yield higher tissue concentrations in biota at a given concentration of dissolved methylmercury in water. Consequently, allowable water concentrations based on the OEHHA alternate California-

specific BAFs would be lower than those based on the geometric mean U.S. EPA BAFs. Thus, the California-specific BAFs will be more health protective, but could not be developed for all environments and trophic levels. U.S. EPA BAFs could be used for environments and trophic levels where California-specific BAFs are not available. In order to determine if the California-specific or U.S. EPA BAFs would work best in the methylmercury implementation policy they should be tested to see how well they predict biota tissue concentrations at different trophic levels based on water data for various water bodies in California. This is a necessary step in validating both the U.S. EPA and California-specific BAFs and determining their limitations in a practical application. This testing could also show which BAFs would be more applicable in California or help find environmental conditions for which default BAFs do not work.

Table 31: Summary of Bioaccumulation Factors (BAFs) from the U.S. EPA and California data

			Trophic Level		
Agency	Environment/Comments	Mean	2	3	4

NP: Not possible to calculate from current California or national database.
ND: Not done.
*Maximum BAF for this trophic level and this water body environment.
!!Maximum BAF for this trophic level
These values were calculated using U.S. EPA estuarine translators. This was necessary because the SWRCB database did not contain data needed to calculate a total mercury to dissolved methylmercury translator.
These values were calculated using directly measured dissolved methylmercury concentrations from a limited number of measurements from the San Francisco estuary in the SWRCB database, March 2004.

3.6.2 Conclusions Concerning California Translators

Translators were not originally calculated from the California data compiled in the SWRCB California database. However, OEHHA determined that, in some cases, there were data in the database that could be used to calculate California-specific translators using the same method used to calculate California-specific BAFs. Just as California-specific BAFs might be more representative of California environments than national BAFs, California-specific translators

might work better to convert water data from California into dissolved methylmercury for calculating California-specific BAFs. OEHHA calculated translators from data in the database. These are shown with U.S. EPA translators in Table 32. These translators are subject to the same data quality limitations as the California-specific BAFs.

Translators are very important because they are often necessary to convert the form of mercury measured in water into dissolved methylmercury, the form needed to calculate BAFs. U.S. EPA derived three different translators for each aquatic environment (lentic, lotic, and estuarine): a translator between measured total mercury and dissolved total mercury (DHg/THg); a translator between measured total mercury and dissolved methylmercury (DMeHg/THg); and a translator between measured total methylmercury and dissolved methylmercury (DMeHg/TmeHg).

OEHHA found "gaps" in the data available for the SWRCB California database that limited which California-specific translators could be calculated. No California-specific translators could be calculated for lentic environments due to insufficient data. Water data are for all forms of mercury in water from lentic water bodies throughout California would be needed in order to calculate California-specific translators for the lentic environment. The only California-specific translator that could be calculated for the estuarine environments was DHg/THg. Data were insufficient to calculate other translators for this environment. The samples sizes for these calculations were small and the geographic range of water bodies in California was limited. It is possible to develop estuarine translators for DMeHg/THg and DMeHg/TMeHg from California-specific data from published studies in the literature (Conway *et al.*, 2003; Choe, *et al.* 2003a,b).

It was possible to calculate all three translators for lotic environments from the SWRCB database. All of these California-specific translators were similar to the corresponding U.S. EPA translator. The California and U.S. EPA translators were not statistically different. The samples sizes for these calculations were reasonable (all above 35 samples) but the geographic range of water bodies in California was limited. The limited geographic range of lotic, lentic, and estuarine water bodies compiled in the SWRCB California database (as discussed for BAFs) could also affect the California-specific translators. Additional data for all forms of mercury in water are needed from water bodies throughout California in order to calculate more representative California-specific translators.

There is no clear-cut scientific basis that shows that either the national or California-specific translators will yield more accurate results if used in a methylmercury implementation policy. The U.S. EPA data quality might be better but this cannot be proven and censoring some California data improves the overall SWRCB database quality. The chief reason to use the California-specific translators is that they may be more representative of California environmental conditions. But a significant problem is that appropriate translators could not be calculated in all environments due to a lack of data. SWRCB should also attempt to fill translator data gaps.

Table 32: Summary of Translators: comparison of U.S. EPA and California-based translators

Translator (f_d)	Data Source	Statistic	Lentic	Lotic	Estuarine
f_d Hg	U.S. EPA*	Geometric	0.60	0.37	0.35
	U.S. EPA	Arithmetic	NC	0.44	CR
	California	Arithmetic	ND	0.31	0.15
f_d $MeHg_d/MeHg_t$	U.S. EPA	Geometric	0.032	0.014	0.19
	U.S. EPA	Arithmetic	NC	0.020	NC
	California	Arithmetic	ND	0.015	ND
f_d $MeHg_d/MeHg_t$	U.S. EPA	Geometric	0.61	0.49	0.61
	U.S. EPA	Arithmetic	NC	0.53	NC
	California	Arithmetic	ND	0.51	ND

ND Data do not exist in the SWRCB database

NC Not calculated: because comparison of U.S. EPA data not possible because California data do not exist.

CR OEHHA cannot reproduce U.S. EPA's geometric mean value of 0.35 for this translator. Therefore, OEHHA is unsure that we have all of the data used by U.S. EPA and have not attempted to recalculate the arithmetic mean.

U.S. EPA values are from Table 9 and U.S. EPA (2000). California translators are calculated from the SWRCB database, March 2000. See Table 29 and 30 and text.

4 TESTING PREDICTIONS OF BIOTA MERCURY CONCENTRATIONS FROM DISSOLVED METHYLMERCURY CONCENTRATIONS IN WATER USING BIOACCUMULATION FACTORS

U.S. EPA calculated national default BAFs but did not evaluate their practical application by using them to predict fish tissue methylmercury concentrations from measured dissolved methylmercury concentrations in water. Predictions using default BAFs and translators should be tested for accuracy for multiple water bodies to evaluate their potential strengths, weaknesses and limitations. Water and tissue mercury concentrations from water bodies in the California SWRCB database compiled by SAIC will be used to test the U.S. EPA national default BAFs. Ten California lotic water bodies were selected for this testing. These water bodies were selected because data for dissolved methylmercury in water (converted and/or directly measured) and methylmercury in biota from one or more trophic levels were available from each of them for one or more trophic levels. It was not possible to perform a comparable test for lentic water bodies and BAFs due to gaps in available California data. Water and tissue measurements from all "sites" and times within each water body were used to derive a single water and tissue arithmetic mean value for that water body in this prediction exercise. Biota tissue levels for all trophic levels with BAFs (Trophic Levels 2, 3, and 4) were only available for the Sacramento River and Putah Creek. All ten lotic water bodies and their mean dissolved methylmercury levels are shown in Table 33, 34, and 35. Table 33 shows the predicted biota methylmercury level for Trophic Level 2 in all water bodies, and the actual arithmetic mean measured level, where available. Table 34 shows predicted and actual measured methylmercury levels for Trophic Level 3 from these water bodies, and Table 35 does the same for Trophic Level 4. The predicted values were derived by multiplying arithmetic mean BAFs derived from the U.S. EPA data (see discussion in the prior section) by the arithmetic mean of water concentrations of dissolved methylmercury (converted and/or directly measured) in each river.

Accompanying each table is a figure that plots the predicted and actual measured biota values for the subset of water bodies that have actual measured biota values for one trophic level at a time. Figures 7, 8, and 9 show plots corresponding to the respective trophic levels in Tables 33, 34, and 35. In each figure, some predicted values are close to the measured values. The predicted values closest to their respective measured values are indicated within a dashed circle. The drawing of the dashed circles or ovals in figures is not based on quantitative characterization of a mathematically defined cluster, but is qualitative and intended to call the reader's attention to the observation that, for the water bodies represented by the points within the dashed lines, the BAFs yielded a reasonable prediction of the actual values. Matched water and biota sampling using larger sample sizes are recommended to enable testing these observations more quantitatively.

Table 33. BAF predicted and measured biota concentrations in Trophic Level 2 Biota

Location	**Water** (mg/L) DMeHg	**Biota (mg/kg)** Predicted[+]	Measured
Sacramento River (23)*	$9.00x10^{-08}$	0.019	0.018
Napa River (2)	$2.66x10^{-07}$	0.057	0.016
Redwood Creek (9)	9.09x10-^{08}	0.020	0.015
Putah Creek (5)	$7.06x10^{-08}$	0.015	0.013
Mokelumne River (0)	$9.62x10^{-08}$	0.021	-
San Joaquin River (0)	$8.06x10^{-08}$	0.017	-
Bear River (0)	$3.51x10^{-07}$	0.076	-
Coyote Creek (0)	$3.07x10^{-07}$	0.066	-

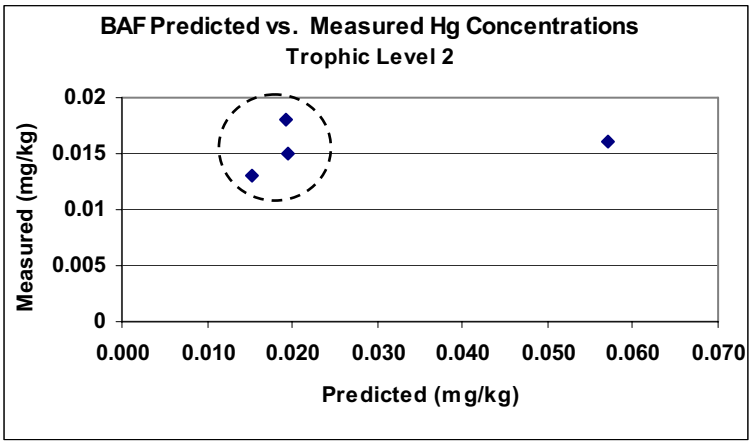
* Number of biota samples

[+] Calculated from mean measured or converted water concentration (mg/L) x arithmetic mean BAF (2.15E+05 L/kg)

Measured water and biota data from the SWRCB database, March 2004.

Figure 7.



Plotted data are from water bodies in Table 33 where data were available for water and biota. Circle indicates predicted BAF values that are closest to their respective measured BAF value.

Table 33 and Figure 7 show that estimates based on the arithmetic BAFs from U.S. EPA data predicted a tissue level similar to the measured biota methylmercury level in three out of the four water bodies selected because data were available for water and biota. The outlying point in Figure 7 is from the Napa River where the water concentration was much higher than the other three rivers, but the biota concentration was similar. The mean values for the three water bodies

with similar predicted and measured values of methylmercury in biota (excluding the Napa River outlier in Figure 7) were 0.018 and 0.015 ppm, respectively. A two-tailed t-test assuming unequal variance yielded a p = 0.27, thus indicating that these means were not statistically different.

Table 34. BAF predicted and measured biota concentrations in Trophic Level 3 biota

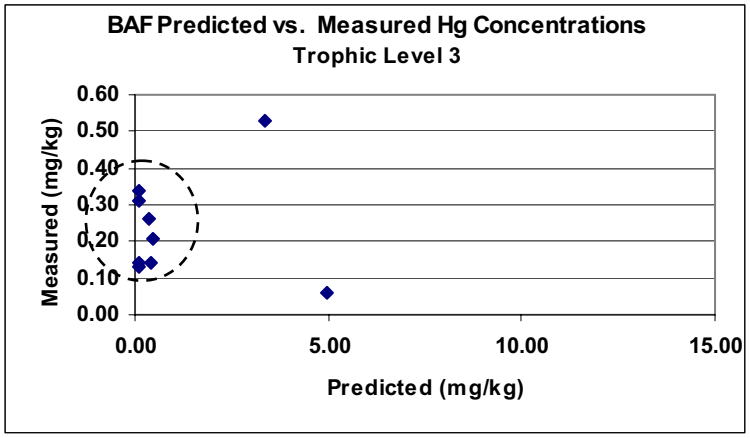
	Water (mg/L)	**Biota (mg/kg)**	
Location	DMeHg	Predicted[+]	Measured
Sacramento River (45)*	$9.00x10^{-08}$	0.119	0.340
Napa River (6)	$2.66x10^{-07}$	0.351	0.260
Redwood Creek (0)	$9.09x10^{-08}$	0.120	-
Putah Creek (10)	$7.06x10^{-08}$	0.093	0.130
Mokelumne River (9)	$9.62x10^{-08}$	0.127	0.310
San Joaquin River (32)	$8.06x10^{-08}$	0.106	0.140
Bear River (2)	$3.51x10^{-07}$	0.463	0.210
Coyote Creek (5)	$3.07x10^{-07}$	0.405	0.140
Guadalupe River (5)	$2.54x10^{-06}$	3.353	0.530
Alamo River (5)	$3.78x10^{-06}$	4.990	0.060

* Number of biota samples

[+] Calculated from mean measured or converted water concentration (mg/L) x arithmetic mean BAF $1.32E^{+06}$ (L/kg)

Measured water and biota data from the SWRCB database, March 2004.

Figure 8.



Plotted data are from water bodies in Table 34 where data were available for water and biota. Oval indicates predicted BAF values that are closest to their respective measured BAF value.

Table 34 and Figure 8 show that using the U.S. EPA arithmetic mean BAF for Trophic Level 3 fish predicted the mean mercury tissue level well in seven out of nine cases from the mean concentration of dissolved methylmercury in these water bodies selected because data were available for water and biota. Figure 8 shows two data points that fall outside of the dashed oval. Measured methylmercury in Trophic Level 3 biota was not predicted well for these two water bodies. The Guadalupe River, which is in the highly contaminated New Almaden mercury-mining district, had the highest concentration of methylmercury in water and in fish. The Alamo River had a relatively high concentration of methylmercury in water but a very low concentration in fish. This is the only river on this list that is not in northern California, and this river is not known to be associated with potential contamination from mining. In both cases the water concentrations for these outlier water bodies were higher than in the other water bodies, but in one case the predictions were off because the actual biota values were higher (*i.e.*, Guadelupe River), while in the other case they were lower (*i.e.*, Alamo River). These differences might indicate other factors specific to these water bodies are having a large effect on bioaccumulation. The variation in the measured biota data is about four-fold (0.13 to 0.53 mg/kg) compared to the higher variation in the predicted values that range >50-fold (0.09 to 5.0 mg/kg). The mean values for the similar predicted and measured values (excluding the two outlier water body in Figure 9) were 0.24 and 0.22 ppm, respectively. A two-tailed t-test assuming unequal variance yielded a $p = 0.79$, thus indicating that the means were not statistically different.

Table 35. BAF predicted and measured biota concentrations in Trophic Level 4 biota

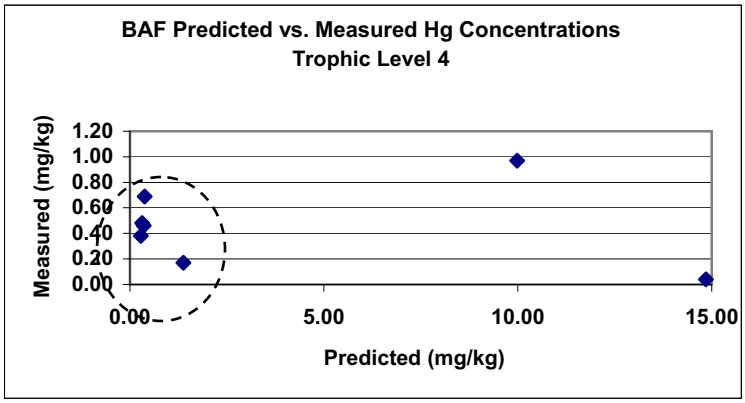
	Water (mg/L)	**Biota (mg/kg)**	
Location	DMeHg	Predicted[+]	Measured
Sacramento River (125)*	9.00×10^{-08}	0.354	0.460
Napa River (0)	2.66×10^{-07}	1.045	-
Redwood Creek (0)	9.09×10^{-08}	0.357	-
Putah Creek (28)	7.06×10^{-08}	0.277	0.380
Mokelumne River (39)	9.62×10^{-08}	0.378	0.690
San Joaquin River (261)	8.06×10^{-08}	0.317	0.480
Bear River (15)	3.51×10^{-07}	1.379	0.170
Coyote Creek (0)	3.07×10^{-07}	1.207	-
Guadalupe River (41)	2.54×10^{-06}	9.982	0.970
Alamo River (6)	3.78×10^{-06}	14.855	0.040

* Number of biota samples

[+] Calculated from mean measured or converted water concentration (mg/L) x arithmetic mean BAF ($3.93 \times 10^{+06}$ L/kg)

Measured water and biota data from the SWRCB database, March 2004.

Figure 9.



Plotted data are from water bodies in Table 35 where data were available for water and biota. Oval indicates predicted BAF values that are closest to their respective measured BAF value.

Table 35 and Figure 9 show that using the U.S. EPA mean BAF for Trophic Level 4 predicts the mean mercury tissue level well in five out of seven cases from the mean concentration of dissolved methylmercury in these water bodies selected because data were available for water and biota. The measured values range about 25-fold (0.04 to 0.97 mg/kg), whereas the predicted values range about 55-fold (0.28 to 14.9 mg/kg). If the low measured value of 0.04 mg/kg is removed from the measured data, then the range is slightly more then five-fold (0.17 to 0.97 mg/kg). This low value was for fish from the Alamo River, which is the only river in this list outside of northern California, an area where mercury from mining is typically a source of mercury in water. As in the case of Trophic Level 3, the two outliers with poor predictability were the Guadalupe and Alamo rivers. These two rivers had higher water concentrations of dissolved methylmercury than others in this list. The mean values (excluding the two outlier water bodies) for the predicted and measured levels of methylmercury in biota were 0.33 and 0.50 ppm, respectively. A two-tailed test with unequal variance for these data yielded a p value of 0.07, not quite significantly different using $p < 0.05$ as the measure of statistical difference.

4.1 OBSERVATIONS CONCERNING THE RESULTS OF TESTING LOTIC BAFs

This exercise shows that the U.S. EPA mean BAFs for Trophic Level 2, 3 and 4 predicted methylmercury tissue values from dissolved water concentrations from California lotic water bodies within qualitative limits in 15 out of 20 simulations, *i.e.*, 75 percent of the time. This is encouraging, but if BAFs are to be used in a regulatory situation it seems prudent to also test them more quantitatively. There are no clear regulatory criteria to use for "predictability," and the database used here is not necessarily complete enough for good statistical testing. One problem with doing this sort of testing is that that it would be necessary to separate natural variation in water and fish concentrations of mercury from lack of predictability. Thus, an additional step for quantifying predictability would be to establish good measurements of natural variation. Some studies have collected potentially useful data for water bodies in California. In five locations in the Sacramento River, Domalgalski (2001) observed an average of 183-fold

fluctuation in the concentration of total methylmercury measured once monthly (dissolved methylmercury is usually about 40-60 percent of total methylmercury, so it is likely that this species would vary about the same amplitude as total methylmercury). Slotton and Ayers (2003), in a study in Cache Creek, reported about four-fold maximum variation in mercury levels in four small forage fish species (red shiners, fathead minnows, green sunfish, mosquito fish) over four seasons. This is less than the observed variation in water concentrations of dissolved methylmercury (greater than biota but less than 10-fold) in Slotton *et al.* (2004). These limited data suggest that natural variability in dissolved methylmercury may be the most important variability to understand and quantify.

A second observation also shows the potential importance of understanding variation in dissolved methylmercury levels. All of the outliers in the qualitative prediction exercise were estimated from water bodies with adequate data for test that had unusually high water concentrations of dissolved methylmercury. At Trophic Level 2, the highest water concentration used in the predictions was for the Napa River. The mean dissolved methylmercury concentration for the four rivers used for prediction was 1.29×10^{-7} mg/L and the standard deviation was 0.92×10^{-7}. The water concentration in the Napa River (2.66×10^{-7} mg/L) was the only value greater than one standard deviate from the mean. This same pattern is seen for the other trophic levels and water concentrations. For Trophic Level 3, the qualitative outliers for prediction were from the Guadalupe and Alamo Rivers. In this case, the mean dissolved methylmercury concentration for the nine rivers used for prediction was 8.42×10^{-7} mg/L and the standard deviation was 13.54×10^{-7}. The water concentrations in the Guadalupe (2.54×10^{-6} mg/L) and Alamo Rivers (3.78×10^{-6} mg/L) were the only values greater than one standard deviate from the mean. For Trophic Level 4, the qualitative outliers were again from the Guadalupe and Alamo Rivers. In this case, the mean dissolved methylmercury concentration for the seven rivers used for prediction was 10.01×10^{-7} mg/L and the standard deviation was 15.21×10^{-7}. And the water concentrations in the Guadalupe and Alamo Rivers were the only values greater than one standard deviate from the mean. It appears that the BAF concept may not work well for California water bodies with dissolved methylmercury concentrations greater than about 10^{-7} mg/L. This should be tested further using more recent data not in the SWRCB database or by collecting new data.

Since the BAF used within a trophic level is the same, the failure in prediction is from applying the BAF to concentrations of dissolved methylmercury that are relatively higher than other water bodies. One standard deviate was a convenient line to use in the current examination, but it might be the wrong criteria to use for the entire distribution of dissolved methylmercury concentrations in lotic water bodies in California. In order to develop a better understanding of factors common to outliers, additional water and tissue data of this type must be subjected to this predictive paradigm and a quantitative criterion to evaluate prediction (*e.g.*, one standard deviate). More needs to be known about the distribution of dissolved methylmercury concentrations in lotic water bodies in California in order to identify important factors effecting water concentrations and bioaccumulation and to determine criteria to test predictions. Similar information should also be gathered about lentic and estuarine water bodies. This information could be used for predictive exercises and possibly to identify and exclude water bodies that are

at the extremes of the distribution of dissolved methylmercury concentrations where default BAFs should not be used because they are not predictive.

One final observation is that the lack of predictability may also be related to situations where extremes of factors that contribute to variation in methylmercury bioaccumulation are at work. The Alamo and the Guadalupe Rivers were identified as outliers in these examples at Trophic Levels 3 and 4. As noted above, the Alamo River was the only river on the list of water bodies used in this exercise that is not in northern California in an area associated with gold or mercury mining. The Alamo River is also in an area impacted by high runoff of salts from agricultural drainage. Both of these factors (salinity/alkalinity or contamination source) are known to effect bioaccumulation, and either could have contributed to the low fish concentrations of methylmercury measured in the Alamo River. On-the-other-hand, the Guadalupe River is in a former mercury mining area and this high contamination could have resulted in unusual conditions in this water body. Identifying extremes of other confounding factors may be important when attempting to test predictability.

4.2 CONCLUSIONS CONCERNING THE RESULTS OF TESTING BAF PREDICTIONS

The California SWRCB database contained data for the lotic environment that were useful for testing the accuracy of predicted biota mercury concentrations from dissolved methylmercury water levels through use of arithmetic mean BAFs, which were recalculated from the U.S. EPA BAF data. Due to gaps in available California data for lentic water bodies it was only possible to test BAFs for lentic water bodies. The test dataset contained data from 10 California rivers for which both mercury concentrations in water and biota were compiled in the database. The U.S. EPA translators and BAFs were used to convert water data into tissue concentrations. They qualitatively predicted tissue values in 75 percent of the water body examples for three trophic levels. New water and biota data would be needed to test the California BAFs developed from the SWRCB dataset in the same way. Examination of the results suggests that developing additional quantitative tests would be appropriate since BAFs will be used in a regulatory setting. Examination of the outliers suggests that additional information on natural variation, especially for dissolved methylmercury in California water bodies, is necessary to establish criterion to use to measure predictability and determine when BAFs might not be appropriate. Additional data to determine the distribution of dissolved methylmercury in lentic, lotic and estuarine water bodies in California should be collected. These data could be used to verify whether the default BAF concept works for California water bodies, in particular those with dissolved methylmercury concentrations greater than about 10^{-7} mg/L. Data to determine the distribution of mercury in biota in lentic, lotic and estuarine water bodies in California would also be useful in determining how to test and apply default BAFs.

5 SUMMARY OF EVALUATION OF BAFs AND TRANSLATORS

OEHHA found that U.S. EPA made a careful effort to compile available data and ensure quality control for the data they used to develop BAFs and translators. Despite their efforts they were not able to compile data representative of all categories of aquatic environments and organisms. In particular their database did not include enough data from which U.S. EPA could develop BAFs for estuarine environments. OEHHA and others noted problems with the U.S. EPA methodology and data. Some of the problems included: the potential for inaccurate identification of biota trophic levels; basing Trophic Level 2 BAFs on organisms that people do not eat; combining data based on different (*i.e.*, not pre-standardized) sampling and measurement techniques; using geometric means without testing the data distributions; low sample size for estuarine translators; and that their database had an uneven geographical and ecological coverage of water bodies. This last point could be especially relevant to California because most of the U.S. EPA data came from the Midwest United States and other areas where the source of mercury in water bodies was atmospheric deposition. California data included by U.S. EPA were from Clear Lake, and some scientific reviewers suggested that these data should be removed because the source of mercury in Clear Lake was different (mercury mining) than for other data. But legacy mining is the predominant source of mercury in many California water bodies, and therefore basing BAFs and translators on conditions associated with this source is important in California. It was also suggested that separate BAFs for a greater number of aquatic environmental categories should be developed and used rather than combining lotic and lentic BAFs into single national default values for each trophic level as U.S. EPA did. OEHHA did find that lotic BAFs were more variable than lentic BAFs and that combining them increased variability. OEHHA also noted that the translator for MeHgt/Hgt was more variable than that for MeHgd/MeHgt, and that directly measuring dissolved methylmercury in water, rather than using translators, helped reduce data variability. But overall OEHHA found that U.S. EPA's methods and results met their goal of developing BAFs and translators that were broadly applicable, especially for lentic and lotic water bodies.

OEHHA reviewed the SWRCB database of mercury measurements in water and biota from California as provided by SWRCB, and examined the BAFs calculated by SAIC. OEHHA found a difference between the way SAIC and U.S. EPA calculated BAFs. In the SWRCB California database measurements of mercury in water and fish were done in different studies and by different researchers. In contrast, mercury in water and biota were measured by the same researchers in the U.S. EPA database. OEHHA grouped measurements on the same water bodies and recalculated BAFs from the SWRCB database in a way analogous to that used by U.S. EPA. OEHHA also calculated translators for some forms of mercury using data available in this database. A number of gaps in available data were identified in the SWRCB database that prevented OEHHA from calculating lentic BAFs and some translators. OEHHA was able to calculate estuarine BAFs for Trophic Level 2 and 4, whereas, U.S. EPA had not calculated BAFs for the estuarine environment. In addition, OEHHA noted that the sample size on which BAFs and translators were based was variable and low in some cases, and that the location of water bodies for which data were available was not evenly distributed throughout the state (*i.e.*, more water bodies were from northern California). OEHHA compared the BAFs calculated from the SWRCB California database for organisms in lotic environments to the U.S. EPA lotic BAFs and demonstrated that they were very similar. The BAF values OEHHA calculated for the estuarine

environment were similar to the national default values, and translators developed from the SWRCB California data were also similar to the U.S. EPA translators. Based on the limited comparisons possible, BAFs and translators based on the California SWRCB dataset and international studies (U.S. EPA database) were found to be similar.

The final step in evaluation of BAFs and translators was to determine how accurately they would predict fish tissue mercury concentrations from water concentrations. U.S. EPA did not test their translators and BAFs. OEHHA was able to test the U.S. EPA national translators and BAFs to see if they accurately predicted mercury levels in fish for several California lotic water bodies by using the SWRCB California database. OEHHA found that the national values predicted California tissue concentrations very well (*i.e.,* no statistical difference between measured and predicted mercury concentration) except for some water bodies where mercury concentrations in water were statistically higher. Mercury concentrations (approximately $2x10^{-7}$ mg/L or more) in these water bodies were found to be more than one standard deviate from the mean for other data used in these tests. This suggests that translators and BAFs will work well in some lotic water bodies, but not in others, and that it will be important to identify characteristics of water bodies where they work and where they do not. This water value should not be considered a screening level because it has not been tested for enough water bodies. It was not possible to perform similar tests for fish in other types of water bodies due to gaps in the available data for the SWRCB database.

Based on OEHHA's evaluation the national default values for BAFs and translators are well established values that SWRCB can use in an implementation policy for the methylmercury tissue criterion. However, SWRCB should consider OEHHA's finding that these values may not work well for all water bodies in California. With this in mind, OEHHA has identified three alternatives for consideration by SWRCB when selecting BAFs and translators to use to implement the U.S. EPA ambient water quality criterion for methylmercury: 1) use the U.S. EPA BAFs and translators as developed by U.S. EPA for California water bodies; 2) use some BAF (*i.e.*, lotic BAFs) and translator values developed from the California database, and others developed by U.S. EPA; 3) before using BAFs and translators for a methylmercury criterion institute a program of data gathering that would fill in gaps in the California data and enable development and testing of additional BAFs and translators using data from different types of water bodies throughout the state. Alternative 1 is a practical solution that could be implemented without collecting additional data and would be consistent with national implementation. Based on OEHHA's evaluation using available data it will also yield predictions that are similar to measured concentrations of mercury in fish for many but not all lotic water bodies. It is unknown how well this alternative will work for other California water bodies. Alternative 2 is appealing because it would incorporate California data and values for lotic water bodies, but due to data gaps it would also require using national values for lentic water bodies and some translators. However, since OEHHA's evaluation found no significant difference between U.S. EPA and California values based on the existing database there is no scientific basis to support this alternative over Alternative 1. Alternative 3 would require collecting additional data on mercury concentrations in water and biota before full implementation and should include establishing standards for sampling, analytical methods, and Quality Assurance/Quality Control before data collection begins. Additional data collection is important to consider because

OEHHA was not able to test Alternative 1 for California lentic and estuarine water bodies using the current datasets and because some water bodies were identified where Alternative 1 did not work well.

OEHHA recommends that SWRCB consider collecting additional data representing a wide variety of water bodies spread throughout the state where BAFs and translators will be used as part of regulatory implementation for the methylmercury criterion. Alternative 1 could be used on a short term basis and collecting additional data could be used on a longer term basis to improve BAFs and translators used in California. Additional data for mercury concentrations in fish and water could fill data gaps, help identify biogeochemical factors with the greatest impact on methylmercury production and bioaccumulation, and better characterize how these affect variability in BAFs and translators. With enough good data it should be possible to identify water body types or geographic regions where national or California default BAFs and translators are more or less accurate. This would be a continual test of the BAF concept and default values. The results could be used to further test and verify the U.S. EPA or California values, or lead to developing better options, or options for water body types where the current values work poorly. SWRCB should consider prioritizing data collection based on which type(s) of water bodies are most impacted by regulatory implementation.

In particular more fish and water data are needed for: 1) lentic BAFs and translators; 2) to fill in data gaps for estuarine translators and Trophic Level 3 biota; and 3) to collect enough data to test lentic and estuarine BAFs and translators. Standard collection and analysis methods for mercury in water should be established as part of a program to collect more data. Measuring dissolved methylmercury directly should be considered as part of this program to reduce the variability that occurs when converting between mercury forms in water. It would be useful to also measure other forms of mercury in water (*e.g.*, total physical and chemical mercury, dissolved total mercury, etc.) to develop and test translators that might still be needed in some cases.

Collecting additional California data is also recommended to better characterize variability in mercury concentration in California water bodies and biota. Natural variability in mercury concentrations will occur in water and fish from any water body. Statistical tests such as those used by OEHHA to test BAF predictions account for variability when testing for true differences. But statistical testing is not typically used in regulatory applications and permits. One way to recognize variability in a regulatory setting would be to collect more data to separate variablility due to environmental differences from variablility common to all environments and use this to verify predictions and set regulatory limits.

Further data and testing would put BAFs and translators on a more sound scientific footing in California and provide data to determine whether the mining source of much of the mercury in California water bodies (at least in the Central Valley, northern California, and the Coast Ranges) lead to significant differences in BAFs and translators for some parts of the state.

GLOSSARY OF TERMS

arithmetic mean (AM): is a measure of central tendency for the values in a distribution. It is commonly called the average, and is calculated by summing the data values and dividing the sum by the total number of data values.

BAF (Converted): Converted BAFs are derived from studies where the concentration of the measured mercury form in the water must be converted to dissolved methylmercury in order to calculate a BAF.

BAF (Direct): Direct BAFs are derived from studies where the concentration of dissolved methylmercury was measured and therefore can be used directly in the calculation a BAF.

bioaccumulation: The accumulation of chemicals in living organisms through the food web, *i.e.*, the accumulation of chemicals from one organism into another after it is eaten. When chemical metabolism and elimination of a chemical are slow chemicals may biomagnify through the food web. In this case the concentration increases with every step in the food web.

bioaccumulation factor (BAF): A bioaccumulation factor is the ratio between the concentration of a chemical measured in an organism and the concentration of the same chemical in water. This ratio is derived from field-collected samples of organisms and water.

biota: the living organisms (plant and animal life) in an area or ecosystem.

estuarine environment: The aquatic environment formed where freshwater from an inland river meets and mixes with saltwater from the ocean. Organisms in this environment are usually adapted to the different environmental conditions that occur where there is a mixture of fresh and saltwater. An example in California is the San Francisco Bay estuary that lies between the Pacific Ocean and the Sacramento and San Joaquin rivers.

geometric mean (GM): A geometric mean is used as a central tendency estimate for data that are log-normally distributed. The geometric mean is calculated by converting all data values to a $\log_{10}$ value, then the arithmetic mean of these transformed values is calculated. Finally the antilog of the arithmetic mean is calculated which is then geometric mean. Geometric means are used as estimates of central tendencies to reduce the influence of high values in the distribution.

lentic environment: An aquatic environment characterized by still (not flowing) water, *e.g.*, lakes and reservoirs.

log-normal data distribution: A distribution of values that is normally distributed when the raw values are transformed by taking the natural logarithm of each value. The values in log-normal distributions may range over several orders of magnitude, 1-100, 1,000, 10,000.

lotic environment: An aquatic environment characterized by flowing water, *e.g.*, streams and rivers.

mercury: dissolved: Dissolved mercury is any chemical form of mercury (inorganic or organic) measured in the water that passes through a small pore (micron) filter.

mercury: total: Total mercury is the sum of the concentrations of all chemical and physical forms of mercury in some medium. In fish tissue total mercury is the sum of inorganic and organic (methyl) mercury. In water it is the sum of all dissolved chemical and physical forms that are measured in water that flows through a filter plus the concentrations of the same forms retained on the filter. So total mercury might, in some cases, refer to the dissolved inorganic mercury plus inorganic mercury that is retained on the micron filter. The text specifies whether this term refers to all chemical and physical forms or some subset.

methylmercury: dissolved: Dissolved methylmercury is measured as the concentration of methylmercury from that passes through a micron filter. It is the form that is used in BAF calculation because it is considered the form that is most easily accumulated from water by biota, and the form which of greatest human health concern.

methylmercury: total: Total methylmercury is the sum of dissolved methylmercury that passes through a micron filter and the concentration of methylmercury mercury that is retained on a micron filter.

micron filter: Filters with small pore (hole) sizes. Micron filters used for characterizing of the forms (dissolved and non-dissolved) of mercury in water have diameters in the range 0.2-0.8 μm (2E-07 to 8E-07 meter) range.

microseston: The total suspended microscopic organic and inorganic matter in an aquatic environment.

phytoplankton: The portion of the plankton community comprised of living tiny plants (*e.g.* algae, diatoms) that are primary producers of energy.

p-value (statistic): The probability of a Type I error (*i.e.*, rejecting a true null hypothesis) occurring based on a statistical test. Typically a p-value of 0.05 (5% significance level) or below is used as the smallest level of significance to declare that there is a true difference between two data sets being compared (*e.g.*, finding that the arithmetic mean values for two data sets are different). Lower and higher p-values can be used. A p-value of $p \leq 0.05$ (5% significance) has been used in the report.

SAIC: Science Applications International Corporation. This organization compiled a database of California mercury measurements in water and biota.

SWRCB: State Water Resources Control Board.

Translators: Empirically derived factors (ratios) used for the conversion between forms of mercury. In this case, the translators are for different forms of mercury in water and are based on field-collected samples that occur in water into forms that can be used in the regulatory process. The U.S. EPA derived translators for the relationships of dissolved inorganic mercury to total inorganic mercury, dissolved methylmercury to total inorganic mercury and dissolved methylmercury to total methylmercury.

trophic level: Trophic means eating. Trophic levels are steps in a food chain characterized by feeding interactions. Energy moves up the food chain from lower to higher trophic levels as a result of organisms in one level feeding on those in a lower level. Organisms in Trophic Level 1 are primary producers that fix energy in an ecosystem (*e.g.*, plants and other organisms that fix energy. Trophic Level 2 organisms are herbivorous and feed on the primary producers. In aquatic ecosystems Trophic Level 3 organisms eat the herbivores and are forage fish for the next level. Trophic Level 4 organisms are carnivorous and eat primarily Trophic Level 3 organisms. In aquatic ecosystems these are the top predatory fish. Humans mostly eat fish and other aquatic organisms from Trophic Level 3 and 4.

zooplankton: Small (often microscopic) free-floating aquatic animals near the base of the food web (*i.e.* primary consumers).

APPENDIX 1: Criteria for Including Data in the California MeHg Database*

1. Data should be a primary source (provided by the funding organization or data collectors). It should not be from a database such as STORET where there are multiple sources combined, unless the source of the data is clearly identified.

2. The methods used (including sample preservation, sample handling, and analytical method) should be ascertainable. Note that sometimes the analytical method defines sample preservation and handling, so analytical method may sometimes be sufficient.

3. The units of all observations must be clearly identified.

4. Sampling dates – year should be specified at a minimum (day, month, and year are preferred)

5. Location of samples should be identified, including water depth, if appropriate. Location of samples should be by lat long, or other unique coordinates that locate the sample within a waterbody, not just in a waterbody or waterbody segment. May also use location naming information such as Sac River at river mile 44 or if map is available with station locations.

6. Fish Tissue Sample Type – sample must be filet either with or without skin (whole fish is not acceptable).

7. Fish Species – The common name or species name of the fish sampled must be apparent so that the trophic level can be determined.

8. Any notes on individual samples should be interpretable. We need to know what a "j," "k," or "l" means, and what samples were nondetects.

9. The analytical laboratory should be identifiable. The objective here is to ensure that data are professionally analyzed.

10. The sampling organization should be identifiable if different from the analytical laboratory. Particularly with Method 1631, sampling is complicated and should be done by fully trained and qualified staff.

DISCLAIMER

This guidance provides advice on how to implement the water quality criterion recommendation for methylmercury that the U.S. Environmental Protection Agency (EPA) published in January 2001. This guidance does not impose legally binding requirements on EPA, states, tribes, other regulatory authorities, or the regulated community, and may not apply to a particular situation based upon the circumstances. EPA, state, tribal, and other decision makers retain the discretion to adopt approaches on a case-by-case basis that differ from those in the guidance where appropriate. EPA may update this guidance in the future as better information becomes available.

The Office of Science and Technology, Office of Water, U.S. Environmental Protection Agency has approved this guidance for publication. Mention of trade names, products, or services does not convey and should not be interpreted as conveying official EPA approval, endorsement, or recommendation for use.

The suggested citation for this document is:

FOREWORD

On January 8, 2001, the U.S. Environmental Protection Agency (EPA) announced the availability of its recommended Clean Water Act (CWA) section 304(a) water quality criterion for methylmercury. This water quality criterion, 0.3 milligram (mg) methylmercury per kilogram (kg) fish tissue wet weight, describes the concentration of methylmercury in freshwater and estuarine fish and shellfish tissue that should not be exceeded to protect consumers of fish and shellfish among the general population. EPA recommends that states, territories, and authorized tribes use the criterion and this guidance in establishing or updating water quality standards for waters of the United States and in issuing fish and shellfish consumption advisories. States and authorized tribes remain free to adjust EPA's recommended criterion, provided that their new or revised water quality criteria protect the designated uses and are based on scientifically defensible methodology.

The publication of the 2001 methylmercury criterion was the first time EPA issued a water quality criterion expressed as a fish and shellfish tissue value rather than as a water column value. EPA recognizes that this approach differs from traditional water column criteria and might pose implementation challenges. In the January 8, 2001 Federal Register notice, EPA stated that it planned to develop more detailed guidance to help states, territories, and authorized tribes with implementation of the methylmercury criterion in water quality standards and related programs. This document provides that detailed guidance.

EPA wrote the *Guidance for Implementing the January 2001 Methylmercury Water Quality Criterion* to provide technical guidance to states, territories, and authorized tribes exercising responsibility under CWA section 303(c), which provides for state review and revision of water quality standards every three years, and adoption of criteria for toxic pollutants, such as mercury, for which EPA has published criteria under CWA section 304(a). The document provides guidance on how to use the new fish tissue-based criterion recommendation in developing water quality standards for methylmercury and in implementing those standards in Total Maximum Daily Loads (TMDLs) and National Pollutant Discharge Elimination System (NPDES) permits. EPA also wrote the guidance to discuss approaches for managing the development of TMDLs for waterbodies impaired by mercury and to recommend an approach for directly incorporating the methylmercury tissue criterion into NPDES permits.

For more information on the methylmercury criterion, see the criteria page on EPA's Web site at http://www.epa.gov/waterscience/criteria/methylmercury/index.html. For more information on EPA's water quality standards program, see the standards page on EPA's Web site at http://www.epa.gov/waterscience/standards. For more information about this guidance document, contact U.S. Environmental Protection Agency, Office of Science and Technology (4305T), 1200 Pennsylvania Avenue, NW, Washington, DC 20460.

Assistant Administrator for Water
U.S. Environmental Protection Agency

CONTENTS

1 Executive Summary....1

2 Introduction....9

2.1 What is the interest in mercury?....9

2.1.1 What are the health effects of methylmercury?....9

2.1.2 How frequent are the environmental problems?....11

2.2 What are the sources of mercury in fish?....14

2.3 How does methylmercury get into fish and shellfish?....15

2.4 Why is EPA publishing this document?....17

2.5 What is the effect of this document?....18

3 Water Quality Criteria and Standards Adoption....19

3.1 What must states and authorized tribes include as they adopt the methylmercury criterion?....19

3.1.1 What do the CWA and EPA's regulations require?....19

3.1.2 What is the recommended form of the methylmercury criterion?....20

3.1.3 What approaches should states or authorized tribes consider when developing a water column concentration criterion?....24

3.2 What options are available to address site-specific conditions and concerns?....38

3.2.1 How can the methylmercury water quality criterion be modified for site-specific conditions?....38

3.2.2 How do water quality standards variances apply?....44

3.2.3 How are use attainability analyses conducted?....47

4 Monitoring and Assessment....51

4.1 What are the analytical methods for detecting and measuring mercury and methylmercury concentrations in fish and water?....51

4.1.1 Analytical Methods for Methylmercury....52

4.1.2 Analytical Methods for Mercury....52

4.1.3 Summary of Recommended Analytical Methods....53

4.2 What is the recommended guidance on field sampling plans for collecting fish for determining attainment of the water quality standard?....54

4.2.1 What fish species should be monitored?....55

4.2.2 What sample types best represent exposure?....56

4.2.3 What is the recommended study design for site selection?....56

4.2.4 How often should fish samples be collected?....57

4.2.5 How many samples should be collected?....58

4.2.6 What form of mercury should be analyzed?....58

4.2.7 Other sampling considerations....58

4.3 How should waterbody impairment be assessed for listing decisions?....59

4.3.1 How should nondetections be addressed?....59

4.3.2 How should data be averaged across trophic levels?....61

4.3.3 How should older data be assessed? 63
4.3.4 How should fish consumption advisories be used to determine impairment? 63

5 Other Water Quality Standards Issues 65

5.1 How does this criterion relate to the criteria published as part of the Great Lakes Initiative? 65
5.2 What is the applicable flow for a water column-based criterion? 66
5.3 How are mixing zones used for mercury? 67
5.3.1 What is a mixing zone? 67
5.3.2 How does a mixing zone apply for the fish tissue-based methylmercury criterion? 67
5.3.3 Does the guidance for the fish tissue-based criterion change the Great Lakes Initiative approach to mixing zones for bioaccumulative pollutants? 68
5.4 How are fish consumption advisories and water quality standards harmonized? 68
5.4.1 What is the role of state and tribal Fish Advisory Programs? 68
5.4.2 How are consumption limits for consumption advisories determined? 69
5.4.3 How does the criterion differ from the advisory level? 69
5.4.4 What if there is a difference between assessing criterion attainment and issuance of a fish consumption advisory? 70
5.4.5 Should existing advisories be revised to reflect the new criterion? 71
5.4.6 What federal agencies issue advisories? 71
5.4.7 How is the criterion related to FDA action levels? 72
5.5 What public participation is recommended for implementing the methylmercury criterion? 72

6 TMDLs 73

6.1 What is a TMDL? 73
6.2 How have states and tribes approached mercury TMDLs? 73
6.2.1 What geographic scales have been used for mercury TMDLs? 75
6.2.2 What are the considerations in developing mercury TMDLs? 76

7 National Pollutant Discharge Elimination System (NPDES) Implementation Procedures 93

7.1 What are the general considerations in NPDES permitting? 93
7.2 What is the EPA-recommended NPDES permitting approach for methylmercury? 94
7.2.1 Developing NPDES permit limits based on the fish tissue criterion 94
7.2.2 Determining reasonable potential 95
7.2.3 Implementing antidegradation 96
7.2.4 Establishing appropriate WQBELs 96
7.3 How does EPA recommend implementing the fish tissue criterion for NPDES permits? 99
7.4 What are the procedures for developing permit limits when the criterion is adopted as a water column value or when the criterion is adopted as a fish

tissue value and the permitting authority uses a water column translation of the fish tissue value? 101
7.5 What are the procedures for developing permit limits when the criterion is adopted as a fish tissue value and the permitting authority does not use a water column translation of the fish tissue value? 103
7.5.1 How to determine the need for permit limits to control mercury (how to determine reasonable potential) 103
7.5.2 Where reasonable potential exists, how can WQBELs be derived from a fish tissue value? 114

8 Related Programs 125
8.1 What are EPA and others doing as a whole to address mercury? 125
8.2 How does pollution prevention play a role in the methylmercury criterion? 125
8.3 What regulations has EPA issued pursuant to the CAA to address air emissions of mercury? 127
8.3.1 Municipal waste combustors 128
8.3.2 Hospital, medical, and infectious waste incinerators 128
8.3.3 Chlor-alkali plants 129
8.3.4 Hazardous waste combustors 129
8.3.5 Coal-fired power plants 130
8.3.6 Other 130

1 Executive Summary

In January 2001 EPA published ambient water quality criteria (AWQC) recommendations for methylmercury for the protection of people who eat fish and shellfish. This criterion, 0.3 milligram (mg) methylmercury per kilogram (kg) fish tissue wet weight, marks EPA's first issuance of a water quality criterion expressed as a fish and shellfish tissue value rather than as an ambient water column value.

Research shows that exposure to mercury and its compounds can cause certain toxic effects in humans and wildlife (USEPA 1997a). As of 2008, 50 states, 1 territory, and 3 tribes had issued fish consumption advisories for mercury covering 16.8 million lake acres and 1.3 million river miles (USEPA 2009a). Mercury is widely distributed in the environment and originates from natural and human-induced (anthropogenic) sources, including combustion and volcanoes. Methylmercury is highly bioaccumulative, especially in aquatic food webs. Nearly 100 percent of the mercury that bioaccumulates in upper-trophic-level fish (predator) tissue is methylmercury (Akagi et al. 1995; Becker and Bigham 1995; Bloom 1992; Kim 1995).

Under section 303(c) of the Clean Water Act (CWA), states and authorized tribes must adopt water quality criteria that protect designated uses. Section 303(c)(1) provides that states and authorized tribes review their water quality standards every three years and modify and adopt water quality standards as appropriate. In light of the new science used to develop the 2001 methylmercury fish tissue criterion, EPA believes that states should consider reviewing and revising their mercury human health criteria during their next triennial review. This document provides technical guidance to states and authorized tribes that exercise responsibility under CWA section 303(c) on how to use the new fish tissue-based criterion recommendation as they develop water quality standards for methylmercury.

EPA expects that, as states adopt methylmercury water quality criteria and as monitoring of effluents, receiving waters, and fish tissue with the more sensitive methods recommended by EPA increases, the number of waterbodies that states report on CWA section 303(d) lists as impaired due to methylmercury contamination might increase. This guidance is designed to assist states and authorized tribes to address those impairments. Furthermore, this guidance addresses coordination across various media and program areas in implementing the criterion, which will be important because atmospheric deposition and multimedia cycling of mercury are significant in many waterbodies.

EPA recognizes the complexity and comprehensive nature of this guidance. As is always the case when EPA issues technical guidance, EPA will provide outreach and technical assistance to states and authorized tribes in implementing this guidance.

The following tables (tables 1a through 1d) provide a brief summary of the most important recommendations applicable to states and authorized tribes that are contained in the guidance.

NOTE: These tables are provided as a convenience to the reader, but are not comprehensive and are not a substitute for the full content of the guidance contained in the other chapters of this document.

Table 1a. Recommendations for water quality standards adoption

	Most applicable to criteria expressed as…	For a full discussion see section…
Recommended form of a methylmercury criterion EPA recommends that states and authorized tribes adopt a methylmercury criterion expressed as a fish tissue value. When adopting a fish tissue criterion, states and authorized tribes will need to decide whether to:		3.1.2 and 3.1.3
• Implement the fish tissue criterion without water column translation, or	FT (fish tissue value)	
• Translate the fish tissue criterion to a water column value using bioaccumulation factors (BAFs). Three approaches include: 1. Site-specific BAFs 2. Modeled BAFs 3. BAFs derived using the results of field studies that are not site-specific (in limited circumstances); or	WC (water column value)	
• Combination (fish tissue criterion for some or all waters, combined with water column criteria for some or all waters).	Both FT and WC	
• States and authorized tribes may consider retaining their existing water column criteria, on a temporary basis, particularly for waters where there is a relatively high direct water input of mercury.	FT alone	
Adoption considerations • When adopting a fish tissue criterion, EPA encourages states and authorized tribes to develop implementation procedures.	FT or WC	3.1.2.1
• This guidance does not supersede requirements in EPA's Great Lakes Initiative (GLI) regulation for waters in the Great Lakes system.		5.1
Criterion adjustments • Adjusting for local fish consumption rates. • Adjusting for other sources of mercury (marine fish).	FT or WC	3.2.1
Mixing zones		5.3
• Not relevant when applying a fish tissue criterion that has not been translated to a water column value.	FT alone	
• If the fish tissue criterion is converted to water column values, EPA advises caution in the use of any mixing zones for mercury. Restricting or eliminating mixing zones may be appropriate.	WC	
Variances • Guidance on when variances are appropriate. • Considerations before granting a variance.	WC	3.2.2

Table 1b. Recommendations for monitoring and assessment

	Most applicable to criteria expressed as…	For a full discussion see section…
Recommended analytical methods		4.1
• Methods 1631, revision E and 245.7 for mercury in water.	WC	
• Draft Appendix A of Method 1631 for mercury in fish tissue.	FT	
• Method 1630 for methylmercury in water.	WC	
• Method 1630 (with draft modifications) for methylmercury in fish tissue.	FT	
Other available methods are listed in appendix C of this guidance.	FT or WC	App. C
Field sampling recommendations	FT alone	4.2
• Select fish for monitoring that are commonly eaten in the study area.		
• Choose large fish because these are typically highest in methylmercury.		
• If local consumption data are not available, match assumed consumption pattern to sampled species, or sample trophic level 4 species.		
• Use composite samples of fish fillets.		
• EPA recommends biennial sampling if resources allow, otherwise waterbodies should be screened a minimum of every 5 years.		
Assessing non-attainment of fish tissue criterion	FT alone	4.3
• Use statistical tests if enough data, or consider sample-by-sample comparisons if very limited data.		

Table 1c. Recommendations for total maximum daily loads (TMDLs)

	Most applicable to criteria expressed as…	For a full discussion see section…
States' timing of TMDL development • States with comprehensive mercury reduction programs in place may defer TMDLs for waters impaired by mercury mainly from atmospheric sources. (Summarizing EPA's voluntary "5m" category for listing impaired waters.) • The greater the relative contribution to a waterbody from mercury sources other than air deposition, such as water point sources, the more appropriate it may be to use the TMDL process to characterize and address those sources sooner, rather than deferring TMDL development.	FT or WC	6.2 and 7.5.2.2
Approaches in approved mercury TMDLs Examples in guidance text and appendix D discuss: • Types of mercury sources; tools for assessing point sources, atmospheric deposition, past metals mining activity, sediments, and natural sources. • Example allocation scenarios involving waters where predominant sources are air deposition or mining. • Post-TMDL monitoring.	FT or WC	6.2
Geographic scale Describes scales that have been used for developing mercury TMDLs: • Waterbody-specific. • Watershed-level. • Statewide or regional.	FT or WC	6.2.1
Available models and example TMDL applications • Example models for different situations (steady state, dynamic, detail geometry, regression). • Factors leading to model selection (methylation, BAFs, sediments). • Use of linked models without having explicit water column criteria or translations. • Other analytical approaches, e.g., proportionality approach: Where air deposition is the only significant mercury source and steady-state conditions apply, TMDLs have been developed to meet fish tissue targets by relying on a proportional relationship between mercury deposition and fish tissue methylmercury concentration.	FT or WC FT alone FT	6.2.2.2 6.2.2.2.1

Table 1d. Recommendations for permitting procedures

	Most applicable to criteria expressed as…	For a full discussion see section…
Two implementation approaches		
• If a TMDL or a water column translation derived from a fish tissue criterion or site-specific data to translate is available at time of permit issuance, implement using the approaches described in the Technical Support Document (TSD) for Water Quality-based Controls (USEPA 1991).	WC	7.4
• If a TMDL or water column translation or site-specific data to translate are not available, implement approaches described below.	FT alone	7.5
Finding "reasonable potential" (RP)[a] Depending on the particular facts, a permitting authority may reasonably conclude that a facility has RP if: • There is a quantifiable level of mercury in the discharge, using a sufficiently sensitive EPA-approved analytical method and • Fish tissue from the receiving water is close to or exceeds the criterion.	FT alone	7.5.1
Where mercury effluent levels are unknown EPA recommends that permitting authorities: • Require effluent monitoring using a sufficiently sensitive EPA-approved analytical method. • Include a reopener clause in the permit to allow permit to be modified if effluent data indicate a water quality-based effluent limit (WQBEL) is necessary.	FT alone	7.5.1.1.1
Where quantifiable amounts of mercury are not found • If the permitting authority believes the monitoring data are representative of the discharge, no further permit conditions may be necessary.	FT alone	7.5.1.1.2
Where fish tissue concentrations are unknown EPA recommends that permitting authorities: • Include a special permit condition to conduct a mercury fish tissue survey for the receiving waterbody. • Include a reopener clause in the permit to allow permit to be modified if fish tissue data become available indicating a WQBEL is necessary. • Encourage the permittee to develop and implement a mercury minimization plan (MMP) tailored to the facility's potential to discharge mercury.	FT alone	7.5.1.2.1

Table 1d. Recommendations for permitting procedures *(continued)*

	Most applicable to criteria expressed as…	For a full discussion see section…

Permits with quantifiable mercury but without RP
Where a discharge contains a quantifiable amount of mercury but fish tissue in the receiving water does not exceed the criterion:
• If the discharger will undertake an activity that could result in an increase in receiving water or fish tissue mercury concentration
  ○ Conduct tier 2 antidegradation analysis and develop appropriate permit conditions.
  ○ Require permittee to implement an MMP tailored to the facility's potential to discharge mercury.
  ○ Require effluent monitoring.
• If the discharger will not undertake an activity that could result in an increase in receiving water or fish tissue mercury concentration:
  ○ Encourage the facility to develop and implement an MMP tailored to the facility's potential to discharge mercury.
	FT alone	7.5.1.2.2

Other factors in determining RP • EPA recommends that the permitting authority account for other factors that may constitute the basis for a finding of RP. These include rising fish tissue concentrations and the impact on downstream waters.	FT alone	7.5.1.2.2
Mercury in intake water • Where the only source of mercury in a discharge may be the intake water taken directly from the same body of water, and where there are no known sources or additional contributions of mercury at the facility, the permitting authority may reasonably conclude, based on the particular facts, that there is no RP to exceed water quality standards.	FT or WC	7.5.1.3

Table 1d. Recommendations for permitting procedures *(continued)*

	Most applicable to criteria expressed as…	For a full discussion see section…
WQBELs where there is a finding of RP[b] EPA recommends that permitting authorities: • Require the permittee to implement an MMP tailored to its potential to discharge mercury. • Depending on the particular facts, the permitting authority should consider including in an MMP an effluent trigger level, a mercury reduction goal, or an enforceable numeric level representing existing effluent quality or some increment of the mercury reduction determined achievable as a result of the measures and practices specified in the MMP. • Require effluent monitoring using a sufficiently sensitive EPA-approved method to enable evaluation of the effectiveness and implementation of the MMP. • Include a reopener clause to modify the permit conditions if the MMP is found to be not effective or if a water column translation of the criterion is developed. Other considerations and requirements may be necessary: • Where a discharger undertakes an activity that could result in an increase in receiving water or fish tissue mercury concentrations, it must be consistent with applicable antidegradation requirements. Additional requirements may also be necessary under the CWA and EPA's NPDES regulations. • Include appropriate technology-based limits pursuant to CWA section 301(b) and 40 CFR sections 125.3 and 122.44(a)(1). • For modified or reissued permits with existing effluent limits for mercury, any less stringent effluent limit must be consistent with anti-backsliding requirements.	FT alone	7.5.2.1 7.2.4

Table 1d. Recommendations for permitting procedures *(continued)*

	Most applicable to criteria expressed as…	For a full discussion see section…
Permits with RP where direct water inputs are relatively high In addition to the above: • EPA recommends that states and authorized tribes specifically consider developing TMDLs in the short term. • Where a state or tribe chooses not to develop a TMDL in the short term, the state or tribe should develop an analysis of sources and loading capacity similar to what a TMDL would provide, or a water column translation of the fish tissue criterion. • EPA recommends that permitting authorities work together with mercury dischargers in the watershed to collect data necessary to develop: o A TMDL, or o An analysis of sources and loading capacity similar to what a TMDL would provide, or o A water column translation of the fish tissue criterion for future permitting. One approach is for the permitting authority to invoke its authority under CWA section 308 (or comparable state authority).	FT alone	7.5.2.2
Additional requirements that may apply • Additional requirements for: POTWs with pretreatment programs; technology-based limits; anti-backsliding; permit documentation.	FT or WC	7.5.2.3
Mercury minimization plans (MMPs) This section provides guidance on appropriate MMPs.	FT	7.5.2.4

Notes:

[a] "Reasonable potential" refers to the reasonable potential to cause or contribute to an excursion above a numeric or narrative criterion for water quality. 40 CFR 122.44(d)(1)(i). NPDES permits for discharges with "reasonable potential" must include water quality-based effluent limits (WQBELs).

[b] As noted at the beginning of table 1d, this section refers to situations where neither a TMDL nor a water column translation is available at time of permit issuance. Where a TMDL has been developed, the WQBEL for that discharge must be consistent with the TMDL's wasteload allocation. Where a TMDL is not available at the time of permit discharge, but where a water column translation of the fish tissue criterion has been developed, or where site-specific data to do so are readily available, include a numeric WQBEL.

2 Introduction

2.1 What is the interest in mercury?

Mercury occurs naturally in the earth's crust and cycles in the environment as part of natural and human-induced activities. The amount of mercury mobilized and released into the biosphere has increased since the beginning of the industrial age. Most of the mercury in the atmosphere is elemental mercury vapor, which circulates in the atmosphere for up to a year and therefore can be widely dispersed and transported thousands of miles from sources of emission (USEPA 1997b). Most of the mercury in water, soil, sediments, plants, and animals is in the form of inorganic mercury salts and organic forms of mercury (e.g., methylmercury). Inorganic mercury salts, when bound to airborne particles, are readily removed from the atmosphere by precipitation and are also dry deposited. Even after mercury deposits, it commonly returns to the atmosphere, as a gas or associated with particles, and then redeposits elsewhere. As it cycles between the atmosphere, land, and water, mercury undergoes a series of complex chemical and physical transformations, many of which are not completely understood (USEPA 1997b).

This guidance focuses on an organic mercury compound known as methylmercury. Methylmercury most often results from microbial activity in wetlands, the water column, and sediments, and it is the form of mercury that presents the greatest environmental risks to human health (66 FR 1344; January 8, 2001). The methylation process and methylmercury bioaccumulative patterns are discussed in more detail in section 2.3.

2.1.1 What are the health effects of methylmercury?

Exposure to methylmercury can result in a variety of health effects in humans. Children that are exposed to low concentrations of methylmercury prenatally might be at risk of poor performance on neurobehavioral tests, such as those measuring attention, fine motor function, language skills, visual-spatial abilities, and verbal memory (NRC 2000; USEPA 2002a). Mercury and its compounds are listed as a "toxic" pollutant under section 307(a) of the Clean Water Act (see 40 CFR 401.15).

In 2000 the National Academy of Sciences (NAS)/National Research Council (NRC) reviewed the health studies on mercury (NRC 2000). EPA's assessment of the methylmercury reference dose (RfD) relied on the quantitative analyses performed by the NRC (USEPA 2002a). The RfD is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure of the human population, including sensitive subgroups, that is likely to be without an appreciable risk of deleterious effects during a lifetime (USEPA 2002a). In its review of the literature, NRC found neurodevelopmental effects to be the most sensitive endpoints and appropriate for establishing a methylmercury RfD (NRC 2000).

On the basis of the NRC report, EPA established an RfD of 0.0001 mg/kg-day (0.0001 milligram of methylmercury per day for each kilogram of a person's body mass) (USEPA 2002a). EPA believes that exposures at or below the RfD are unlikely to be associated with an appreciable risk of deleterious effects. It is important to note, however, that the RfD does not define an exposure level corresponding to zero risk; mercury exposure near

or below the RfD could pose a very low level of risk that EPA deems nonappreciable. It is also important to note that the RfD does not define a bright line above which individuals are at risk of adverse effects (USEPA 2005a).

The primary route by which the U.S. population is exposed to methylmercury is through the consumption of fish containing methylmercury. The exposure levels at which neurological effects have been observed in children can occur through maternal consumption of fish (rather than high-dose poisoning episodes) (USEPA 2005a).

In 2005 the National Health and Nutrition Examination Survey (NHANES) published the results of a study of blood mercury levels in a representative sample of U.S. women of childbearing age (CDC 2005). The report data for the period 1999–2002 show that all women of childbearing age had blood mercury levels below 58 μg/L, a concentration associated with neurological effects in the fetus. These data show that 5.7 percent of women of childbearing age had blood mercury levels between 5.8 and 58 μg/L; that is, levels within an order of magnitude of those associated with neurological effects. Typical exposures for women of childbearing age were generally within two orders of magnitude of exposures associated with these effects, according to data from NHANES (CDC 2005; USEPA 2005a).

With regard to other health effects of methylmercury, some recent epidemiological studies in men suggest that methylmercury is associated with a higher risk of acute myocardial infarction, coronary heart disease, and cardiovascular disease in some populations (Salonen et al. 1995, as cited in USEPA 2001a). Other recent studies have not observed this association. The studies that have observed an association suggest that the exposure to methylmercury might offset the beneficial effects of fish consumption (USEPA 2005a). There also is some recent evidence that exposures to methylmercury might result in genotoxic or immunotoxic effects ([Amorim et al. 2000; ATSDR 1999; Silva at al. 2004], as cited in USEPA 2005a). Other research with less corroboration suggests that reproductive, renal, and hematological impacts could be of concern. There are insufficient human data to evaluate whether these effects are consistent with methylmercury exposure levels in the U.S. population (USEPA 2005a).

Deposition of mercury to waterbodies can also have an adverse impact on ecosystems and wildlife. Plant and aquatic life, as well as birds and mammalian wildlife, can be affected by mercury exposure; however, overarching conclusions about ecosystem health and population effects are difficult to make. Mercury contamination is present in all environmental media; aquatic systems experience the greatest exposures because of bioaccumulation. *Bioaccumulation* refers to the net uptake of a contaminant from all possible pathways. It includes the accumulation that might occur by direct exposure to contaminated media, as well as uptake from food. Elimination of methylmercury from fish is so slow that long-term reductions of mercury concentrations in fish are often due to growth of the fish (“growth dilution“), whereas other mercury compounds are eliminated relatively quickly. Piscivorous avian and mammalian wildlife are exposed to mercury mainly through consuming contaminated fish, and as a result they accumulate mercury to levels greater than those in their prey (USEPA 1997a).

EPA's mercury Web site, at http://www.epa.gov/mercury, provides a broad range of information about mercury, including a full discussion of potential human health and ecosystem effects.

2.1.2 How frequent are the environmental problems?

As of the 2008 listing of impaired waters (i.e.: water not attaining water quality standards) under section 303(d) of the clean Water Act, 43 states and Puerto Rico reported at least one waterbody as impaired due to mercury, and more than 8,800 specific waterbodies were listed as impaired due to mercury, either solely or in combination with other pollutants. All states have numeric criteria for mercury. About seven states, plus Washington D.C. and two territories have adopted a fish tissue criterion for methylmercury. Once additional states, tribes and territories begin to adopt EPA's recommended fish tissue criterion, the number of waterbodies listed as impaired for methylmercury is expected to increase since the revised criterion is more stringent than the water concentration criteria most states currently have in their water quality standards.

In 2001 EPA mapped concentrations of mercury in fish tissue from fish collected from waterbodies all over the country (i.e., not limited to the waters identified by the states as impaired) and compared them to the 2001 national recommended water quality criterion, 0.3 mg methylmercury/kg fish tissue wet weight. These data were not randomly or systematically collected, but rather reflect fish tissue information that states had collected as part of their fish consumption advisory programs. Approximately 40 percent of the watershed-averaged fish tissue concentrations exceeded 0.3 mg methylmercury/kg fish tissue wet weight (USEPA 2001b).

Figure 1 shows fish tissue mercury concentrations averaged by watershed (by 8-digit hydrologic unit code, or HUC).

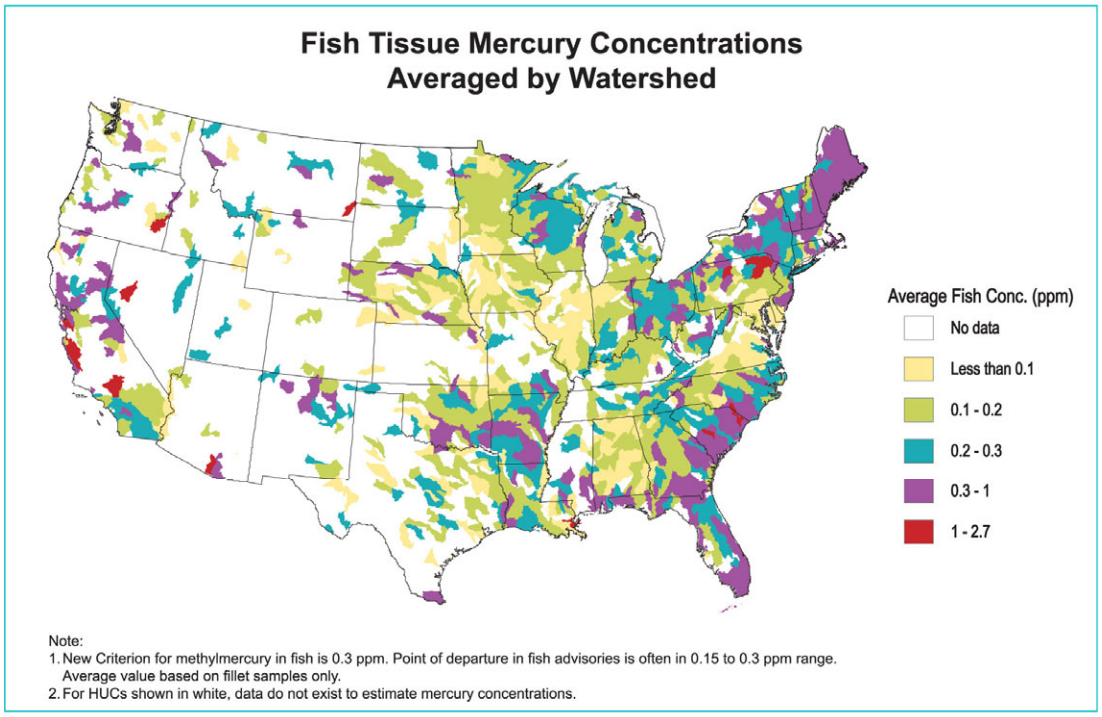

Figure 1. Average fish tissue concentrations by HUC watershed (USEPA 2005a).

In EPA's *Environmental Monitoring and Assessment Project (EMAP) Western Streams and Rivers Statistical Study* (USEPA 2005b), 626 streams and rivers were sampled in 12 states of the western United States. Mercury was detected at 100 percent of sites and samples in the study. The 0.3 mg/kg criterion (equivalent to 0.3 parts per million, ppm) was exceeded in 56.8 percent of waters surveyed, which represent 20–30 percent of all western rivers (Peterson et al. 2007). Results from the 2009 National Lake Fish Tissue Study, a statistically-based survey conducted by EPA, showed that 49% of the sampled population of lakes (76,559 lakes in the lower 48 states with surface areas greater than or equal to 1 hectare or about 2.5 surface acres) had mercury concentrations that exceeded the 0.3 ppm tissue-based mercury criterion (USEPA 2009b).

As of December 2008, 50 states, 1 territory, and 3 tribes had issued fish consumption advisories[1] for mercury covering 16.8 million lake acres and 1.3 million river miles (figure 2). Twenty-seven states had issued advisories for mercury in all freshwater lakes and rivers in the state, 13 states had statewide advisories for mercury in their coastal waters and one state had a deep sea advisory (USEPA 2009a). The thresholds for the levels of mercury in fish that trigger the issuance of an advisory for women of childbearing age vary among the states and authorized tribes, but generally range from 0.07 to 1 ppm, with most threshold values in the range of 0.1 to 0.3 ppm.

Although states, territories, tribes, and local governments continue to issue new fish advisories and most new fish advisories involve mercury, EPA believes that the increase in advisories is a result of increased monitoring and assessment of previously untested waters rather than increased domestic releases of mercury or increased levels or frequency of contamination. In fact, U.S. releases of mercury to the air have declined by more than 58 percent between 1990 and 2005 (USEPA 2008b).

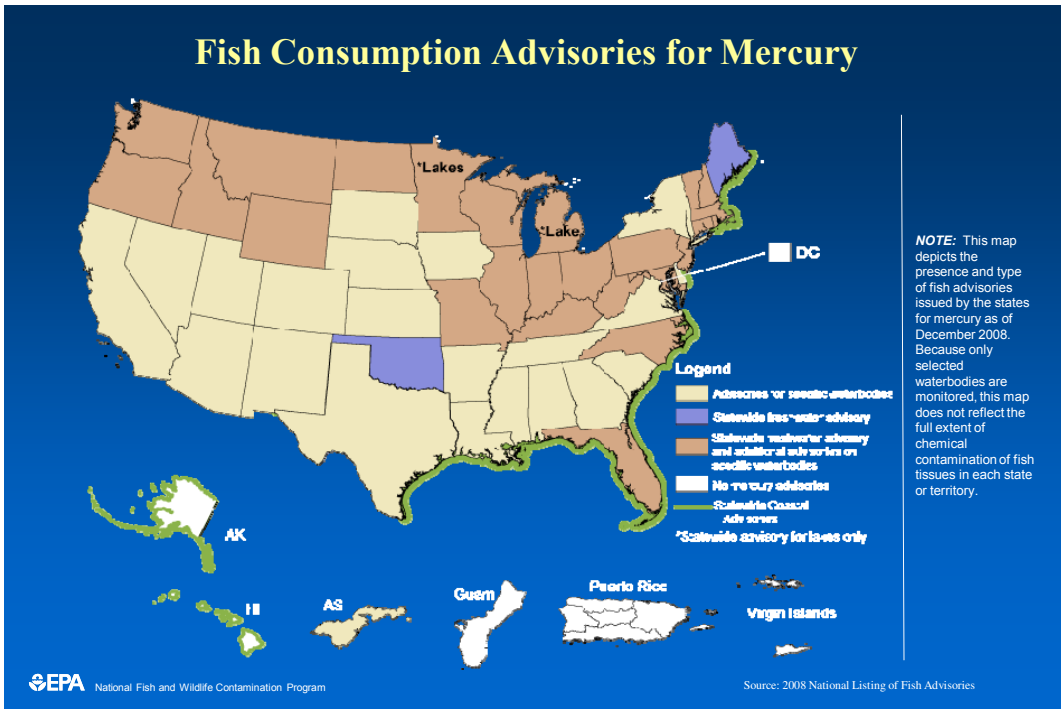

Figure 2. Fish Consumption Advisories for Mercury 2008 (USEPA 2009a).

[1] States and tribes issue their advisories and guidelines voluntarily and have flexibility in which criteria they use and how they collect data. As a result, there are significant variations in the numbers of waters tested, the pollutants tested for, and the threshold for issuing advisories. Based on self-reporting, the national trend is for states to monitor different waters each year, generally without retesting waters monitored in previous years. Note that EPA does not issue fish advisories; states and tribes issue advisories (with the exception of national advisories, regional advisories, and Superfund-related advisories). EPA issues guidance on the level of contaminants in fish, which states and tribes may use in issuing their advisories.

2.2 What are the sources of mercury in fish?

Mercury is emitted from both natural and anthropogenic sources. Its residence time in the atmosphere is much longer than that of most other metals because mercury can circulate for up to a year (USEPA 1997b). Such mobility enables elemental mercury to disperse and be transported over thousands of miles from likely sources of emission, across regions, and around the globe. As a result, the mercury detected in fish in U.S. surface waters is from both U.S. and international sources (USEPA 2005c). EPA estimates that approximately 83 percent of the atmospheric mercury deposited on land and water in the country is from a combination of sources outside the United States and Canada, as well as from natural and re-emitted sources. EPA's current air quality modeling indicates a substantial variation across the country: domestic sources influence mercury deposition much more in the East, and global sources are a more significant contributor to mercury deposition in the West, where relatively few domestic sources exist. This estimate was based on a modeling assessment of the atmospheric fate, transport, and deposition of mercury conducted by EPA for the Clean Air Mercury Rule[2] (USEPA 2005d).

Natural sources of mercury include geothermal emissions from volcanoes and crustal degassing in the deep ocean, as well as dissolution of mercury from other geologic sources (Rasmussen 1994). Anthropogenic sources of mercury in the United States include combustion (e.g., utility boilers; municipal waste combustors; commercial/industrial boilers; hospital, medical, and infectious waste incinerators), manufacturing sources (e.g., chlor-alkali and cement manufacturers), and mining (USEPA 1997b).

U.S. anthropogenic emissions of mercury to the air have declined more than 58 percent from the passage of the 1990 Clean Air Act (CAA) Amendments to 2005 (most recent data available). These amendments provided EPA new authority to reduce emissions of mercury and other toxic pollutants to the air. In 1990 more than two-thirds of U.S. human-caused mercury emissions came from just three source categories: coal-fired power plants; municipal waste combustion; and hospital, medical, and infectious waste incineration (figure 4, section 6.2.2.1). Regulations were issued in the 1990s to control mercury emissions from waste combustion. In addition, actions to limit the use of mercury—most notably voluntary and Congressional action to limit the use of mercury in batteries and EPA regulatory limits on the use of mercury in paint—contributed to the reduction of mercury emissions from waste combustion during the 1990s by reducing the mercury content of waste. Regulation of mercury emissions from chlorine production facilities that use mercury cells and regulation of industrial boilers will further reduce emissions of mercury.[3]

[2] On February 8, 2008, the D.C. Circuit Court of Appeals vacated the Section 112(n) Revision Rule and the Clean Air Mercury Rule.

[3] Rules controlling mercury emissions, which implement the 1990 CAA amendments, include standards for municipal waste combustors (40 CFR part 60, subpart Da, and parts 72 and 75); standards for hospital, medical, and infectious waste incinerators (40 CFR part 60, subpart Ce); standards for chlor-alkali plants (40 CFR part 63, subpart IIIII); standards for existing and new hazardous waste-burning incinerators (40 CFR 63.1203 [a][2] and [b][2]); standards for existing and new hazardous waste-burning cement kilns (40 CFR 63.1204 [a][2] and [b][2]); and standards for existing and new hazardous waste-burning lightweight aggregate kilns (40 CFR 63.1205 [a][2] and [b][2]). See also section 8.3 of this document.

At present, the largest single source of anthropogenic mercury emissions to the air in the country is coal-fired power plants. Mercury emissions from U.S. power plants are estimated to account for about one percent of total global mercury emissions (70 FR 15994; March 29, 2005). In May 2005, EPA adopted the Clean Air Act Section 112(n) Revision Rule and the Clean Air Mercury Rule (CAMR). CAMR regulated mercury emissions from coal-fired utilities. On February 8, 2008, the D.C. Circuit Court of Appeals vacated the Section 112(n) Revision Rule and CAMR. EPA is developing air toxics emissions standards for power plants under Clean Air Act (Section 112(d). EPA currently intends to propose and finalize air toxics standards for coal- and oil-fired electric generating units by the end of 2011. Point sources of mercury discharging into waters are also regulated by NPDES permits. Chlor-alkali facilities are subject to effluent guidelines that impose treatment levels reflective of the Best Available Technology Economically Achievable (40 CFR part 415). All NPDES permits must ensure that permitted discharges achieve water quality standards (40 CFR 122.44(d)). Nonpoint source runoff is not regulated under federal regulations, but to the extent that these sources cause a water to exceed its water quality standards, states will develop TMDLs that identify the necessary reductions from these sources for achieving the water quality standards.

Anthropogenic emissions, however, are only one part of the mercury cycle. Releases from human activities today add to the mercury reservoirs that already exist in land, water, and air, both naturally and as a result of previous human activity.

2.3 How does methylmercury get into fish and shellfish?

Mercury is widely distributed in the environment. Understanding the distribution and cycling of mercury among the abiotic (nonliving) and biotic (living) compartments of aquatic ecosystems is essential to understanding the factors that govern methylmercury uptake in fish and shellfish tissue. The following is a synopsis of the current understanding of mercury cycling in the environment.

Mercury occurs naturally in the environment as several different chemical species. Most mercury in the atmosphere (95–97 percent) is present in a neutral, elemental state, Hg^0 (Lin and Pehkonen 1999). In water, sediments, and soils, most mercury is found in the oxidized, divalent state, Hg^{II} (Morel et al. 1998). A small fraction of this pool of divalent mercury is transformed by microbes into methylmercury (CH_3Hg^{II}) (Jackson 1998). Methylmercury is retained in fish tissue and is the only form of mercury that biomagnifies in aquatic food webs (Kidd et al. 1995). Transformations among mercury species within and between environmental media result in a complicated chemical cycle.

The relative contributions of local, regional, and long-range sources of mercury to fish mercury levels in a given waterbody are strongly affected by the speciation of natural and anthropogenic emission sources. Elemental mercury is oxidized in the atmosphere to form the more soluble mercuric ion, Hg^{II} (Schroeder et al. 1989). Particulate and reactive gaseous phases of Hg^{II} are the principal forms of mercury deposited onto terrestrial and aquatic systems because they are more efficiently scavenged from the atmosphere through wet and dry deposition than is Hg^0 (Lindberg and Stratton 1998). Because Hg^{II} species or reactive gaseous mercury (RGM) and particulate mercury (Hg_p) in the atmosphere tend to be deposited more locally than Hg^0, differences in the species of

mercury emitted affect whether the mercury is deposited locally or travels longer distances in the atmosphere (Landis et al. 2004).

A portion of the mercury deposited in terrestrial systems is re-emitted to the atmosphere. On soil surfaces, sunlight might reduce deposited Hg^{II} to Hg^{0}, which might then escape back to the atmosphere (Carpi and Lindberg 1997, Frescholtz and Gustin 2004, Scholtz et al. 2003). Significant amounts of mercury can be co-deposited to soil surfaces in throughfall and litterfall of forested ecosystems (St. Louis et al. 2001), and exchange of gaseous Hg^{0} by vegetation has been observed (e.g., Gustin et al. 2004). Hg^{II} has a strong affinity for organic compounds such that inorganic mercury in soils and wetlands is predominantly bound to dissolved organic matter (Mierle and Ingram 1991). Concentrations of methylmercury in soils are generally very low. In contrast, wetlands are areas of enhanced methylmercury production and account for a significant fraction of the external methylmercury inputs to surface waters that have watersheds with a large portion of wetland coverage (e.g., St. Louis et al. 2001).

In the water column and sediments, Hg^{II} partitions strongly to silts and biotic solids, sorbs weakly to sands, and complexes strongly with dissolved and particulate organic material. Hg^{II} and methylmercury sorbed to solids settle out of the water column and accumulate on the surface of the benthic sediment layer. Surficial sediments interact with the water column through resuspension and bioturbation. The amount of bioavailable methylmercury in water and sediments of aquatic systems is a function of the relative rates of mercury methylation and demethylation. In the water, methylmercury is degraded by two microbial processes and sunlight (Barkay et al. 2003; Sellers et al. 1996). Mass balances for a variety of lakes and coastal ecosystems show that *in situ* production of methylmercury is often one of the main sources of methylmercury in the water and sediments (Benoit et al. 1998; Bigham and Vandal 1994; Gbundgo-Tugbawa and Driscoll 1998; Gilmour et al. 1998; Mason et al. 1995). Changes in the bioavailability of inorganic mercury and the activity of methylating microbes as a function of sulfur, carbon, and ecosystem-specific characteristics mean that ecosystem changes and anthropogenic "stresses" that do not result in a direct increase in mercury loading to the ecosystem, but alter the rate of methylmercury formation, might also affect mercury levels in organisms (e.g., Grieb et al. 1990).

Dissolved Hg^{II} and methylmercury accumulate in aquatic vegetation, phytoplankton, and benthic invertebrates. Unlike Hg^{II}, methylmercury biomagnifies through each successive trophic level in the benthic and pelagic food chains such that mercury in predatory, freshwater fish is found almost exclusively as methylmercury (Bloom 1992; Watras et al. 1998). In fish, methylmercury bioaccumulation is a function of several uptake pathways (diet, gills) and elimination pathways (excretion, growth dilution) (Gilmour et al. 1998; Greenfield et al. 2001). Factors such as pH, length of the aquatic food chain, temperature, and dissolved organic carbon (DOC) can affect bioaccumulation (Ullrich et al. 2001). As a result, the highest mercury concentrations for a given fish species correspond to smaller, long-lived fish that accumulate methylmercury over their life span with minimal growth dilution (e.g., Doyon et al. 1998). In general, higher mercury concentrations are expected in top predators, which are often large fish relative to other species in a waterbody.

2.4 Why is EPA publishing this document?

In a January 8, 2001, *Federal Register* notice (66 FR 1344), EPA announced the availability of its recommended water quality criterion for methylmercury. In that notice, EPA also stated that development of the associated implementation procedures and guidance documents would begin by the end of 2001. Therefore, EPA makes this guidance available to fulfill that commitment to assist states and authorized tribes to adopt into their water quality standards the recommendations set forth in *Water Quality Criterion for the Protection of Human Health: Methylmercury* (USEPA 2001a), or other water quality criteria for methylmercury where such other criteria are based on scientifically defensible methods.

This nontraditional approach—developing a water quality criterion as a fish and shellfish tissue value—raises several implementation questions on both technical and programmatic fronts. Development of water quality standards, NPDES permits, and TMDLs presents many challenges because these activities have usually been based on a water concentration (e.g., as a measure of mercury levels in effluent or receiving waters). This guidance addresses issues associated with states' and authorized tribes' adoption of the new water quality criterion into their water quality standards programs and implementation of the revised water quality criterion in TMDLs and NPDES permits. Furthermore, because atmospheric deposition is a large source of mercury for many waterbodies, implementation of this criterion involves coordination across various media and program areas, which is also addressed in this guidance.

At this time, about seven states, plus Washington D.C. and two territories have adopted a fish tissue criterion for methylmercury with EPA approval. EPA expects that with the publication of this guidance, states and authorized tribes will include new or revised criteria for methylmercury in their waters as part of the next three year review of standards required by section 303(c) of the Clean Water Act. This expanded adoption of the 2001 methylmercury fish tissue criterion, together with a more sensitive method for detecting mercury in effluent and the water column and increased monitoring of previously unmonitored waterbodies, is expected to result in an increase in the number of waterbodies that states identify as impaired by mercury on CWA section 303(d) lists.

This guidance includes recommended approaches for relating a concentration of methylmercury in fish tissue to a concentration of mercury in ambient water (see chapter 3); a recommended approach for directly using the methylmercury tissue criterion as a basis for issuing NPDES permits (see chapter 7); and approaches that have been used in approved TMDLs for waterbodies impaired by mercury. This guidance includes examples of TMDL approaches for waterbodies where much of the mercury comes from atmospheric sources, as well as examples of TMDLs for waterbodies where the mercury is predominantly from past mining activity. Finally, the guidance describes ongoing EPA efforts to address sources of mercury, such as programs under the CAA and pollution prevention activities.

EPA recognizes the complexity and comprehensive nature of this guidance. As is always the case when EPA issues technical guidance, EPA will provide outreach and technical assistance to states and authorized tribes in implementing this guidance.

2.5 What is the effect of this document?

This guidance document presents suggested approaches—but not the only technically defensible approaches—to criteria adoption and implementation. The guidance is not a substitute for applicable sections of the CWA or EPA's regulations; nor is it a regulation itself. Thus, it cannot impose legally binding requirements on EPA, states, authorized tribes, or the regulated community and may not apply to a particular situation. EPA, state, territorial, and tribal decision makers retain the discretion to adopt other scientifically defensible approaches that differ from this guidance. EPA may change this guidance in the future.

3 Water Quality Criteria and Standards Adoption

3.1 What must states and authorized tribes include as they adopt the methylmercury criterion?

3.1.1 What do the CWA and EPA's regulations require?

The CWA and EPA's regulations specify the requirements for adoption of water quality criteria into state or tribal water quality standards. States and authorized tribes must adopt water quality criteria[4] that protect designated uses. See CWA section 303(c)(2)(A). Water quality criteria must be based on a sound scientific rationale and must contain sufficient parameters or components to protect the designated uses (see 40 CFR 131.11). States and authorized tribes are required to review standards every three years and submit changes to EPA for approval.

Whenever they review or revise standards, states and authorized tribes are to adopt numeric criteria for all toxic pollutants for which EPA has established national recommended ambient water quality criteria (AWQC) and where the discharge or presence of these pollutants could reasonably interfere with the designated uses (see CWA section 303(c)(2)(B)). Mercury and related compounds are identified as toxic pollutants in EPA regulations (40 CFR 401.15) and EPA published a criterion under 304(a) for methylmercury in 2001. EPA issued guidance on how states and authorized tribes may comply with CWA section 303(c)(2)(B), which is now contained in the *Water Quality Standards Handbook: Second Edition* (USEPA 1994). This document provides three options for compliance:

- Option 1: States and authorized tribes may adopt statewide or reservation-wide numeric chemical-specific criteria for all toxic pollutants for which EPA has issued CWA section 304(a) criteria guidance.
- Option 2: States and authorized tribes may adopt numeric chemical-specific criteria for those stream segments where the state or tribe determines that the priority toxic pollutants for which EPA has issued CWA section 304(a) criteria guidance are present and can reasonably be expected to interfere with designated uses (e.g., a designated use of "fishing" is interfered with by nonattainment of the mercury water quality criterion).

[4] The term *water quality criteria* has two different definitions under the CWA. Under CWA section 304(a), EPA publishes recommended water quality criteria guidance that consists of scientific information regarding concentrations of specific chemicals or levels of parameters in water that protect aquatic life and human health. The 2001 methylmercury criterion is an example of a recommended section 304(a) criterion. States may use these recommended criteria as the basis for developing water quality standards. Water quality criteria are also elements of state water quality standards adopted under CWA section 303(c).

- Option 3: States or authorized tribes may adopt a chemical-specific translator procedure[5] that can be used to develop numeric criteria as needed.

EPA considers the 2001 methylmercury criterion a sound, scientifically based approach for meeting human health designated uses. In addition, this guidance addresses a range of complex technical issues and responds to the questions that states and authorized tribes have raised. Thus, EPA strongly encourages states and authorized tribes to adopt the 2001 methylmercury criterion or any sound, scientifically based approach for methylmercury or mercury, into their water quality standards at the upcoming triennial review of standards to fulfill the requirements of section 303(c) (2)(B) of the Clean Water Act and 40 CFR part 131. Numerical criteria for mercury in water, rather than fish tissue, published by EPA and in effect prior to 2001, may be included temporarily as part of revised mercury criteria at the next triennial review as provided for below.

3.1.2 What is the recommended form of the methylmercury criterion?

EPA's current recommended CWA section 304(a) water quality criterion for methylmercury is expressed as a fish[6] tissue concentration value (0.3 milligram methylmercury per kilogram of wet-weight fish tissue, or 0.3 mg/kg). With the publication of the fish tissue criterion, EPA withdrew the previous human health water quality criterion for mercury as the recommended section 304(a) water quality criterion for states and authorized tribes to use as guidance in adopting water quality standards (USEPA 2001c). These water column criteria, however, may be temporarily part of revised mercury criteria until the triennial review that follows the criterion adoption to help the transition in implementing the fish tissue criterion.

States and authorized tribes have several options for adopting a new or revised methylmercury criterion into their water quality standards. They may:

- Adopt the 2001 criterion or other scientifically defensible criterion as a fish tissue residue concentration, and implement it without water column translation; or
- Adopt a water column concentration, using the translation methodologies outlined in section 3.1.3.1, and implement it using traditional approaches; or
- Use a combination of the above approaches. For example, states and tribes could adopt a fish tissue criterion and implement it without water column translation for some or all waters, and translate the criterion to water column values for some or all waters.

Site-specific data for translating the fish tissue criterion to water column concentration, where needed, may take time to collect. Accordingly, states and authorized tribes may

[5] A *translator procedure* is simply the detailed process adopted by a state or authorized tribe, that explains how the state or authorized tribe will interpret its narrative criteria for toxics so that a quantifiable term can be used in assessment, permitting, and TMDL development. For example, a state or tribe could use EPA's water quality criteria as the means for interpreting its narrative criteria.

[6] The criterion applies to both finfish and shellfish. For purposes of simplifying language in this document, the term *fish* means both finfish and shellfish.

consider retaining their existing water column criteria, on a temporary basis, particularly for waters where there is a relatively high direct water input of mercury. In such a case, where the state has retained the existing water column criteria, permits must include both a limit based on the existing numeric water column criterion and other requirements based on the fish tissue criterion (see chapter 7).

Where a water column translation of the fish tissue criterion has been developed or where site-specific data to do so are readily available using one of the options in Section 3.1.3.1, states and authorized tribes should translate the fish tissue criterion, and implement using traditional approaches. If site-specific data are not available to translate, the state or authorized tribe may design data collection activities to obtain the necessary data. States and authorized tribes should focus data collection activities on water bodies where methylmercury impairments are high priorities for action because of high direct water inputs. EPA recommends that states and tribes not only focus on data collection but also on the development of translators for waters with high direct water inputs of mercury. Additionally, EPA recommends that states and tribes include such translators in their criterion implementation plans.

States and authorized tribes remain free not to use EPA's current recommendations, provided that their new or revised water quality criteria for methylmercury protect the designated uses and are based on a scientifically defensible methodology. In doing this, states and authorized tribes should consider bioaccumulation and local or statewide fish consumption. EPA will evaluate criteria submitted by states and authorized tribes case by case.

If states and authorized tribes decide to adopt the tissue criterion expressed as a fish tissue concentration without translating it to a traditional water column concentration, this decision will lead to choices on how to implement the tissue criterion. A state or authorized tribe could decide to develop TMDLs and to calculate WQBELs in NPDES permits directly without first measuring or calculating a BAF. This guidance provides options for such approaches in chapters 6 and 7.

EPA does not require states and tribes to translate the fish tissue criterion into water column criteria. For waters with relatively high direct water inputs of mercury (mercury from point sources and nonpoint sources other than air deposition), EPA does recommend developing TMDLs, an analysis of sources and loading capacity similar to what would be provided in a TMDL, or a water column translation of the fish tissue criterion, to provide important information for developing appropriate permit limits. See section 7.5.2.2 for a further discussion of this situation.

3.1.2.1 Developing a methylmercury criterion implementation plan

Regardless of the approach a state decides to use to implement its criterion, EPA encourages states and authorized tribes to develop a methylmercury criterion implementation plan to ensure environmentally protective and effective administration of all water quality related programs with respect to methylmercury. Developing a methylmercury implementation plan can facilitate adoption of the tissue-based criterion and provide transparency on state or tribal approaches to the numerous implementation issues associated with this type of criterion. This benefits not only the state or tribe but the regulated community and the public.

Examples of potential implementation issues the plan could cover include criterion adoption into the water quality standards (e.g., tissue or water column value with translators, BAF development methods), reasonable potential and permitting decisions, ambient monitoring strategies, and impairment determinations.

Developing an implementation plan could also facilitate subsequent regulatory decisions. Working with stakeholders and the public to develop an appropriate implementation plan concurrent with adoption of a tissue-based criterion could facilitate subsequent implementation decisions (e.g., application of the criterion in the context of 303(d) listing decisions or NPDES permitting actions) and decrease the likelihood of legal challenges.

It may be most useful to states and tribes to develop such an implementation plan prior to the adoption of the fish tissue criterion. States and tribes could propose draft plans when they are developing updates or revisions to their water quality standards. Additionally, EPA encourages states and tribes to take public comment on their draft plan during the time when the state or tribe is proposing to adopt the fish tissue criterion.

If a state or tribe develops a methylmercury implementation plan during adoption of its criterion, the state or tribe should submit the plan to EPA with the state's new criterion. Although the plan itself is not subject to EPA review and approval, the plan could facilitate EPA's review of the new criterion.

3.1.2.2 Why is the fish tissue concentration criterion recommended?

EPA recommends that when states and authorized tribes adopt new or revised methylmercury water quality criteria, they adopt the criteria in the form of a fish tissue methylmercury concentration. This is the preferred form for the following reasons:

- A criterion expressed as a fish tissue concentration is closely tied to the "fishable" designated use goal applied to nearly all waterbodies in the United States.
- A fish tissue concentration value is expressed in the same form (fish tissue) through which humans are exposed to methylmercury.
- A fish tissue concentration value is more consistent with how fish advisories are issued.
- At environmentally relevant concentrations, methylmercury is currently easier to detect in fish tissue than in water samples.

3.1.2.3 How is the fish tissue concentration criterion calculated?

The derivation of a methylmercury water quality criterion uses a human health toxicological risk assessment (e.g., a reference dose [RfD]), exposure data (e.g., the amount of pollutant ingested, inhaled, or absorbed per day), and data about the target population to be protected. The methylmercury fish tissue residue criterion (TRC) for the protection of human health is calculated as:

$$\text{TRC} = \frac{BW \times (RfD - RSC)}{\sum_{i=2}^{4} FI} \qquad \text{(Equation 1)}$$

Where:

- *TRC* = fish tissue residue criterion (in mg/kg) for freshwater and estuarine fish and shellfish
- *RfD* = reference dose (based on noncancer human health effects); for methylmercury, it is 0.1 µg/kg body weight/day
- *RSC* = relative source contribution (subtracted from the RfD to account for methylmercury in marine fish consumed[7]), estimated to be 0.027 µg/kg body weight/day
- *BW* = human body weight (default value of 70 kg for adults)
- *FI* = fish intake at trophic level (TL)*i* (*i* = 2, 3, 4); total default intake of uncooked freshwater and estuarine fish is 17.5 g fish/day for the general U.S. adult population[8]

This equation and all values used in the equation are described in *Water Quality Criterion for the Protection of Human Health, Methylmercury* (USEPA 2001a). This equation is essentially the same equation used in the 2000 Human Health Methodology (USEPA 2000b) to calculate a water quality criterion for a pollutant that may cause noncancerous health effects. Here, it is rearranged to solve for a protective concentration in fish tissue rather than in water. Thus, it does not include a BAF or drinking water intake value (methylmercury exposure from drinking water is negligible (USEPA 2001c)).

When all the numeric values are put into the generalized equation, the TRC of 0.3 mg methylmercury/kg fish is the concentration in fish tissue that should not be exceeded on the basis of a consumption rate of 17.5 g fish/day of freshwater or estuarine fish.

EPA encourages states and authorized tribes to collect, as quickly as possible, local or regional data to modify the fish consumption rate rather than using the default values if the state or authorized tribe believes that such a fish consumption rate would be more appropriate for its target population. This gives states and tribes the flexibility to develop criteria that provide additional protection appropriate for highly exposed populations that may be at greater risk than the general population protected by the 304(a) criterion (USEPA 2000b). Where states do not have site-specific data, but intend to collect this

[7] The RSC accounts for exposures from all anticipated sources so that the entire RfD is not apportioned to freshwater/estuarine fish and shellfish consumption alone. In the assessment of human exposure in the methylmercury water quality criterion document, EPA found that human exposures to methylmercury were negligible except from freshwater/estuarine and marine fish. Therefore, in developing the criterion on the basis of consumption of freshwater/estuarine fish, EPA subtracted the exposure due to consumption of marine fish. See 66 FR 1354–1355; January 8, 2001.

[8] The consumption rate value of 17.5 grams uncooked fish per day is the 90th percentile of freshwater and estuarine fish consumed by the public according to the *1994–96 Continuing Survey of Food Intakes by Individuals* (USEPA 2000a). EPA uses this value as the default consumption rate in development of water quality criteria. The default trophic level values for the general population are 3.8 g fish/day for TL2, 8.0 g fish/day for TL3, and 5.7 g fish/day for TL4. The rationale behind the selection of this value is described in the Human Health Methodology (USEPA 2000b).

data over time to develop a more appropriate criterion, states should use EPA's default fish consumption rate on a temporary basis to be able to adopt and implement the fish tissue criterion in a timely manner.

The TRC value is not based on any default breakout of fish consumption by trophic level.The trophic levels assigned to the fish consumption value should reflect those that each target population consumes. For assessing impairment or attainment of the TRC, a state or authorized tribe may choose to assign the TRC value to only trophic level 4 or to the highest trophic level consumed. This approach is conservative in that it assumes that all fish consumed are at the highest trophic level, and it will likely protect most, if not all, populations at an uncooked freshwater or estuarine fish consumption rate of 17.5 grams/day. If a state or authorized tribe wishes to calculate the TRC value on the basis of consumption at each trophic level for monitoring and compliance purposes, it would first determine consumption patterns at each trophic level for the target population(s). (For information on determining consumption patterns, see chapter 4.) This approach might be more precise and is less likely to be overprotective; however, developing it could be resource-intensive.

3.1.3 What approaches should states or authorized tribes consider when developing a water column concentration criterion?

As described in section 3.1.2 above, there may be situations where it is appropriate to adopt a criterion expressed as a water column concentration. EPA recognizes that a fish tissue residue water quality criterion is new to states and authorized tribes and might pose implementation challenges for traditional water quality programs. Water quality standards, water quality-based effluent limits[9] (WQBELs), total maximum daily loads (TMDLs), and other activities generally employ a water column value. This section provides information for states and authorized tribes that decide to adopt a water concentration criterion derived from a fish tissue criterion.

Alternatively, a state or authorized tribe may decide to adopt a fish tissue criterion with a site-specific procedure for translating the tissue criterion to a water column concentration. Because methylmercury bioaccumulation can vary substantially from one location to another, this option allows for the tissue criterion to be translated to a water concentration using site-specific information on methylmercury bioaccumulation (i.e., site-specific BAFs). Administratively, this option might be more efficient compared to adopting a water concentration criterion for an entire state or tribal jurisdiction or adopting or approving site-specific criteria on an individual waterbody basis. Approaches for translating a tissue concentration-based criterion to a water concentration are provided in the following section (section 3.1.3.1).

Developing a water column translation of the fish tissue criterion requires assessment of methylmercury bioaccumulation at an appropriate geographic scale. The uncertainty associated with differential bioaccumulation of methylmercury across sites within a state or tribal jurisdiction will be embedded in the state or tribal water-based criterion.

[9] A WQBEL is a requirement in an NPDES permit that is derived from, and complies with, all applicable water quality standards and is consistent with the assumptions and requirements of any approved wasteload allocation (see 40 CFR 122.44(d)(1)(vii)).

Reducing such uncertainty is one of the primary reasons EPA chose to express its national recommended criterion for methylmercury as a tissue concentration rather than as a water concentration.

To express the methylmercury tissue concentration-based criterion as a water concentration, a state or authorized tribe would translate the methylmercury criterion concentration in fish tissue to methylmercury concentrations in the water column. To accomplish this, the state or authorized tribe would develop BAFs. In the 2001 *Federal Register* notice of the methylmercury criterion, EPA identified three different possible approaches for developing a BAF. These approaches are discussed in more detail in section 3.1.3.1. The basic equations used in developing a water column criterion are presented below, and additional discussion of calculating BAFs is presented in the following section.

The following equation may be used to translate the tissue concentration-based human health AWQC to a water concentration-based methylmercury criterion using a BAF as

$$AWQC = TRC / BAF \qquad \text{(Equation 2)}$$

Where:

AWQC = water concentration-based ambient water quality criterion for methylmercury in milligrams per liter (mg/L)
TRC = tissue residue concentration; the water quality criterion for methylmercury in fish tissue in mg/kg
BAF = bioaccumulation factor for trophic levels 2, 3, and 4, weighted on the basis of fish consumption rates for each trophic level in liters per kilogram (L/kg)

The BAF is the ratio of the concentration of the chemical in the appropriate tissue of the aquatic organism and the concentration of the chemical in ambient water at the site of sampling. BAFs are trophic-level-specific. EPA recommends that they be derived from site-specific, field-measured data as

$$\text{BAF} = \frac{C_t}{C_w} \qquad \text{(Equation 3)}$$

Where:

BAF = bioaccumulation factor, derived from site-specific field-collected samples of tissue and water in L/kg
Ct = concentration of methylmercury in fish tissue in mg/kg, wet tissue weight
Cw = concentration of methylmercury in water in mg/L

When such data are unavailable, other approaches for deriving BAFs may be used, as outlined in section 3.1.3.1.

In the calculation to derive an AWQC as a water column concentration, the BAFs for the different trophic levels are combined to provide a weighted BAF value. For example, if a

state wants to protect a population that eats on average 17.5 grams per day of uncooked fish from a waterbody, and 75 percent of the fish eaten are in trophic level 4 and 25 percent of the fish eaten are in trophic level 3, the weighted BAF would be the sum of 0.25 times the trophic level 3 BAF and 0.75 times the trophic level 4 BAF. Section 3.2.1.2 provides guidance on estimating fish intake rates.

3.1.3.1 How is the methylmercury fish tissue concentration translated to a water concentration?

Should a state or authorized tribe decide to translate the methylmercury fish tissue criterion into a water column concentration, it would assess the extent to which methylmercury is expected to bioaccumulate in fish tissue for the site(s) of interest. Assessing and predicting methylmercury bioaccumulation in fish is complicated by a number of factors that influence bioaccumulation. These factors include the age or size of the organism; food web structure; water quality parameters such as pH, DOC, sulfate, alkalinity, and dissolved oxygen; mercury loadings history; proximity to wetlands; watershed land use characteristics; and waterbody productivity, morphology, and hydrology. In combination, these factors influence the rates of mercury bioaccumulation in various—and sometimes competing—ways. For example, these factors might act to increase or decrease the delivery of mercury to a waterbody, alter the net production of methylmercury in a waterbody (through changes in methylation and/or demethylation rates), or influence the bioavailability of methylmercury to aquatic organisms. Although bioaccumulation models have been developed to address these and other factors for mercury, their broad application can be limited by the site- or species-specific nature of many of the factors that influence bioaccumulation and by limitations in the data parameters necessary to run the models.

The bioaccumulation of nonionic organic chemicals[10] such as methylmercury can also be affected by a number of these same physicochemical factors (e.g., loading history, food web structure, dissolved oxygen, DOC). However, a substantial portion of the variability in bioaccumulation for nonionic organic chemicals can be reduced by accounting for lipid content in tissues and organic carbon content in water and "normalizing" BAFs using these factors (Burkhard et al. 2003; USEPA 2003). Normalizing to the age or size (length, weight) of fish has been shown to reduce variability in measures of bioaccumulation (Brumbaugh et al. 2001; Glass et al. 2001; Sonesten 2003; Sorensen et al. 1990; Wente 2004).

The United States Geological Survey (USGS) developed a procedure called the National Descriptive Model for Mercury in Fish Tissue (NDMMF) (Wente 2004). This model provides a translation factor to convert a mercury concentration taken from one species/size/sample method to an estimated concentration for any other user-predefined species/size/sample method.

[10] Nonionic organic compounds are those organic compounds that do not ionize substantially when dissolved in water and therefore are more likely to associate with sediment compounds, lipids, or other compounds in water (USEPA 2000b).

Mercury Terminology

For the purposes of this document, the following definitions apply:

Mercury (or total mercury): The sum of all forms of mercury, including methylmercury, other organic forms, inorganic, and elemental mercury. All of these are toxic, and inorganic and elemental mercury can be methylated in the environment.

Methylmercury: The organic form of mercury, that bioaccumulates in the food chain. (Other organic forms of mercury exist, but exposure to them through environmental pathways is not significant.)

Dissolved mercury (or filtered mercury): The portion of mercury that passes through a filter.

Dissolved methylmercury (or filtered methylmercury): The portion of methylmercury which passes through a filter.

Total recoverable mercury (or unfiltered mercury): The dissolved portion plus the particulate portion of mercury in a water sample.

Total recoverable methylmercury (or unfiltered methylmercury): The dissolved portion plus the particulate portion of methylmercury in a water sample.

Taking into account the previous discussion, EPA has outlined in this document three different approaches that could be considered for relating a concentration of methylmercury in fish tissue to a concentration of methylmercury in ambient water, should a state decide to develop or implement its standard in this manner:

1. Use site-specific methylmercury BAFs derived from field studies.

2. Use a scientifically defensible bioaccumulation model.

3. Where appropriate, use BAFs derived using the results of field studies that are not site-specific. Appropriate situations for using such BAFs include waters where direct water inputs are relatively high and where ambient fish tissue data are unavailable, where deriving site-specific, field-measured BAFs is not feasible, or where using a model is not feasible. Such BAFs may include the draft national BAFs presented in appendix A of Water Quality Criterion for the Protection of Human Health: Methylmercury (USEPA 2001a) and discussed in more detail below. Alternatively, BAFs may be derived using other approaches, such as a combination of national and site-specific data in conjunction with other, non-site-specific data, to create better estimates.

Of these approaches, 1 and 2 are preferred over 3. Because of the significant uncertainties inherent in non-site-specific estimates of BAFs (including the draft national BAFs), they should be used as defaults only in limited circumstances such as:

- When a state determines that use of the draft national BAFs are appropriate (for example, where direct water inputs are relatively high, where no other data are available to derive site-specific field-measured BAFs, and use of an appropriate BAF model is not feasible)

- When a state can show that such BAFs are appropriate for its situation (e.g., a state has data or analyses that demonstrate that the draft national BAFs would be appropriate)

- As an interim approach until more appropriate BAFs can be developed using other data and/or an alternate approach

The reasons for preferring approaches 1 and 2 are discussed in more detail below. However, the hierarchy assigned to the approaches is not intended to be inflexible. For example, in some cases, the site-specific information available may be so limited in quality or quantity that BAFs derived using other data may be preferable. In other cases, there might be enough site-specific information to indicate that the local conditions approximate the draft national values.

In situations where the state or tribe has some data available on fish tissue and water column levels in its jurisdiction, but data are insufficient to support broad development of site-specific translations, the state or tribe may be able to use these data in combination with an evaluation of the draft national BAFs to help develop water column translations. For example, California's Office of Environmental Health Hazard Assessment compiled mercury concentration data for water and biota, and calculated state-specific BAFs for different types of waters and different trophic levels. The office found enough similarities between the state-specific BAFs and EPA's draft national BAFs that it recommended using EPA's draft national values as an interim approach until more complete state-specific data becomes available (Sanborn and Brodberg 2006). The state is in the process of deciding whether to adopt this approach.

If the state or tribe chooses to derive BAFs using the third approach above, the state or tribe should provide an accompanying rationale that acknowledges an understanding of the potential limitations of the approach.

Developing site-specific data to support approaches 1 and 2 can be facilitated by efforts involving stakeholders, states, and authorized tribes. Developing site-specific data is one possible approach EPA recommends permitting authorities consider to help develop NPDES permits in watersheds where mercury loadings from point sources are relatively high. See section 7.5.2.2.

3.1.3.1.1 Site-specific bioaccumulation factors derived from field studies

The use of site-specific BAFs based on data obtained from field-collected samples of tissue from aquatic organisms that people eat and water from the waterbody of concern—referred to as a "field-measured site-specific BAF"—is the most direct and most relevant measure of bioaccumulation. This approach is consistent with EPA's bioaccumulation guidance contained in the 2000 Human Health Methodology (USEPA 2000b) and the Technical Support Document for developing national BAFs (USEPA 2003). Although a BAF is actually a simplified form of a bioaccumulation model, the field-measured site-specific BAF approach is discussed separately here because of its widespread use and application.

A field-measured site-specific BAF is derived from measurements of methylmercury concentrations in tissues of aquatic organisms and the ambient water they inhabit. Because the data are collected from a natural aquatic ecosystem, a field-measured BAF reflects an organism's exposure to a chemical through all relevant exposure routes (e.g., water, sediment, diet). Although a BAF can be measured for the aggregate of fish in a location, site-specific BAFs are often specific to trophic level and species of fish. The BAF can also be measured based on a predatory indicator species with a high propensity

for bioaccumulation, such as largemouth bass. A field-measured site-specific BAF also reflects biotic and abiotic factors that influence the bioavailability and metabolism of a chemical that might occur in the aquatic organism or its food web at a given location. By incorporating these factors, field-measured site-specific BAFs account for the actual uptake and accumulation of the chemical.

States and authorized tribes should exercise caution, however, in developing a site-specific BAF for a migratory fish because its exposure to methylmercury occurred in part in areas other than where the fish was caught and therefore might not accurately predict the water column mercury concentrations associated with the fish tissue concentration of mercury. States and tribes should consider the life history of the migratory fish and the consumption patterns of the local population when considering BAFs for migratory species. States and tribes should also review how the applicable RSC considers migratory fish when considering including those species in BAF calculations (see section 3.2.1.1).

For the purposes of developing a criterion expressed as a water concentration, states and authorized tribes should calculate the BAF as the ratio of the concentration of methylmercury in the tissue of aquatic organisms that people eat to the concentration of methylmercury in water[11] (Equation 3). To predict the corresponding methylmercury concentration in water for a site, the tissue-based methylmercury criterion would then be divided by the site-specific BAF (Equation 2). Using the site-specific BAF approach assumes that at steady state, the accumulation of methylmercury by the aquatic organism varies in proportion to the methylmercury concentration in the water column.

As an example, California is currently employing a site-specific BAF approach in its Central Valley Region. In this approach, the state evaluated graphs of average concentrations of methylmercury in water and the corresponding concentrations in fish at multiple sites in a watershed. Researchers found statistically significant, positive relationships between concentrations of unfiltered methylmercury in water and in various trophic levels of the aquatic food chain (Slotton et al. 2004). California linearly regressed fish tissue methylmercury concentrations for specific trophic level (TL) 3 and 4 fish against aqueous methylmercury concentrations ($P < 0.001$, $R^2 = 0.98$, and $P < 0.01$, $R^2 = 0.9$, respectively) and determined methylmercury concentrations in unfiltered water that correspond to the fish tissue criteria used in the TMDL analyses (0.15 ng/L for TL3 fish and 0.14 ng/L for TL4 fish) (Central Valley Water Board 2005). California assumed that sites that fit in a statistically significant regression have similar processes controlling methylmercury accumulation. In other words, site-specific BAFs for such sites are nearly identical.

Strengths associated with using a site-specific BAF approach include simplicity, widespread applicability (i.e., site-specific BAFs can be derived for any waterbody, fish species, and the like), and that the net effects of biotic and abiotic factors that affect

[11] Although BAFs are sometimes calculated to represent the relationship between methylmercury in fish tissue and dissolved methylmercury in the water column, data can be collected to determine the relationship between methylmercury in fish tissue and total recoverable methylmercury or dissolved or total recoverable mercury in the water column. The Great Lakes Water Quality Initiative (GLI) used site-specific BAFs to convert directly from methylmercury in fish to total recoverable mercury in the water column. See 40 CFR part 132, and appendix B to part 132, Methodology for Deriving Bioaccumulation Factors.

bioaccumulation are incorporated within the measurements used to derive the BAF. Specifically, it is not required that the exact relationship between methylmercury accumulation and the factors that can influence it be understood or quantified to derive a site-specific BAF. By measuring the methylmercury concentrations empirically, these factors have been incorporated such that site-specific BAFs provide an accounting of the uptake and accumulation of methylmercury for an organism in a specific location and at a specific point in time.

Limitations to the site-specific BAF approach relate primarily to its cost and empirical nature. For example, the level of effort and associated costs of developing site-specific BAFs increase as the spatial scale of the site of interest increases. Furthermore, the amount of data necessary to obtain a representative characterization of methylmercury in the water and fish might take considerable time to gather. (For a discussion on sampling considerations for developing a site-specific BAF, see section 3.1.3.2.) The strictly empirical nature of this approach is also a barrier to extrapolating BAFs among species, across space, and over time because the site-specific factors that might influence bioaccumulation are integrated within the tissue concentration measurement and thus cannot be individually adjusted to extrapolate to other conditions.

3.1.3.1.2 Bioaccumulation models

Bioaccumulation models for mercury vary in the technical foundation on which they are based (empirically or mechanistically based), spatial scale of application (specific to waterbodies, watersheds or regions, and species of fish), and level of detail in which they represent critical bioaccumulation processes (simple, mid-level, or highly detailed representations). Thus, it is critical that states and tribes use a model that is appropriately developed, validated, and calibrated for the species and sites of concern.

Empirical bioaccumulation models that explicitly incorporate organism-, water-chemistry-, and waterbody/watershed-specific factors that might affect methylmercury bioaccumulation (e.g., fish species, age, length, pH, DOC, sulfate, alkalinity, sediment acid-volatile sulfide concentration, proximity to wetlands, land use, morphology, hydrology, productivity) usually take the form of multivariate regression models. Many examples of such models are available in the literature (e.g., Brumbaugh et al. 2001; Kamman et al. 2004; Sorensen et al. 1990). The model developed by Brumbaugh et al. (2001) is based on a national pilot study of mercury in 20 watersheds throughout the United States. Specifically, Brumbaugh et al. (2001) developed a multiple regression relationship between five factors: length-normalized mercury concentration in fish, methylmercury concentration in water, percentage of wetland area in the watershed, pH, and acid-volatile sulfide concentration in sediments ($r^2 = 0.45$; all fish species). When data were restricted to a single species (e.g., largemouth bass) and a single explanatory variable (e.g., methylmercury in water), a highly significant relationship was found ($p < 0.001$) with a similar degree of correlation ($r^2 = 0.50$). This demonstrates the importance of species specificity in the strength of such regression relationships and, in this case, methylmercury in water as an explanatory variable.

States and tribes should consider several important issues when using regression-based bioaccumulation models for translating from a tissue concentration to a water column concentration. First, a number of such regression models have been developed without

explicitly incorporating methylmercury (or mercury) concentrations in the water column. Instead, the models relate fish tissue methylmercury concentrations to variables that serve as proxies for methylmercury exposure (e.g., atmospheric deposition rates, ratio of the watershed drainage to the wetland area, pH, lake trophic status), often because of the costs associated with obtaining accurate measurements of mercury in the water column. Obviously, such models cannot be directly solved for the parameter of interest (methylmercury in water). Second, correlation among independent or explanatory variables in these multiple regressions is common and expected (e.g., pH and methylmercury concentration in water). Such correlations among explanatory variables can cause bias and erroneous estimates of an explanatory variable (in this case, methylmercury concentration in water) when back-calculated from the regression equation (Neter et al. 1996). In such cases, using the underlying data set to develop a separate regression model with methylmercury concentration in water as the dependent variable is more appropriate. Last, because these regression models are based on empirical data, uncertainty is introduced when the results are extrapolated to aquatic ecosystems with different conditions. Only in a few cases have such models been tested using independent data sets (e.g., Kamman et al. 2004).

Mechanistic bioaccumulation models are mathematical representations of the natural processes that influence methylmercury bioaccumulation. The process of methylation itself is incompletely understood, and general models for reliably predicting rates of methylation do not exist, although EPA's WASP model might be useful in some environments. Three examples of mechanistic bioaccumulation models are the Dynamic Mercury Cycling Model, or D-MCM (EPRI 2002); the Bioaccumulation and Aquatic System Simulator, or BASS (Barber 2002), and the Quantitative Environmental Analysis Food Chain model, or QEAFDCHN (QEA 2000). A conceptual advantage of mechanistically based bioaccumulation models is that methylmercury bioaccumulation can be predicted under different conditions (e.g., different growth rates of fish, different water chemistry conditions, and different mercury loading scenarios) because the models include mathematical representations of various processes that affect bioaccumulation. This advantage comes at the cost of additional input data necessary to run the model. Notably, only a few models have been used to predict methylmercury bioaccumulation. Such models have not been widely used and have been applied only to mercury in a few aquatic ecosystems under specific environmental conditions. Of the examples listed above, only the D-MCM was developed specifically for mercury. The D-MCM has not been applied to lotic systems (i.e. streams, rivers, estuaries) and therefore probably should be used only for static environments (lakes) at this time. The other models have been developed more generally, for nonionic organic chemicals that bioaccumulate, and require substantial modification and validation for application to mercury.

Most mechanistic bioaccumulation models use a chemical mass balance approach to calculate bioaccumulation in fish or other aquatic organisms. This approach requires considerable understanding of mercury loadings to and cycling within the environment. None of the example models presented can predict bioaccumulation without considerable site-specific information, at least some degree of calibration to the waterbody of interest, and, in some cases, considerable modification of the model. The amount and quality of data necessary for proper model application may equal or exceed that necessary to develop site-specific methylmercury BAFs, although these models might also help in

determining BAFs if the kinetic condition in the waterbody is not steady state. Because of the need for site-specific data and calibration, these models are likely to cost as much to implement as a site-specific BAF. Their value comes from the ability to represent a wider range of explanatory and policy-relevant variables.

Regardless of the type of model used, states' and authorized tribes' methodologies should be consistent with the *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (section 5.6: National Bioaccumulation Factors for Inorganic and Organometallic Chemicals; USEPA 2000b) and *Technical Support Document Volume 2: Derivation of National Bioaccumulation Factors* (USEPA 2003). These documents provide detailed discussion of topics such as BAF derivation procedures, bioavailability, and the steps involved in procedures 5 and 6 of the Human Health Methodology. States and tribes should document how they derive the site-specific parameters used in the bioaccumulation models and should describe the uncertainty associated with the BAFs derived using any of the models.

3.1.3.1.3 Draft national bioaccumulation factors

EPA acknowledges that using site-specific BAFs or model-derived BAFs might not be feasible in all situations. Without site-specific methylmercury bioaccumulation data or an appropriate bioaccumulation model, another approach is to use EPA's empirically derived draft national methylmercury BAFs as defaults. EPA used *Technical Support Document Volume 3: Development of Site-Specific Bioaccumulation Factors* of the 2000 Human Health Methodology (USEPA 2000b, 2003) and the BAF methods in volume III, appendix D, of the *Mercury Study Report to Congress* (USEPA 1997c) to derive draft methylmercury BAFs as part of its initial efforts to derive a water column-based recommended section 304(a) ambient water quality criterion for methylmercury. These draft national BAFs were developed from field data collected from across the United States and reported in the published literature. The draft national BAFs and the uncertainties associated with them are discussed in appendix A, section I, of *Water Quality Criterion for the Protection of Human Health: Methylmercury* (USEPA 2001a). The draft national BAFs (50th percentile values) are listed by trophic level in table 2.

Table 2. Draft national BAFs for dissolved methylmercury

BAF trophic level 2 (L/kg)	BAF trophic level 3 (L/kg)	BAF trophic level 4 (L/kg)
120,000	680,000	2,700,000

Source: USEPA 2001a.

Note: Expressed as milligrams methylmercury/kilogram fish tissue per milligram methylmercury/liter water, or liters per kilogram (L/kg).

To develop the draft national BAFs for each trophic level, EPA calculated the geometric mean of the field-measured BAFs obtained from the published literature. EPA believes the geometric mean BAFs are the best available central tendency estimates of the magnitude of BAFs nationally, understanding that the environmental and biological conditions of the waters of the United States are highly variable. Specifically, the data presented in *Water Quality Criterion of the Protection of Human Health: Methylmercury* (USEPA 2001a) indicate that BAFs for trophic levels 3 and 4 vary by a factor of 100

(two orders of magnitude) between the 5th and 95th percentiles. EPA does not recommend basing an AWQC on BAF values associated with the extremes of the distribution (e.g., 10th or 90th percentile), unless supported by site-specific data. Such values might introduce an unacceptable level of uncertainty into the calculation of a water column-based AWQC. States and authorized tribes should consider the magnitude of the potential error when proposing to use the draft national BAFs.

When states and authorized tribes calculate a water column-based criterion using draft national BAFs that differ greatly from the BAFs for the waterbody of concern, the resulting water column-based criterion will be either over- or under-protective. As a result, evaluation of the results of the analysis of water samples might result in the false conclusion that a fish tissue concentration has been exceeded (when it actually has not) or a false conclusion that a fish tissue concentration has not been exceeded (when it actually has). For more information on the draft national BAFs, see chapter 6 and appendix A, section I, of EPA's 304(a) water quality criterion for methylmercury (USEPA 2001a). The following examples illustrate the potential impact of calculating a water quality criterion using a BAF that is substantially different from the actual BAF.

- *Underprotective scenario*
  A state uses the draft national BAF of 2,700,000 L/kg for trophic level 4 fish, but the BAF based on site-specific data for the trophic level 4 fish in the waterbody is three times that, or 8,100,000 L/kg. In using the draft national BAF, a state would consider water column concentrations up to 0.11 nanogram per liter (ng/L) (0.3 mg/kg / 2,700,000 L/kg) to indicate attainment of the water quality column criterion. Using the BAF based on site-specific data, however, a water column criterion of 0.11 ng/L would correspond to a fish tissue concentration of 0.9 mg/kg, which is three times the 0.3 mg/kg criterion recommended to protect human health. Thus, load reductions or permits using the draft national BAF of 2,700,000 L/kg would be underprotective.

- *Overprotective scenario*
  A state uses the draft national BAF of 2,700,000 L/kg for trophic level 4 fish, but the BAF based on site-specific data for the trophic level 4 fish in the waterbody is one-third that, or 900,000 L/kg. As a result, a state would consider water column concentrations up to 0.11 ng/L (0.3 mg/kg / 2,700,000 L/kg) to indicate attainment of the water quality criterion. Using the BAF based on site-specific data, however, attainment of the water quality criterion could be achieved at a higher water column concentration, 0.33 ng/L. Thus, load reductions or permits using the draft national BAF of 2,700,000 L/kg would be overprotective.

EPA cautions water quality managers that methylmercury bioaccumulation is generally viewed as a site-specific process and that BAFs can vary greatly across ecosystems. The uncertainty in the estimates of a draft national BAF comes from uncertainty arising from natural variability, such as size of individual fish, and from uncertainty due to measurement error, such as error in measurements of mercury in water or lack of knowledge of the true variance of a process (e.g., methylation). Users of the draft national BAFs are encouraged to review appendix A of *Water Quality Criterion for the Protection of Human Health: Methylmercury* (USEPA 2001a), which describes the uncertainties

inherent in these values. The following is a synopsis of the discussion of uncertainty in that appendix.

- *Uncertainty due to sampling and chemical analysis:* In many cases, water methylmercury concentrations reported in the available studies incorporated limited or no cross-seasonal variability, incorporated little or no spatial variability, and were often based on a single sampling event. Because fish integrate exposure of mercury over a lifetime, comparing fish concentrations to a single sample or mean annual concentrations introduces bias to the estimates. The geographic range represented by the waterbodies was also limited.

- *Uncertainty due to estimation method:* The approaches used to estimate the draft national BAFs have their own inherent uncertainties. The approaches assume that the underlying process and mechanisms of mercury bioaccumulation are the same for all species in a given trophic level and for all waterbodies. They are also based on a limited set of data.

- *Uncertainty due to biological factors:* With the exception of deriving BAFs on the basis of river or lake waterbody type, there were no distinctions in the BAFs as to the size or age of fish, waterbody trophic status, or underlying mercury uptake processes. In reality, methylmercury bioaccumulation for a given species can vary as a function of the age (body size) of the organisms examined.

- *Uncertainty due to universal application of BAFs:* There is uncertainty introduced by failure of a single trophic-level-specific BAF to represent significant real-world processes that vary from waterbody to waterbody. The simple linear BAF model relating methylmercury in fish to mercury in water simplifies a number of nonlinear processes that lead to the formation of bioavailable methylmercury in the water column and subsequent accumulation. Much of the variability in field data applicable to the estimation of mercury BAFs can be attributed to differences in biotic factors (e.g., food chain, organism age or size, primary production, methylation or demethylation rates) and abiotic factors (e.g., pH, organic matter, mercury loadings, nutrients, watershed type or size) between aquatic systems. Unfortunately, although the concentration of methylmercury in fish tissue is presumably a function of these varying concentrations, published BAFs are typically estimated from a small number of measured water values whose representativeness of long-term exposure is not completely understood. Furthermore, although it is known that biotic and abiotic factors control mercury exposure and bioaccumulation, the processes are not well understood, and the science is not yet available to accurately model bioaccumulation on a broad scale.

Peer reviewers expressed concerns about the use of the draft national BAFs as defaults to predict bioaccumulation across all ecosystems and about using them to derive a national recommended section 304(a) water quality criterion for methylmercury that would suitably apply to waterbodies across the nation. EPA recognized the peer reviewers' concerns and acknowledges that these draft national BAF values might significantly over- or underestimate site-specific bioaccumulation. As a result, EPA decided not to use the draft national BAFs to develop a national water-column-based AWQC for methylmercury. Furthermore, the draft national BAFs are EPA's least preferred means

for assessing the BAF. States and tribes should also consider whether more recent data and/or data that are more reflective of local conditions are available to supplant or supplement the limited database used to derive the draft national BAFs.

Risk managers should also understand that in using the draft national BAFs as defaults, one assumes that the biotic and abiotic processes affecting mercury fate and bioaccumulation are similar across different waterbodies, and therefore using the draft national BAFs does not address site-specific factors that might increase or decrease methylation and bioaccumulation. A state's or tribe's decision to use the draft national BAFs would be a risk management decision. The decision would reflect the state's or tribe's judgment that, for specific reasons, translating the fish tissue criterion to a water column value using such a BAF is preferable to implementing the fish tissue criterion directly (e.g., using the approaches discussed in this guidance), or conducting studies to develop a site-specific BAF (e.g., site-specific field studies or bioaccumulation modeling).

3.1.3.2 What are the sampling considerations for deriving site-specific field-measured BAFs?

For both fish tissue and water, states and authorized tribes should analyze for methylmercury when deriving site-specific BAFs. EPA has not yet published analytical methods to measure methylmercury in water or fish in 40 CFR part 136. A discussion of analytical methods for mercury and methylmercury can be found in section 4.1. For fish tissue, however, states and authorized tribes can estimate methylmercury concentrations and determine attainment by using the same analytical method used to measure for mercury, at least for upper-trophic-level fish (levels 3 and 4). This is because 80 to 100 percent of the mercury found in the edible portions of freshwater fish greater than three years of age from these two trophic levels is in the form of methylmercury (USEPA 2000c). In fish greater than approximately three years of age, mercury has had sufficient time to bioaccumulate to roughly steady levels in the fish. Appendix A summarizes eight studies of the relative proportion of the mercury concentration in North American freshwater fish that is in the form of methylmercury. In six of the eight studies, methylmercury on average accounted for more than 90 percent of the mercury concentration in fish tissue. In the remaining two studies, methylmercury on average accounted for 80 to 90 percent of the mercury concentration in trophic level 3 and 4 fish.

States and tribes should consider a number of issues when sampling aquatic organism tissue and water to derive a site-specific BAF. The goal of deriving site-specific methylmercury BAFs is to reflect or approximate the long-term bioaccumulation of methylmercury in commonly consumed aquatic organisms of a specified trophic level. Hence, an important sample design consideration is how to obtain samples of tissue and water that represent long-term, average accumulation of methylmercury. Methylmercury is often slowly eliminated from fish tissue. Therefore, concentrations of methylmercury in fish tissue tend to fluctuate much less than the concentration of methylmercury in water. Thus, for calculating representative site-specific BAFs, states and tribes should consider how to integrate spatial and temporal variability in methylmercury concentrations in both water and tissue. States and tribes should address the variability in methylmercury concentrations in fish tissue with age or size of the organism either by restricting sample collection to organisms of similar age or size classes or by using

appropriate normalization techniques. EPA's fish sampling guidance recommends that fish should be of similar size so that the smallest individual in a composite is no less than 75 percent of the total length (size) of the largest individual (USEPA 2000c). One way of normalizing data is by using the National Descriptive Model for Mercury in Fish Tissue, or NDMMF (Wente 2004). The NDMMF is a statistical model that normalizes Hg fish tissue concentration data to control for species, size, and sample type variability. An example use of the NDMMF is in the combination of mercury fish tissue data from two databases (USEPA 2005a).

States and tribes should assess the fish consumption patterns of the exposed human population when designing a site-specific sampling plan. Because the age and size of aquatic organisms are correlated with the magnitude of methylmercury accumulation, the types and sizes of aquatic organisms being consumed should be considered when determining which fish to sample for deriving BAFs. States and tribes should consider the fish being consumed by various subpopulations (e.g., sport anglers, subsistence fishers) as well as culturally and economically diverse communities. This information should also guide the decision on whether the site-specific BAF should be based on a single trophic level (e.g., trophic level 4) or on multiple trophic levels.

States and authorized tribes should review site-specific data used to calculate field-measured BAFs and thoroughly assess the quality of the data and the overall uncertainty in the BAF values. States and authorized tribes should also consider the following general factors when determining the acceptability of field-measured BAFs reported in the published scientific literature. The same general issues and questions should also be addressed when designing a field study to generate site-specific field-measured BAFs.

- Calculate a field-measured BAF using aquatic organisms that are representative of the aquatic organisms commonly consumed at the site of interest (e.g., river, lake, ecoregion, state). Review information on the ecology, physiology, and biology of the target organisms when assessing whether an organism is a reasonable surrogate of a commonly consumed organism.

- Determine the trophic level of the study organism by taking into account its life stage, its diet, and the food web structure at the study location. Information from the study site (or similar sites) is preferred when evaluating trophic status. If such information is lacking, states and authorized tribes can find general information for assessing the trophic status of aquatic organisms in *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories*, volume 1, *Fish Sampling and Analysis* (USEPA 2000c).

- Collect length, weight, and age data for any fish used in deriving a field-measured BAF because current information suggests that variability in methylmercury accumulation is dependent on fish age and size (USEPA 2001a). This information helps normalize the BAF to a standardized fish size within the range of fish sizes and species known to be consumed by the human population of interest.

- Verify that the study used to derive the field-measured BAF contains sufficient supporting information from which to determine that tissue and water samples were collected and analyzed using appropriate, sensitive, accurate, and precise analytical methods.

- Verify that the water concentrations used to derive a BAF reflect the average exposure of the aquatic organism of concern that resulted in the concentration measured in its tissue. Concentrations of methylmercury in a waterbody vary seasonally and diurnally (Cleckner et al. 1995) because of a variety of biological and physical factors.

- Attempt to design a field sampling program that addresses potential temporal and spatial variability and that allows estimation of average exposure conditions. The study should be designed to sample an area large enough to capture the more mobile organisms and also to sample across seasons or multiple years when methylmercury concentrations in waters are expected to have large fluctuations. Longer sampling durations are necessary for waters experiencing reductions in mercury loadings, changes in water chemistry that affect methylation, and changes in the composition of the food web.

Volume I of the *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories* (USEPA 2000c) provides additional guidance on selecting target species to sample, specific sampling design procedures, analytical measurement procedures, and quality assurance guidance. Chapter 10 of EPA's *Exposure Factors Handbook* provides additional guidance on collecting information about local species (USEPA 1997d). Additional guidance on evaluating existing site-specific bioaccumulation studies for use in deriving trophic-level-specific BAFs and designing sampling plans for obtaining data for deriving site-specific BAFs is provided in *Technical Support Document—Volume 2: Developing National Bioaccumulation Factors* (USEPA 2003). A publication by Burkhard (2003) is also a good source of information on designing BAF field studies and on deriving field-measured site-specific BAFs.

3.1.3.3 How is methylmercury in water translated into its mercury equivalent in water?

Given that permit limits are often derived using a mercury water column concentration criterion, a state or tribe may wish to take another step after using a BAF to determine a methylmercury water concentration criterion to derive a mercury water column concentration criterion. Although not necessary to develop a water quality criterion, a state can translate a methylmercury water concentration into a mercury water concentration criterion by converting the concentration of methylmercury in water to the equivalent concentration of mercury in water. This step might be necessary because although the BAF is typically based on the concentration of methylmercury in water, the assessment of water quality is typically based on an evaluation of mercury concentrations since other forms of mercury are converted to methylmercury in the environment. As a result, a relationship between (dissolved or total recoverable) methylmercury and (dissolved or total recoverable) mercury in the water needs to be developed. NPDES permits and other water quality-based pollution control activities traditionally rely on the total recoverable concentration of mercury, not the dissolved methylmercury form.

Many of the issues surrounding the uncertainty in predicting and transferring methylmercury BAFs across different waterbodies also apply to translating methylmercury concentrations to mercury concentrations. As with BAFs, one approach for translating between methylmercury and mercury concentrations is for states and

authorized tribes to measure site-specific concentrations of methylmercury and mercury to determine the relative amounts of each form. This field-measured, site-specific approach is the most direct and the most appropriate approach to the translation.

Where a site-specific approach is not feasible, states and authorized tribes may consider applying EPA's draft national methylmercury-to-mercury translator factors. In the 2001 methylmercury criterion document (USEPA 2001c), EPA derived these translator factors for rivers/streams and lakes as geometric means from data collected from the literature reporting concentrations of mercury in aquatic environments. Thus, like the draft national BAFs, the methylmercury-to-mercury translators were empirically derived based on various water data from across the United States. As with the draft national BAFs, the draft national methylmercury-to-mercury translator factors vary greatly across ecosystems and are subject to many of the same uncertainties. Therefore, EPA suggests that states and tribes that may be considering using the draft national translator values as defaults carefully review the discussion in the 2001 criterion document, particularly the discussions concerning uncertainty and limitations, before deciding to apply them in a regulatory context (see appendix A, section II, USEPA 2001a). States and tribes should consider whether more recent data and/or data that are more reflective of local conditions are available to supplant or supplement the limited database used to derive the draft national translators.

Alternatively, states and tribes that choose to develop water column criteria can consider collecting data to develop BAFs that relate methylmercury in fish tissue directly to total mercury in the water column. See the footnote to section 3.1.3.1.1 for more information.

3.2 What options are available to address site-specific conditions and concerns?

3.2.1 How can the methylmercury water quality criterion be modified for site-specific conditions?

The 2000 Human Health Methodology (USEPA 2000b) describes how states and authorized tribes can adopt site-specific modifications of a section 304(a) criterion to reflect local environmental conditions and human exposure patterns. "Local" may refer to any appropriate geographic area where common aquatic environmental or exposure patterns exist. Thus, it may signify a statewide or regional area, a river reach, or an entire river. Such site-specific criteria may be developed as long as the site-specific data, either toxicological or exposure-related, are justifiable. For example, when using a site-specific fish consumption rate, a state or authorized tribe should use a value that represents at least the central tendency for the consumption rate of the population surveyed. When defining a target population, a state or authorized tribe should focus on protecting populations with high rates of fish consumption from the local area.

States and authorized tribes may modify EPA's recommended 304(a) criterion for methylmercury by using different assumptions for certain components of EPA's criterion to derive a criterion that maintains and protects the designated uses. For example, states and authorized tribes may:

- Use an alternative RSC factor or

- Use a daily uncooked freshwater and estuarine fish consumption rate that is more reflective of local or regional consumption patterns than the 17.5 grams/day default value. EPA encourages states and authorized tribes to consider using local or regional consumption rates instead of the default values if the former would better reflect the target population.

If a state or authorized tribe intends to modify both the RSC and the fish consumption rate, it might find collecting the data at the same time advantageous.

3.2.1.1 How does one modify the RSC?

Section 5 of the methylmercury criterion document (USEPA 2001a) provides detailed discussions on how EPA assessed exposure to methylmercury and how EPA derived the RSC factor used in calculating the criterion. The methylmercury RSC is an exposure, subtracted from the RfD to account for exposure to methylmercury from sources other than freshwater or estuarine fish. By accounting for other known exposures, the RSC seeks to ensure that methylmercury exposures do not exceed the RfD.

If a state or tribe proposes to change the RSC, it should document the modifications with data supporting the modifications and share the proposed modifications to the RSC with EPA prior to recalculating the criterion. See appendix B for the tables from the methylmercury criterion document. States and authorized tribes should review section 5 of the methylmercury criterion document and modify the media-specific exposure estimates using local data that reflect the exposure patterns of their populationsTo modify this factor, states and authorized tribes should review the amount of marine fish and shellfish estimated to be consumed (table 5-1, USEPA 2001a) and the concentration of methylmercury in the commonly consumed marine species (table 5-14, USEPA 2001a).

3.2.1.2 How does one modify the daily fish intake rate?

EPA derived the recommended methylmercury water quality criterion on the basis of a default fish intake rate for the general population (consumers and nonconsumers) of 17.5 grams/day[12], uncooked (USEPA 2001a). States and authorized tribes may use a different intake rate based on local or regional consumption patterns and are encouraged to use consumption rates that are protective of a range of culturally and economically diverse communities. The fish consumption value in the TRC equation may be changed if the target population eats a higher or lower amount of fish. For example, if the 90th percentile of a target population eats approximately 15 grams/day of freshwater and estuarine fish of various trophic levels, the fish intake value in equation 1 would simply be 15 grams/day, rather than the national default value of 17.5 grams/day used in calculating the 0.3 mg/kg TRC.

EPA encourages states and authorized tribes to develop a water quality criterion for methylmercury using local or regional fish consumption data rather than the default values if they believe that such a water quality criterion would be more appropriate for

[12] This value represents the 90th percentile of freshwater and estuarine finfish and shellfish consumption reported by the 1994–1996 *Continuing Survey of Food Intakes by Individuals*. For more information, see *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (USEPA 2000b).

their target population. However, states and authorized tribes should consider whether the fish consumption rates reflect existing public concern about contamination of fish when collecting survey data, rather than local preference for fish consumption (i.e., the presence of fish advisories limits the consumption of fish). In this instance, the state or authorized tribe should take this into account and try to conduct surveys in a manner that accounts for the effects of fish advisories on the consumption of fish. Where there is afish consumption advisory, surveys should be designed to evaluate how much fish a local population would consume if the fish were safe to eat and incorporate that consumption level into the criterion.

EPA suggests that states and authorized tribes follow a hierarchy when deriving fish intake estimates (USEPA 2000b). From highest preferred to lowest preferred, this hierarchy is as follows (1) use local data protective of culturally and economically diverse communities when available, (2) use data reflecting similar geography or population groups, (3) use data from national surveys, and (4) use EPA's default fish intake rates. Additional discussion of these four preferences is provided below.

When a state or authorized tribe develops a site-specific criterion on the basis of local fish consumption, site-specific BAFs, or a site-specific RSC, states and authorized tribes might want to include EPA in the development of the study plan and submit the data supporting the site-specific criterion for EPA's consideration when EPA approves or disapproves state or tribal water quality standards under CWA section 303(c). Including EPA at the study plan development stage may help to avoid problems and facilitate development of a defensible site-specific criterion.

3.2.1.2.1 Use local data

If a state or authorized tribe believes a fish consumption rate other than the default would be appropriate for their target population, EPA's first preference is that they use fish intake rates derived from studies of consumption of local fish. Such studies could include results of surveys designed to obtain information on the consumption of freshwater or estuarine species caught from local watersheds within the state or tribal jurisdiction. When estimating the fish intake rate, all freshwater fish, whether caught recreationally or bought commercially, should be included. States and authorized tribes may choose to develop either fish intake rates for the local population as a whole, or individual fish intake rates for various subpopulations (e.g., sport anglers, subsistence fishers) as well as culturally and economically diverse consumers.

States and authorized tribes might wish to conduct their own surveys of fish intake. *Guidance for Conducting Fish and Wildlife Consumption Surveys* (USEPA 1998a) provides EPA guidance on methods for conducting such studies. States and authorized tribes should take care to ensure that the local data are of sufficient quality and scope to support development of a criterion and are representative of the population of people that eat local fish. EPA's consumption survey guidance offers recommendations on how to develop appropriate quality assurance and quality control procedures to help ensure the quality of the survey. Results of studies of the broader geographic region in which the state or authorized tribe is located can also be used, but they might not be as applicable as study results for local watersheds. Because such studies would ultimately form the basis of a state's or authorized tribe's methylmercury criterion, EPA would consider any surveys of

fish intake as part of its review of the methylmercury criterion's scientific defensibility as part of the Agency's review of water quality standards under CWA section 303(c).

States and authorized tribes may use either high-end (such as 90th or 95th percentile) or central tendency (such as median or mean) consumption values for the population of interest (e.g., subsistence fishers, sport fishers, or the general population). EPA generally recommends that a central tendency value be the lowest value states or authorized tribes should use when deriving a criterion. When considering median values from fish consumption studies, states and tribes should ensure that the distribution is based on survey respondents that reported consuming fish because surveys of both consumers and nonconsumers can often result in median values of zero. EPA believes the approach described above is a reasonable procedure and is also consistent with other Agency positions such as that of the Great Lakes Water Quality Initiative, known as the GLI (USEPA 1995a).

3.2.1.2.2 Use similar geography or population groups

If surveys conducted in the geographic area of the state or authorized tribe are not available, EPA's second preference is that states and authorized tribes consider results from existing surveys of fish intake in similar geographic areas and population groups (e.g., from a neighboring state or authorized tribe or a similar watershed type) and follow the method described above regarding target values to derive a fish intake rate. For instance, states or tribes with subsistence fisher populations might wish to use consumption rates from studies that focus specifically on these groups, or use rates that represent high-end values from studies that measured consumption rates for a range of types of fishers (e.g., recreational or sport fishers, subsistence fishers, minority populations). A state or authorized tribe in a region of the country might consider using rates from studies that surveyed the same region; for example, a state or authorized tribe that has a climate that allows year-round fishing might underestimate consumption if it uses rates from studies taken in regions where people fish for only one or two seasons per year. A state or authorized tribe that has a high percentage of an age group (such as older persons, who have been shown to have higher rates in certain surveys) might wish to use age-specific consumption rates, which are available from some surveys. For additional information on the use of fish consumption rates, see EPA's 2000 Human Health Methodology (USEPA 2000b). Again, EPA recommends that states and tribes use only uncooked weight intake values and freshwater or estuarine species data.

3.2.1.2.3 Use national surveys

If applicable consumption rates are not available from local, state, or regional surveys, EPA's third preference is that states and authorized tribes select intake rate assumptions for different population groups from national food consumption surveys. EPA has analyzed two such national surveys, the 1994–1996 and 1998 Continuing Survey of Food Intakes by Individuals (CSFII). These surveys, conducted by the U.S. Department of Agriculture (USDA), include food consumption information from a probability sample of the population of all 50 states. Respondents to the survey provided 2 days of dietary recall data. A separate EPA report provides a detailed description of the combined 1994–1996 and 1998 CSFII surveys, the statistical methodology, and the results and uncertainties of the EPA analyses (USEPA 2002b). The estimated fish consumption rates

in the CSFII report are presented by fish habitat (i.e., freshwater or estuarine, marine, and all habitats) for the following population groups: (1) all individuals, (2) individuals age 18 and over, (3) women ages 15–44, and (4) children age 14 and under. Three kinds of estimated fish consumption rates are provided: (1) per capita rates (rates based on consumers and nonconsumers of fish from the survey period), (2) by consumers-only rates (rates based on respondents that reported consuming finfish or shellfish during the 2-day reporting period), and (3) per capita consumption by body weight (per capita rates reported as mg/kg-day). For purposes of revising the fish consumption rate in the methylmercury criterion, EPA recommends using the rates for freshwater and estuarine fish and shellfish.

The CSFII surveys (USDA/ARS 1998, 2000) have advantages and limitations for estimating per capita fish consumption. The primary advantage of the CSFII surveys is that USDA designed and conducted them to support unbiased estimation of food consumption across the population in the United States and the District of Columbia. One limitation of the CSFII surveys is that individual food consumption data were collected for only 2 days—a brief period that does not necessarily depict "usual intake." Usual dietary intake is defined as "the long-run average of daily intakes by an individual." Upper percentile estimates might differ for short-term and long-term data because short-term food consumption data tend to be inherently more variable. It is important to note, however, that variability due to duration of the survey does not result in bias of estimates of overall mean consumption levels. Also, the multistage survey design does not support interval estimates for many of the subpopulations because of sparse representation in the sample. Subpopulations with sparse representation include American Indians on reservations and certain ethnic groups. Although these persons were participants in the survey, they were not present in sufficient numbers to support fish consumption estimates. The survey does support interval estimates for the U.S. population and some large subpopulations (USEPA 2002b).

3.2.1.2.4 Use EPA default fish intake rates

EPA's fourth preference is that states and authorized tribes use as fish intake assumptions, default rates on the basis of the 1994–1996 CSFII data for the U.S. population, which EPA believes are representative of freshwater and estuarine fish and shellfish intake for different population groups. The 1994–1996 CSFII data for U.S. fish consumption among both consumers and nonconsumers of fish is delineated below in table 3.

Because the combined 1994–1996 CSFII survey is national in scope, EPA uses the results from it to estimate fish intake for deriving national criteria. EPA applies a default rate of 17.5 grams/day for the general adult population. EPA selected an intake rate that is protective of a majority of the population (the 90th percentile of consumers and nonconsumers, according to the 1994–1996 CSFII survey data) (USEPA 2000b). EPA also recommends a default rate of an average of 17.5 grams/day for sport fishers.

Table 3. Estimates of freshwater and estuarine combined finfish and shellfish consumption from the combined 1994–1996 and 1998 CSFII surveys (U.S. population)

	Mean	Median	90th percentile	95th percentile	99th percentile
All ages	6.30	N/a	11.65	41.08	123.94
Age 18 and over	7.50	0.00*	17.53	49.59	142.41
Women ages 15-44	5.78	N/a	6.31	32.37	109.79
Children age 14 and under	2.64	0.00	0.00	13.10	73.70

Note: All values expressed as grams per day for uncooked fish.

* The median value of 0 grams/day might reflect the portion of persons in the population that never eat fish, as well as the limited reporting period (2 days) during which intake was measured.

Similarly, EPA believes the 99th percentile of 142.4 grams/day is within the range of consumption estimates for subsistence fishers, according to the studies reviewed, and that it represents an average rate for subsistence fishers. EPA knows that some local and regional studies indicate greater consumption among American Indian, Pacific Asian American, and other subsistence consumers and recommends the use of those studies in appropriate cases, as indicated by the first and second preferences. Again, states and authorized tribes have the flexibility to choose intake rates higher than the average values for these population groups. If a state or authorized tribe has not identified a separate well-defined population of exposed consumers and believes that the national data from the 1994–1996 CSFII are representative, the state or tribe may choose these recommended rates.

EPA has made these risk management decisions after evaluating numerous fish intake surveys. These values represent the uncooked weight intake of freshwater and estuarine finfish and shellfish. As with the other preferences, EPA requests that states and authorized tribes routinely consider whether a substantial population of sport fishers or subsistence fishers exists in the area when establishing water quality criteria rather than automatically using data for the general population.

The CSFII surveys also provide data on marine species, but EPA considered only freshwater and estuarine fish intake values for determining default fish consumption rates because EPA considered exposure from marine species of fish in calculating an RSC for dietary intake.[13] States and authorized tribes should ensure that when evaluating overall exposure to a contaminant, marine fish intake is not double-counted with the other dietary intake estimate used. Coastal states and authorized tribes that believe accounting for total fish consumption (fresh or estuarine *and* marine species) is more appropriate for protecting the population of concern may do so, provided that the marine intake component is not double-counted with the RSC estimate (USEPA 2000b).

[13] See the discussion of the RSC in sections 3.1.2.3 and 3.2.1.1.

3.2.2 How do water quality standards variances apply?

Where a discharger or waterbody cannot meet a water quality standard, a state or authorized tribe may adopt a temporary water quality standard through a variance process. The variance would then, in effect, serve as a substitute standard for a point source, and the WQBEL contained in an NPDES permit would then be based on the variance. As a revision to the otherwise applicable water quality standard (designated use and criteria), water quality standards variances must be supported by one of the six justifications under 40 CFR 131.10(g) (see section 3.2.3.4 below). Variances are generally determined based on the discharger's ability to meet a WQBEL and, therefore, are considered after an evaluation of controls necessary to implement water quality standards. In addition, EPA recommends that the permitting authority require the facility seeking a variance to develop and implement a mercury minimization plan (MMP) to both reduce mercury loading and to determine the highest level of water quality achievable to inform future permit decisions (see section 7.5.2.4 for more discussion of MMPs).

Variances typically apply for a limited period but may be reviewed at the time of the state triennial review of water quality standards, and require the same procedural steps that are required of a change in the standards. Where the term of a variance extends beyond three years, as for example in an NPDES permit, the variance must still be reassessed as part of the state's three year triennial review to confirm that the underlying attainability analysis remains relevant and accurate. A variance must continue to protect "existing uses" (defined in 40 CFR 131.3(e) as uses actually attained in the waterbody on or after November 28, 1975). Typically, variances apply to specific pollutants and facilities, which would mean that a water quality standards variance for mercury would apply to only the new methylmercury criterion in a stated waterbody and specifically to the discharger requesting the variance. The state or authorized tribe, however, may provide justification for more than one discharger or for an entire waterbody or segment to receive a variance (as discussed in section 3.2.2.3 of this document). See section 3.2.3 for a discussion of the requirement to conduct a use attainability analysis for changes to water quality standards, including the prohibition on removing existing uses.

3.2.2.1 When is a variance appropriate?

Some regulated point sources discharging mercury might apply for variances for their discharges into impaired waters where the largest source of mercury is atmospheric deposition. In other cases, limits to technology or naturally elevated levels of methylmercury in a waterbody could preclude attainment of standards. To address these types of issues, the following scenarios are examples of demonstrations that could satisfy the requirements under 40 CFR 131.10(g). The demonstrations are more thoroughly explained below and in the *Water Quality Standards Handbook* (USEPA 1994).

- *Economic or social impacts* (131.10(g)(6)). Demonstrate that, in the short term, the costs of constructing controls necessary to meet the methylmercury criterion (beyond those required by sections 301(b)(1)(A) and (B) and 306 of the CWA) would result in substantial and widespread economic and social impact.

- *Human-caused conditions that cannot be remedied* (131.10(g)(3)). Demonstrate that, in the short term, none of the present technologies for improving the quality of

an effluent are capable of bringing methylmercury levels in the discharge down to a level as stringent as necessary to meet the criterion (i.e., there is no technological remedy or it is technologically infeasible).

- *Natural conditions that preclude attainment* (131.10(g)(1)). Demonstrate that local conditions of an aquatic system result in high methylmercury levels. For example, elevated methylmercury concentrations might occur naturally in a system because of a short-term condition.

During the period the variance applies, any permit issued must be consistent with applicable water quality standards (40 CFR 122.44(d)(1)(vii)), which in this case would be the temporary standard approved in the variance. The permit would need to be modified to derive from and comply with the underlying standard if the variance is not re-issued.

3.2.2.2 What should a state or tribe consider before granting a variance?[14]

In general, the temporary revised standard established by a variance should be set at a level representing the highest attainable water quality (like all water quality standards). Variances may not interfere with existing uses, and variances should ensure progress toward ultimate attainment of the designated use for the waterbody. Regarding procedural considerations, the same requirements apply for a variance as for a new or revised standard (e.g., public review and comment, EPA approval or disapproval) because a variance is a change to the water quality standards. In addition, the following describes more specific issues that states and authorized tribes should take into account when considering granting a variance.

- *Variance protocols.* If a state or authorized tribe anticipates receiving a number of variance requests for mercury discharges, it could consider establishing a mercury variance protocol, with EPA's participation and agreement. The protocol would govern the development and processing of variance requests. It would specify the information needed and the criteria the state would use in considering whether to adopt the variance. Although the state or tribe would need to submit each variance to EPA for approval (40 CFR 131.20), EPA's advance agreement to the protocol could streamline EPA's review of any variances developed in accordance with the protocol. Public notice requirements for variances could be satisfied through the process of issuing the NPDES permit that incorporates limits based on such temporary standards, as long as the variance is identified and all the necessary information pertaining to the variance is included.

- *Time frames.* A variance is typically a time-limited change in the water quality standards. Although EPA part 131 regulations do not specify a time limit for variances, EPA's triennial review regulations at 40 CFR 131.20 require that variances, as part of water quality standards, are reexamined every three years to

[14] Federal or state regulations also govern the granting of a variance. For example, regulations promulgated under 40 CFR part 132, appendix F, procedure 2, specify the conditions for granting variances in the Great Lakes and prohibit the granting of variances to new dischargers or recommending Great Lakes dischargers.

determine if new information has become available and modified as appropriate. Variances that extend longer than three years are traditionally revisited in the context of a triennial review. Once a variance has expired, to justify the continuation of the variance, the state must demonstrate that meeting the standard is still unattainable based on one of the factors at 131.10(g). The state should also ensure that the permittee has made reasonable progress to control mercury in the discharge during the period of the previously approved variance (i.e. has adopted a mercury minimization plan.)

As with any other revision to the water quality standards, the permit and permit conditions implementing the variance do not automatically change back to the previous permit conditions if the variance expires, unless that is a condition of a variance and permit. Although water quality standards can change with every triennial review, states and authorized tribes are not obliged to reopen and modify permits immediately to reflect those changes, but may do so where the permit contains a reopener condition to address such revised water quality standards. In the Great Lakes, however, permits with limits based on variances must include a provision enabling the permitting authority to reopen and modify the permit based on triennial revisions to water quality standards. (40 CFR part 132, appendix F, procedure 2, section F.4). Any new or reissued permit must implement the water quality standards applicable at time of permit issuance. 40 CFR 122.44(d)(1).

- *Antidegradation.* Permits with effluent limits based on a variance for methylmercury must conform, as do all permits, to the state or authorized tribe's antidegradation policy.

- *Mercury Minimization Plans (MMPs).* EPA recommends that states and authorized tribes require dischargers receiving a variance to adopt and implement an MMP as described in section 7.5.2.4. By reducing mercury sources up front, as opposed to traditional reliance on treatment at the end of a pipe, diligent implementation of MMPs might mitigate any adverse effects of a variance by improving the water quality. As noted above, MMPs also serve to inform the evaluation of controls needed to grant a variance and to determine the highest attainable water quality

3.2.2.3 What is involved in granting a variance on a larger scale?

Traditionally, variances are specific to a pollutant and a facility. However, for situations where a number of NPDES dischargers are located in the same area or watershed and the circumstances for granting a variance are the same, states and authorized tribes may consider administering a multiple-discharger variance for a group of dischargers collectively. Such a group variance can be based on various scales and may depend largely on the rationale for adopting a variance for methylmercury. Possible applications of a group variance may include facilities with similar discharge processes, a watershed basis, particularly for states that issue NPDES permits on a watershed basis, or a broader geographic basis, analogous to a general NPDES permit.

For example, Ohio adopted a statewide mercury variance applicable to point source dischargers in the state that meet specified criteria. In addition, Michigan has authorized multiple discharger variances for mercury with permit requirements, including development and implementation of an MMP.

It is important to note that, despite the coverage of a multiple-source variance, an individual discharger must still demonstrate that the underlying criterion is not attainable with the technology-based controls identified by CWA sections 301(b) and 306 and with cost-effective and reasonable best management practices (BMPs) for nonpoint sources (40 CFR 131.10(h)(2)).

3.2.3 How are use attainability analyses conducted?

3.2.3.1 What is a use attainability analysis?

A use attainability analysis (UAA) is defined in 40 CFR 131.3(g) as a structured scientific assessment of the factors affecting the attainment of a use, which may include physical, chemical, biological, and economic factors, that must be conducted whenever a state wishes to remove a designated use specified in section 101(a)(2) of the CWA, or to adopt subcategories of uses specified in section 101(a)(2) of the CWA, which require less stringent criteria (see 40 CFR 131.3 and 40 CFR 131.10(g)).

Where a UAA indicates that the current use is unattainable, the state or tribe will need to identify and assign the "highest attainable use," which should reflect the factors and constraints on the attainability of a use that were evaluated as part of the UAA process. Once the state or tribe has determined the highest attainable use, it should propose adopting this designated use in place of the designated use deemed unattainable. For example, to the extent allowed by state or tribal law, the state or tribe could refine its designated use from "fish consumption" to "mercury-limited fish consumption." That way the waterbody would still be expected to meet other pollutant criteria designed to protect fish consumption.

3.2.3.2 What is EPA's interpretation of CWA section 101(a)?

CWA section 101(a) (2) establishes as a national goal "water quality [that] provides for the protection and propagation of fish, shellfish, and wildlife and provides for recreation in and on the water," wherever attainable. These goals are commonly referred to as the "fishable/swimmable" goals of the CWA. EPA interprets these goals as providing for the protection of aquatic communities and human health related to the consumption of fish and shellfish. In other words, EPA views "fishable" to mean that fish and shellfish can thrive in a waterbody and, when caught, can also be safely eaten by humans. This interpretation also satisfies the CWA section 303(c)(2)(A) requirement that water quality standards protect public health. Including human consumption of fish and shellfish as the appropriate interpretation of the definition of section 101(a)(2) uses is not new. For example, in the National Toxics Rule, all waters designated for even minimal aquatic life protection (and therefore a potential fish and shellfish consumption exposure route) are protected for human health (57 FR 60859, December 22, 1992).

3.2.3.3 When is a UAA needed for a "fishable" use?

Under 40 CFR 131.10(j) of the Water Quality Standards Regulation, states and authorized tribes are required to conduct a UAA whenever the state or authorized tribe designates or has designated uses that do not include the "fishable/swimmable" use specified in CWA section 101 (a)(2); or the state or authorized tribe wishes to remove a

designated use that is specified in CWA section 101(a)(2) or adopt subcategories of the uses specified in that section that require less stringent criteria.

An important caveat to the process of removing a designated use is that states and authorized tribes may not remove an "existing use" as defined by the Water Quality Standards Regulation. An existing use is defined in 40 CFR 131.3(c) as any use that has been actually attained on or after November 28, 1975, when the CWA regulations regarding use designation were originally established. In practical terms, waters widely used for recreational fishing would not be good candidates for removing a "fishable" use, especially if the associated water quality supports, or has until recently supported, the fishable use, on the basis, in part, of the "existing use" provisions of EPA's regulations.

In addition, EPA considers designated uses attainable, at a minimum, if the use can be achieved (1) through effluent limitations under CWA sections 301(b)(1)(A) and (B) and 306 and (2) through implementation of cost-effective and reasonable BMPs for nonpoint sources. The federal regulations at 40 CFR 131.10(g) further establish the basis for finding that attaining the designated use is not feasible, as long as the designated use is not an existing use. EPA emphasizes that when adopting uses and appropriate criteria, states and authorized tribes must ensure that such standards provide for the attainment and maintenance of the downstream uses (40 CFR part 131.10(b)). States and tribes are not required to conduct UAAs when designating uses that include those specified in CWA section 101(a) (2), although they may conduct these or similar analyses when determining the appropriate subcategories of uses.

3.2.3.4 What conditions justify changing a designated use?

EPA's regulations at 40 CFR 131.10(g) list the following six reasons for states or authorized tribes to use to support removal of a designated use or adoption of a subcategory of use that carries less stringent criteria:

- Naturally occurring pollutant concentrations prevent the attainment of the use.
- Natural, ephemeral, intermittent, or low-flow conditions or water levels prevent the attainment of the use, unless these conditions may be compensated for by the discharge of sufficient volume of effluent discharges without violating state water conservation requirements to enable uses to be met.
- Human-caused conditions or sources of pollution prevent the attainment of the use and cannot be remedied or would cause more environmental damage to correct than to leave in place.
- Dams, diversions, or other types of hydrologic modifications prevent the attainment of the use, and it is not feasible to restore the waterbody to its original condition or to operate such modification in a way that would result in attainment of the use.
- Physical conditions related to the natural features of the waterbody, such as the lack of a proper substrate, cover, flow, depth, pools, riffles, and the like, unrelated to water quality, prevent attainment of aquatic protection uses.

- Controls more stringent than those required by CWA sections 301(b) and 306 would result in substantial and widespread economic and social impact.

In addition to citing one or more of these factors to support removal of a use, states and authorized tribes use the same six factors to guide analysis and decision-making with respect to establishing an attainable use.

In all cases, states and authorized tribes must obtain scientifically sound data and information to make a proper assessment. It is also recommended that they conduct pollutant source surveys to define the specific dominant source of mercury in the waterbody. Sources may include point source loadings, air deposition, mining waste or runoff, legacy levels (e.g., mercury resulting from historical releases), and geologic "background levels." This is similar to source assessments under the TDML program. Existing documents provide guidance on obtaining data and conducting analyses for the other components of a UAA. These documents are at http://www.epa.gov/waterscience/standards/uaa/info.htm. The *Technical Support Manual: Waterbody Surveys and Assessments for Conducting Use Attainability Analyses* (USEPA 1983) covers the physical and chemical components of UAAs. Technical support for assessing economic and social impacts is offered through the *Interim Economic Guidance for Water Quality Standards Workbook* (USEPA 1995b).

EPA recognizes that there may be naturally occurring concentrations of methylmercury which may exceed the national recommended 304(a) criterion. However, EPA policy, whereby criterion may be set at ambient conditions if contaminant levels are due only to non-anthropogenic sources, applies only to aquatic life uses. The policy does not apply to human health uses. The policy states that for human health uses, where the natural background concentration is documented, this new information should result in, at a minimum, a re-evaluation of the human health use designation (USEPA 1997e).

4 Monitoring and Assessment

Water quality monitoring and assessment are essential elements in implementing the CWA at the local, state, and national levels. In implementing the water quality-based approach, the most obvious uses of monitoring information are in determining attainment of water quality standards and in developing TMDLs and permits. In the case of mercury, analyzing for mercury and methylmercury in water and fish is particularly important for states and tribes that choose to develop BAFs and methylmercury-to-mercury translators. This chapter provides guidance on analytical methods, field sampling, and assessment considerations for mercury. Additional information on developing site-specific BAFs and translators is provided in section 3.1.3 of this guidance.

4.1 What are the analytical methods for detecting and measuring mercury and methylmercury concentrations in fish and water?

Over the past two decades, EPA and other organizations have developed several analytical methods for determining mercury and methylmercury concentrations in fish and water. In 2001 EPA conducted a literature review to assess the availability of different analytical methods and to determine which of the analytical methods would be most useful for implementing the new methylmercury criterion. After the review, EPA concluded that nearly all current research on low-level concentrations of mercury and methylmercury is being performed using techniques that are based on procedures developed by Bloom and Crecelius (1983) and refined by Bloom and Fitzgerald (1988), Bloom (1989), Mason and Fitzgerald (1990), and Horvat et al. (1993).

To assist states and authorized tribes in selecting an analytical method to use, this chapter describes selected analytical methods available (sections 4.1.1 and 4.1.2), and identifies five specific methods that EPA recommends for use in implementing this guidance (section 4.1.3). In addition, appendix C of this document presents a list of available methods in more detail. Table C1 of the appendix summarizes 4 methods to analyze mercury and methylmercury in fish tissue, and table C2 summarizes 18 methods for the analysis of mercury and methylmercury in water and other nontissue matrices. Each table identifies the forms and species of mercury targeted by each method, estimated or known sensitivity, the techniques employed in the method, and any known studies or literature references that use the techniques employed in the method.

The CWA establishes an EPA approval process for certain methods used in the NPDES program and for section 401 certifications. As described in section 4.1.2 below, EPA has approved two of the above methods for analysis of mercury in water under 40 CFR part 136: method 1631, revision E and method 245.7. EPA's regulations generally require that these methods be used whenever such analyses are required for the NPDES program and for CWA section 401 certifications issued by states and authorized tribes (40 CFR 136.1). Sections 7.4 and 7.5.1.1 of this guidance provide additional information on appropriate analytical methods for measuring mercury in water for NPDES permitting purposes.

There are no regulatory requirements for the use of particular methods in setting water quality standards, evaluating the attainment of standards, or developing TMDLs,

although any methods used need to be scientifically defensible. Although this chapter provides recommendations for methods that can be used for these purposes, states and tribes are not precluded from using other methods, including those in appendix C.

4.1.1 Analytical Methods for Methylmercury

For measuring methylmercury in water, EPA method 1630 (USEPA 2001d), developed by EPA's Office of Water, reflects the techniques developed by Bloom and Crecelius (1983) and refined by Bloom and Fitzgerald (1988), Bloom (1989), Mason and Fitzgerald (1990), and Horvat (1993). This method has a quantitation level of 0.06 ng/L.

Draft modifications to method 1630, described in table C1 (see appendix C) and in Horvat et al. (1993), allow for measurement of methylmercury in fish tissue as low as 0.001 to 0.002 mg/kg, well below the water quality criterion for methylmercury in tissue (0.3 mg/kg). EPA recommends using these techniques when direct measurements of methylmercury in fish tissue are desired.

Three additional methods for measuring methylmercury in water are listed in table C2 (see appendix C). These methods are UW-Madison's standard operating procedure, or SOP (Hurley et al. 1996), used by the Great Lakes National Program Office for its Lake Michigan Mass Balance Study; USGS Wisconsin-Mercury Lab SOPs 004 (DeWild et al. 2002), used by USGS and EPA in the Aquatic Cycling of Mercury in the Everglades study; and a recently released USGS method (DeWild et al. 2002). All these procedures are based on the same techniques and have detection limits of 0.01 ng/L, 0.05 ng/L and 0.04 ng/L, respectively.

Because the four methods are nearly identical test procedures, they are expected to produce very similar results with sensitivity as low as 0.01 to 0.06 ng/L in water. These levels are well below the expected range of water column concentrations associated with the methylmercury fish tissue criterion.

4.1.2 Analytical Methods for Mercury

For measuring low level mercury in water, EPA method 1631, revision E (USEPA 2002c), developed by EPA's Office of Water, reflects the techniques developed by researchers mentioned previously. It has a quantitation level of 0.5 ng/L. EPA made this revision to clarify method requirements, increase method flexibility, and address frequently asked questions. The revision includes recommendations for using the clean techniques contained in EPA's *Method 1669: Sampling Ambient Water for Trace Metals at EPA Water Quality Criteria Levels* (USEPA 1996a). The benefits of using method 1631 are that it has been fully validated, numerous laboratories are routinely using the method, and it is sensitive enough to measure at the water concentrations expected to be associated with the criterion. This method was approved in 2002 under 40 CFR part 136 for NPDES permitting and other purposes under the CWA (67 FR 65876).

In addition, EPA method 245.7 (USEPA 2005e), which has a quantitation level of 5.0 ng/L, was approved under part 136 in 2007 (72 FR 11200). Developed by EPA's Office of Water, method 245.7 is similar to EPA method 1631E because both methods require use of a cold-vapor atomic fluorescence spectrometry (CVAFS) detector to measure low levels of mercury. Method 245.7 has been validated in two EPA

laboratories, one university laboratory, and an interlaboratory validation study. Results from these studies indicate that the method is capable of producing reliable measurements of mercury at some toxic criteria levels (40 CFR 136).

Appendix A to method 1631 (64 FR 10596) details the researcher's techniques for determining total and dissolved mercury in tissue, sludge, and sediments. The appendix was developed for processing fish tissue samples to be analyzed for mercury using the previously validated and approved method 1631 analytical procedures. The procedures are expected to be capable of measuring mercury in the range of 0.002 to 5.0 mg/kg.

EPA recognizes that some users might find Method 1631 (appendix A) costly or difficult to implement. Appendix C summarizes three other methods available for analyzing mercury in fish tissue that are less costly and less difficult to implement, but they have not undergone the same extensive interlaboratory validation studies as Method 1631 (appendix A). Two are listed in table C1 (Methods 245.6 and 7474). The third—Method 7473 for analyzing mercury in water, listed in table C2—has been adapted by some users for analyzing mercury in fish tissue; this approach has been used to measure mercury in fish tissue to support state fish consumption advisories.

Because researchers have found that nearly all mercury in fish tissue is in the form of methylmercury (USEPA 2000c), EPA also suggests that analysis of tissue for mercury, as a surrogate for methylmercury, might be a useful means for implementing the methylmercury criterion. If mercury concentrations in tissue exceed the criterion, further investigation of the methylmercury component might be desired.

4.1.3 Summary of Recommended Analytical Methods

In summary, on the basis of the available information, EPA believes that the most appropriate methods for measuring low levels of mercury concentrations in the water column are method 1631, revision E (mercury in water by CVAFS) and method 245.7 (mercury in water by CVAFS). Likewise, EPA believes that the most appropriate method for measuring methylmercury concentrations in the water column is method 1630 (methylmercury in water by CVAFS), and the most appropriate methods for measuring mercury concentrations in fish tissue are appendix A to method 1631 (mercury in tissue by CVAFS) and modifications to method 1630 for handling tissues. EPA recommends these procedures for the following reasons:

- EPA developed methods 1631 and 1630 to support implementation of water quality criteria for mercury and methylmercury, respectively. Both are already in the appropriate EPA format and include all standardized quality control elements needed to demonstrate that results are reliable enough to support CWA implementation.

- EPA developed method 245.7 specifically to address state needs for measuring mercury at ambient water quality criteria levels, when such measurements are necessary to protect designated uses. In addition, it has been validated in two EPA laboratories, one university laboratory, and an interlaboratory validation study.

- EPA developed appendix A to method 1631 to support its National Study of Chemical Residues in Lake Fish Tissue. Appendix A provides information on

preparing a fish tissue sample for analysis using method 1631. The method was validated by Brooks Rand (USEPA 1998b) and was used by Battelle Marine Sciences to analyze more than a thousand tissue samples collected during EPA's national study (USEPA 2000d). Successful use of these techniques also has been widely reported in the literature. This history, combined with the fact that appendix A supplements the already well-characterized and approved method 1631, makes this method a good candidate for use with the new fish tissue criterion.

- Method 1630 already has been used in several studies, including EPA's Cook Inlet Contaminant Study (USEPA 2001e) and the Savannah River TMDL study (USEPA 2001f). The techniques described in the method and in the recommended method modifications also have been successfully applied in numerous studies described in the published literature. Furthermore, the procedures in method 1630 are nearly identical to those given in the USGS method and in the University of Wisconsin SOP (Hurley et al., 1996), listed in table C2. The University of Wisconsin SOP was used in EPA's Lake Michigan Mass Balance Study (USEPA 2001g).

Table 4 summarizes the recommendations discussed above.

Table 4. Recommended analytical methods for detecting and measuring low levels of methylmercury and mercury in fish tissue and water

Recommended for analysis of:	Methylmercury… (see section 4.1.1)	Mercury… (see section 4.1.2)
...in fish tissue (for additional available methods, see appendix C, table C1)	Method 1630 with draft modifications for tissue	Method 1631, draft Appendix A
…in water (for additional available methods, see appendix C, table C2)	Method 1630	Method 1631, revision E* Method 245.7*

*Approved under 40 CFR part 136. See sections 7.4 and 7.5.1.1 for further information on appropriate methods for NPDES permitting purposes.

4.2 What is the recommended guidance on field sampling plans for collecting fish for determining attainment of the water quality standard?

EPA has published guidance providing information on sampling strategies for a fish contaminant monitoring program in volume 1, *Fish Sampling and Analysis*, of a document series, *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories* (USEPA 2000c). This guidance provides scientifically sound recommendations for obtaining a representative sample for issuing fish consumption advisories, and can be applied for obtaining a representative sample for determining attainment. The guidance also includes recommendations for quality control and quality assurance considerations. In all cases, states and authorized tribes should develop data quality objectives for determining the type, quantity, and quality of data to be collected (USEPA 2000e).

4.2.1 What fish species should be monitored?

EPA's fish sampling guidance (USEPA 2000c) provides recommendations for selecting finfish and shellfish species for monitoring to assess human consumption concerns. According to the guidance, the most important criterion for selecting fish is that the species are commonly eaten in the study area and have commercial, recreational, or subsistence fishing value. States and tribes also should ensure that the species monitored reflect the fish species consumed by culturally and economically diverse communities. Fish creel data (from data gathered by surveying recreational fishers) from state fisheries departments are a justifiable basis for estimating types and amounts of fish consumed from a given waterbody. States and authorized tribes should ensure that the creel data are of sufficient quality and are representative of the local population of people that eat fish.

The fish sampling guidance also identifies recommended target species for inland fresh waters and for Great Lakes waters. Walleye and largemouth bass have been identified as freshwater fish that accumulate high levels of methylmercury. Reptiles, such as turtle species and alligators, are recommended as target species for mercury if they are part of the local diet. Larger reptiles can also bioaccumulate environmental contaminants in their tissues from exposure to contaminated sediments or consumption of contaminated prey.

The fish sampling guidance further recommends that the size range of the sampled target fish ideally should include the larger fish individuals harvested at each sampling site because larger (older) fish within a population are usually the most contaminated with methylmercury (Phillips 1980, Voiland et al. 1991). In addition, the methylmercury concentrations in migratory species are likely to reflect exposures both inside and outside the study area, and the state or authorized tribe should take this into account when determining whether to sample these species. For migratory species, EPA's fish sampling guidance recommends that neither spawning populations nor undersized juvenile stages be sampled in fish contaminant monitoring programs (USEPA 2000c). States and authorized tribes should consider the life history of migratory species and the consumption patterns of the local population when including migratory species in their fish sampling protocols. Sampling of target finfish species during their spawning period should be avoided because contaminant tissue concentrations might decrease at that time.

If states and authorized tribes do not have local information about the types of fish that people eat, the following two options provide an alternative for identifying which fish to sample:

- *Match assumed or known consumption pattern to sampled species.* If the state has some knowledge of the fish species consumed by the general population or by individuals in another target population, a monitoring sample could be composited to reflect this knowledge. For example, a state might decide that 75 percent of the fish consumed are trophic level 4 species, 20 percent are trophic level 3 species, and 5 percent are trophic level 2 species. A composite sample (see section 4.2.2) would reflect the determined trophic level breakout.

- *Use trophic level 4 fish only.* Predator species (e.g., trout, walleye, largemouth bass, and smallmouth bass) are good indicators for mercury and other persistent pollutants that are biomagnified through several trophic levels of the food web. Increasing mercury concentrations correlate with an increase in fish age, with some

variability, so that consumption of larger (older) individuals correlates with greater risks to human health. Increasing mercury concentrations also correlate with higher trophic levels, and thus consumption of higher-trophic-level species would provide greater risks to human health. Therefore, targeting trophic level 4 species should serve as a conservative approach (depending on the species most frequently consumed by recreational fishers) for addressing waterbodies with highly varying concentrations of methylmercury.

4.2.2 What sample types best represent exposure?

EPA recommends using composite samples of fish fillets from the types of fish that people in the local area eat because methylmercury is found primarily in fish muscle tissue (USEPA 2002c). Using skinless fillets is a more appropriate approach for addressing mercury exposures for members of the general population and most recreational fishers because fish consumers typically eat the fillets without skin. Because mercury is differentially concentrated in muscle tissue, leaving the skin on the fish fillet actually results in a lower mercury concentration per gram of skin-on fillet than per gram of skinless fillet (USEPA 2000c). Analysis of skinless fillets might also be more appropriate for some target species, such as catfish and other scaleless finfish species. Some fish consumers, however, do eat fish with the skin on. In areas where the local population eats fish with the skin or eats other parts of fish, the state or authorized tribe should consider including these parts of fish in the sample.

Composite samples are homogeneous mixtures of samples from two or more individual organisms of the same species collected at a site and analyzed as a single sample. Because the costs of performing individual chemical analyses are usually higher than the costs of sample collection and preparation, composite samples are most cost-effective for estimating average tissue concentrations in target species populations. In compositing samples, EPA recommends that composites be of the same species and of similar size so that the smallest individual in a composite is no less than 75 percent of the total length (size) of the largest individual (USEPA 2000c). Composite samples can also overcome the need to determine how nondetections will be factored into any arithmetical averaging because the composite represents a physical averaging of the samples. However, depending on the objectives of a study, compositing might be a disadvantage because individual concentration values for individual organisms are lost. *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories,* volume 1, at sections 6.1.1.6 and 6.1.2.6, provides additional guidance for sampling recommendations.

4.2.3 What is the recommended study design for site selection?

Ideally, states and authorized tribes should collect samples over a geographic area that represents the average exposure to those who eat fish from the waterbody. However, if there are smaller areas where people are known to concentrate fishing, those areas should be used as the sampling area. Fish sampled in locations with mercury point sources should be included in the average concentration if fishing occurs in those areas but not included if the areas are not used for fishing.

Once the state or tribe identifies the geographic area, EPA recommends that they use a probabilistic sampling design to select individual sites or sampling locations. Use of a

probabilistic design can address the spatial variability of methylmercury levels in fish. This approach allows statistically valid inferences to be drawn about tissue levels in the area as a whole. EPA's *Guidance on Choosing a Sampling Design for Environmental Data Collection, for Use in Developing a Quality Assurance Project Plan* (USEPA 2002d) contains information about probabilistic site selection.

4.2.4 How often should fish samples be collected?

EPA's *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories,* volume 1 (USEPA 2000c), at section 6.1.1.5, provides recommendations for how frequently to sample fish tissue. If program resources are sufficient, this guidance recommends biennial sampling of fish in waterbodies where recreational or subsistence harvesting is commonly practiced. If biennial screening is not possible, waterbodies should be screened at least once every five years. Also, the state or authorized tribe should sample during the period when the target species is most frequently harvested or caught.

In fresh waters, the guidance recommends that the most desirable sampling period is from late summer to early fall (August to October). Water levels are typically lower during that time, simplifying collection procedures. Also, the fish lipid content is generally higher, allowing the data to also provide information for other contaminant levels. The guidance does not recommend the late summer to early fall sampling period if it does not coincide with the legal harvest season of the target species or if the target species spawns during that period. In estuarine and coastal waters, the guidance recommends that the most appropriate sampling time is during the period when most fish are caught and consumed (usually summer for recreational and subsistence fishers).

EPA recommends that states and authorized tribes sample consistently in a season to eliminate seasonal variability as a confounding factor when analyzing fish monitoring data. Moreover, focused seasonality studies could be used both to assess the impact of seasonal variability on fish concentrations and to normalize concentrations to a standard season(s). Several studies have measured seasonality in the mercury concentrations in fish fillet muscle in estuaries and reservoirs (Kehrig et al. 1998; Park and Curtis 1997; Szefer et al. 2003). In these studies, concentrations were generally higher in cold seasons than in warm seasons by as much as two to three times. Slotten et al. (1995) showed that the uptake of methylmercury in zooplankton and fish increased dramatically during the fall mixing of Davis Creek Reservoir, a California reservoir contaminated by mercury mining activities.

No studies of seasonality of mercury concentrations in fish were found for rivers or natural lakes. On the basis of literature-reported fish mercury depuration rates, EPA does not expect seasonal fluctuations in fish mercury levels. Though reported mercury elimination half-lives cover a wide range of rates, from a few days to several years, the central tendency is 100–200 days (Burrows and Krenkel 1973; Giblin and Massaro 1973; Huckabee et al. 1979 [literature review]; McKim et al. 1976; Rodgers and Beamish 1982). Such slow depuration rates are expected to dampen strongly any fluctuations in methylmercury concentrations in fish. Instead, seasonal variations in fish tissue are likely linked to seasonal nutrition variability that affects fish body conditions but not mercury body burden.

4.2.5 How many samples should be collected?

EPA's *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories, v*olume 1 (USEPA 2000c), at section 6.1.2.7.2, provides information to help determine the number of composite samples needed for comparing fish tissue information to a target value. The guidance does not recommend a single set of sample size requirements (e.g., number of replicate composite samples per site and number of individuals per composite sample) for all fish contaminant monitoring studies, but rather presents a more general approach that is both scientifically defensible and cost-effective. The guidance provides the means for determining an optimal sampling design that identifies the minimum number of composite samples and of individuals per composite necessary to detect a minimum difference between a target (in this case, the water quality criterion) and the mean concentration of composite samples at a site. Under optimal field and laboratory conditions, at least two composite samples are needed at each site to estimate the variance. To minimize the risk of a destroyed or contaminated composite sample's preventing the site-specific statistical analysis, at least three replicate composite samples should be collected at each site.

4.2.6 What form of mercury should be analyzed?

Because of the higher cost of methylmercury analysis (two to three times greater than that for mercury analysis), one approach for the states and authorized tribes could be to first measure mercury in fish tissue. States and tribes may find that more labs have the capability for mercury analysis and that the analysis time may be quicker.

When measuring only mercury, the state or authorized tribe might make the conservative assumption that all mercury in fish tissue is methylmercury. Appendix A summarizes eight studies of the relative proportion of the mercury concentration in North American freshwater fish that is in the form of methylmercury. In six of the eight studies, methylmercury, on average, accounted for more than 90 percent of the mercury concentration in fish tissue. In the remaining two studies, methylmercury, on average, accounted for 80 to 90 percent of the mercury concentration in trophic level 3 and 4 fish. If the measured mercury level exceeds the methylmercury criterion, states and tribes may wish to repeat the sampling (if sufficient tissue is not left) and analyze for methylmercury.

4.2.7 Other sampling considerations

EPA recommends that states and tribes routinely collect both weight and length data when assessing the potential influence of fish nutritional state on mercury concentration, and potentially for normalizing fish concentrations to a standard body condition. Greenfield et al. (2001), Cizdziel et al. (2002, 2003), and Hinners (2004) reported a negative correlation between fish body condition (a ratio of weight to cubed length) and fish tissue mercury concentration. Regardless of the exact mechanism, body condition offers a useful method to explain variability in fish mercury.

4.3 How should waterbody impairment be assessed for listing decisions?

Section 303(d)(1) of the CWA and EPA's implementing regulations require states and authorized tribes to identify and establish priority ranking for waters that do not, or are not expected to, achieve or maintain water quality standards. In accordance with this ranking, a TMDL for such waters must then be established. For purposes of determining impairment of a waterbody and whether to include it on section 303(d) lists, or in category 5 of the Integrated Report under sections 303(d) and 305(b)[15], states and authorized tribes must consider all existing and readily available data and information (see 40 CFR 130.7).

States and authorized tribes determine attainment of water quality standards by comparing ambient concentrations to the numeric and narrative AWQC (40 CFR 130.7 (b)(3)). Where a fish tissue criterion has been adopted, states and tribes should consider observed concentrations in fish tissue in comparison to the criterion. Where a water column translation of the fish tissue criterion has been developed and is adopted as part of the state's or tribe's water quality standards, states and tribes should consider ambient water concentrations in comparison to the translation.

For assessment of concentrations in fish tissue, resources may typically be unavailable to collect an adequate number of replicate composite samples to support rigorous statistical testing, especially where it is desirable to evaluate each individual target species separately. In these situations, states should make direct comparisons between composite sample concentrations and the criterion, as each composite effectively represents the average concentration observed in several fish.

Statistical tests for comparing the average concentration from multiple replicate composite samples to the criterion may be conducted where a sufficient number of replicates have been collected. EPA's *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories,* volume 1 (USEPA 2000c), at section 6.1.2.7.2, recommends using the t-test to determine whether the mean concentration of mercury in composite fish tissue samples exceeds the screening value. This test involves a statistical comparison of the mean of all fish tissue data to the criterion. States and authorized tribes can evaluate whether the t-test statistic of the mean exceeds the water quality standards. This procedure could also be used to determine impairment, provided it is consistent with a state's water quality standards. States and authorized tribes might also want to consider the guidance in appendixes C and D of the *Consolidated Assessment and Listing Methodology*: *Toward a Compendium of Best Practices* (USEPA 2002e). Ultimately, the method that states and authorized tribes choose depends on how they express their water quality standards and apply their water quality assessment methodology.

4.3.1 How should nondetections be addressed?

When computing the mean of mercury in fish tissue, a state or authorized tribe might encounter a data set that includes analyzed values below the detection level. EPA does

[15] See EPA's guidance for Integrated Reports described at http://www.epa.gov/owow/tmdl/2006IRG/.

not expect this to occur frequently for two reasons. First, if the samples are physically composited (see section 4.2.2.), the composite itself provides the average, and there is no need to mathematically compute an average. Second, the newer analytical methods 1630 and 1631 can quantify mercury at 0.002 mg/kg, which should be lower than the observed mercury in most fish tissue samples being analyzed.

If, however, a state or authorized tribe is mathematically computing an average of a data set that includes several values below the detection level, the water quality standards and/or assessment methodology should discuss how it will evaluate these values. The convention recommended in EPA's *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories,* volume 1, at section 9.1.2, is to use one-half of the method detection limit for nondetects in calculating mean values (USEPA 2000c). The guidance also recommends that measurements that fall between the method detection limit and the method quantitation limit be assigned a value of the detection limit plus one-half the difference between the detection limit and the quantitation limit. EPA notes, however, that these conventions provide a biased estimate of the average concentration (Gilbert 1987) and, where the computed average is close to the criterion, might suggest an impairment when one does not exist or, conversely, suggest no impairment when one does exist.

States or authorized tribes can calculate the average of a data set that includes values below the detection level using other statistical methods (e.g., sample median and trimmed means) (Gilbert 1987). EPA has published a review of several methods and analyzed the potential bias each can introduce into the calculation of the mean (USEPA 2001h).

One approach that a state or authorized tribe could take is to conduct a sensitivity analysis to ascertain the consequence of what value is used to quantify samples below the detection level. In a sensitivity analysis, the state or authorized tribe would compute the mean concentration by first using the value of the detection level to quantify samples below the detection level and then using a zero value for samples below the detection level. If both calculated means are above or below the criterion, it is clear that the choice of how to quantify samples below the detection level does not affect the decision. However, if one calculated mean is below the criterion and the other is above, it is clear that the choice of how to quantify samples below the detection level does affect the decision, and a more sophisticated approach such as the ones in *Robust Estimation of Mean and Variance Using Environmental Data Sets with Below Detection Limit Observations* (USEPA 2001h) should be used.

All methods have advantages and disadvantages. A state or authorized tribe should understand the consequences of which method it uses, especially if the choice makes a difference as to whether a waterbody is considered impaired or not. Furthermore, a state or authorized tribe should be clear about which approach it used. Again, the selected methodology must be consistent with the state's water quality standards and their published assessment method.

4.3.2 How should data be averaged across trophic levels?

If target populations consume fish from different trophic levels, the state or authorized tribe should consider factoring the consumption by trophic level when computing the average methylmercury concentration in fish tissue. To take this approach, the state or authorized tribe would need some knowledge of the fish species consumed by the general population so that the state or authorized tribe could perform the calculation using only data for fish species that people commonly eat. (For guidance on gathering this information, see section 3.2.1.2.) States and authorized tribes can choose to apportion all the fish consumption, either a value reflecting the local area or the 17.5 grams fish/day national value for freshwater and estuarine fish if a local value is not available, to the highest trophic level consumed for their population or modify it using local or regional consumption patterns. Fish creel data from state fisheries departments are one reasonable basis for estimating types and amounts of fish consumed from a given waterbody. The state or authorized tribe must decide which approach to use.

As an example of how to use consumption information to calculate a weighted average fish tissue concentration, see table 5 and equation 4.

Table 5. Example data for calculating a weighted average fish tissue value

Species	Trophic level	Number of samples	Geometric mean methylmercury concentration (mg/kg)
Cutthroat trout	3	30	0.07
Kokanee	3	30	0.12
Yellow perch	3	30	0.19
Smallmouth bass	4	95	0.45
Pumpkinseed	3	30	0.13
Brown bullhead	3	13	0.39
Signal crayfish	2	45	0.07

These concentrations are used to compute a weighted average of tissue methylmercury concentrations for comparison to the 0.3 mg/kg criterion. All fish measured are classified as trophic level 3 except signal crayfish, which are trophic level 2, and smallmouth bass, which are trophic level 4. The mean methylmercury concentration in trophic level 3 fish in this example is 0.15 mg/kg. This is calculated by weighting the geometric mean methylmercury concentration in each trophic level 3 species by the number of samples of each of the trophic level 3 species, and then averaging the weighted geometric means. Had the concentrations been averaged without weighting for the number of samples, the average concentration would have been 0.18 mg/kg and would have given more weight to the methylmercury concentrations in brown bullhead than to the concentrations in the other species. (Note that this averaging approach does not consider that the trophic level 3 fish in this sample are of different sizes, or that some fish might be consumed more or less frequently than is represented by the number of samples.) Equation 4 shows how the total (all trophic levels) weighted concentration is calculated using the 0.15 mg/kg value as representative of trophic level 3 fish and the default consumption for each trophic level:

$$C_{avg} = \frac{3.8 * C_2 + 8.0 * C_3 + 5.7 * C_4}{(3.8 + 8.0 + 5.7)} = 0.23 \text{ mg/kg} \qquad \text{(Equation 4)}$$

Where:

C_2 = average mercury concentration for trophic level 2
C_3 = average mercury concentration for trophic level 3
C_4 = average mercury concentration for trophic level 4

This calculation is based on apportioning the 17.5 grams/day national default consumption rate for freshwater and estuarine fish and shellfish by trophic level (5.7 grams/day of trophic level 4 fish, 8.0 grams/day of trophic level 3 fish, and 3.8 grams/day of trophic level 2 fish[16]). As noted throughout this document, however, the consumption pattern of the target population should be used if available.

If fish tissue concentration data from a trophic level are missing, one would drop the consumption factor for that trophic level from both the numerator and denominator. For example, if there were no tissue concentration data for trophic level 2 fish in the previous example, equation 5 shows the revised calculation:

$$C_{avg} = \frac{8.0 * C_3 + 5.7 * C_4}{(8.0 + 5.7)} = 0.27 \text{ mg/kg} \qquad \text{(Equation 5)}$$

This revised calculation preserves the relative contribution of each trophic level to consumption patterns. This approach (i.e., dropping a trophic level from Equation 4), however, should not be used if there are no fish tissue data for trophic level 4 fish. Since level 4 fish are the type of fish that people most often consume, dropping trophic level 4 from Equation 4 may result in underprotection if trophic level 4 fish are actually consumed at the site. Instead, the state or authorized tribe should collect information to determine the consumption rate for fish in trophic level 4. If the state or authorized tribe finds that no trophic level 4 fish are eaten, the state or tribe may drop trophic level 4 from Equation 4.

If the state or authorized tribe has developed a site-specific fish consumption rate for the criterion, the state or authorized tribe should incorporate this site-specific rate into equation 4. In this case, the state or authorized tribe would replace the values of 5.7 grams/day of trophic level 4 fish, 8.0 grams/day of trophic level 3 fish, and 3.8 grams/day of trophic level 2 fish with the values that the state or authorized tribe developed.

As an alternative approach, states or authorized tribes might wish to translate fish tissue sample data to a standard size, length, or species of fish that is more commonly consumed or is representative of the risk considerations of the state. Regression models

[16] The values for each trophic level are the same as those discussed in section 3.2.1.2; they can be found in *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (USEPA 2000b).

have been developed for this purpose (Rae 1997; Wente 2003). An inherent assumption is that concentrations will differ between samples of two different species/lengths/sample cuts in a fixed equilibrium distribution relationship among all fish. If this relationship is known and at least one tissue sample concentration is measured from a species/length/sample cut that is accurately described by this relationship, fish consumption risk analyses could be performed for any species/lengths/sample cuts described by the relationship at this site.

Such regression models may include independent variables that account for species, aquatic environment (e.g., lotic vs. lentic, or other waterbody characteristics), sample cut (e.g., whole fish, skin-on fillet, skinless fillet), specific characteristics (e.g., age and retention time) of reservoirs, temporal trends, and fish length. The response variable is fish mercury concentration, which is typically assumed to be lognormally distributed. In a graphic sense, the model shows the covariance of each combination of nominal scale variables (e.g., whole fish, lentic waterbody) with fish length, with the slope representing the concentration/length ratio. Regression slopes can vary from lake to lake, resulting in models that inappropriately retain some fish size covariation (Soneston 2003).

EPA used the USGS National Descriptive Model for Mercury in Fish Tissue in various analyses (USEPA 2005a). This model is a statistical model related to covariance, and it allows the prediction of methylmercury concentrations in different species, cuts, and lengths of fish for sampling events, even when those species, lengths, or cuts of fish were not sampled during those sampling events. The model can also prove useful to states and authorized tribes in averaging fish tissue across trophic levels.

4.3.3 How should older data be assessed?

For purposes of determining waterbody impairment and inclusion on section 303(d) lists or category 5 of the Integrated Report, states and authorized tribes must consider all existing and readily available water quality-related data and information (40 CFR 130.7). Ideally, a state or authorized tribe would have collected fish tissue information within the past five years, as recommended in section 4.2.4. Such recent information might not always be available, however, and the available data often includes mercury samples collected and analyzed several years in the past. When the state or authorized tribe evaluates this information, it should take into account the reliability of this information and its compliance with applicable data collection or quality assurance/quality control program requirements.

4.3.4 How should fish consumption advisories be used to determine impairment?

On October 24, 2000, EPA issued guidance on the use of fish advisories in CWA section 303(d) listing and 305(b) reporting decisions (USEPA 2000j). This guidance notes EPA's general interpretation that fish consumption advisories on the basis of waterbody-specific information can demonstrate impairment of CWA section 101(a) "fishable" uses. Although the CWA does not explicitly direct the use of fish consumption advisories to determine attainment of water quality standards, states and authorized tribes must consider all existing and readily available data and information to identify impaired waterbodies on their section 303(d) lists. For purposes of determining waterbody

impairment and inclusion on a section 303(d) list or in an Integrated Report, EPA considers a fish consumption advisory and the supporting data existing and readily available data and information.

When listing waters under CWA sections 303(d) or in the Integrated Reporting format on the basis of a fish advisory for a migratory fish species, the state or authorized tribe should include the waters the migratory fish are known to inhabit because those are the waters where the fish potentially would be exposed to mercury. In addition, a state or authorized tribe has the discretion to include any other water having a fish consumption advisory as impaired on its section 303(d) list if the state or authorized tribe believes inclusion is appropriate.

A state or authorized tribe should include on its section 303(d) list or in its Integrated Report, at a minimum, those waters for which waterbody-specific data that were the basis of a fish or shellfish consumption advisory demonstrate nonattainment of water quality standards. EPA believes that a fish or shellfish advisory demonstrates nonattainment when the advisory is based on tissue data, the data are from the specific waterbody in question, and the risk assessment parameters of the advisory or classification are cumulatively equal to or less protective than those in the water quality standards.[17]

For example, consider a state or authorized tribe that bases its water quality criterion on eating two fish meals a month. If the state or authorized tribe finds fish tissue information showing that the level of mercury is at a level where it decides to advise people not to eat more than one fish meal a month and all other risk assessment factors are the same, the advisory also may serve to demonstrate a water quality standard exceedance and that the waterbody should be placed on the 303(d) list or in the Integrated Report. In contrast, if this same state or authorized tribe finds the level of mercury in fish in another waterbody is at a level at which it would advise people to eat no more than three meals a month, and all other risk assessment factors are the same, the advisory is not necessarily the same as an impairment and the waterbody might not need to be listed.

[17] The October 2000 EPA guidance assumes that the fish tissue monitoring that supports the advisory is sufficiently robust to provide a representative sample of mercury in fish tissue. EPA's fish tissue guidance (USEPA 2000c) provides recommendations on how public health officials can collect sufficient information about contaminants in fish.

5 Other Water Quality Standards Issues

5.1 How does this criterion relate to the criteria published as part of the Great Lakes Initiative?

The 2001 recommended methylmercury fish tissue criterion and EPA's recommendations for its implementation do not supersede the requirements applicable to the Great Lakes at 40 CFR part 132. The Great Lakes regulatory requirements, known as the Great Lakes Initiative, or GLI, apply to all the streams, rivers, lakes and other bodies of water within the U.S. portion of the Great Lakes drainage basin. For those waters, a state or authorized tribe must adopt requirements (including water quality criteria) that are consistent with (as protective as) regulations EPA promulgated on March 23, 1995. See 60 FR 15366 and 40 CFR 132.1(b) and 132.4.

Under these regulations, if a state or authorized tribe adopts a fish tissue residue methylmercury criterion for the protection of human health, EPA, in its review of the new state or tribal criterion, must determine whether it is as protective as the mercury water column criterion for human health protection promulgated at 40 CFR 132.6, table 3, and whether all implementation procedures are as protective as the implementation procedure. See 40 CFR 132.5(g).

As described below, it is unlikely that adoption of EPA's 2001 recommended methylmercury fish tissue-based criterion of 0.3 mg/kg to protect human health would result in TMDLs or NPDES permit limits addressing mercury impairments in the Great Lakes basin less stringent than those that would be required under the existing GLI regulations. The reasons for this include the following:

- The GLI requires all states and authorized tribes to adopt the GLI wildlife water column criterion. The GLI wildlife criterion has a significantly more stringent methylmercury fish tissue basis than either the 2001 criterion or the GLI human health criteria and would therefore likely be the controlling basis for any TMDLs or NPDES permit limits addressing mercury pollution.

- Even if that were not the case, the 2001 criterion is more stringent than the methylmercury fish tissue basis for the GLI human health water column criteria for mercury.

Furthermore, using the 2001 fish tissue criterion would not necessarily result in lower transaction costs than the GLI. The GLI implementation procedures (e.g., the mixing zone prohibition, 40 CFR part 132, appendix F, procedure 3) require the use of water column criteria, so the 2001 methylmercury fish tissue criterion would need to be converted to a water column criterion following the GLI site-specific modification procedures before it could be approved by EPA and implemented using other GLI implementation procedures.

The human health criterion for mercury established by the GLI is 3.1 ng/L[18]. This water column criterion for mercury is equivalent to a methylmercury fish tissue residue value of 0.35 mg/kg using the Great Lakes-specific BAFs for mercury—27,900 L/kg for trophic level 3 and 140,000 L/kg for trophic level 4—as well as other Great Lakes-specific information (USEPA 1995c). Because EPA's 2001 methylmercury criterion (0.30 mg/kg) is more stringent than the GLI fish tissue residue value, the 2001 criterion would result in more stringent water column concentrations than the GLI human health criteria unless other, site-specific factors were significantly less stringent. This could occur, for example, if a state or authorized tribe applied the GLI site-specific modification procedures and found that the current, local BAF is significantly lower than the one used to develop the GLI criterion. In that case, the state or tribe could use the lower, local BAF and EPA's recommended fish tissue-based criterion to recalculate the water column criterion using the GLI site-specific modification procedures and submit it to EPA for review and approval. If the site-specific water column criterion was approved by EPA, the state or authorized tribe could use it and the GLI implementation procedures to develop TMDLs and NPDES permits.

Finally, as indicated above, if a state or authorized tribe were to adopt the 2001 human health criterion in the Great Lakes basin, this action most likely would not result in a change to TMDLs or NPDES permits. The GLI also includes a 1.3 ng/L criterion for the protection of wildlife, and in most instances, this more stringent criterion will drive the calculation of TMDLs or NPDES permit limits.

5.2 What is the applicable flow for a water column-based criterion?

If a state or authorized tribe adopts new or revised methylmercury criteria based on a water column value rather than a fish tissue value, it should consider the dilution flow specified in the state's or tribe's water quality standards when applying the new mercury criterion. Where a state's or authorized tribe's water quality standards do not specify the appropriate flow for use with the mercury criterion, EPA recommends using a harmonic mean flow. EPA used this flow for application of the human health criteria for mercury in the Great Lakes (40 CFR part 132). EPA also used this flow for application to the human health criteria in the National Toxics Rule (40 CFR 131.36) and the California Toxics Rule, or CTR (40 CFR 131.38). The Agency considers this flow to better reflect the exposure of fish to mercury. The technical means for calculating a harmonic mean is described in section 4.6.2.2.a of the *Technical Support Document for Water Quality-based Toxics Control* (USEPA 1991).

[18] EPA promulgated the GLI human health criteria of 1.8 ng/L in 40 CFR part 132, table 3, in March 1995, based on an RfD of 0.06 µg/kg/d. In May 1995 EPA revised the RfD to the current 0.1 µg/kg/d, which would result in GLI criteria of 3.1 ng/L. In October 1996 EPA issued guidance indicating that the 3.1 ng/L criteria were considered as protective as the promulgated 1.8 ng/L.

5.3 How are mixing zones used for mercury?

5.3.1 What is a mixing zone?

A mixing zone is the area beyond a point source outfall (e.g., a pipe) in which concentrations of a pollutant from a wastewater discharge mix with receiving waters. Under 40 CFR 131.13, states and authorized tribes may, at their discretion, include mixing zones in their water quality standards. Within a mixing zone, the water may be allowed to exceed the concentration-based water quality criterion for a given pollutant. The theory of allowing mixing zones is based on the belief that by mixing with the receiving waters within the zone, the concentration of the pollutant being discharged will become sufficiently diluted to meet applicable water quality criteria beyond the borders of that zone and fully protect the designated use of the waterbody as a whole. More information on mixing zones is available in the *Technical Support Document for Water Quality-based Toxics Control* (USEPA 1991) and the *Water Quality Standards Handbook* (USEPA 1994). States and authorized tribes often authorize mixing zone provisions and methodologies for calculating mixing zones for later application to NPDES point source discharge points.

5.3.2 How does a mixing zone apply for the fish tissue-based methylmercury criterion?

The question of mixing zones is not relevant when applying the fish tissue-based criterion, which refers to the level of mercury found in fish flesh. The criterion is fish tissue-based, not water column-based. The criterion reflects the exposure of the fish to mercury in the water column and food over the life of the fish, and thus it reflects an integration of the exposure over time and over spatially varying water column concentrations. The total load of mercury in the waterbody, taking into account the methylation rate and bioaccumulation of mercury in fish, affects the level of methylmercury in the fish tissue.

Some states and authorized tribes, however, might choose to adopt a water column criterion based on the fish tissue criterion and thus have a criterion for which a mixing zone might apply. In this situation, a state or authorized tribe should follow its existing procedures for determining appropriate mixing zones. EPA advises caution in the use of mixing zones for mercury. While fish tissue contamination tends to be a far field problem affecting entire waterbodies, rather than a narrow scale problem confined to mixing zones, EPA's guidance recommends restricting or eliminating mixing zones for bioaccumulative pollutants such as mercury so that they do not encroach on areas often used for fish harvesting (particularly for stationary species such as shellfish). Restriction or elimination might also be used to compensate for uncertainties regarding the ability of aquatic life or the aquatic system to tolerate excursions above the criteria, uncertainties inherent in estimating bioaccumulation, or uncertainties in the assimilative capacity of the waterbody. See the *Water Quality Standards Handbook*, section 5.1.3 (USEPA 1994).

5.3.3 Does the guidance for the fish tissue-based criterion change the Great Lakes Initiative approach to mixing zones for bioaccumulative pollutants?

To reduce the adverse effects from bioaccumulative chemicals of concern (BCCs) in the Great Lakes, on November 13, 2000, EPA promulgated an amendment to the Final Water Quality Guidance for the Great Lakes System (40 CFR part 132, appendix F, procedure 3). The regulation requires prohibition of mixing zones for bioaccumulative pollutants from existing discharges in the Great Lakes to the greatest extent technically and economically feasible. Specifically, existing discharges of BCCs are not eligible for a mixing zone after November 10, 2010 (although under certain circumstances mixing zones may be authorized). For new BCC discharges, the rule essentially prohibits mixing zones of bioaccumulatives immediately upon commencing discharge. This means that NPDES permit limitations for mercury discharged to the Great Lakes system must not exceed the water quality criterion. This also limits the flexibility that states and authorized tribes would otherwise have to adjust point source controls on the basis of nonpoint source contributions.

EPA reiterates that the new methylmercury criterion, and EPA's recommendations on its implementation, does not supersede the requirements applicable to the Great Lakes at 40 CFR part 132. The criteria for the Great Lakes are water column-based, and therefore they can be applied as an effluent requirement at the end of a pipe. EPA continues to view the prohibition of a mixing zone for mercury and other bioaccumulative pollutants for the Great Lakes as appropriately protective for water column-based water quality criteria applied to these waters.

If a state or authorized tribe adopts the new fish tissue-based criterion for a Great Lake or tributary to the Great Lake, the state or tribe would do this using the site-specific modification procedures of part 132 (see section 5.1 of this document). The state or tribe would have determined a site-specific BAF in this process and therefore would have the means for calculating a water column-based criterion. Under the part 132 regulations, EPA in its review of the new state or tribal implementation procedures would determine whether they are as protective as the Great Lakes procedures for human health protection (40 CFR 132.5(g)(3)). Specifically, EPA would determine whether the implementation procedures are as protective as applying the table 3 (in 40 CFR part 132) criterion for protection of human health without a mixing zone, consistent with the prohibition on mixing zones for BCCs (40 CFR 132, appendix F.3.c.). In addition, if the state's or tribe's implementation procedures involve converting the fish tissue-based criterion into an equivalent water column-based number, the mixing zone prohibition requirements of 40 CFR part 132 still apply.

5.4 How are fish consumption advisories and water quality standards harmonized?

5.4.1 What is the role of state and tribal Fish Advisory Programs?

States and authorized tribes have the primary responsibility of estimating the human health risks from the consumption of chemically contaminated, noncommercially caught finfish and shellfish (e.g., where water quality standards are not attained). They do this by

issuing consumption advisories for the general population, including recreational and subsistence fishers, and for sensitive subpopulations (such as pregnant women, nursing mothers and their infants, and children). These advisories are nonregulatory and inform the public that high concentrations of chemical contaminants, such as mercury, have been found in local fish. The advisories recommend either limiting or avoiding consumption of certain fish from specific waterbodies or, in some cases, from specific waterbody types (e.g., all lakes). In the case of mercury, many states and authorized tribes have calculated a consumption limit to determine the maximum number of fish meals per unit of time that the target population can safely eat from a defined area.

5.4.2 How are consumption limits for consumption advisories determined?

EPA has published guidance for states and authorized tribes to use in deriving their recommended fish consumption limits, titled *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories*, volumes 1 and 2 (USEPA 2000c, 2000f). This guidance describes the two main equations necessary to derive meal consumption limits on the basis of the methylmercury RfD. Basically, the first equation is used to calculate the daily consumption limits of grams of edible fish (in g/day); a second equation is used to convert daily consumption limits to meal consumption limits over a specified period of time. Variables used to calculate the advisory consumption limits include fish meal size and frequency, consumer body weight, contaminant concentration in the fish tissue, the time-averaging period selected, and the reference dose for methylmercury health endpoints.

In the absence of site-specific fish consumption data, EPA recommends using a fish consumption rate of 17.5 grams/day of fish (uncooked) eaten from the local water as a screening level. This consumption rate equates to approximately two 8-ounce meals per month. Using this consumption rate, and assuming a 70-kg body weight (the same assumption used to derive the methylmercury criterion), the concentration of methylmercury in locally caught fish that would result in exposures that do not exceed the RfD (0.0001 mg/kg-day) is about 0.4 mg/kg and lower ([0.001 mg/kg-day x 70 kg bw]/0.0175 kg fish/day). This means that you can safely consume approximately two 8-ounce meals per month of locally-caught fish, where concentrations in such fish are 0.4 mg/kg or lower, and where there is no additional exposure (i.e., consumption of store bought or marine-caught fish).

Advisory limits can differ from one state or tribe to another. This inconsistency is due to a host of reasons, some of which speak to the flexibility states and authorized tribes have to use different assumptions (chemical concentrations, exposure scenarios and assumptions) to determine the necessity for issuing an advisory. The nonregulatory nature of fish advisories allows such agencies to choose the risk level deemed appropriate to more accurately reflect local fishing habits or to safely protect certain subpopulations (e.g., subsistence fishers).

5.4.3 How does the criterion differ from the advisory level?

Although EPA derived its recommended screening value for a fish advisory limit for mercury and human health methylmercury criterion from virtually identical

methodologies, it is important to clarify the distinctions between the two values. They are consistently derived, but because each value differs in purpose and scope, they diverge at the risk management level. Fish advisories are intended to inform the public about how much consumers should limit their intake of individual fish species from certain waterbodies. Alternatively, the Agency uses its methylmercury criterion, like other CWA section 304(a) criteria, as a basis for both nonregulatory and regulatory decisions. The criterion can serve as guidance to states and authorized tribes for use in establishing water quality standards, which, in turn, serve as a benchmark for attainment, compliance, and enforcement purposes.

The main risk management difference between EPA's recommended methylmercury water quality criterion and the fish advisory default screening value for mercury is that the criterion includes an RSC[19] and the screening value does not. In deriving the criterion, EPA assumed an RSC value of 2.7×10^{-5} mg/kg-day to account for exposure from marine fish and shellfish. The guidance for setting fish consumption limits also discusses using an RSC to account for exposures other than those from noncommercially caught fish, but the guidance may be applied without using an RSC. The RSC guidance in the 2000 Human Health Methodology (USEPA 2000b) provides more detail and specific quantitative procedures to account for other exposure pathways. EPA's advisory guidance recommends that states and authorized tribes consider using an RSC to account for exposure from other sources of pollutants (such as mercury) when deriving a fish consumption limit and setting a fish advisory for mercury.

5.4.4 What if there is a difference between assessing criterion attainment and issuance of a fish consumption advisory?

In many states and authorized tribes, numeric water quality criteria and fish and shellfish consumption limits differ because of inherent differences in the technical and risk assumptions used to develop them. As discussed in section 4.2, EPA considers a fish consumption advisory to demonstrate nonattainment of water quality standards when the advisory is based on tissue data, the data are from the specific waterbody in question, and the risk assessment parameters of the advisory or classification are cumulatively equal to or less protective than those in the water quality standards. Two situations in which the presence of an advisory might not imply an exceedance of the water quality standard (USEPA 2005f) are as follows:

- *Statewide or regional advisory.* States have issued statewide or regional warnings regarding fish tissue contaminated with mercury, on the basis of data from a subset of waterbodies, as a precautionary measure. In these cases, fish consumption advisories might not demonstrate that a CWA section 101(a) "fishable" use is not being attained in an individual waterbody and might not be appropriate for determining attainment based on exceedance of water quality criteria.

- *Local advisory.* States have issued local advisories using a higher fish consumption value than that which they use in establishing water quality criteria for protection of human health. Again, in this case the fish consumption advisories might not

[19] See discussion on the RSC in section 3.1.2.3 and 3.2.1.1.

demonstrate that a section 101(a) "fishable" use is not being attained in an individual waterbody and might not be as appropriate as comparison with water quality criteria as a basis for determining attainment.

For example, consider a state or authorized tribe that adopts EPA's methylmercury criterion of 0.3 mg/kg, which is based on eating approximately two 8-ounce fish meals a month. If the state or authorized tribe finds that a waterbody has fish with a mercury level of 0.2 mg/kg, this water would not be exceeding the water quality criterion. Yet, this mercury concentration is sufficient for the state or authorized tribe to issue a fish consumption advisory recommending that people eat no more than four 8-ounce meals a month. In this case, because the fish consumption advisory uses a higher fish consumption value than that used to develop the water quality criterion (and the fish tissue concentration does not exceed the criterion), consistent with EPA's 2000 guidance, the waterbody is not necessarily impaired (USEPA 2005f).

In the case where a local advisory is based on a higher fish consumption value which is considered representative of local consumption, the state or authorized tribe should consider whether it should adopt a site-specific criterion for the waterbody. A local advisory generally reflects actual contaminant monitoring data and may reflect local fish consumption patterns, and it might identify more representative fish species. The information gathered in developing the advisory might provide valid grounds for revising the level of a numeric water quality criterion to match that of the advisory.

5.4.5 Should existing advisories be revised to reflect the new criterion?

Although EPA's screening value for fish advisory studies and the recommended 304(a) criterion for mercury are based on similar methodologies and are intended to protect people who consume mercury-contaminated fish, they do not necessarily have to be the same value. As explained above, each limit is predicated on different risk-management decisions and thus incorporates different assumptions. However, recognizing that differences in consumption advisories and waterbody impairment for the methylmercury criterion can be confusing to the public, states may wish to consider explaining the differences in the information that these two types of listings provide. Likewise, there is merit in adopting a site-specific methylmercury criterion on the basis of a local fish advisory, if that advisory is supported by sufficient fish tissue and fish consumption data that are representative and of acceptable quality. Alternatively, states may wish to consider issuing a fish consumption advisory, where appropriate, if a waterbody is considered impaired based on the methylmercury 304(a) criterion and no such consumption warning exists.

5.4.6 What federal agencies issue advisories?

The Food and Drug Administration's (FDA's) mission is to protect the public health with respect to levels of chemical contaminants in all foods, including fish and shellfish, sold in interstate commerce. To address the levels of contamination in foods, FDA has developed both action levels and tolerances. An action level is an administrative guideline that defines the extent of contamination at which FDA may regard food as adulterated and represents the limit at or above which FDA may take legal action to

remove products from the marketplace. It is important to emphasize that FDA's jurisdiction in setting action levels is limited to contaminants in food shipped and marketed in interstate commerce; it does not include food that is caught locally by recreational or subsistence fishers. FDA also issues fish consumption advice on fish and shellfish sold in commerce in cases where contaminants have been detected at levels that may pose public health concerns for some consumers.

As described in section 5.4.2, EPA provides guidance to states, tribes, local governments and others on scientifically sound, cost-effective methods for developing and managing noncommercial fish consumption advisories on local waters. See EPA's *Guidance for Assessing Chemical Contaminant Data for Use in Fish Advisories* (USEPA 2000c, 2000f). In addition, EPA has issued advice under CWA section 104(b)(6) to supplement state and/or tribal advice on local waters.

In March 2004, EPA and FDA issued a joint national fish advisory about mercury in fish and shellfish. The purpose of the advisory is to inform women who may become pregnant, pregnant women, nursing mothers, and parents of young children how to get the positive health benefits from eating fish and be confident that they have reduced their exposure to the harmful effects of mercury. The 2004 advisory lists fish sold in interstate commerce that are known to be high in mercury as well as fish that that are low in mercury to help consumers choose the most appropriate fish. The advisory also contains recommendations about eating fish harvested from local waters where no advice has been provided by state or tribal authorities. Information regarding the national advisory is at http://www.epa.gov/waterscience/fish/.

5.4.7 How is the criterion related to FDA action levels?

The current FDA action level for mercury in fish is 1 mg/kg. Generally, an action level is different from a fish advisory limit—and even more different from a CWA section 304(a) criterion. FDA action levels are intended for members of the general population who consume fish and shellfish typically purchased in supermarkets or fish markets that sell products harvested from a wide geographic area. The underlying assumptions used in the FDA methodology were never intended, as local fish advisories are, to be protective of recreational, tribal, ethnic, and subsistence fishers who typically consume fish and shellfish from the same local waterbodies repeatedly over many years. EPA and FDA have agreed that the use of FDA action levels for the purposes of making local advisory determinations is inappropriate. Furthermore, it is EPA's belief that FDA action levels and tolerances should not be used as a basis for establishing a state's or tribe's methylmercury criterion.

5.5 What public participation is recommended for implementing the methylmercury criterion?

By applicable regulations, water quality standards, TMDL, and NPDES permit decisions require public notice and the opportunity for the public to comment on tentative decisions. Some public interest groups might have an interest in decisions related to mercury, especially in areas where local citizens rely heavily on locally caught fish as a food source. EPA recommends that organizations with an interest in environmental justice issues be included in the public notice.

6 TMDLs

6.1 What is a TMDL?

CWA section 303(d)(1) and EPA's implementing regulations require states and authorized tribes to identify and establish priority rankings for waters that do not, or are not expected to, achieve or maintain water quality standards with existing or anticipated required controls. This list is known as the state's or tribe's list of "impaired" waterbodies or 303(d) list. States and authorized tribes then must establish TMDLs for the impaired waterbodies.

A TMDL is a calculation of the maximum amount of a pollutant that a waterbody can receive and still meet water quality standards. A TMDL also allocates the pollutant loads among the contributing sources, both point and nonpoint. The TMDL calculation must include a margin of safety to take into account any uncertainty in the TMDL calculation and must account for seasonal variation in water quality. The current statutory and regulatory framework governing TMDLs includes CWA section 303(d) and the TMDL regulations published in 1985 at 40 CFR 130.2 and 130.7 and amended in 1992 (see 50 FR 1774 (Jan. 11, 1985); 57 FR 33040 (July 24, 1992)).

As of the 2008 303(d) listing cycle, 43 states and Puerto Rico reported at least one waterbody as impaired due to mercury, and more than 8,800 specific waterbodies were listed as impaired due to mercury, either solely or in combination with other pollutants. As mentioned previously in section 2.4, with the implementation of the new methylmercury fish tissue criterion, monitoring of previously unmonitored waterbodies, and use of more sensitive analytical methods, EPA expects that the number of waterbodies listed as impaired due to mercury might increase.

6.2 How have states and tribes approached mercury TMDLs?

Developing TMDLs for waters impaired by mercury raises a number of technical and policy issues. For example, air deposition is the predominant source of mercury to many waterbodies, especially in the eastern United States. The mercury deposited from air comes from local, regional, and international sources, and identifying how each of these sources contributes to the mercury load in the waterbody is challenging. In other waterbodies, significant loadings might come from other sources, such as past metal-mining activity or geologic sources. Frequently, states and authorized tribes do not have the authority to address all the sources that contribute mercury to their waterbodies and rely on efforts conducted under a variety of programs, such as regulations under the CAA, pollution prevention programs, and international efforts to reduce releases and emissions from mercury sources. States and EPA have found that, in many cases, it is important to coordinate closely with programs other than those under the CWA to address these mercury sources.

Given these challenges, EPA is working with states, tribes, and stakeholders to determine how best to use TMDLs and the 303(d) listing process to provide a basis for reducing mercury releases to water, including consideration of air deposition, to meet applicable

water quality standards and CWA goals. In areas where large numbers of waterbodies are impaired due to mercury derived from air deposition, some states have begun to explore ways to address mercury impairments efficiently, such as through development of TMDLs on various geographic scales. As of April 2010, mercury TMDLs have been approved for more than 6,700 waterbodies, including a "statewide" mercury TMDL in Minnesota and a multi-state mercury TMDL for the Northeast states (see below).

On March 8, 2007, EPA issued a memorandum describing a voluntary approach for listing waters impaired by atmospheric mercury under CWA section 303(d) and managing the development of mercury TMDLs. (USEPA 2007) (http://www.epa.gov/owow/tmdl/mercury5m/Mercury5m.pdf). EPA recommends this approach for states that have in place a comprehensive statewide mercury reduction program with elements recommended by EPA. These states may separate their waters impaired by mercury predominantly from atmospheric sources in a subcategory of their impaired waters list ("5m") and defer the development of TMDLs for those waters. A state using the 5m subcategory may continue to defer the development of mercury TMDLs where the state demonstrates continuing progress in reducing in-state mercury sources. Recommended elements of a mercury reduction program include identification of air and multimedia sources within a state and programs to address those sources; mercury reduction goals and target dates; multimedia monitoring; public reporting on the state's mercury reduction efforts; and multistate coordination. The 5m subcategory is intended to recognize states with comprehensive mercury programs and to allow states to focus on early implementation actions.

Because the 5m subcategory is focused primarily on waterbodies impaired by mercury from air deposition, EPA recommends that the 5m subcategory include waters where the proportion of mercury from air deposition is high compared to other mercury sources. In the 5m memorandum, EPA recommends that states describe how such waterbodies were identified. Such information will help determine whether the 5m approach is appropriate. EPA also believes that, as the relative contribution to a waterbody from sources other than air deposition increases, such as water point sources, it may be more appropriate to use the TMDL process to characterize and address those sources sooner, rather than deferring TMDL development. As stated in the 5m memorandum, states have the option to continue developing mercury TMDLs sooner, whether or not they place waterbodies in subcategory 5m.

On September 29, 2008, EPA issued a document titled *Elements of Mercury TMDLs Where Mercury Loadings Are Predominantly from Air Deposition*, to assist states, EPA regional staff, and other stakeholders in identifying approaches for the development of mercury TMDLs (USEPA 2008a). Compiled in a checklist format, approaches described in the document are drawn largely from approaches and best practices used in approved mercury TMDLs. The checklist summarizes considerations in addressing the required and recommended TMDL elements described in the *Guidelines for Reviewing TMDLs under Existing Regulations Issued in 1992* (USEPA 2002f) when developing mercury TMDLs on geographic scales ranging from waterbody-specific to multi-state.

While the checklist is based on existing guidance for reviewing TMDLs, this guidance document supplements the checklist by providing additional information and case studies on approaches that have been used in approved mercury TMDLs to date, and examples of

technical tools available to assist in mercury TMDL development. Technical tools available to assist in the development of mercury TMDLs include screening-level analyses of mercury loadings and sources using the Mercury Maps tool and more complex water and air models. Many of these tools are discussed in the sections below.

EPA recommends that states continue to develop TMDLs for mercury-impaired waters where appropriate, taking into account the considerations and approaches described in this guidance. States may also consider using the 5m subcategory for waters impaired by mercury predominantly from air deposition if the state has a comprehensive mercury reduction program as described in the 5m memorandum.

6.2.1 What geographic scales have been used for mercury TMDLs?

Many mercury TMDLs approved to date were developed on a waterbody-specific basis. They include some of the first approved mercury TMDLs, such as those developed for waterbodies in middle and south Georgia. Other examples include TMDLs developed for waterbodies in Louisiana, such as the Ouachita River, the Narraguinnup and McPhee reservoirs in Colorado, and Pena Blanca and Arivaca lakes in Arizona. Various aspects of these TMDLs are described further in appendix D.

In areas of the country where many waterbodies are listed as impaired due to mercury primarily from atmospheric sources, some states have begun to explore the development of mercury TMDLs on a watershed scale or on the basis of a large geographic area, such as a state or region. One example of a regional or grouped approach is the mercury TMDL for the Coastal Bays and Gulf Waters of Louisiana, approved in June 2005. The TMDL covers six segments of coastal Louisiana. Because of the large geographic extent of mercury in the coastal waters and the similar extent of mercury contributions from air deposition, the TMDL was developed on a watershed basis rather than waterbody by waterbody. The TMDL used air deposition modeling results from the Regional Modeling System for Aerosols and Deposition (REMSAD) to estimate wet and dry deposition of mercury for the six segments. The air deposition modeling results, in turn, were used to model runoff or nonpoint source mercury loadings. As described in the following section, mercury loadings can include direct deposition to waterbodies and deposition to the watershed that is subsequently transported to the waterbody via runoff and erosion. Additional information on this TMDL can be found on EPA's TMDL webpage at http://iaspub.epa.gov/tmdl/waters_list.tmdl_report?p_tmdl_id=11642.

A "statewide" mercury TMDL developed by Minnesota was approved by EPA on March 27, 2007. The TMDL report covers 998 mercury impairments and is the first approved mercury TMDL covering such a large number of waterbodies and large geographic area. (Note: Although called statewide, the TMDL does not cover all mercury-impaired waterbodies in the state.) Minnesota used a statewide approach because the predominant mercury source in those waterbodies—air deposition—is relatively uniform across the state. The final TMDL report includes two TMDLs—one for the northeast region of the state and the other for the southwest region of the state. Waterbodies were grouped into the two regions on the basis of differences in fish tissue concentrations, with higher fish mercury concentrations in the northeast region compared to the southwest region. The difference in mercury concentrations is thought to be due to the effect of land use and other factors on the methylation of mercury. For example, the

northeast region is dominated by wetlands, where mercury tends to be methylated more readily; the southwest is dominated by cultivated lands. A summary of the Minnesota mercury TMDL approach is provided in appendix D, and the allocation approach is described further below. The final TMDL and EPA decision document are at http://www.pca.state.mn.us/water/tmdl/tmdl-ercuryplan.html#approval.

On December 20, 2007, EPA approved the Northeast Regional Mercury TMDL covering waterbodies in Connecticut, Maine, Massachusetts, New Hampshire, New York, Rhode Island and Vermont. In using a regional approach, the TMDL document provides aggregate wasteload allocations and load allocations for the region. The regional approach was based on an analysis of data showing similar levels of mercury in fish throughout waterbodies in the region, and the states' finding that air deposition is the predominant mercury source. The TMDL document focuses on waters impaired by mercury primarily from atmospheric sources; it excludes coastal and marine waters and a few areas of high localized deposition and high fish mercury levels. The number of individual waterbodies covered by the regional TMDL document amounts to over 5,300 (the specific number of waterbodies covered by the TMDL document vary from state to state and are cited in EPA's approval documents). The TMDL target is EPA's recommended fish tissue criterion of 0.3 ppm methylmercury for each of the states except for Connecticut and Maine, where the targets are 0.1 ppm and 0.2 ppm, respectively. The TMDL allocates approximately 2.0 percent of the loading capacity to point sources and 98 percent to nonpoint sources (predominantly atmospheric deposition). The TMDL assumes that most of the reductions would need to come from atmospheric sources. The Northeast Regional Mercury TMDL are at http://www.epa.gov/region1/eco/tmdl/assets/pdfs/ne/Northeast-Regional-Mercury-TMDL.pdf, and the EPA approval documents for each of the states are at http://www.epa.gov/region1/eco/tmdl/approved.html.

6.2.2 What are the considerations in developing mercury TMDLs?

A TMDL must identify the applicable water quality standards for each listed segment and identify the loading capacity of a water (40 CFR 130.2). In addition, a TMDL must allocate the pollutant loads among the sources, both point and nonpoint (40 CFR 130.2(i)). EPA guidance further notes that a TMDL should identify the pollutant sources, both point and nonpoint, including the location of the sources and quantity of the loading. Where feasible, states are encouraged to consider waterbodies affecting disadvantaged communities and tribal issuses in setting priorities for TMDL development. Some of the considerations in developing a mercury TMDL and approaches used in approved mercury TMDLs are described in more detail in the text below.

6.2.2.1 What are potential mercury sources to waterbodies?

An important step in TMDL development is an evaluation of the loadings from various sources. The potential sources of mercury to waterbodies include the following: (1) direct discharges of mercury from water point sources, including industrial dischargers and wastewater treatment plants; (2) atmospheric deposition, including direct deposition to the waterbody surface and deposition to the watershed, which subsequently is transported to the waterbody via runoff and erosion, including via stormwater; (3) runoff, ground water flow, acid mine drainage, and erosion from mining sites or mining wastes, and

other waste disposal sites such as landfills and land application units; (4) sediments, which might have mercury contamination or hot spots resulting from past discharges; and (5) "naturally occurring" mercury in soils and geologic materials. Sediments containing mercury from past discharges might continue to contribute mercury to the overlying waterbody. Further discussion of each of these types of sources follows.

Point sources. Point source discharges of mercury include POTWs, electric utilities, and other industrial facilities. Sources of data on point source discharges of mercury include the Permit Compliance System, as well as a study of domestic mercury sources by the Association of Metropolitan Sewerage Agencies (AMSA 2000), now called the National Association of Clean Water Agencies (NACWA). Without accurate discharge data, a sample of a representative portion of dischargers has been used in mercury TMDLs to estimate the mercury discharges from point sources. In addition, some point source dischargers, such as chlor-alkali plants and POTWs, might have permits requiring monitoring for mercury, although most dischargers, especially smaller dischargers, are not likely to have such monitoring requirements. NPDES-permitted stormwater sources might also include mercury discharges, which in turn might include mercury originating from atmospheric deposition.

Atmospheric deposition. Deposition of mercury from the air can be a significant source of mercury in many waterbodies. Some waterbodies have been identified as receiving as much as 99 percent of their total loading from atmospheric deposition, either directly or indirectly via runoff and erosion. (See Ochlockonee, Georgia, TMDL in appendix D.) The mercury in atmospheric deposition originates from anthropogenic sources, including U.S. and international sources, as well as natural sources. Examples of specific anthropogenic sources that emit mercury to the air include medical and municipal waste incinerators, electric utilities, chlor-alkali plants, and active metals mining, among others.

Mercury is emitted to the air in several chemical forms or species. Common measurements of mercury in air differentiate between reactive gaseous mercury (RGM), elemental mercury (Hg^0), and particulate mercury (Hg_p). Some chemical forms of mercury emissions to air deposit relatively close to their sources, while others are transported over longer distances and even globally. The mix of chemical forms or species emitted from a given source determines what fraction of the mercury from that source is depositing locally and what proportion is transported over longer distances, making the task of identifying sources of deposition to a waterbody challenging. At any given location, the mercury deposited from air can originate from several sources. Figure 3 depicts the current understanding of deposition from U.S. and international sources. It shows that in many parts of the United States, the source of deposited mercury is not a U.S. source.

Of the approved mercury TMDLs involving atmospheric loadings, most have characterized the contributions from air deposition in terms of total or aggregate loadings. Atmospheric mercury loadings include both direct deposition to the waterbody surface and indirect deposition to the watershed. Indirect deposition is that which is deposited to the watershed and then transported to the waterbody via runoff and erosion. Atmospheric mercury loadings include both wet and dry deposition of mercury.

It is important to use the most current information about deposition because U.S. mercury emissions into the air have decreased over time. Older data on deposition might not reflect current deposition conditions. For example, figure 4 depicts a summary of U.S. mercury air emissions between 1990 and 2005 and shows a 58 percent overall decrease.

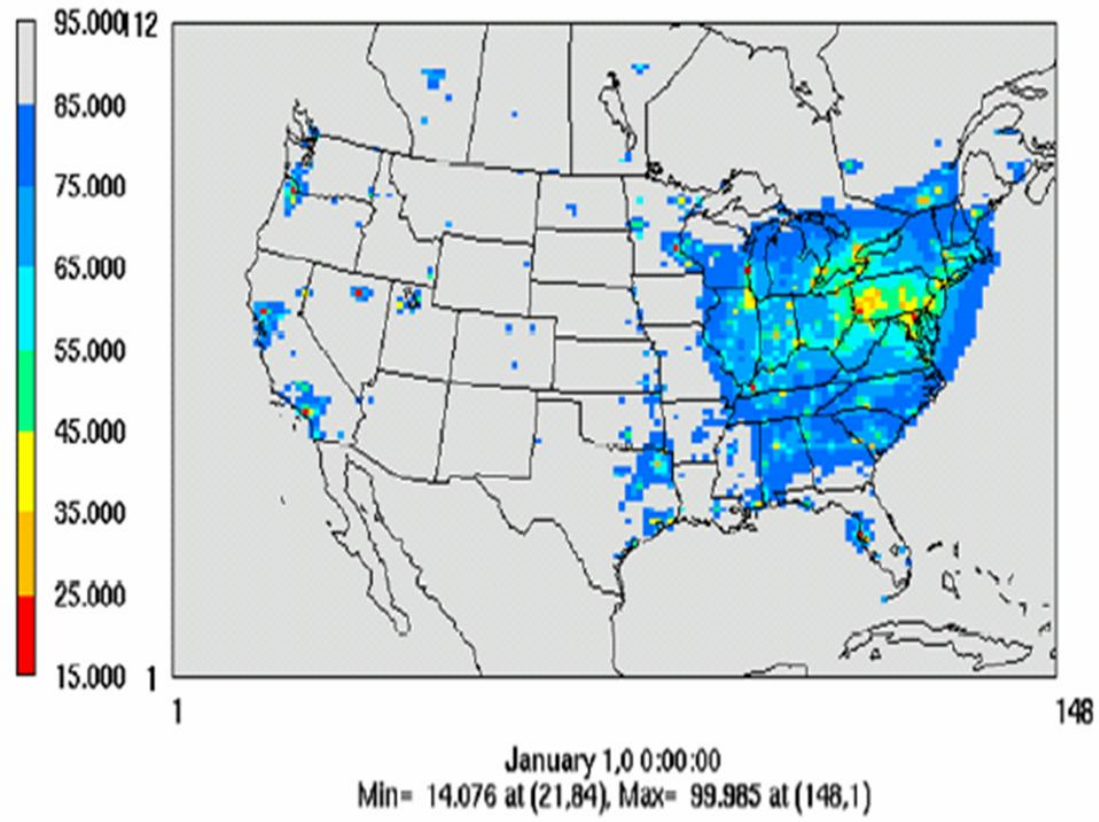

Figure 3. Percentage of total mercury deposition attributable to global sources (USEPA 2005a).

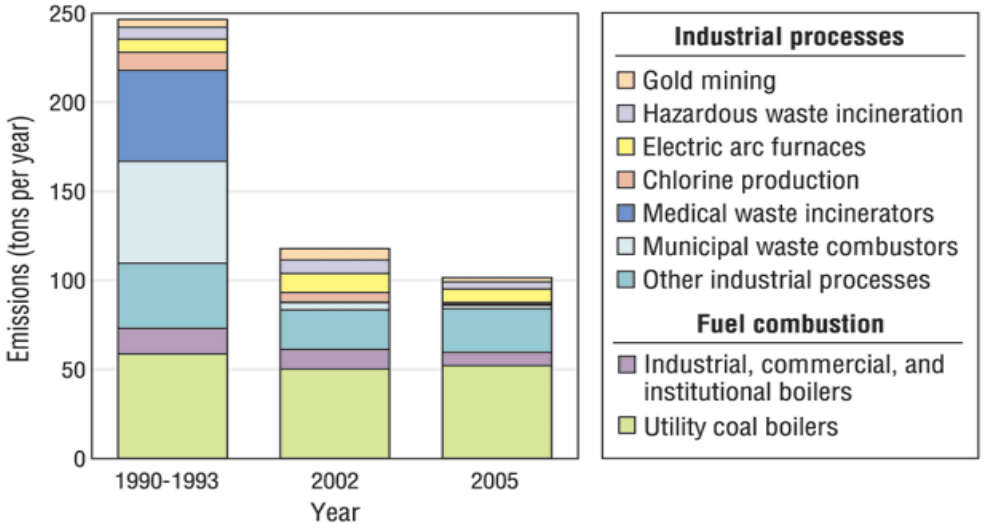
Exhibit 2-39. Mercury emissions in the U.S. by source category, 1990-1993, 2002, and 2005[a,b]



[a]1990-1993 is considered the baseline period for mercury emissions. The baseline period spans multiple years due to the availability of emissions data for various source categories. The data presented for the baseline period are annual emissions (tons per year) and are therefore comparable to the 2002 and 2005 data.

[b]Mercury emissions from mobile sources are not depicted because they have been estimated only for inventory years 2002 (0.8 tons) and 2005 (1.1 tons), not for the baseline period.

Data source: *U.S. EPA, 2009*

Figure 4. Trends in mercury air emissions between 1990 and 2005 (USEPA 2008b).

Additional decreases in mercury air emissions may have occurred since 2005 as the result of EPA's regulatory efforts under the CAA. At the same time, however, global emissions might have increased.

The 2005 National Emissions Inventory (NEI) is EPA's latest comprehensive national emission inventory. It contains emission measurements and estimates for 7 criteria pollutants and 188 hazardous air pollutants (HAPs). The NEI contains emissions for all major contributors to air pollution, including point sources (large industrial sources such as electric utilities and petroleum refineries), mobile sources (both onroad sources such as cars and trucks and nonroad engines such as those in construction equipment and agricultural equipment), and nonpoint sources (small stationary sources such as residential fuel use and various types of fires). The NEI includes emission estimates for the entire United States. For point sources, the NEI inventories emissions for each individual process at an industrial facility. For mobile and nonpoint sources, the NEI contains county-level emission estimates. The NEI is developed using the latest data and best estimation methods, including data from Continuous Emissions Monitors; data collected from all 50 states, as well as many local and tribal air agencies; and data generated using EPA's latest models such as the MOBILE and NONROAD models. More information on the 2005 NEI is at http://www.epa.gov/ttn/chief/net/2005inventory.html.

Some approved mercury TMDLs have identified the types or categories of sources likely to contribute to mercury deposition in a waterbody. An example of this type of source analysis is included in the Savannah River mercury TMDLs issued February 28, 2001, and a series of mercury TMDLs issued February 28, 2002, for a number of watersheds in middle and south Georgia (see http://gaepd.org/Documents/TMDL_page.html). These TMDLs included an analysis of the categories of air sources contributing deposition to the waterbodies and the reductions in loadings expected from controls in place when the TMDL was approved. To estimate the total contributions from air deposition, data from the Mercury Deposition Network (MDN) were used. Modelers also used the existing Regional Langrangian Model of Air Pollution (RELMAP) deposition results developed for the 1997 Mercury Report to Congress to estimate the relative contributions from local sources within a 100-kilometer airshed.

EPA has evaluated water and air deposition modeling tools as part of two mercury TMDL pilot projects in Wisconsin and Florida. In particular, the pilots examined approaches for combining the results of air deposition and water quality modeling, which in turn might be used in a TMDL context. In the Florida pilot, air modelers used a combination of modeling tools to predict the amount of mercury deposition to the study area from local sources in southern Florida. Using the Mercury Cycling Model, aquatic modelers then used results from the atmospheric modeling and other data to examine how mercury levels in fish might respond to reductions in deposition. The Florida pilot report is complete (see ftp://ftp.dep.state.fl.us/pub/labs/assessment/mercury/tmdlreport03.pdf) (Atkeson et al. 2002).

In the Wisconsin pilot project, EPA evaluated modeling tools such as the Regional Modeling System for Aerosols and Deposition (REMSAD) for identifying the sources or categories of sources contributing mercury deposition to a waterbody, as well as how to use the deposition results as input to aquatic models, similar to the approach used in the Florida pilot. REMSAD is a three-dimensional grid model designed to calculate the concentrations of both inert and chemically reactive pollutants by simulating the physical and chemical processes in the atmosphere that affect pollutant concentrations (ICF International 2006). REMSAD simulates both wet and dry deposition of mercury. (See appendix E for further information on REMSAD.) In the Wisconsin pilot, the results of the air deposition modeling were used as input to the Mercury Cycling Model to examine how mercury levels in fish might respond to potential changes in deposition.

Other TMDLs in which the results of REMSAD modeling were used include the mercury TMDL for the Coastal Bays and Gulf Waters of Louisiana approved in 2005. The results of earlier air modeling for the *Mercury Study Report to Congress* were used in the mercury TMDLs for middle and south Georgia approved in 2002 (see Ochlockonee TMDL in appendix D). EPA plans to provide each state or authorized tribe with modeled estimates of mercury deposition from sources within the state or on the tribal land and contributions from sources outside the state or tribe. The modeling results will help EPA and the states and authorized tribes develop TMDLs and determine the appropriate strategies for addressing mercury deposition from sources within their jurisdictions.

Additional tools available for determining mercury deposition loadings include the Community Multi-Scale Air Quality (CMAQ) model. The CMAQ modeling system is a comprehensive, three-dimensional, grid-based Eulerian air quality model designed to

estimate pollutant concentrations and depositions over large spatial scales (Dennis et al. 1996; Byun and Ching 1999; Byun and Schere 2006). The CMAQ model is a publicly available, peer-reviewed, state-of-the-science model with a number of science attributes that are critical for simulating the oxidant precursors and nonlinear chemical relationships associated with mercury formation. Version 4.3 of CMAQ (Bullock and Brehme 2002; Byun and Schere 2006) reflects updates to earlier versions in a number of areas to improve the underlying science and address comments from peer review. Further information on the CMAQ model is provided in appendix E.

As with any analysis based on limited data, uncertainty is inherent in the estimates of all analytical outputs of modeling. Model uncertainty results from the fact that models and their mathematical expressions are simplifications of reality used to approximate real-world conditions, processes, and their relationships. Models do not include all parameters or equations necessary to express real-world conditions because of the inherent complexity of the natural environment and the lack of sufficient data to describe the natural environment. Consequently, models are based on numerous assumptions and simplifications and reflect an incomplete understanding of natural processes. As a result, there will be some uncertainty when using models to quantify the sources of air-deposited mercury.

Other tools available to help states characterize mercury deposition include existing national monitoring networks and modeling tools, such as the MDN. Examples of these tools are provided in appendix F. Published results of national modeling studies could also be available to help estimate atmospheric deposition loadings. Further information on tools and approaches for characterizing atmospheric deposition to waterbodies can be found in the Frequently Asked Questions about Atmospheric Deposition section of EPA's Web site at http://www.epa.gov/oar/oaqps/gr8water/handbook/.

An analysis of deposition should take into account both direct deposition to the waterbody, as well as mercury deposited within the watershed (indirect deposition). In addition, fires, flooding, and other landscape disturbances could re-mobilize mercury previously deposited within the watershed and cause an increase in mercury transported to the waterbody. Studies are underway to examine the extent to which mercury deposited to a watershed is transported to a waterbody. For example, the Mercury Experiment to Assess Atmospheric Loading in Canada and the United States (METAALICUS) project is a mercury loading experiment to examine the timing and magnitude of the relationship between mercury loading to ecosystems and mercury concentrations in fish (Harris et al. 2006). Using stable mercury isotopes, researchers are examining the fate of mercury deposited to uplands, wetlands, and directly to lakes. It is being carried out at the Experimental Lakes Area (ELA) in northwestern Ontario by U.S. and Canadian researchers. A discussion of factors affecting mercury transport and bioavailability is included in chapter 2 of this guidance.

As part of a source evaluation, EPA encourages states to conduct a careful analysis to verify and quantify the contributions of air deposition as compared to other sources. Such information is important for determining the appropriate management approaches. For example, an analysis of the contribution from air sources is the basis for determining whether it may be appropriate to defer TMDLs under the 5m approach, or whether it is more appropriate to develop TMDLs to address significant local sources.

Although not required for a TMDL, states may wish to examine the contributions to the watershed from local air sources within the state as compared to out-of-state sources. Such information provides a basis for determining the appropriate allocations. In turn, such source information can help to develop a meaningful TMDL implementation plan and identify the extent to which state and local programs may be appropriate for addressing the mercury sources.

Metals mining activity. Loadings from metals mining activities might reflect both historical and recent mining activity within the watershed. Mining areas of interest are those involving "placer" deposits, in which mercury itself is present in the ore, or those deposits for which mercury is used to extract other metals such as gold. For example, sulfide replacement deposits are often associated with mercury. Locations at mining sites that might serve as sources of mercury include direct seeps, as well as leachate from tailings or spoil piles. In the Clear Lake TMDL (see appendix E), ground water from an abandoned mining site was reported to contain mercury that is readily methylated. In Clear Lake, acid mine drainage was found to contain high sulfate concentrations, which might enhance methylation by sulfate-reducing bacteria. Sources of data on potential mercury deposits associated with mining activity include USGS, the U.S. Bureau of Mines (for a list of major deposits of gold and silver), the State Inactive Mine Inventory, and the EPA Superfund program. Examples of TMDLs involving mercury associated with mining are provided in appendix E.

Sediments. A TMDL analysis should account for any mercury present in sediments as a result of current and past mercury loadings. Mercury in sediments may be the result of past metals mining activity as described above, past industrial activity, and historical air deposition. Data on levels of mercury in sediments are important in determining which sources are most significant, the most appropriate approach for addressing the sources and how long it will take to achieve water quality standards. For example, development of appropriate allocations, and in turn development of management strategies, may need to address both current sources of deposition as well as legacy sources. An examination of past industrial practices in the watershed could include whether sediments might serve as a reservoir for mercury. Various national databases, such as the National Sediments Database (USEPA 2002g) and data collected by USGS might help to identify isolated locations of elevated mercury in sediments. EPA has also developed a detailed guide on sediment source analysis in the first edition of *Protocol for Developing Sediment TMDLs*: http://www.epa.gov/owow/tmdl/sediment/pdf/sediment.pdf.

In the absence of sediment data for a waterbody, site-specific monitoring might be needed to confirm the levels of mercury in sediments to use as input to water quality models. In the sediment TMDL for Bellingham Bay, Washington, site-specific sediment analyses for mercury and other pollutants were conducted, including sediment sampling and toxicity analyses. Two kinds of modeling were also conducted:

- Modeling of contaminant transport and mixing to determine whether loadings from a location were contributing to water quality standards violations
- Screening modeling to identify other potential sources of sediment contamination (see the TMDL at http://www.epa.gov/waters/tmdldocs/1991_Bellingham%20Bay%20TMDL.pdf)

Other examples of TMDLs involving an analysis of mercury contributions from sediments include the TMDLs for Pena Blanca, Arizona, and the Cache Creek watershed in California (see appendix D). As described in the section on allocations, the Cache Creek watershed TMDL also accounts for methylmercury production in sediments.

Natural or background levels of mercury in soils. Soils and sediments can include mercury of geologic origin or mercury produced by the weathering of geologic materials, together with mercury of anthropogenic origin (mercury emitted over time from human sources and then deposited on soils). Mercury in soils can also re-emit or become re-suspended and subsequently redeposit to soils. Local studies have been used in some TMDLs to estimate the geologic contributions of mercury to waterbodies. For example, a TMDL developed for the Ouachita watershed in Arkansas relied on a study of mercury concentrations in the rocks of the Ouachita Mountains (FTN 2002). The mercury concentration estimated to be of geologic origin was then subtracted from the total concentration of mercury measured in soils to estimate the nongeologic concentration of mercury in soils.

6.2.2.2 What modeling tools are available to link mercury sources and water quality?

When developing a TMDL, states and authorized tribes should characterize the association between the concentration of methylmercury in fish tissue and the identified sources of mercury in a watershed. The association is defined as the cause-and-effect relationship between the selected targets, in this case the fish tissue-based criterion and the sources. The association provides the basis for estimating the total assimilative capacity of the waterbody and any needed load reductions. TMDLs for mercury typically link models of atmospheric deposition, watershed loading, and mercury cycling with bioaccumulation. For example, a watershed model (e.g., Grid Based Watershed Mercury Model, GBMM) might be linked with a receiving water mercury model (e.g., Water Quality Analysis Simulation Program, WASP) and a bioaccumulation model (e.g., Bioaccumulation and Aquatic Simulator, BASS). These models are described further in appendix E. Linking models together can enable a translation between the endpoint for the TMDL (expressed as a fish tissue concentration of methylmercury) and the mercury loads to the water without having explicit water column criteria or translations. The analysis determines the loading capacity as a mercury loading rate consistent with meeting the endpoint fish tissue concentration. This section describes some of the modeling tools available for use in mercury TMDLs.

When selecting a model or models for developing a mercury TMDL, states and authorized tribes should first consider whether the models will effectively simulate the management action(s) under consideration. If a percent reduction in mercury load to the waterbody is the sole action considered, a simple model might suffice; to answer more complex questions, a more complex or detailed model might be needed. Some questions decision makers should address include:

- How much do specific mercury loads need to be reduced to meet the criterion?
- What are the relative sources of the mercury load to the segment?

- Are mercury loads to the waterbody from sediments and watershed runoff and concentrations in fish at equilibrium with respect to current deposition levels? If not, how much will an equilibrium assumption affect the accuracy of predicted future fish concentrations?
- Could other pollution-control activities reduce mercury loads to the waterbody or affect the mercury bioaccumulation rate?
- After regulatory controls are implemented, how long will it take for fish tissue levels to meet the criterion?

Depending on the types of questions states and authorized tribes ask and the management approaches they consider, appropriate models could range from a very simple steady state model to a comprehensive dynamic simulation model, as described below. In addition, models are often used in TMDL analyses but are not required. For more information on the specific models described here, see http://www.epa.gov/athens and http://www.epa.gov/crem.

6.2.2.2.1 Steady state models and the proportionality approach

Steady state modeling describes the dynamic equilibrium between environmental media established in response to constant loads over the long term. Consequently, complex mercury cycling processes can be compressed into simple equations. One such approach, assumes that a ratio of current to future fish tissue concentration equals the ratio of current to future mercury loads to the waterbody. This approach, often referred to as the proportionality approach and explained in detail in the Mercury Maps report (USEPA 2001b), assumes that where air deposition is the sole significant source, factors affecting methylation remain unchanged. As a result, the ratio of current to future fish tissue concentrations can be assumed to equal the ratio of current to future air deposition loads in this situation. Mercury Maps, and the situations in which the proportionality assumption may or may not apply, are described further in appendix E.

A number of mercury TMDLs where air deposition is the predominant mercury source have been developed using an assumption of proportionality between mercury deposition and fish tissue methylmercury concentration. Specifically, such TMDLs have reasoned that a reduction in deposition will result in a proportional reduction in mercury concentrations in fish over time. Such an approach applies to situations where air deposition is the only significant mercury source and relies on steady-state conditions. This approach may also be used to estimate the reductions needed to meet a fish tissue target without necessarily calculating a water column target.

Mercury TMDLs which applied a proportional relationship between reductions in deposition and reductions in fish tissue methylmercury concentration include TMDLs for waterbodies in Louisiana, such as the Ouachita Basin (FTN 2002), the Mermentau and Vermillion-Teche River Basins (USEPA 2001i, 2001j) and the Coastal Bays and Gulf Waters of Louisiana (Parsons 2005). Using the Everglades Mercury Cycling Model, the pilot mercury TMDL study in the Florida Everglades also reported a linear relationship between mercury deposition and the concentrations of mercury in largemouth bass (Atkeson et al. 2002).

More recently, the Minnesota statewide mercury TMDL applied the proportionality approach. As described in section 6.2.1 above, waterbodies within the state were grouped into two regions, and a TMDL developed for each region. Minnesota calculated a reduction factor for each region, or the percent reduction in total mercury load needed in each region to achieve the fish tissue target of 0.2 mg/kg for the 90th percentile of the standard-length fish (MPCA 2007). Using the proportionality assumption, Minnesota applied the regional reduction factor (51 percent for the southwest region and 65 percent for the northeast region) to the total source loadings to determine the load reduction goal. The Minnesota TMDL explains in further detail the basis for using the proportionality approach.

Mass balance models are somewhat more complex implementations of the steady state approach. In place of a simple ratio, such models describe fluxes of mercury in and out of the model domain (e.g., impaired segment) and, optionally, balance fluxes (e.g., methylation and demethylation) within the model domain. The advantage provided by this approach is that individual fate processes can also be simulated. For example, if soil erosion and sediment runoff are modeled, decreased mercury soil erosion load can be related to decreased fish tissue concentrations (AZDEQ 1999). Where all other aspects of a watershed and waterbody remain unchanged, steady state models can produce as accurate an estimate of the necessary load reductions as a dynamic model, generally with less-intensive data collection and analysis. In addition, such simple approaches might be less prone to calculation error and are much easier for the public to understand.

6.2.2.2.2 Continuous-simulation and dynamic models

Continuous-simulation and dynamic models take into account time-varying effects such as variable pollutant inputs, precipitation, hydrologic responses, seasonal ecosystem changes, and effects on fish tissue concentrations. For mercury, they might also include a variety of physical and chemical fate and transport processes such as oxidation, demethylation, volatilization, sedimentation, resuspension, and adsorption and desorption. Dynamic models can be important in establishing cause-and-effect relationships. They assemble available scientific knowledge on mercury fate and transport into a single picture. Such models have been used to demonstrate how mercury moves from air emission to deposition to watershed runoff to subsequent bioaccumulation in fish at observed levels in remote waterbodies (USEPA 1997c).

Dynamic models could be used to describe waterbodies in dis-equilibrium (e.g., a recent surface water impoundment with elevated methylation rates). The Everglades Mercury TMDL pilot project (USEPA 2000g) simulated the amount of time necessary to attain equilibrium in response to reduced mercury loads using the Everglades Mercury Cycling Model. The model results predicted that sediments would continue to supply as much as 5 percent of the mercury load 100 years after air deposition reductions occurred. The Dynamic Mercury Cycling Model (D-MCM) was used in the mercury TMDLs for McPhee and Narraguinnep reservoirs in Colorado and the TMDLs for Arivaca and Pena Blanca lakes in Arizona (see appendix D) (Tetra Tech 2001).

The SERAFM model incorporates more recent advances in scientific understanding and implements an updated set of the IEM-2M solids and mercury fate algorithms described in the 1997 *Mercury Study Report to Congress* (USEPA 1997c).

Dynamic models can also describe how fish tissue concentrations are expected to respond to environmental variability, such as seasonal or year-to-year changes in meteorology. Thus, they can be used to better interpret how samples collected in a specific season of a specific year would be expected to vary relative to other seasons or years with mercury loads being constant.

6.2.2.2.3 Spatially detailed models

Spatially detailed models, such as that used in the Savannah River mercury TMDL (USEPA 2001j), can demonstrate how mercury fish tissue concentrations are expected to vary with distance downstream of the impaired segment(s). For the Savannah River, EPA used the Water Quality Analysis Simulation Program (WASP) model. WASP is a dynamic, mass balance framework for modeling contaminant fate and transport in surface water systems. The model helps users interpret and predict water quality responses to natural phenomena and man-made pollution for various pollution management decisions. Another model that has been used for mercury TMDLs is the EPA Region 4 Watershed Characterization System (WCS). WCS is a geographic information system (GIS)-based modeling system for calculating soil particle transport and pollutant fate in watersheds (Greenfield et al. 2002).

As with the steady state mass balance model, including additional processes can allow a modeler to determine the impact of different environmental regulatory or management controls on mercury fish tissue concentrations. For example, where mercury transport to a waterbody occurs predominantly through soil erosion, erosion control might be identified as a useful nonpoint source control on mercury to waterbodies (Balogh et al. 1998). As another example, controls on acid deposition and, thus, changes in lake pH and their effect on fish tissue mercury concentrations can also be modeled (Gilmour and Henry 1991, Hrabik and Watras 2002). Finally, spatially detailed landscape models hypothetically could be used to reflect the local effects of wetlands and their impacts on mercury methylation rates.

6.2.2.2.4 Regression models

In general, a regression model is a statistical model describing how a parameter, such as mercury levels in fish, is related to one or more variables. Regression models provide only approximations of real trends.

One example of a regression model for mercury is the regression-based model under development for New England. The model, known as MERGANSER (Mercury Geospatial Assessments for the New England Region), is being developed by EPA and several partners. The partners include USGS, the Biodiversity Research Institute, the State of Vermont, the Clean Air Association of the Northeast States, and the New England Interstate Water Pollution Control Commission. The model will integrate recent atmospheric mercury-deposition models with many databases on mercury sources, mercury levels in fish and bird tissue, and ecosystem features that might be associated with the risk of mercury contamination in biota and, ultimately, humans.

The intent of the project is to identify, by using regression modeling, explanatory variables that contribute to elevated mercury levels in fish and wildlife in New England. The model can then be applied in a predictive mode to lakes throughout New England

that have no mercury fish tissue or loon blood data. Specifically, the model will (1) identify watershed and other factors associated with high mercury levels in fish and wildlife; (2) identify likely sources of mercury; (3) provide estimates of mercury levels in fish and wildlife at any lake or stream in New England; (4) provide estimates of mercury reductions needed from air deposition to meet water-quality criteria; and (5) identify optimal locations for long-term monitoring. Modeling will be done within a GIS environment so that the spatial distribution of data is retained and results can be displayed watershed by watershed. Maps from MERGANSER will show the areas in New England that are susceptible to high mercury levels in biota and that are, therefore, areas where human health impacts (through fish consumption) and ecological impacts (bird tissue mercury levels) are potentially occurring. In addition, the model can be used to produce maps that identify mercury sources and show the relative magnitude of mercury loading from those sources.

6.2.2.2.5 Model selection

When selecting a model, a state or authorized tribe should be aware of the assumptions inherent in each type of model and consider the potential effects of those assumptions on relationships between loadings and fish tissue levels or water quality. The first consideration for model assumptions is methylation. Several factors, including pH, redox, potential sulfate concentrations, temperature, dissolved organic carbon (DOC) concentrations, salinity, and microbial populations, influence the speciation of mercury (Ullrich et al. 2001). If these factors fluctuate seasonally around an average condition, a waterbody could be at a dynamic equilibrium and the steady state assumption would still apply over the long term. If these factors change over time such that they might have a significant impact on fish tissue concentrations, the equilibrium assumptions inherent in steady state modeling might not hold, and a dynamic model like the D-MCM (EPRI 1999) should be used. In using this model, the state or authorized tribe should consider the amount of environmental media concentration data needed to initialize the model to represent its non-equilibrium state.

The second consideration for model assumptions is the BAF. As discussed in section 3.1.3.1, the BAF assumes a constant proportionality between fish tissue methylmercury concentrations, water column methylmercury concentrations, and water column mercury concentrations. Mercury in a waterbody might not be at a steady state because of ongoing reductions in mercury emissions, changes in water chemistry that affect methylation, changes in aquatic ecosystem makeup, or changes in fish biomass. If these factors change with time, the equilibrium assumptions inherent in steady state modeling might not hold, and a dynamic model should be used.

The third consideration for model assumptions is the relative importance of the mercury in aquatic sediments to the concentrations in fish tissue. Depending on previous loadings to the watershed, the deposition pattern of solids, and the chemistry in the aquatic sediments, the mercury in sediments can significantly influence the mercury concentrations in fish tissue. Sediments are repositories, and the loading that caused sediment mercury could be a legacy source. If so, a simplified steady state approach cannot simulate changes in mercury concentrations in fish tissue due to external loading reductions, and a dynamic model should be used.

6.2.2.2.6 Model limitations

To effectively estimate fish methylmercury concentrations in an ecosystem, it is important to understand that the behavior of mercury in aquatic ecosystems is a complex function of the chemistry, biology, and physical dynamics of different ecosystems. The majority (95 to 97 percent) of the mercury that enters lakes, rivers, and estuaries from direct atmospheric deposition is in an inorganic form (Lin and Pehkonen 1999). Microbes convert a small fraction of the pool of inorganic mercury in the water and sediments of these ecosystems into methylmercury. Methylmercury is the only form of mercury that biomagnifies in organisms (Bloom 1992). Ecosystem-specific factors that affect both the bioavailability of inorganic mercury to methylating microbes (e.g., sulfate, DOC) and the activity of the microbes themselves (e.g., temperature, organic carbon, redox status) determine the rate of methylmercury production and subsequent accumulation in fish (Benoit et al. 2003). The extent of methylmercury bioaccumulation is also affected by the number of trophic levels in the food web (e.g., piscivorous fish populations) because methylmercury biomagnifies as large piscivorous fish eat smaller organisms (Watras and Bloom 1992; Wren and MacCrimmon 1986). These and other factors can result in considerable variability in fish methylmercury levels among ecosystems at the regional and local scales.

The lack of complete knowledge about key mercury process variables, such as the functional form of equations used to quantify methylation rate constants, is a major contributor to overall uncertainty in models that cannot be quantified at this time.

6.2.2.3 What are the allocation approaches in mercury TMDLs?

A requirement for an approvable TMDL is that the state or authorized tribe allocate the pollutant load necessary to achieve water quality standards among point and nonpoint sources. EPA's regulations, however, leave the decision regarding how to allocate loadings to the state or authorized tribe developing the TMDL. States and authorized tribes have discretion in selecting a method or system for allocating pollutant loads among sources, provided that the allocations will result in attainment of water quality standards represented by the loading capacity (40 CFR 130.2). States and authorized tribes could reasonably consider the relative contribution of each source as one factor in developing allocations. Other factors might include cost-effectiveness, technical and programmatic feasibility, previous experience with the approach being considered, likelihood of implementation, and past commitments to load reductions. These same considerations apply to mercury TMDLs.

A number of pollutant loading and allocation scenarios have occurred in mercury TMDLs, each with a different mix of point and nonpoint sources. The scenarios have ranged from situations where mercury loadings are predominantly from air deposition, with small loadings from point sources or other sources, to situations where mercury loadings are predominantly from past mining activity. In addition, allocation approaches in mercury TMDLs have included allocations to individual sources as well as allocations to sectors and regions where appropriate. Examples of scenarios involving different source mixes and allocation approaches in approved mercury TMDLs are provided below.

Mercury loadings predominantly from air deposition, with very small loadings from point sources or other sources

Contributions from air deposition, such as direct deposition to the waterbody and deposition to the watershed transported to the waterbody by runoff and erosion, are typically included as part of the load allocation. As discussed in EPA guidance on reviewing TMDLs, allocations for nonpoint sources may range from reasonably accurate estimates to gross allotments (USEPA 2002f). TMDLs where air deposition is the predominant mercury source have usually allocated only a small portion of the reductions to the point sources or wasteload allocation, as described in the examples below. Many mercury TMDLs have included an allocation to air deposition as a whole; in some mercury TMDLs, the contributions from air deposition are further allocated to within-state and out-of-state sources, and contributions from anthropogenic and natural contributions are distinguished.

The Savannah River mercury TMDL is one of the first examples of an approach to allocating loadings where the predominant mercury source is atmospheric deposition. Many of the TMDLs developed to date are for situations where air deposition is the predominant mercury source. The Savannah River mercury TMDL indicated that NPDES point sources contribute 1 percent of the mercury loadings, while atmospheric deposition contributes 99 percent of the loadings. The TMDL identified only one point source on the Georgia side of the river that has a permit to discharge mercury to the Savannah River. It identified 28 point sources in Georgia that might have the potential to discharge larger amounts of mercury in their effluent according to the nature of the discharge or the mercury levels that have been found in their effluents above the water quality standard level.

The Savannah River mercury TMDL assigned 99 percent of the load reductions to the air sources and 1 percent of the reductions to point sources. The TMDL provides specific wasteload allocations for these 28 sources on the basis of meeting the water quality criterion at the end of a pipe or, alternatively, implementing a pollutant minimization program. In addition, the TMDL identifies about 50 other point sources expected, on the basis of their size and nature, to discharge mercury at levels below the water quality standard or not add mercury in concentrations above the concentrations in their intake water. Individual wasteload allocations are given to these point sources on the basis of their holding their effluents at current levels. The wasteload allocations for these point sources are expressed in the TMDL as a sum or aggregate allocation.

Note: After the Savannah River mercury TMDL was issued, Georgia adopted a new interpretation of its narrative water quality criteria that used EPA's new recommended fish tissue criterion for methylmercury. On the basis of the new interpretation, Georgia determined, and EPA agreed, that the Savannah River was meeting water quality standards for mercury. EPA therefore withdrew the TMDL. EPA believes, however, that the decisions, policies, and interpretations set forth in the TMDL are still valid and provide an example of a possible approach to mercury TMDLs. The Savannah River mercury TMDL is at http://www.gaepd.org/Files_PDF/techguide/wpb/TMDL/Savannah/EPA_Savannah_River_Watershed_Hg_TMDL.pdf.

The series of mercury TMDLs issued February 28, 2002, for watersheds in middle and south Georgia, such as the Ochlockonee watershed, also illustrate the first scenario. In

these basins, point source loadings contribute very little to the mercury loadings (the cumulative loading of mercury from all point sources is less than 1 percent of the total estimated current loading), with the vast majority of loading to the basins as air deposition.

The Ochlockonee mercury TMDL assigns most of the load reductions to the air sources, with a load allocation of 1.16 kg/yr and a wasteload allocation of 0.06 kg/yr. Although point sources collectively contribute a very minute share of the mercury load, the Ochlockonee and other mercury TMDLs for middle and south Georgia include wasteload allocations for the point sources. The TMDLs include wasteload allocations for each facility identified as a significant discharger of mercury, with the remainder of the allocation assigned collectively to the remaining point sources, considering that these smaller point sources would reduce their mercury loadings using appropriate, cost-effective minimization measures. The TMDL was written so that all NPDES-permitted facilities would achieve the wasteload allocation through discharging mercury at concentrations below the applicable water quality standard or through implementing a pollutant minimization program. A summary of the Ochlockonee mercury TMDL is provided in appendix D and is at http://gaepd.org/Files_PDF/techguide/wpb/TMDL/Ochlockonee/EPA_Ochlockonee_River_Hg_TMDL.pdf.

The Minnesota "statewide" mercury TMDL document takes a regional approach to allocations, providing a single wasteload allocation and a single load allocation that applies to each region rather than to individual waterbodies. The TMDL document indicates that such a regional allocation serves as a regional "cap." The predominant source is atmospheric deposition, with a small contribution (about 1.2 percent of the total source load for both regions combined) from point sources. The wasteload allocation is set at 1 percent of the TMDL or the 1990 baseline load, whichever is lower, with the remainder allocated to nonpoint sources. Point sources, including NPDES-permitted stormwater sources, municipal treatment facilities, and industrial dischargers that impact the waterbodies covered by the TMDL, are subject to the wasteload allocation. For the load allocation, the Minnesota TMDL estimates the contributions to air deposition from within-state and out-of state sources, as well as from global sources and anthropogenic sources. A summary of the Minnesota mercury TMDL is included in appendix D. The TMDL and related documents can be found at http://www.pca.state.mn.us/water/tmdl/tmdl-mercuryplan.html.

Mercury loadings predominantly from past mining activity, with small or no contributions from atmospheric deposition and/or NPDES point source contributions

One example of a TMDL for this scenario is the Cache Creek Watershed TMDL. Cache Creek is a tributary to the Sacramento-San Joaquin Delta in California. Sources of mercury entering the Cache Creek watershed include leaching from waste rock and tailings from historical mercury and gold mines, erosion of naturally mercury-enriched soils, geothermal springs, and atmospheric deposition. There are multiple inactive mercury and gold mines in the Cache Creek watershed and no NPDES-permitted discharges. Methylmercury is also produced *in situ* in the streambed of Cache Creek. The TMDL analysis provides load allocations for Cache Creek, as well as each of the tributaries. For each waterbody, load reductions are provided for both methylmercury and total mercury. Allocations are expressed as a percentage of the existing methylmercury

loads. Estimated atmospheric contributions of mercury, from direct deposition and runoff after deposition, are very small compared to loads of mercury from mine sites or erosion of the stream bed and banks, and thus no allocations are made to air deposition. Reducing the methylmercury loads will require a multifaceted approach that includes controlling inorganic mercury loads and limiting the entry of inorganic mercury into sites with high rates of methylmercury production. The Cache Creek watershed mercury TMDL and the allocation approach are summarized further in appendix D.

Mercury loadings from a combination of different sources, including atmospheric deposition, past mining, and point sources

The Mercury TMDL for the Willamette Basin, Oregon, identifies atmospheric deposition (direct plus indirect deposition: 47.7 percent) and erosion of mercury-containing soils (47.8 percent) as the top sources, along with small contributions from legacy mining (0.6 percent) and NPDES-permitted point sources (3.9 percent). The point source loadings consist of 2.7 percent from POTWs and 1.2 percent from industrial discharges. The TMDL assigns interim allocations to each of the source categories or sectors, rather than individual sources, based on the considerable uncertainty in the loading estimates and other factors. The TMDL specifies an across-the-board reduction of 27 percent in each source. After the 27 percent reduction to each source, the allocations for the Willamette mainstem are approximately similar to their relative contribution to the total loadings: 44.7 kg/yr for air deposition, 44.8 kg/yr for erosion, 0.6 kg/yr for legacy mine discharges, 2.6 kg/yr for POTWs, 1.1 kg/yr for industrial discharges, and 0.8 kg/yr for reserved capacity. Allocations are also provided for other waterbodies in the basin. The TMDL is at http://www.deq.state.or.us/wq/tmdls/docs/willamettebasin/willamette/chpt3mercury.pdf.

Mercury loadings from point sources predominate or are not insignificant compared to other sources

A small number of approved TMDLs have been developed for situations where mercury is primarily or exclusively from point sources, including TMDLs for waterbodies in Colorado. Examples of such TMDLs can be found at http://iaspub.epa.gov/tmdl_waters10/attains_impaired_waters.control?p_state=CO&p_pollutant_id=693.

6.2.2.4 What kinds of monitoring provisions have been associated with approved TMDLs?

Monitoring provisions in approved TMDLs have included point source effluent and influent monitoring, as well as water column, fish tissue, sediment, and air deposition monitoring. Examples of mercury TMDLs with post-TMDL monitoring are the middle and south Georgia mercury TMDLs approved in 2002. For facilities with the potential to discharge significant amounts of mercury on the basis of their large flow volume or other factors, the TMDL provides the permitting authority with two options for the wasteload allocation:

- Implement the criteria-end-of-pipe (i.e., apply the TMDL water quality target to a discharger's effluent at the outfall point).
- Monitor for mercury in the facilities' influent and effluent using more sensitive analytical techniques (e.g., EPA method 1631) and implement cost-effective mercury minimization if mercury is present in effluent at concentrations greater

than source water concentrations and if the discharge exceeds the water quality target.

Other facilities expected to discharge at levels below the water quality target will be expected to verify through monitoring whether or not they are significant dischargers of mercury. Other follow-up activities include further characterization of the air sources and additional ambient monitoring of mercury concentrations in water, sediment, and fish.

The mercury TMDL for the coastal bays and gulf waters of Louisiana (approved July 2005) includes similar monitoring provisions for point source dischargers with flows above a specified discharge volume. The TMDL also indicates that Louisiana will conduct water, fish tissue, and air deposition monitoring and that the state will develop a statewide mercury risk reduction program, including an assessment of all mercury sources. (See the TMDL and supporting documents at http://iaspub.epa.gov/tmdl/waters_list.tmdl_report?p_tmdl_id=11642.)

TMDLs involving past mining activity have also included follow-up monitoring; examples include three of the TMDLs described in appendix D (Clear Lake, California; Arivaca Lake, Arizona; and Cache Creek, California). The mercury TMDL for Arivaca Lake lists several follow-up actions and monitoring activities, such as additional watershed investigations to identify other potential mine-related mercury sources, including sediment sampling; evaluation of livestock BMPs to reduce erosion of soils containing mercury and follow-up monitoring; and fish tissue monitoring to evaluate progress toward the TMDL target (see the TMDL at http://www.epa.gov/waters/tmdldocs/17.pdf). The Clear Lake, California, mercury TMDL also identifies the need for follow-up monitoring of fish tissue and sediment (see appendix D, and the TMDL at http://www.swrcb.ca.gov/rwqcb5/water_issues/tmdl/central_valley_projects/clear_lake_hg/cl_final_tmdl.pdf. The Cache Creek TMDL indicates that monitoring will be conducted to determine whether mercury loads have been reduced and to measure progress toward the TMDL target, as well as to better characterize areas of methylmercury production and mercury loadings from tributaries. Monitoring will include fish tissue, sediment, and water monitoring.

EPA recommends that states and authorized tribes periodically review TMDLs during implementation to ensure that progress is being made toward achieving water quality standards. Such “adaptive implementation” provides the flexibility to refine and improve a TMDL as data on the success of implementation activities are collected. States may refine information on the contributions from sources such as runoff from abandoned mining sites, sediment loading of mercury-laden sediments, and air deposition as data and modeling tools improve. States should consider the application of adaptive implementation in determining load allocations for these sources. Although a monitoring plan is not required in a TMDL, EPA guidance documents recommend using a monitoring plan to track the effectiveness of a TMDL; see *Guidance for Water Quality-Based Decisions: the TMDL Process* (EPA 440/4-91-001). Post-TMDL monitoring is an important tool for evaluating implementation success and, if necessary, refining the TMDL. Follow-up monitoring may include monitoring of water quality, fish tissue, air deposition, and sediments.

7 National Pollutant Discharge Elimination System (NPDES) Implementation Procedures

7.1 What are the general considerations in NPDES permitting?

Section 301(a) of the CWA prohibits the discharge of any pollutant, including mercury, from a point source into waters of the United States except in compliance with certain enumerated provisions of the CWA, among them section 402. CWA section 402 establishes the NPDES program, under which EPA or states and tribes authorized to administer the program issue permits that allow the discharge of pollutants into waters of the United States, notwithstanding the general prohibition established by section 301(a). These permits must contain (1) technology-based effluent limitations, which represent the degree of control that can be achieved by point sources using various levels of pollution control technology (see CWA sections 301, 304, and 306) and (2) more stringent limitations, commonly known as water quality-based effluent limitations (WQBELs), when necessary to ensure that the receiving waters achieve applicable water quality standards (see CWA section 301(b)(1)(C)).[20]

Most WQBELs are expressed as numeric limits on the amounts of specified pollutants that may be discharged. However, WQBELs may also be expressed in narrative form such as best management practices (BMPs) or pollutant minimization measures (e.g., practices or procedures that a facility follows to reduce pollutants to waters of the United States) when it is infeasible to calculate a numeric limit (see 40 CFR 122.44(k)(3)). In addition, BMPs may be imposed in the form of NPDES permit conditions to supplement numeric effluent limitations when the permitting authority determines that such requirements are necessary to carry out the purposes and intent of the CWA (see CWA section 402(a)(1)(B) and 40 CFR 122.44(k)(4)).

As noted above, NPDES permits must contain WQBELs when necessary to achieve applicable water quality standards. The procedure for determining the need for WQBELs is called a "reasonable potential" analysis. Under EPA's regulations at 40 CFR 122.44(d)(1)(i), effluent limitations must control all pollutants that the permitting authority determines "are or may be discharged at a level that will cause, have the reasonable potential to cause, or contribute to an exceedance of any applicable water quality standard." Thus, if a pollutant discharge has the reasonable potential to cause or contribute to an exceedance of applicable water quality standards, the discharger's NPDES permit must contain a WQBEL for that pollutant (see 40 CFR 122.44(d)(1)(iii)–(vi)). The procedure for determining reasonable potential must consider the variability of the pollutant in the effluent, other loading sources, and dilution (when allowed by the water quality standards) (see 40 CFR 122.44(d)(1)(ii)). The procedure specifies only

[20] When developing WQBELs, the permitting authority must ensure that the level of water quality achieved by such limits derives from and complies with water quality standards (see 40 CFR 122.44(d)(1)(vii)(A)).

whether a discharge must have a WQBEL; it does not specify the actual permit limits. The NPDES regulations at 40 CFR 122.44(d)(1)(vii) specify that the level of water quality to be achieved by the WQBEL must derive from and comply with water quality standards, as required by CWA section 301(b)(1)(C) (requiring "any more stringent limitation… necessary to meet water quality standards"). This would necessarily be a permit-by-permit determination.

7.2 What is the EPA-recommended NPDES permitting approach for methylmercury?

The recommendations below assume that an approved TMDL is not available at the time of permit issuance. If EPA has approved or established a TMDL containing wasteload allocations for the discharge of mercury (and methylmercury where appropriate), the WQBEL for that discharge must be consistent with the wasteload allocation (see 40 CFR 122.44(d)(1)(vii)(B)).

EPA believes, depending on the particular facts, that a permit writer may reasonably conclude that limits on point sources consistent with this guidance are likely to be as stringent as necessary to achieve water quality standards. As described in more detail below, the permit writer should conduct a reasonable potential analysis to determine whether a discharger will cause or contribute to the exceedance of applicable water quality standards. Once such a determination is made, limits can be imposed consistent with this guidance. In circumstances where waters are not yet impaired, the permit writer should consider other factors or conditions when determining whether a facility has reasonable potential with the goal of preventing future impairments. (See Sections 7.2.2, 7.5.1.2.2 and 7.5.1.2.3).

7.2.1 Developing NPDES permit limits based on the fish tissue criterion

The first component of the recommended NPDES permitting approach for methylmercury is to determine how the methylmercury criterion is expressed in the applicable water quality standard and to determine whether a water column translation of the fish tissue criterion or site-specific data to translate are available at the time of permit issuance. This will inform the selection of the appropriate recommended implementation option. If the methylmercury criterion is expressed as a water column value, the permit writer should develop permit limits based on this criterion according to procedures described in section 5.4.4 of the *Technical Support Document for Water Quality-based Toxics Control*, or TSD (USEPA 1991). If the criterion is expressed as a fish tissue value and a water column translation of the fish tissue criterion or site-specific data to translate are available at the time of permit issuance, the permit limits based on the translated water concentration value should again be developed according to procedures described in section 5.4.4 of the TSD.

If, however, the criterion is expressed as a fish tissue value and a water column translation of the fish tissue criterion or site-specific data to translate are not available at the time of permit issuance, the permitting authority may reasonably conclude that a numeric WQBEL is infeasible to calculate. In that instance, EPA recommends that the permitting authority develop NPDES permit limits based on the criterion using the

procedures described below. Section 7.3 contains additional information about expressing and developing permit limits based on the methylmercury criterion.

7.2.2 Determining reasonable potential

The second component of the recommended NPDES permitting approach for methylmercury is to conduct a reasonable potential analysis to determine whether the discharge will cause or contribute to an exceedance of applicable water quality standards. The recommended reasonable potential analysis consists of two steps. Step one is to determine whether there is a quantifiable amount of mercury in the discharge using a sufficiently sensitive analytical method (see sections 7.4 and 7.5.1.1 for more information on sufficiently sensitive methods.) If this information is unknown, EPA recommends including a monitoring requirement in the permit to collect this information and a reopener clause to allow establishment of appropriate requirements if the permitting authority determines that the discharge has reasonable potential. If, using a sufficiently sensitive analytical method, there is not a quantifiable amount of mercury in the discharge, depending on the particular facts, the permitting authority may reasonably conclude that the discharge does not have reasonable potential and that no water quality-based limits are necessary. If there is a quantifiable amount of mercury, however, the permitting authority should move to step two of the reasonable potential analysis. Section 7.5.1.1 contains additional information on step one of the reasonable potential analysis.

Step two of the reasonable potential analysis is to determine whether the fish tissue concentration of methylmercury in the receiving water is close to or exceeds the criterion.

If the fish tissue concentration of methylmercury in the receiving water is below and not close to the criterion, depending on the particular facts, the permitting authority may reasonably conclude that the discharge does not have reasonable potential, but tier 2 antidegradation provisions should be considered. This situation is described below in the third component of the NPDES permitting approach.

If the fish tissue concentration of methylmercury in the receiving water is close to or exceeds the criterion, depending on the particular facts, the permitting authority may reasonably conclude that the discharger has reasonable potential, and a WQBEL must be included in the permit. Recommended WQBELs for this situation are described below in the fourth component of the NPDES permitting approach. Section 7.5.1.2 contains additional information on step two of the reasonable potential analysis. If information for step two is unknown, EPA recommends including in the permit a special permit condition to conduct a fish tissue survey of the receiving waterbody and a reopener clause so that reasonable potential can be determined when the fish tissue data become available. EPA further recommends that in this situation the permitting authority encourage permittees to develop and implement mercury minimization plans (MMPs) to reduce mercury loading to the waterbody.

In order to prevent future impairments, EPA recommends that a state or authorized tribe consider other factors or conditions such as rising fish tissue concentrations or the relative contribution of mercury or methylmercury from the source when determining whether a facility has reasonable potential in waters that are not yet impaired. Section

7.5.1.2.2 contains additional examples of other factors, such as downstream impacts, that should be considered in a reasonable potential analysis.

7.2.3 Implementing antidegradation

The third component of the recommended NPDES permitting approach for methylmercury is to determine whether the discharger will undertake an activity that can increase mercury loading to the waterbody. If the discharger will not undertake such an activity, no additional permit conditions are necessary. EPA recommends, however, that in this situation the facility voluntarily develop and implement an MMP to reduce the facility's mercury loading to the receiving water. If the discharger will undertake such an activity, EPA recommends that a tier 2 antidegradation analysis be conducted in accordance with the state or tribe's antidegradation policy and that permit conditions consistent with the analysis be included in the permit.

As part of conducting a tier 2 antidegradation analysis, the state or authorized tribe would evaluate the activity's potential to lower water quality, whether there are alternatives that would avoid lowering water quality, and whether lowering of water quality would be necessary to accommodate important economic or social development in the area of the discharge. EPA considers analyses of potential pollution prevention and enhanced treatment alternatives as an appropriate starting point for the antidegradation review for both industrial and municipal dischargers. See 67 FR 68971, 68979. The results of such an analysis of potential alternatives could provide the basis for developing an MMP.

EPA further recommends that the permit contain a special condition requiring the permittee to implement an MMP and conduct effluent monitoring to allow for evaluation of the effectiveness and implementation of the MMP. Section 7.5.1.2.2 contains additional information on antidegradation considerations.

7.2.4 Establishing appropriate WQBELs

The fourth component of the recommended NPDES permitting approach for methylmercury is to develop appropriate WQBEL requirements. Where a TMDL containing wasteload allocations for the discharge of mercury (and methylmercury where appropriate) has been developed, the WQBEL for that discharge must be consistent with the wasteload allocation (see 40 CFR 122.44(d)(1)(vii)(B)). Where a TMDL is not available at the time of permit issuance, to satisfy 122.44(d)(1)(vii)(A), EPA recommends the following WQBEL requirements, which are explained in greater detail in section 7.5.2.1:

- Where a water column translation of the fish tissue criterion has been developed, or where site-specific data to do so are readily available, include a numeric water quality-based limit.
- Where a water column translation or site-specific data are not available and the permit writer determines that a numeric limit is infeasible to calculate:
    - Require the permittee to implement an MMP tailored to the facility's potential to discharge mercury. Depending on the particular facts, the permitting authority may include in the MMP a trigger level, reduction goal, or

enforceable numeric level (e.g., existing effluent quality) to further manage mercury discharges.

- Require effluent monitoring using a sufficiently sensitive EPA-approved method to enable evaluation of the effectiveness and implementation of the MMP. (See sections 7.4 and 7.5.1.1 for more information on sufficiently sensitive methods.)
- Include a reopener clause to modify the permit conditions if the MMP is not found to be effective or if a water column translation of the fish tissue criterion is developed.

Since permitting authorities need to establish and maintain WQBELs as stringent as necessary to meet water quality standards, if a state or tribe has yet to complete the transition from an existing water column criterion to a fish tissue-based criterion, states may consider retaining their existing water column criteria until translators are developed. Alternatively, until a translator is available, EPA recommends that one of the approaches outlined in this document for relating a concentration of methylmercury in fish tissue to a concentration of methylmercury in ambient water be considered, especially for waters with relatively high direct water inputs of mercury. (See section 3.1.3.1.)

In modifying or reissuing permits with existing WQBELs for mercury, permit writers must also ensure compliance with CWA anti-backsliding requirements. As described elsewhere in this Guidance, CWA section 402(o)(1) prohibits the revision of WQBELs to make them less stringent than existing permit limits unless a specific exception applies under 402(o)(2) or 303(d)(4).

Exceptions under Section 402(o)(2), which would allow for the establishment of less stringent limits are:

(1) There have been material and substantial alterations or additions to the permitted facility which justify the less stringent limit.

(2) New information (other than revised regulations, guidance, or test methods) is available that was not available at the time of permit issuance, and that would have justified a less stringent limit.

(3) Good cause exists due to events beyond the permittee's control (e.g., natural disasters) and for which there is no reasonably available remedy.

(4) The permit has been modified under 301(c), 301(g), 301(h), 310(i), 301(k), 301(n), or 316(a).

CWA section 303(d)(4) provides additional exceptions to the anti-backsliding prohibition: paragraph (A), which applies to "non-attainment waters," and paragraph (B), which applies to "attainment waters".

- **Non-attainment water:** CWA section 303(d)(4)(A) allows the establishment of a less stringent effluent limitation when the receiving water does not meet applicable water quality standards (i.e., a "non-attainment water") if the permittee meets two conditions. First, the existing effluent limitation must have been based on a total maximum daily load (TMDL) or other wasteload allocation established under

CWA section 303. Second, relaxation of the effluent limitation is allowed only if the cumulative effect of all revised limitations would assure the attainment of water quality standards, or the designated use not being attained is removed in accordance with the water quality standards regulations.

- **Attainment water:** CWA section 303(d)(4)(B) applies to waters where the water quality equals or exceeds levels necessary to protect the designated use, or to otherwise meet applicable water quality standards (i.e., an "attainment water"). Under CWA section 303(d)(4)(B), a limitation based on a TMDL, wasteload allocation, other water quality standard, or any other permitting standard may only be relaxed where the action is consistent with the state's antidegradation policy.

The application of these exceptions is limited under 402(o)(3), which prohibits the relaxation of effluent limitations in all cases if a revised effluent limitation would result in a violation of applicable effluent limitation guidelines or water quality standards, including antidegradation requirements.

In establishing WQBELs for mercury, permit writers will need to ensure that the CWA anti-backsliding requirements are met. The first step of the inquiry is to determine whether the WQBEL based on the fish tissue criterion is "less stringent" than the WQBEL in the previous permit. If the new permit limit is not less stringent (e.g., if the prior numeric WQBEL is included in the MMP as an enforceable numeric level (see section 7.5.2.4 for additional information)), then the anti-backsliding prohibition should not be triggered and it should be appropriate to include the new limit in the permit. If the WQBEL based on the new fish tissue criterion is in fact less stringent than the prior WQBEL, then the permit writer must retain the existing numeric WQBEL unless there is an available exception to the anti-backsliding prohibition.

Because CWA section 402(o)(2)(B)(i) does not allow backsliding solely because regulations are revised (e.g., adoption of the fish tissue criterion), any applicable exceptions to the anti-backsliding prohibition for impaired waters would be found under section 303(d)(4)(A). In this case, permit limits based on TMDLs or other wasteload allocations established under section 303 can be made less stringent only if: a) the cumulative effect of all loadings meets the WQS or b) the designated use is removed.

Anti-backsliding requirements are further described in EPA's *NPDES Permit Writers' Manual* (USEPA 1996a) and in EPA's *Technical Support Document for Water Quality-Based Toxics Control* (USEPA 1991).

Other considerations and requirements may be necessary in developing permits. They include the following:

- Where a discharger undertakes an activity that could increase mercury loading to the receiving water, the WQBEL must be consistent with applicable antidegradation requirements (see section 7.5.1.2.2). Additional requirements may also be necessary under the CWA and EPA's NPDES regulations (see section 7.5.2.3).

- The permitting authority would need to include appropriate technology-based limits pursuant to CWA section 301(b) and 40 CFR sections 125.3 and 122.44(a)(1) (see section 7.5.2.3).

The entire recommended NPDES permitting approach is summarized in figure 5 and explained in greater detail in the following sections.

7.3 How does EPA recommend implementing the fish tissue criterion for NPDES permits?

As discussed in section 3.1, states and authorized tribes that decide to use the recommended criterion as the basis for new or revised methylmercury water quality standards have the option of adopting the criterion into their water quality standards as a fish tissue concentration, a traditional water column concentration, or both. If states or authorized tribes choose to use both approaches, they should clearly describe in their standards how each will be used for specific applications and describe applicable implementation procedures.

EPA recommends two approaches for implementing the fish tissue-based methylmercury water quality criterion in NPDES permits, depending on the form in which the state or authorized tribe expresses the criterion—as a fish tissue concentration or as a water column concentration. In addition, states and authorized tribes that adopt the recommended criterion as a fish tissue value may choose to implement it through NPDES permitting as a water column translation of the fish tissue value. Each of these approaches is summarized in figure 6 and discussed in more detail in sections 7.4 and 7.5.

The recommendations below assume that an approved TMDL is not available. If EPA has approved or established a TMDL containing a wasteload allocation for the discharge of mercury (and methylmercury where appropriate), the WQBEL for that discharge must be consistent with the wasteload allocation (see 40 CFR 122.44(d)(1)(vii)(B)).

This chapter provides EPA's guidance on how a permitting authority could implement the fish tissue criterion in NPDES permits consistent with the CWA and its implementing regulations. States and authorized tribes retain the discretion to develop and use procedures for determining reasonable potential and establishing effluent limits in NPDES permits that differ from those in the guidance. Such procedures may use other information relevant to determining reasonable potential and establishing effluent limits, where appropriate. If a state or authorized tribe develops its own such permitting procedures, EPA recommends that states and authorized tribes make the procedures public so that all stakeholders can be aware of the requirements and expectations of the permit program. In addition, the permit's fact sheet or statement of basis should also explain the basis of the permit conditions and effluent limitations and how these are consistent with the state's or authorized tribes' permitting procedures, the CWA, and applicable federal regulations.

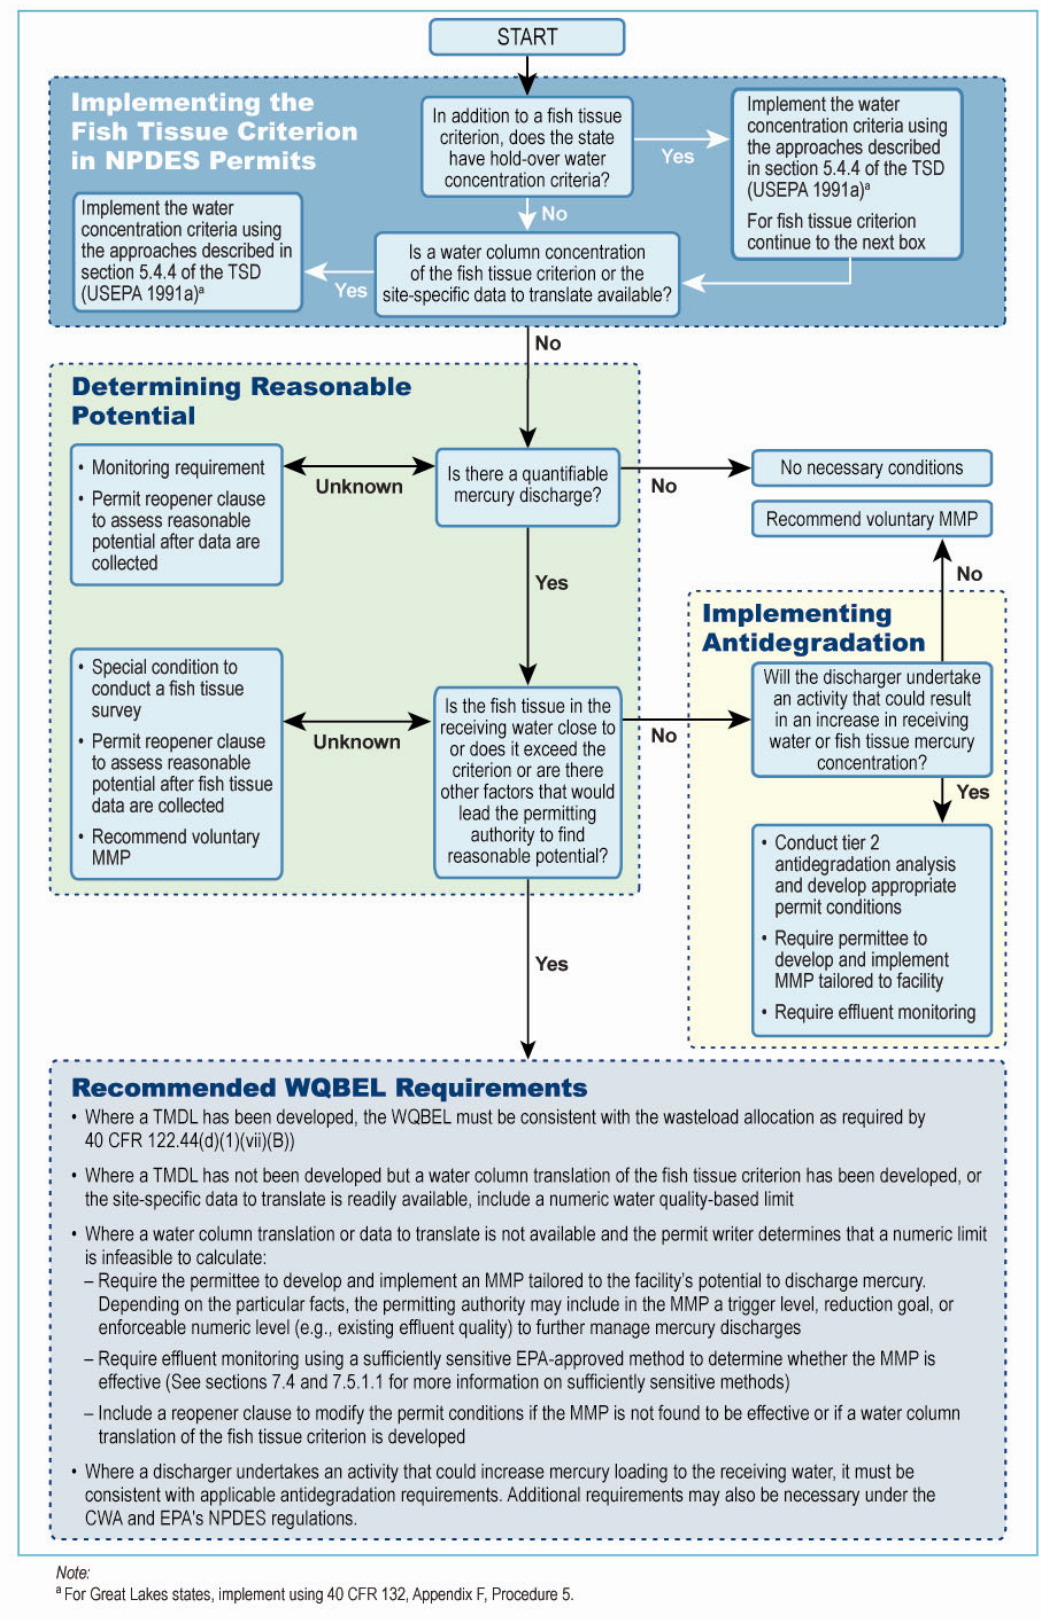


Figure 5. NPDES permitting approach for methylmercury.

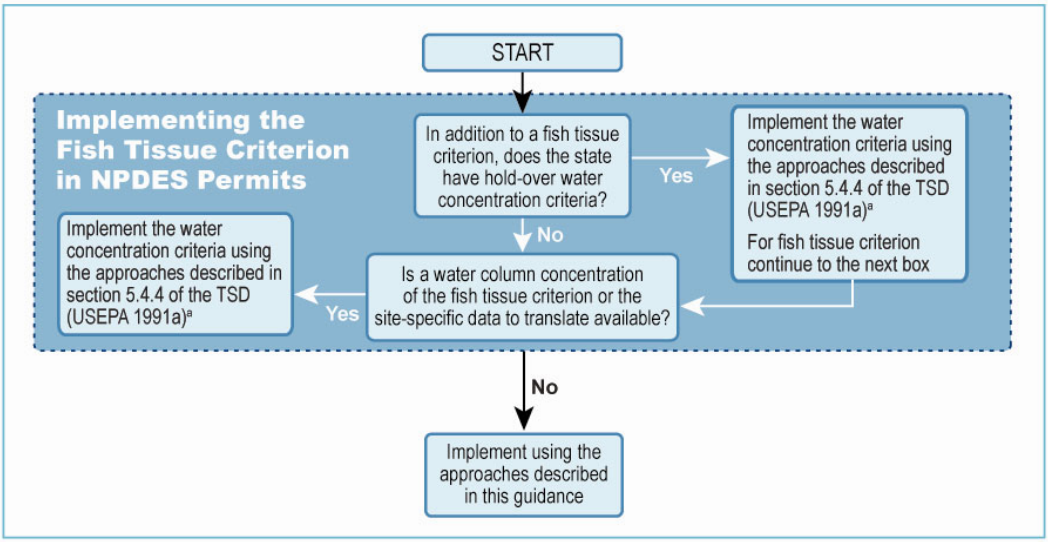

Figure 6. Implementing the fish tissue criterion in NPDES permits.

7.4 What are the procedures for developing permit limits when the criterion is adopted as a water column value or when the criterion is adopted as a fish tissue value and the permitting authority uses a water column translation of the fish tissue value?

This approach assumes that a state or authorized tribe decides to adopt a new or revised water quality criterion for methylmercury in one of the following forms:

- *Water column concentration value*. Expressing a criterion as a water column value is very common, and permitting authorities have considerable historical experience in developing permit limits based on such criteria in NPDES permits.

- *Fish tissue concentration value that is translated into a water column value*. Sections 3.1.3.1 through 3.1.3.3 of this guidance discuss the procedures for translating the fish tissue criterion into a water column value for water quality standards purposes. These procedures may also be used to translate a fish tissue criterion into a water column value for determining reasonable potential and for deriving numeric WQBELs.

In either case described above, the permitting authority should determine reasonable potential and calculate numeric WQBELs using the procedures described in section 5.4.4 of the TSD (USEPA 1991) to derive a numeric WQBEL.

This approach relies on the measurement of mercury in effluent, often at concentrations below the quantitation levels of some analytical methods. Therefore, the permitting authority should specify that the NPDES regulated discharger use a sufficiently sensitive EPA-approved method for the measurement of mercury in the discharge. An analytical method is sufficiently sensitive when (1) its method quantitation level is at or below the

level of the applicable water quality criterion or (2) its method quantitation level is above the applicable water quality criterion, but the amount of mercury in a discharge is high enough that the method detects and quantifies the level of mercury in the discharge. To illustrate the latter, if the water column criterion or water column translation of a fish tissue criterion for mercury in a particular waterbody is 2.0 parts per trillion (ppt), method 245.7 (with a quantitation level of 5.0 ppt) would be sufficiently sensitive when it reveals that the level of mercury in a discharge is 5.0 ppt or greater. In contrast, method 245.7 would not be sufficiently sensitive when it resulted in a level of nondetection for that discharge because it could not be known whether mercury existed in the discharge at a level between 2.0 and 5.0 ppt (less than the quantitation level but exceeding the water quality criterion).[21]

The selection of a sufficiently sensitive method relates method quantitation levels to the water column criterion value. If a water column criterion or a water column translation of a fish tissue criterion is not available to allow for selecting an alternate sufficiently sensitive method, EPA recommends the use of the most recent version of method 1631 to characterize discharges from all facilities for which the mercury levels are unknown or undetected. Method 1631 is relatively new, and the facilities may not have used it to analyze their effluent discharges. As a result, previous monitoring may show undetectable levels of mercury when use of method 1631 shows detectable or quantifiable amounts. Therefore, EPA recommends monitoring using the most recent version of method 1631 to help identify all facilities that contribute to mercury water quality impairment, unless another EPA-approved method can be justified as being sufficiently sensitive.

EPA's regulations require that measurements included on NPDES permit applications and on reports required to be submitted under the permit must generally be made using analytical methods approved by EPA under 40 CFR part 136. Because EPA has approved methods for analyzing mercury in water, these approved methods must be used in water analyses for NPDES permits involving mercury. See 40 CFR sections 122.21(g)(7), 122.41(j), 136.1, 136.3, and 136.6. Selection of an approved method should take into account the above discussion of method sensitivity. For metals, such as mercury, the federal regulations at 40 CFR 122.45(c) generally require effluent monitoring for the total form of the metal.

The discussion above describes analytical methods for measuring mercury in water. Refer to section 4.1 and appendix C for information on analytical methods for measuring mercury in fish tissue and for measuring methylmercury in water or fish tissue.

[21] For more information on choosing a sufficiently sensitive method, see the memorandum *Analytical Methods for Mercury in National Pollutant Discharge Elimination System (NPDES) Permits* from James A. Hanlon, Director of the Office of Wastewater Management, dated August 23, 2007, at http://www.epa.gov/npdes/pubs/mercurymemo_analyticalmethods.pdf.

7.5 What are the procedures for developing permit limits when the criterion is adopted as a fish tissue value and the permitting authority does not use a water column translation of the fish tissue value?

This approach assumes that a state or authorized tribe decides to adopt a new or revised water quality criterion for methylmercury in the form of a fish tissue concentration and that a TMDL, water column translation of the fish tissue criterion, or site-specific data to translate are not available at the time of permit issuance. As a result, the permitting authority will use a different approach than it has previously used for determining reasonable potential and expressing WQBELs. EPA recommends the approach described below, which is summarized in figure 7.

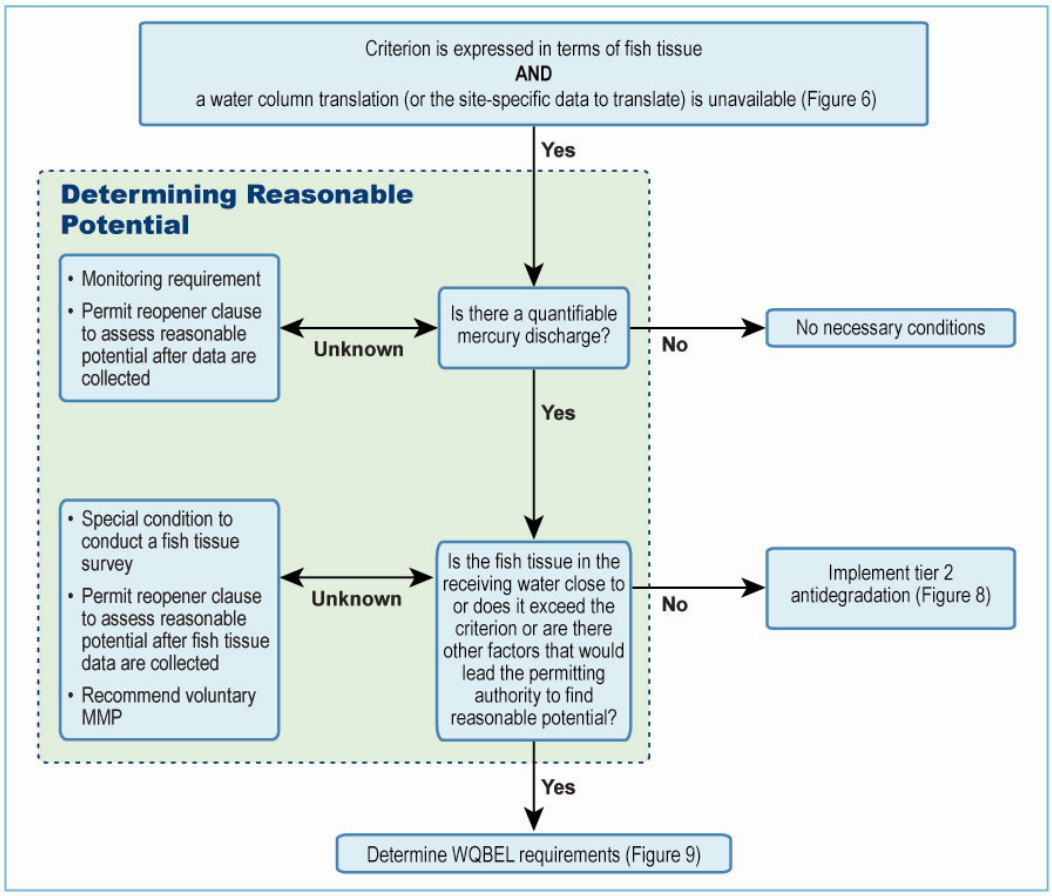

Figure 7. Determining reasonable potential.

7.5.1 How to determine the need for permit limits to control mercury (how to determine reasonable potential)

As discussed in section 3.1.2.2 of this document, EPA recommends that states and authorized tribes adopt new or revised methylmercury water quality criteria in the form of a fish tissue concentration. When a criterion is adopted into standards as a fish tissue value, states and authorized tribes may not have sufficient data to translate from a fish

tissue value to a traditional water column value using BAFs or translators. This section provides recommendations for how a permitting authority can determine reasonable potential in the absence of site-specific data to translate the fish tissue value into a water column value.

When determining reasonable potential, the permitting authority must determine whether the discharge "causes, has reasonable potential to cause, or contributes" to an exceedance of the applicable water quality criterion (see 40 CFR 122.44(d)(1)(ii)). The NPDES permit fact sheet should provide the rationale and assumptions used in determining whether WQBELs proposed in the associated draft permit are appropriate. The recommendations in this guidance could be applied on a permit-by-permit basis where appropriate to support the reasonable potential determination that satisfies 40 CFR 122.44(d)(1)(ii) with respect to a water quality criterion for methylmercury expressed as a fish tissue value in the absence of a TMDL and a water column translation of that value at the time of permit issuance.

EPA believes that, depending on the particular facts, a permitting authority could reasonably conclude that reasonable potential exists if two conditions are present: (1) the NPDES permitted discharger has mercury in its effluent at a quantifiable level and (2) the methylmercury level in fish tissue from the receiving waterbody is close to or exceeds the fish tissue water quality criterion. Under these circumstances, the effluent data indicate that the mercury load in the effluent contributes to the mercury load in the waterbody, and the fish tissue concentration indicates that the mercury load in the waterbody causes or has the potential to cause an exceedance of the water quality criterion. This approach is consistent with federal regulations pertaining to the Great Lakes Basin, which contained an approach for determining reasonable potential using fish tissue data (see 40 CFR part 132, appendix F, procedure 5.F.4). The reasonable potential approach for mercury described in this guidance has the advantage of significantly reducing environmental monitoring costs and does not involve developing a site-specific BAF for each waterbody in a state.

EPA recognizes that the mere presence of mercury at a quantifiable level in an effluent is not necessarily an indication that the mercury discharge is the sole cause of the fish contamination or even a substantial contributor of such contamination. However, mercury in an effluent discharge may contribute to the methylmercury present in fish tissue at levels close to or above the fish tissue criterion, and therefore the discharge may be found to exhibit the reasonable potential to cause or contribute to the exceedance of applicable water quality standards. EPA notes that the reasonable potential procedures as a whole are intended as conservative screening procedures to determine when a permit should contain a WQBEL to reduce the contribution to existing contamination or to prevent further possible degradation.

EPA notes that, unlike typical water quality criteria that are expressed as water column values, the fish tissue water quality criterion integrates spatial and temporal complexity and the cumulative effects of mercury loading from point and nonpoint sources that affect methylmercury bioaccumulation in aquatic systems. As discussed further in section 7.5.1.2.2, EPA believes that comparing the fish tissue concentration in steady state systems directly to the applicable fish tissue criterion appropriately accounts for the

factors specified in 40 CFR 122.44(d)(1)(ii) for a criterion expressed as a fish tissue value.

Finally, EPA further notes that because of the sensitivity of Method 1631E or other sufficiently sensitive methods (as described in section 7.4), it is reasonable to conclude that a discharge below quantitation does not have reasonable potential to exceed the criterion.

7.5.1.1 Step one of the reasonable potential analysis: Determining whether the NPDES-permitted discharger has mercury in its effluent at quantifiable levels

The first step in the reasonable potential analysis is to determine whether the discharge contains a quantifiable amount of mercury. To determine this, EPA recommends that permitting authorities require monitoring using a sufficiently sensitive analytical method approved for use by EPA under 40 CFR part 136. Section 7.4 contains additional information about sufficiently sensitive EPA-approved methods. If an alternate EPA-approved method cannot be justified as being sufficiently sensitive, EPA recommends monitoring using the most recent version of method 1631 to help identify all facilities that contribute to mercury water quality impairment. EPA recognizes that using method 1631 will likely result in a large majority of facilities showing quantifiable mercury discharges. This approach, however, is intended to allow permitting authorities to determine that facilities without quantifiable levels of mercury may not need step two of the reasonable potential analysis (determining whether the fish tissue criterion is being attained).

One of three outcomes will be reached in answering the first condition of the reasonable potential analysis:

- It is unknown whether the discharge includes a quantifiable amount of mercury.
- The discharge does not include a quantifiable amount of mercury.
- The discharge includes a quantifiable amount of mercury.

The recommended reasonable potential determination and recommended permit conditions for each of the outcomes is described in detail below.

7.5.1.1.1 What are the recommended permit conditions when it is unknown whether the discharge includes quantifiable amounts of mercury because there are limited or no effluent data to characterize the discharge of mercury?

In this situation, EPA recommends that the permitting authority include permit conditions that include the following elements:

- Effluent monitoring using a sufficiently sensitive EPA-approved analytical method to characterize the discharger's effluent for mercury (see sections 7.4 and 7.5.1.1 for information on sufficiently sensitive methods)
- A reopener clause to identify the actions that the permitting authority may take should the monitoring information indicate that a WQBEL for mercury is necessary

EPA recommends that permitting authorities require monitoring, using a sufficiently sensitive EPA-approved method, by all facilities for which the mercury levels are unknown or previously undetected (using less sensitive methods) to characterize the discharger's effluent for mercury. EPA recommends this monitoring to help identify all facilities that contribute to mercury loads in the waterbody. The permitting authority could obtain these monitoring data as part of the permit application, by requiring periodic (e.g., quarterly to annually) monitoring as part of the permit, or by invoking its authority under CWA section 308 (or equivalent state authority) to require NPDES facilities to collect information necessary for developing NPDES permit limits. The permit should include a reopener clause so that as soon as there is complete information and an indication that a more stringent limit is required, the permitting authority can establish the necessary requirements. The permitting authority may also decide to no longer require the monitoring if the information shows that the facility is not discharging mercury at quantifiable levels.

EPA recommends that when selecting the monitoring frequency, permitting authorities consider the factors in section 5.7.5 of the TSD (USEPA 1991). This section acknowledges that EPA has not recommended a specific monitoring frequency. However, the TSD recognizes that the choice of a monitoring frequency is a site-specific decision and provides the permitting authority with a number of factors to consider when making these decisions.

Until the permitting authority has sufficient data to determine whether the discharge has reasonable potential, and depending on the particular facts, the permit writer may reasonably conclude that the permit conditions described in this section are as stringent as necessary to achieve water quality standards, as required by CWA section 301(b)(1)(C).

7.5.1.1.2 What are the recommended permit conditions when the discharge does not include quantifiable amounts of mercury?

In this situation, EPA recommends that the permitting authority first review the monitoring data to determine whether they are representative of the effluent. If the permitting authority believes the monitoring data are representative of the discharge, no further permit conditions may be necessary. In contrast, if the permitting authority believes the data are not representative, the authority should consider requiring additional monitoring, as described in section 7.5.1.1.1.

7.5.1.1.3 What are the recommended actions for discharges that include quantifiable amounts of mercury?

In this case, the permitting authority should move to step two of the reasonable potential analysis and evaluate data on the concentrations of methylmercury in the fish tissue from the receiving waterbody to determine appropriate permit conditions (see section 7.5.1.2).

7.5.1.2 Step two of the reasonable potential analysis: Determining whether the fish tissue concentration of methylmercury in the receiving waterbody exceeds the fish tissue criterion

In step two of EPA's recommended fish tissue criterion reasonable potential procedure, the permitting authority has concluded that the first condition of the two-part reasonable potential analysis has been satisfied (i.e., the NPDES-permitted discharger has mercury in

its effluent at a quantifiable level). The permitting authority should then address the second condition of the reasonable potential analysis—determining whether the fish tissue from the receiving waterbody exceeds (or is close to exceeding) the fish tissue water quality criterion.

One of three outcomes will be reached in answering this question:

- The fish tissue concentration of methylmercury is unknown.
- The fish tissue concentration of methylmercury does not exceed the criterion or is not close to the criterion.
- The fish tissue concentration of methylmercury exceeds the criterion or is close to exceeding the criterion.

For discharges with quantifiable levels of mercury, the recommended reasonable potential determination and recommended permit conditions for each outcome is described in detail below.

EPA recognizes that when evaluating reasonable potential, the permitting authority should exercise discretion and careful judgment in determining whether fish tissue data are representative of current ambient conditions. EPA guidance for sampling strategies for fish tissue monitoring is provided in section 4.2 of this document.

7.5.1.2.1 What are the recommended permit conditions when a facility discharges quantifiable amounts of mercury but the fish tissue concentrations of methylmercury in the receiving waterbody are unknown?

In waterbodies for which there are insufficient fish tissue data available, a permitting authority cannot determine whether there is reasonable potential using a fish tissue approach. Therefore, in this case, EPA recommends that the permitting authority take the following actions:

- Include a special permit condition to conduct a mercury fish tissue survey for the receiving waterbody, unless such information will be available from another source in a timely manner.
- Include as a permit condition a reopener clause to identify the actions that the permitting authority may take should fish tissue monitoring information become available and indicate that a WQBEL for mercury is necessary.
- Encourage the permittee to develop and implement an MMP tailored to the facility's potential to discharge mercury.

In this instance, the permitting authority should start a process for collecting fish tissue data in the waterbodies where point source discharges of mercury exist. One approach for collecting this information is for the permitting authority to invoke its authority under CWA section 308 (state permitting authorities would use comparable state authorities) to require NPDES facilities to collect information necessary for the development of NPDES permit limits. In this case, the permitting authority could issue a section 308 letter or include special conditions in the permit to require the permittee to conduct a methylmercury fish tissue monitoring study. EPA recommends that the study design be

consistent with the recommendations on conducting ambient monitoring in section 4.2 of this guidance.

EPA also recommends that the permitting authority require only one study per waterbody. The permitting authority could do this by contacting all facilities that discharge into the waterbody and encouraging them to work jointly to conduct the study, because the outcomes of the study may affect the permit limits of those facilities. For example, the State of Idaho has developed a statewide fish tissue monitoring program for mercury that provides a standardized approach for collecting reliable data while recognizing limited resources for monitoring.

In waterbodies where the permitting authority expects to find high mercury concentrations in the water column or believes it will need a site-specific BAF to finish issuing the permits, the permitting authority should consider requiring the facility to include measurement of water column concentrations of mercury as part of the study.

EPA further recommends that the permit include a reopener clause so that as soon as there is complete information, the permitting authority can establish any additional requirements that are necessary. In this situation EPA recommends that the permitting authority encourage the permittee to develop and implement an MMP for the reasons discussed in section 7.5.1.2.2.1.

7.5.1.2.2 What are the recommended permit conditions when a facility discharges quantifiable amounts of mercury but the fish tissue concentrations of methylmercury in the receiving waterbody do not exceed and are not close to the criterion?

Once the permitting authority has determined that a facility discharges quantifiable amounts of mercury and that the concentration of methylmercury in fish tissue in the receiving waterbody does not exceed and is not close to the criterion, depending on the particular facts, the permitting authority may reasonably conclude that the discharge does not have reasonable potential to cause or contribute to an exceedance of the applicable fish tissue water quality criterion.

To assist in preventing future impairments, in some situations as outlined below, EPA recommends that states and authorized tribes also consider other factors or conditions such as a trend of rising fish tissue concentrations or the relative contribution of mercury or methylmercury from the source when determining whether a facility has reasonable potential in waters that are not yet impaired.

EPA notes that, unlike typical water quality criteria that are expressed as water column values, the fish tissue water quality criterion integrates spatial and temporal complexity as well as the cumulative effects of variable mercury loading from point and nonpoint sources that affect methylmercury bioaccumulation in aquatic systems. EPA believes that comparing the fish tissue concentration in steady state systems directly to the applicable criterion expressed as a fish tissue value appropriately accounts for the factors specified in 40 CFR 122.44(d)(1)(ii) for a criterion expressed as a fish tissue value. Existing tissue-based data are indicators of accumulation that has already occurred. Thus, where fish tissue concentrations in a watershed are expected to be constant (i.e., steady state conditions) or decreasing over time, data that indicate that the fish tissue criterion is

currently being attained may be effective indicators of current and potential continued future attainment.

However, in dynamic systems where the levels in tissue in a watershed may be expected to increase, EPA recommends that the permitting authority account for this as part of the reasonable potential determination that is designed to prevent potential future impairments.

Another factor that permitting authorities may consider is the impact of permitted discharges to downstream waters (e.g., a discharge to a river that flows into a lake where mercury is a concern). In such a circumstance, it may be appropriate to conclude that the discharge has reasonable potential on the grounds that its discharge causes or contributes to the excursion of the fish tissue criterion in the downstream water.

The presence of these other factors or conditions such as the relative contribution of mercury or methylmercury from the source, rising fish tissue concentrations, or potential excursion of the criterion downstream, could constitute a basis for concluding that an effluent limit is necessary depending on the particular facts.

As discussed in section 7.5.1.2.2.2, for discharges to waters that are not impaired, EPA recommends that states and tribes regard any activity that could result in an increase in receiving water or fish tissue mercury concentration as a significant lowering of water quality for the purposes of triggering an antidegradation review.

Implementing tier 2 antidegradation

If the facility undertakes any activity that could increase mercury loading to the receiving waterbody, an antidegradation review may be necessary. Such increases must be consistent with the applicable antidegradation policy. Federal regulations at 40 CFR 131.6 specify that tribal or state water quality standards must include an antidegradation policy, and federal regulations at 40 CFR 131.12 identify the elements of an acceptable antidegradation policy. Section 303(d)(4)(B) requires that applicable antidegradation requirements be satisfied prior to modifying NPDES permits (for example, prior to removing a WQBEL or including less stringent effluent limitations).

The federal antidegradation policy is composed of three levels of protection commonly referred to as tiers. The first tier, identified at 40 CFR 131.12(a)(1), protects the minimum level of water quality necessary to support existing uses and applies to all waters. This tier prohibits lowering water quality to the point where existing uses are impaired. The second tier, found at 40 CFR 131.12(a)(2), protects water quality where water quality is better than that needed to support "fishable/swimmable" uses of the water. Where these conditions exist, the waterbody is typically considered not impaired, and water quality must be maintained and protected unless it is demonstrated that lowering water quality is necessary to support important social and economic development and that existing uses will be fully protected. The third tier, at 40 CFR 131.12(a)(3), involves the protection of water quality in waterbodies that are of exceptional ecological, aesthetic, or recreational significance. Water quality in such waterbodies, identified and specifically designated by states or authorized tribes as Outstanding National Resource Waters, must be maintained and protected.

States and authorized tribes should determine whether the discharger will undertake an activity that can result in an increase in mercury loading to the receiving waterbody.

One of two outcomes will be reached in answering this question:

- The discharger will not undertake an activity that can increase mercury loading to the waterbody.
- The discharger will undertake an activity that can increase mercury loading to the waterbody.

As part of conducting a tier 2 antidegradation analysis, the permitting authority would evaluate the activity's potential to lower water quality, whether there are alternatives that would avoid lowering water quality, and whether lowering of water quality would be necessary to accommodate important economic or social development in the area of the discharge. EPA considers analyses of potential pollution prevention and enhanced treatment alternatives as an appropriate starting point for the antidegradation review for both industrial and municipal dischargers. See 67 FR 68971, 68979. The results of such an analysis of potential alternatives could provide the basis for developing an MMP.

EPA's recommendations for implementing antidegradation provisions and addressing increases in mercury loads are summarized in figure 8 and explained in sections 7.5.1.2.2.1 and 7.5.1.2.2.2. EPA recognizes, however, that states and tribes have the flexibility to interpret their antidegradation policies differently. For example, some states use limits established at existing effluent quality to implement their antidegradation provisions.

7.5.1.2.2.1 What are the recommended permit conditions when a facility discharges quantifiable amounts of mercury into a waterbody in which the fish tissue concentration of methylmercury does not exceed the criterion and the facility will not undertake an activity that could increase mercury loading to the waterbody?

If the facility discharges a quantifiable amount of mercury and the fish tissue concentration of methylmercury in the receiving water does not exceed the criterion, depending on the particular facts, the permitting authority may reasonably conclude that the discharge does not have reasonable potential to cause or contribute to an exceedance of the applicable fish tissue water quality criterion. In such situations, however, EPA recommends that the permitting authority encourage the facility to develop and implement an MMP.

An MMP helps ensure that the discharge will continue to have no reasonable potential to cause or contribute to an exceedance of applicable water quality standards. The recommendation to develop a voluntary MMP is also based on the extent of potential mercury impairment across the country and the scientific complexities of and uncertainties associated with assessing mercury loadings and evaluating their effects.

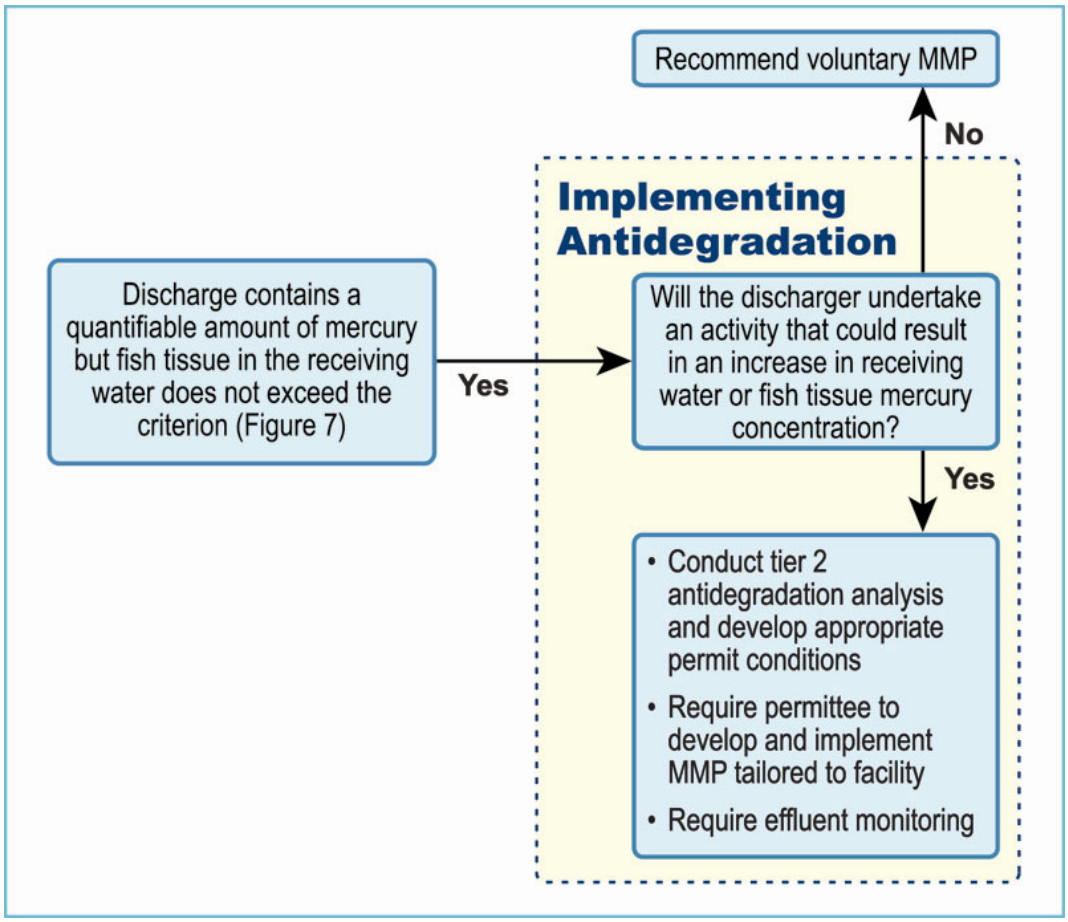

Figure 8. Implementing tier 2 antidegradation.

If future monitoring data demonstrate that a discharge does have reasonable potential, development of a MMP could assist the permit writer in establishing appropriate permit conditions. Furthermore, EPA believes that simply developing an MMP might provide dischargers of mercury with sufficient information to economically reduce the discharge of mercury into our Nation's waters by voluntarily implementing the mercury minimization measures identified in the plan. Section 7.5.2.1 provides additional information on MMPs.

7.5.1.2.2.2 What are the recommended permit conditions when a facility discharges quantifiable amounts of mercury into a waterbody in which the fish tissue concentration of methylmercury does not exceed the criterion but the facility will undertake an activity that could result in an increase in receiving water or fish tissue mercury concentration?

In this situation, the receiving water does not currently exceed the fish tissue criterion. EPA believes that increases in mercury loading to a waterbody should be allowed at levels determined appropriate by an antidegradation analysis and that such dischargers should be required to implement MMPs under the authority of CWA section 402(a)(1)(B) and 40 CFR 122.44(k)(4).

EPA recommends the following WQBEL requirements:

- Include permit conditions consistent with antidegradation requirements.
- Require the permittee to implement an MMP tailored to the facility's potential to discharge mercury. Depending on the particular facts, the permitting authority may include in the MMP a trigger level, reduction goal, or enforceable numeric level to further manage mercury discharges.
- Require the permittee to monitor its effluent using a sufficiently sensitive EPA-approved method (see sections 7.4 and 7.5.1.1 for information on sufficiently sensitive methods).

Other considerations and requirements might be necessary in developing permits:

- The permitting authority would need to include appropriate technology-based limits pursuant to CWA section 301(b) and 40 CFR sections 125.3 and 122.44(a)(1) .
- For modified or reissued permits with existing effluent limits for mercury, any less stringent effluent limit must be consistent with anti-backsliding requirements (see section 7.2.4).

Activities that would lower water quality in a high-quality water must be consistent with the applicable antidegradation provisions of a state's or authorized tribe's water quality standards. Consistent with EPA's antidegradation regulations for water quality standards, state and tribal antidegradation regulations are to provide that the quality of waters at levels better than the levels necessary to support "fishable/swimmable" uses of the water may be lowered only if the state or authorized tribe determines that allowing lower water quality is necessary to accommodate important economic or social development in the area in which the waters are located (see 40 CFR 131.12(a)(2)). EPA recommends that states and authorized tribes regard any activity that could result in an increase in receiving water or fish tissue mercury concentration as a significant lowering of water quality for the purposes of triggering a tier 2 antidegradation review. If the state's or authorized tribe's antidegradation analysis determines that the proposed lowering of water quality should not be allowed, the permitting authority would not authorize or allow any such discharge to occur. If the state's or authorized tribe's antidegradation analysis determines that a lowering of water quality is allowable, the level to which the discharger is ultimately allowed to lower water quality (on the basis of the applicable antidegradation requirements) would then be subject to a reasonable potential analysis. Also, EPA's antidegradation regulations for water quality standards require state and tribal antidegradation regulations to protect the minimum level of water quality necessary to support existing uses by prohibiting lowering of water quality to the point where existing uses are impaired (see 40 CFR 131.12(a)(1)).[22] For new and increased discharges, states have the flexibility to interpret their antidegradation policies differently. For example, some states use limits established at existing effluent quality.

[22] This part of the antidegradation analysis is similar to the reasonable potential determination and WQBEL development process that a permitting authority conducts for an existing discharger.

EPA expects that fluctuations in mercury loadings arising from normal industrial production fluctuations, or loading fluctuations that are not results of change in existing POTW service areas, would generally not trigger a tier 2 antidegradation analysis. EPA expects that increases in mercury loadings from a POTW arising from adding a new subdivision or an unsewered neighborhood to a sewer service area would generally trigger a tier 2 antidegradation review. If an antidegradation review is triggered, the review should consider the source of the increased mercury loading, the potential for source reduction through either treatment, pretreatment or pollution prevention, and the expected benefits likely to accrue to the affected community as a result of the activities that result in increased mercury loadings. EPA recommends that states and tribes tailor the level of detail and documentation for antidegradation demonstrations to the specific circumstances. For example, in some instances, as with diffuse domestic sources of mercury, available treatment and pollution prevention alternatives may be limited or lacking, leaving only the importance of social and/or economic development as the primary focus of the review.

EPA recognizes that an increase in the discharge of mercury might be due to mercury present in stormwater or input process water that does not originate with and is not under the reasonable control of a facility. While an MMP, to the extent that there are available BMPs to minimize mercury discharges, might still be appropriate in such circumstances, EPA would not generally expect that such discharges would trigger the need for an antidegradation review, or numeric WQBELs.

In addition to permit conditions consistent with antidegradation requirements, EPA recommends that the permit require the dischargers to implement an MMP under the authority of CWA section 402(a)(1)(B) and 40 CFR 122.44(k)(4). The MMP should be tailored to the individual facility's potential to discharge mercury. For more information on MMPs, see section 7.5.2.1.

7.5.1.2.3 What are the recommended permit conditions when a facility discharges quantifiable amounts of mercury and the fish tissue concentrations of methylmercury in the receiving waterbody are close to or exceed the criterion?

EPA believes that, depending on the particular facts, a permitting authority may reasonably conclude that reasonable potential exists if two conditions are present: (1) the NPDES-permitted discharger has mercury in its effluent at quantifiable levels, and (2) the fish tissue concentrations of methylmercury from the receiving waterbody are close to or exceed the fish tissue water quality criterion.

Where fish tissue concentrations are below but close to the criterion, EPA recommends that a finding of reasonable potential be made since the effect of current discharges and other relevant factors may not yet be reflected in fish tissue concentrations. For example, where the tissue data are below the water quality criterion, the permitting authority may consider applying an appropriate confidence interval (e.g., 95 percent upper confidence limit on the mean) to such values and compare that value to the fish tissue criterion to the extent necessary to account for variability in fish tissue data. As an example of an

alternative to this statistical approach, the State of Idaho's implementation guidance[23] for its methylmercury fish tissue criterion of 0.3 mg/kg recommends that where the levels in fish exceed 0.24 mg/kg, the permitting authority should determine that reasonable potential exists. Where methylmercury levels in fish tissue are thought to be relatively sensitive to a water point source load of mercury or methylmercury, the permitting authority may take that into account in the reasonable potential determination.

When reasonable potential exists, it is necessary to establish an appropriately protective WQBEL in the permit. For guidance on recommended WQBELs, see section 7.5.2.1.

7.5.1.3 How to consider mercury in intake water with a reasonable potential approach

For some facilities, the only source of mercury in a discharge may be the intake water taken directly from the same body of water to which the facility discharges. An example of this is a discharge of cooling water where the source of the cooling water is upstream of the discharge. In these situations where there are no known sources or additional contributions of mercury at the facility, the permitting authority could reasonably conclude, based on the particular facts, that there is no reasonable potential to cause or contribute to an exceedance of water quality standards. Furthermore, any slight increase in concentration after discharge (due to evaporation or other water loss) should not have an effect on the bioaccumulation of methylmercury in fish tissue unless the fish are known to frequently inhabit the water in the area immediately adjacent to the discharge. In making this decision, the permitting authority should consider the monitoring data from both the intake and discharge to verify that there are no known sources of additional contributions of mercury at the facility. EPA also recommends that permitting authorities consider evaluating whether the methylmercury concentration in fish tissue significantly increases for facilities with anaerobic conditions in the discharge. This procedure represents a comprehensive approach for conducting a site-specific analysis of the potential for a discharge to cause or contribute to an excursion above a water quality standard, which can lead to a decision to not require a WQBEL. This approach is consistent with the rationale for the federal regulations pertaining to the Great Lakes Basin, which included consideration of intake pollutants in finding reasonable potential (see 40 CFR part 132, appendix F, procedure 5.D).

7.5.2 Where reasonable potential exists, how can WQBELs be derived from a fish tissue value?

As discussed in section 3.1.2.2 of this document, EPA recommends that states and authorized tribes adopt a new or revised methylmercury water quality criterion in the form of a fish tissue concentration. When the criterion is adopted into standards as a fish tissue value, some states and authorized tribes may not have sufficient data to translate from a fish tissue value to a traditional water column value using BAFs or translators. When developing WQBELs, the permitting authority must ensure that the level of water quality to be achieved by such limits derives from and complies with water quality

[23] *Implementation Guidance for the Idaho Mercury Water Quality Criteria* is available at http://www.deq.state.id.us/water/data_reports/surface_water/monitoring/idaho_mercury_wq_guidance.pdf.

standards (see 40 CFR 122.44(d)(1)(vii)). This section provides recommendations on how a permitting authority could derive appropriate WQBELs in the absence of a TMDL and a water column translation of the fish tissue criterion at the time of permit issuance. The information discussed in this section is summarized in figure 9.

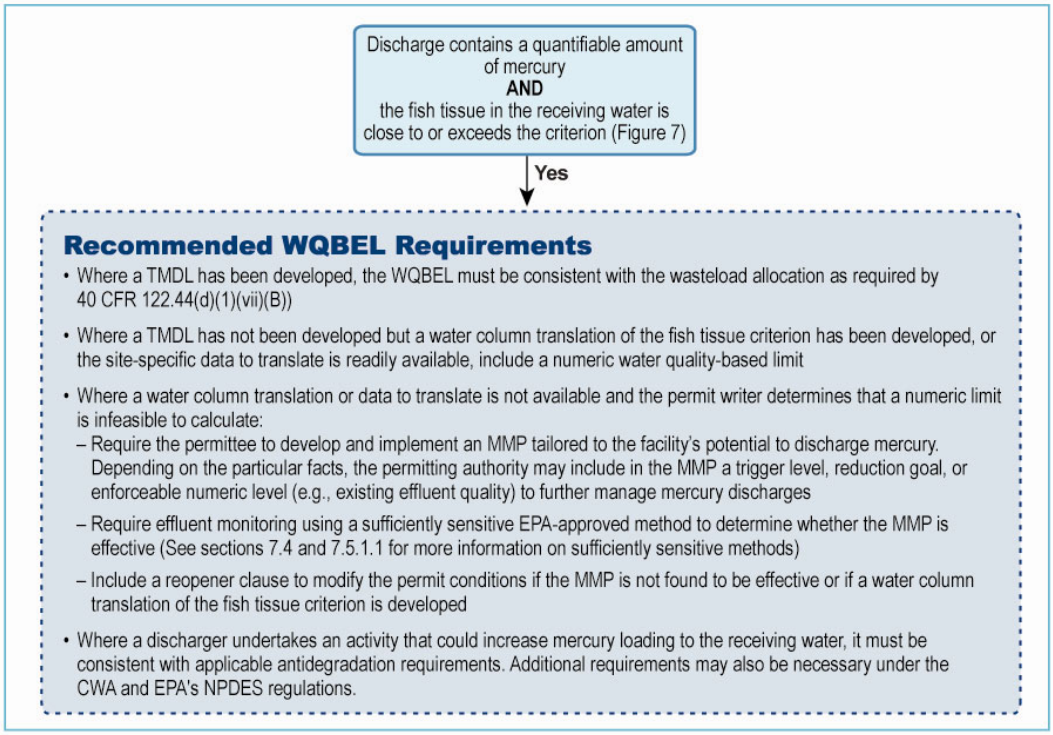

Figure 9. Determining WQBEL requirements.

7.5.2.1 What are the recommended WQBELs?

If the facility has a quantifiable amount of mercury in its discharge and the concentration of methylmercury in fish tissue in the receiving water is close to or exceeds the criterion, depending on the particular facts, the permitting authority may reasonably conclude that the discharge has reasonable potential to cause or contribute to an exceedance of the applicable fish tissue water quality criterion. In this situation, in the absence of a TMDL and a water column translation of the fish tissue criterion, it may be appropriate to conclude that it is infeasible to calculate a numeric WQBEL at the time of permit issuance and to instead express the WQBEL as narrative BMPs, as provided in 122.44(k)(3).

Where a TMDL containing wasteload allocations for the discharge of mercury (and methylmercury where appropriate) has been developed, the WQBEL for that discharge must be consistent with the wasteload allocation (see 40 CFR 122.44(d)(1)(vii)(B)). Where a TMDL is not available at the time of permit issuance, to satisfy 122.44(d)(1)(vii)(A), EPA recommends that the WQBEL consist of the following elements:

- Where a water column translation of the fish tissue criterion has been developed, or site-specific data to do so are readily available, include a numeric water quality-based limit.
- Where a water column translation or site-specific data are not available and the permit writer determines that a numeric limit is infeasible to calculate:
    - Require the permittee to implement an MMP tailored to the facility's potential to discharge mercury. Depending on the particular facts, the permitting authority may include in the MMP a trigger level, reduction goal, or enforceable numeric level to further manage mercury discharges.
    - Require effluent monitoring using a sufficiently sensitive EPA-approved method to enable evaluation of the effectiveness and implementation of the MMP. (See sections 7.4 and 7.5.1.1 for more information on sufficiently sensitive methods.)
    - Include a reopener clause to modify the permit conditions if the MMP is not found to be effective or if a water column translation of the fish tissue criterion is developed.

Other considerations and requirements may be necessary in developing permits:

- Where a discharger undertakes an activity that could increase mercury loading to the receiving water, it must be consistent with applicable antidegradation requirements. Additional requirements may also be necessary under the CWA and EPA's NPDES regulations.
- The permitting authority would need to include appropriate technology-based limits pursuant to CWA section 301(b) and 40 CFR sections 125.3 and 122.44(a)(1) .
- For modified or reissued permits with existing effluent limits for mercury, any less stringent effluent limit must be consistent with anti-backsliding requirements (see section 7.2.4).

7.5.2.2 What does EPA recommend where direct water inputs are relatively high?

This section describes EPA's recommendations where direct water inputs of mercury are relatively high. In this section, EPA discusses the recently developed "5m" listing approach for waters impaired by mercury from primarily atmospheric sources, as well as approaches for developing TMDLs, analyses of sources and loading capacity similar to what would be provided in a TMDL, or water column translations of the fish tissue criterion, to serve as the basis for permit limits.

As described in section 6.2, EPA recently developed an optional voluntary approach for deferring TMDL development for waters impaired by mercury predominantly from atmospheric sources pursuant to CWA section 303(d). Under this approach, states with comprehensive mercury reduction programs may consider waters appropriate for inclusion in a subcategory of their impaired waters lists (category 5m under the Integrated Report Guidance) and defer the development of TMDLs for those waters. EPA's 5m guidance states that in deciding on the scope of waterbodies proposed for

subcategory 5m, a contribution for states to consider would be approximately 90 to 95 percent of the loadings or higher from air deposition to the waterbody; the specific percent may vary, however. A full description of the 5m approach is at http://www.epa.gov/owow/tmdl/mercury5m/.

In watersheds where direct water inputs (mercury from point sources and nonpoint sources other than air deposition) represent a relatively high contribution of mercury, EPA recommends that states and authorized tribes specifically consider developing numeric permit limits for mercury dischargers to these waterbodies. States and authorized tribes may develop TMDLs for these waterbodies in the short term to provide important information for developing appropriate permit limits. Where a state or authorized tribe chooses not to develop a TMDL in the short term for such a waterbody, EPA recommends that the state or tribe develop an analysis of sources and loading capacity similar to what would be provided in a TMDL or a water column translation of the fish tissue criterion using the methods outlined in 3.1.3.1. Consistent with the 5m approach for establishing priorities for mercury TMDL development, in deciding whether there is a relatively high contribution from direct water inputs, a contribution for states to consider would be approximately 5 to 10 percent or more of mercury loadings from direct water inputs, taking into account that the specific percent may vary by state. At the same time, states may consider other factors, such as the complexity of the TMDL, in determining schedules for developing TMDLs.

Cumulative loads from point sources and localized nonpoint sources such as abandoned mines, contaminated sediments, and naturally occurring sources can potentially combine to cause localized mercury impairment. These situations are more complicated because the specific location and magnitude of each source could significantly affect fish tissue concentrations. In these situations, a TMDL provides the best basis for developing the appropriate permit limits.

Once EPA has approved or established a TMDL containing a wasteload allocation for the discharge of mercury (and methylmercury where appropriate), the permitting authority develops a WQBEL for a point source discharge that is consistent with the requirements and assumptions of the wasteload allocation in the TMDL (see 40 CFR 122.44(d)(1)(vii)(B)). In addition to developing a WQBEL, the permitting authority specifies monitoring requirements for the WQBEL (see 40 CFR 122.44(i) and 122.48). EPA recommends that permitting authorities require the permittee to use a sufficiently sensitive EPA-approved method for monitoring purposes.

In such watersheds where direct water inputs represent a relatively high mercury loading, EPA recommends that the permitting authority and the mercury dischargers in the watershed work together to collect the data necessary to develop a TMDL, an analysis of sources and loading capacity similar to what would be provided in a TMDL, or a water column translation of the fish tissue criterion. One approach for collecting information for a source analysis described above or a water column translation of the fish tissue criterion is for the permitting authority to invoke its authority under CWA section 308 (state permitting authorities would use comparable state authorities) to require NPDES facilities to collect information necessary for the development of NPDES permit limits. In the absence of a final TMDL, EPA recommends that a permitting authority conduct an analysis of sources and loading capacity similar to what would be provided in a TMDL.

Such an analysis that applied factors similar to those considered in a TMDL could be included in the fact sheet of the draft permit as a justification for the effluent limit being as stringent as necessary to attain the water quality standard. The permitting authority may also use a water column translation of the fish tissue criterion to derive numeric permit limits if such a translation or site-specific data to translate are available.

A water column translation of the fish tissue criterion may not always be necessary in developing a TMDL or an analysis of sources and loading capacity similar to what a TMDL would provide. For example, section 6.2.2.2.1 of this guidance provides descriptions of TMDLs that have been developed using steady state models and the proportionality approach.

Since permitting authorities need to establish and maintain WQBELs as stringent as necessary to meet water quality standards, if a state or tribe has yet to complete the transition from an existing water column criterion to a fish tissue-based criterion, states may consider retaining their existing water column criteria until translators are developed. Alternatively, until a translator is available, EPA recommends that one of the approaches outlined in this document for relating a concentration of methylmercury in fish tissue to a concentration of methylmercury in ambient water be considered (see section 3.1.3.1.)

7.5.2.3 What additional requirements may apply?

Activities that could increase mercury loadings to a receiving waterbody

Permits for sources that are seeking authorization to increase their discharge of mercury (or commence the discharge of mercury) must be consistent with applicable antidegradation requirements. See discussions of antidegradation elsewhere in this chapter, including sections 7.2.3 and 7.5.1.2.2.

The permitting authority may consider whether an offset of such discharges by other pollutant source reductions would support the development of a WQBEL that would ensure that the level of water quality to be achieved by such effluent limitation is derived from and complies with the water quality standards, as required by 40 CFR 122.44(d)(1)(vii)(A) and any other applicable NPDES regulations.

Pretreatment

A POTW is required to prohibit discharges from industrial users in amounts that result in or cause a violation of any requirement of the POTW's NPDES permit (see 40 CFR 403.2(a) and (b), 403.3(i) and 403.3(n)). A POTW that accepts mercury in its collection systems may need to ensure that its pretreatment program prevents its effluent from contributing to exceedance of the fish tissue criterion. The general pretreatment regulations (at 40 CFR part 403) require that each POTW, or combination of POTWs operated by the same water authority, with a design flow of 5.0 million gallons per day (MGD) or more develop an approved pretreatment program that protects against pass-through and interference, which may be caused by industrial discharges to the treatment facilities, by developing local limits for mercury and other pollutants or demonstrating that limits are not necessary for these pollutants. The POTW is also required to prohibit discharges from industrial users in amounts that result in or cause a violation of any requirement of the POTW's NPDES permit (see 403.2(a) and (b), 403.3(i) and 403.3(n)).

Federal categorical pretreatment standards, which are applicable to certain classes of industries, establish technology-based minimum pretreatment standards. The categorical standards, however, do not address POTW-specific problems that may arise from discharges by categorically regulated industries. In addition, many types of industries that discharge significant quantities of pollutants are not regulated by the categorical standards. Hence, there is a need for many POTWs to establish site-specific discharge limits to protect the treatment facilities, receiving water quality, and worker health and safety and to allow for the beneficial use of sludge.

Technology-based limits

When developing effluent limits for an NPDES permit, a permit writer must impose limits based on the technology available to treat mercury (technology-based limits) as a minimum level of control, as required by CWA section 301(b) and 40 CFR sections 125.3 and 122.44(a)(1). There are two general approaches for developing technology-based effluent limits for industrial facilities: national effluent limitation guidelines (ELGs) and best professional judgment (BPJ) on a case-by-case basis (in the absence of ELGs). Technology-based effluent limits for municipal facilities (POTWs) are derived from secondary treatment standards.

Anti-backsliding

Where a facility has a currently effective effluent limit for mercury and seeks a less stringent limit, the permitting authority must also comply with anti-backsliding requirements (see CWA section 402(o) and 40 CFR 122.44(l); see also CWA section 303(d)(4)). These requirements are described in EPA's *NPDES Permit Writers' Manual* (USEPA 1996b).

Permit documentation

Documentation is an important part of the permit development process. The NPDES permit fact sheet should provide an explanation of how the limit proposed in the associated draft permit is as stringent as necessary to achieve water quality standards (40 CFR 124.8 and 124.56). The recommendations in this guidance could be applied on a permit-by-permit basis, where appropriate, to support effluent limitations and other conditions that satisfy CWA section 301(b)(1)(C) and 40 CFR 122.44(d)(1) with respect to mercury.

7.5.2.4 Mercury minimization plans

EPA recommends that the permit contain a special condition requiring the permittee to implement an MMP that includes effluent monitoring using a sufficiently sensitive EPA-approved method (see sections 7.4 and 7.5.1.1 for information on sufficiently sensitive methods), with the expectation that effluent monitoring will allow for evaluation of the effectiveness and implementation of the plan. The MMP would be included in the permit in addition to a numeric WQBEL in cases where a TMDL, a water column translation of the fish tissue criterion, or other water concentration criterion is available at the time of issuance. If neither a TMDL nor a water column translation (or other water criterion) is available at the time of permit issuance, however, the MMP would be included in the permit as part of a narrative WQBEL in lieu of a numeric WQBEL. EPA believes that,

depending on the particular facts, a permit writer may reasonably conclude that such MMPs are as stringent as necessary to achieve water quality standards, for the reasons discussed below.

EPA believes that mercury reductions achieved through implementing MMPs tailored to the facility's potential to discharge mercury could result in important reductions in mercury loadings. EPA's basis for this conclusion is its study of pollutant minimization programs and their success in reducing mercury loadings to the environment. The reports *Mercury Study Report to Congress* (USEPA 1997c) and draft *Overview of P2 Approaches at POTWs* (USEPA 1999b) show that POTWs and industrial dischargers have implemented source controls, product substitution, process modification, and public education programs with great success. These minimization practices focus on sources and wastes that originate with and are under the reasonable control of a facility, not on pollutants in rainwater or source water.

As an example, POTWs can educate the public to prevent pollution by avoiding household products that contain high levels of mercury or substituting for those products ones that are mercury-free or more environmentally friendly. The most cost-effective approach for POTWs to substantially reduce mercury discharges appears to be pollution prevention and waste minimization programs that focus on high-concentration, high-volume discharges to the collection system, with considerable effort also directed at high-concentration, low-volume discharges such as those from medical and dental facilities.

Using pollutant minimization or prevention programs can also reduce the transfer from wastewater to other media through disposal of mercury-containing sludge from which mercury may subsequently reenter the environment. For example, mercury removed at a POTW through treatment is likely to reenter the environment through POTW sludges that are then incinerated or applied to land (although some is captured by air emission controls on incineration). EPA believes that a better approach for reducing mercury releases to the environment is to prevent mercury from entering the wastewater collection system at the source through product substitution, waste minimization or process modification, or removing and recycling mercury at the source (source controls) using state-of-the-art technology. These measures aimed at reducing influent loads to POTWs also reduce the use of mercury in the community, which could reduce the amount of mercury entering the environment through other media or sources. (For example, products that contain low levels of mercury may be disposed of as a nonhazardous solid waste and incinerated, releasing mercury to the air.) Where pollution prevention approaches have been implemented, substantial reductions in mercury concentrations in POTW influents, sludges, and effluents have been achieved. For a discussion of this approach, see the draft *Overview of P2 Approaches at POTWs* (USEPA 1999a). For an example of guidance on developing an MMP, see the EPA Region 5 final document *Mercury Pollutant Minimization Program Guidance*, dated November 2004 (http://www.epa.gov/region5/water/npdestek/mercury_pmp_nov_04_guidance.pdf). Many of the recommendations contained in the document are drawn from existing guidance and practice of state permitting authorities in EPA's Regional Office in Chicago. See also the City of Superior's document, *Mercury Pollutant Minimization Program Guidance Manual for Municipalities*, at http://www.ci.superior.wi.us/

index.asp?NID=129, and EPA's *Local Limits Development Guidance* (USEPA 2004) at http://www.epa.gov/npdes/pubs/final_local_limits_guidance.pdf.

Finally, as explained in section 2.1.1, mercury is a bioaccumulative, persistent pollutant that can cause adverse health effects. Given this fact, EPA believes that point sources that can cost-effectively reduce their mercury discharges should do so. The fact that air sources or historical contamination are likely dominant causes of impairment does not mean that point sources should not implement cost-effective, feasible pollution prevention measures to reduce their contribution of mercury to the environment, however small those contributions may be. In short, EPA believes that it is reasonable to expect NPDES permittees to implement cost-effective, feasible, and achievable measures to reduce the amount of mercury they discharge into the environment and that, depending on the particular facts, permit writers may reasonably conclude that permit limits that require such measures derive from and comply with water quality standards as required by EPA regulations at 40 CFR 122.44(d)(1)(vii)(A).

In cases where a permittee believes it may have reasonable potential, EPA recommends that the permittee provide information that the permitting authority can use in developing appropriate permit conditions and would encourage the permittee to provide a draft MMP. Alternatively, where a draft MMP is not initially submitted by the permittee, the permitting authority may request that the permittee provide a draft MMP. The permitting authority retains the final responsibility for determining reasonable potential, and for incorporating the appropriate permit conditions, including an effective MMP and its implementation, in the permit.

Developing an MMP need not be an intensive or burdensome activity. The content of an MMP should be determined on a case-by-case basis and tailored to the individual facility's potential to discharge mercury and implement reasonable controls. The MMP could be as little as one or two pages or as much as a major engineering study. Table 6 contains suggestions for the content of an MMP based on the type of facility. Of course, MMPs should vary in their level of detail and degree of stringency on the basis of site-specific factors and the degree to which the facility has the ability to reduce environmental releases of mercury. For example, if the mercury analysis performed for the permit application shows a much higher concentration than would be expected for the type of facility, further investigation would be appropriate and could lead to increased requirements. On the other hand, EPA recognizes that MMPs may not be effective in certain cases such as when an increase in the discharge of mercury may be due to the presence in stormwater or input process water that does not originate with and is not under the reasonable control of a facility.

If a permittee has several of the types of sources listed in table 6, each of these sources should be considered in developing an appropriate MMP. For example, if the service area of a POTW contains dental offices and medical facilities, the MMP should contain appropriate measures for both. The mercury minimization measures suggested in table 6 are expected to reduce mercury levels in the wastewater discharge as well as other waste streams and media. Most of the mercury discharged to POTWs, for example, ends up in biosolids that may be incinerated or disposed on the land, thus contributing to the overall mercury burden in the environment. In addition, any measures that reduce releases to the atmosphere should be encouraged.

Table 6. Suggested content for MMPs based on the type of facility

Type of facility	Suggested content
Publicly (or privately) owned treatment works serving a purely residential area. No dental or medical offices or hospitals. No industrial users.	Recommended distribution of outreach materials on fish-consumption advisories and properly disposing of mercury-containing products.
POTW whose service area contains dental offices.	Recommend or require that dental offices follow American Dental Association BMPs.[a] Collect any bulk mercury in the offices. Develop an approach for using amalgam separators.
POTW whose service area contains one or more hospitals.	Recommend or require that hospitals follow the practices recommended by the American Hospital Association.[b]
POTW whose service area contains schools or medical offices.	Recommend or require that schools and medical offices properly dispose of bulk mercury in their possession (including, for example, mercury-containing sphygmomanometers).
Industrial direct or indirect dischargers that use mercury as an intentional component of their process or recover mercury as a by-product of their process.	Generally, such a case would involve a thorough analysis of opportunities to reduce their releases of mercury.
Industrial direct or indirect dischargers that do not use mercury as an intentional component of their process and do not recover mercury as a by-product of their process.	Such facilities should investigate opportunities to reduce their incidental releases of mercury such as recycling fluorescent lamps, switches, thermostats, etc. and replacing them with low-mercury or non-mercury products.

Notes:

[a] For more information on the American Dental Association BMPs, see Best Management Practices for Amalgam Waste (September 2005) at http://www.ada.org/prof/resources/topics/topics_amalgamwaste.pdf.

[b] For more information on American Hospital Association practices, see Replacing Mercury in Healthcare Facilities—A Step-by-Step Approach at http://www.h2e-online.org/hazmat/mercguide.html.

When developing MMPs, EPA recommends beginning with any existing best management plans and spill prevention and containment control plans for that facility. Many of the activities covered by those plans can also reduce mercury sources to wastewater. After reviewing many pollutant minimization programs, EPA recommends that a plan include at least the following elements:

- Identification and evaluation of current and potential mercury sources
- For POTWs, identification of both large industrial sources and other commercial or residential sources that could contribute large mercury loads to the POTW
- Monitoring to confirm current or potential sources of mercury
- Identification of potential methods for reducing or eliminating mercury, including requiring BMPs or assigning limits to all potential sources of mercury to a collection system, material substitution, material recovery, spill control and collection, waste recycling, process modifications, housekeeping and laboratory use and disposal practices, and public education

- Implementation of appropriate minimization measures identified in the plan
- Effluent monitoring to verify the effectiveness of pollution minimization efforts

EPA believes that these minimum permit conditions may be appropriate because they help to ensure that the discharge does not cause or contribute to an exceedance of water quality standards to protect against possible localized impacts and to minimize the discharge of mercury. EPA also believes that, depending on the particular facts, a permit writer may reasonably conclude that such an MMP is as stringent as necessary to achieve water quality standards.

To further manage mercury discharges, the permitting authority should consider including an effluent trigger level or reduction goal in an MMP. Such a trigger level or goal could be set at a level that would provide a basis for evaluating whether the mercury minimization measures or BMPs specified in the MMP are working as anticipated. The level or goal could be expressed numerically or in narrative form. For example, the MMP might provide a trigger level equal to the existing effluent quality that, if exceeded, would indicate that mercury minimization measures may not be effective. Alternately, the MMP might provide goals for mercury reductions that are expected to occur as a result of the implementation of mercury minimization efforts specified in the MMP. As explained in this section and in section 7.5.2.1, an MMP includes a set of BMPs that would be part of an enforceable special condition of the permit. The MMP might specify that exceeding a trigger level or failing to achieve a mercury reduction goal would prompt actions such as reevaluation of the MMP, additional monitoring, or the implementation of additional BMPs. In this case, the failure of the permittee to undertake the additional actions identified in the MMP would be a violation of the permit special condition.

Even where it is infeasible to calculate a numeric WQBEL (for the reasons discussed in section 7.5.2.1), a permitting authority should consider including in the MMP an enforceable numeric level on the discharge of mercury. In this case, the enforceable numeric level would not constitute a stand-alone water quality-based effluent limit, but rather, a baseline for achieving mercury reductions that, combined with the other measures and practices in the MMP, would together constitute the water quality-based effluent limit. Such an enforceable numeric level could represent either existing effluent quality or a level representing some increment of the mercury reduction determined achievable as a result of the measures and practices specified in the MMP. Depending on the particular facts, the permit writer may reasonably conclude that the enforceable numeric level combined with the other measures and practices in the MMP will result in a level of mercury discharge that is controlled as stringently as necessary to meet water quality standards. Where the MMP contains an enforceable numeric level for mercury and/or methylmercury in the effluent, exceeding that value would be a violation of the permit special condition.

The permitting authorities should consider use of effluent trigger levels, effluent reduction goals, and enforceable numeric levels in any discharge permits that are based on MMPs as water quality-based effluent limits. EPA recommends that permitting authorities include such levels or goals in permits where direct water inputs are relatively high.

8 Related Programs

8.1 What are EPA and others doing as a whole to address mercury?

A wide variety of actions are under way in the United States and internationally to address mercury contamination. EPA's mercury Web site, at http://www.epa.gov/mercury, provides a broad range of information about mercury: actions by EPA and others, including international actions, effects on people and the environment, and how people can protect themselves and their families.

With respect to EPA's actions, on July 5, 2006, EPA issued a report titled *EPA's Roadmap for Mercury* ("*Roadmap*"). It is at http://www.epa.gov/mercury/roadmap.htm. EPA's *Roadmap* describes the Agency's progress to date in addressing mercury issues domestically and internationally, and it outlines EPA's major ongoing and planned actions to address risks associated with mercury. The *Roadmap* describes the Agency's most important actions to reduce both mercury releases and human exposure to mercury. Creating the *Roadmap* has enabled EPA to maximize coordination of its many diverse efforts, with the goal of improving its mercury program. In addition to providing a roadmap for EPA, the report provides important information about mercury to other federal agencies; to EPA's partners in state, tribal, and local governments; and to the public.

8.2 How does pollution prevention play a role in the methylmercury criterion?

Under the national pretreatment program, POTWs routinely control the volume and concentration of pollutants contributed by significant industrial users (SIUs)[24] to their collection system and wastewater treatment plant. However, as water quality criteria, sludge standards, and air emissions standards become more restrictive, even low levels of pollutants like mercury might cause noncompliance with these standards. Therefore, POTWs must expand pollutant control efforts or install treatment technologies to remove the problem pollutants.

In many cases, large-scale treatment technology is either not yet available or not economically feasible for controlling mercury at POTWs. Instead, POTWs are choosing to develop and implement pollution prevention (P2) strategies to reduce the amount of mercury received by the wastewater treatment plant. Although SIUs can contribute a significant mercury load to the treatment plant, non-SIU sources can also be identified as causing or contributing to the problem. For example, the Western Lake Superior Sanitary District (WLSSD) determined that one SIU and many small non-SIUs (dental facilities)

[24] EPA defines an SIU as (1) any industrial user (IU) subject to a categorical pretreatment standard (national effluent guidelines); (2) any user that discharges an average of 25,000 gallons per day or more of process wastewater or that contributes a process waste stream making up 5 percent or more of the average dry weather hydraulic or organic capacity of the POTW treatment plant; or (3) any other user designated by the Control Authority (POTW) to be an SIU on the basis that it has a reasonable potential for adversely affecting the POTW's operation or for violating a pretreatment standard or requirement (40 CFR 403.4(v)).

contribute a major portion of the mercury in its wastewater. Sectors historically more difficult to control (e.g., residential) or beyond the POTW's direct control (e.g., pollutants in contaminated inflow/rainfall) can also contribute substantial loadings.

Effective mercury source reduction relies on the POTW's effectively communicating to sector entities that minimal individual efforts can collectively reduce the mercury loading to the environment. Forming partnerships and working with sector representatives to investigate mercury sources, explore alternatives, and assist in implementing selected options is integral to a successful reduction strategy. Permitting authorities developing a P2 plan should consider a POTW's role in compliance assistance. The sections below provide summary-level guidance for developing a POTW P2 plan.

Through the pretreatment program, POTWs should communicate with their permitting authority, as well as maintain close contact with local sewer dischargers and have a good understanding of specific industrial process operations. Thus, they can uniquely promote P2 to numerous facilities and provide public awareness and education. In general, the success of a POTW P2 effort depends on a behavioral change on the part of the POTW and the community. As noted by the City of Palo Alto, "Experience shows that people are more likely to change their behaviors if they fully understand environmental problems and the range of possible solutions, if they have participated in the process leading to a policy decision, and if they believe regulators are dealing with them in good faith...." (City of Palo Alto 1996). A POTW might minimize community resistance and apathy by undertaking the following activities prior to developing its plan:

- Conduct a preliminary investigation of the problem and potential sources. Verify that the problem is not a wastewater treatment plant operational issue. Identify internal sources and any area government facilities in addition to industrial, commercial, and uncontrollable sources that could be contributing to or causing the problem.

- Meet with upper management (e.g., utility director, mayor, council) and discuss the problem, preliminary findings, and potential ramifications. Upper management support will be essential for obtaining necessary resources, funding, equipment, and authority for implementing a P2 plan. Their support will also be necessary for resolving any wastewater treatment plant and government facility issues. Upper management may also advise development of a POTW mission statement that declares goals and the chosen approach. Exhibit 1 provides an example of the WLSSD mission statement (WLSSD 1997).

- Establish a workgroup composed of representatives from government, industry, community, and environmental organizations, preferably those that are familiar with P2 strategies or with the pollutant of concern. The workgroup likely will develop or help develop the plan, guide plan implementation, and measure plan success. Therefore, findings from the preliminary investigation will guide the POTW to select appropriate committee members and experts. Bear in mind that the workgroup size should ensure representation of most interests but not grow so large as to be counterproductive. This group could also prove valuable in disseminating information.

With the support and expertise needed, the POTW and workgroup can draft a plan by doing the following:

- *State the problem* to provide background information about the POTW, problems caused by mercury, and why the POTW is taking action (described in terms that most people can understand).
- *Identify the goals* to determine whether the POTW intends to help minimize mercury introduced to all environmental media (air, water, solid waste), known as "front-end" P2 or merely to minimize the amount of mercury discharged to the wastewater treatment plant. The latter option ignores mercury transfers to other media (e.g., air, solid waste) and is the less environmentally sound option. It may be essential for the POTW to implement a front-end P2 approach and establish waste collection programs for the proper recycling or disposal of mercury-bearing wastes (e.g., thermometers, fluorescent light bulbs).
- Define an approach that outlines the sectors selected for P2 efforts, the criteria for targeting efforts (e.g., size of the source loading, authority available to control the source or sector, time necessary to produce desired results), where efforts will be voluntary or mandatory, who will execute the various program efforts, and how the POTW will proceed where mercury introduction is beyond its control (e.g., contaminated stormwater).
- Identify resources necessary to implement the plan such as staffing, equipment, and funding.
- Create contingency plans that describe actions to be taken if the planned efforts do not succeed, such as obtaining the authority to mandate and enforce P2 or other source control requirements or installing wastewater treatment plant technology.

Exhibit 1. Example Mission Statement

The WLSSD Commitment to Zero Discharge

The WLSSD as a discharger to Lake Superior is committed to the goal of zero discharge of persistent toxic substances and will establish programs to make continuous progress toward that goal. The District recognizes step-wise progress is only possible when pollution prevention strategies are adopted and rigorously pursued. These approaches will focus upon our discharge as well as indirect sources.

WLSSD will work with its users to implement programs, practices, and policies which will support the goal. We will call upon the resources and assistance of the State and federal governments for support, including financial support of the programs to ensure that our users are not penalized unfairly.

WLSSD recognizes that airborne and other indirect sources beyond District control must be addressed in order for significant reductions to occur.

Plans might develop in response to a specific problem (e.g., elevated mercury levels in wastewater treatment plant effluent) or proactively to minimize potential problems. Plans will vary in complexity and in resources necessary to achieve goals. Plan updates should detail successful and failed efforts, such as in the form of lessons learned.

8.3 What regulations has EPA issued pursuant to the CAA to address air emissions of mercury?

As rules and standards pursuant to the CAA have been developed, proposed, and promulgated since the Amendments of 1990, compliance by emitting sources and actions taken voluntarily have already begun to reduce mercury emissions to the air across the country. EPA expects that a combination of ongoing activities will continue to reduce such emissions over the next decade.

EPA has made substantial progress in addressing mercury air emissions under the CAA. In particular, EPA has issued regulations addressing the major contributors of mercury to the air (including, for example, municipal waste combustors; hospital, medical, and infectious waste incinerators; chlor-alkali plants; and hazardous waste combustors). EPA issued regulations for these source categories under different sections of the CAA, including sections 111, 112, and 129. Indeed, as the result of EPA's regulatory efforts, the United States achieved a 58 percent reduction in domestic mercury air emissions between 1990 and 2005 (see figure 4 and http://cfpub.epa.gov/eroe/index.cfm?fuseaction=detail.viewMidImg&lShowInd=0&subtop=341&lv=list.listByAlpha&r=216615#11215).

The relevant regulations that EPA has issued to date under the CAA are described briefly below. For more information about other CAA actions to control mercury, see http://www.epa.gov/mercury under "What EPA and Others Are Doing."

8.3.1 Municipal waste combustors

In 1995 EPA promulgated new source performance standards (NSPS) that apply to all new municipal waste combustor units (both waste-to-energy plants and incinerators) with the capacity to burn more than 250 tons of municipal solid waste, including garbage, per day and emission guidelines that apply to existing units with the same capacity through either an EPA-approved State plan or a promulgated Federal plan (see 60 FR 65,415 [December 19, 1995], codified at 40 CFR part 60, subparts Eb and Cb). These regulations cover approximately 130 existing waste-to-energy plants and incinerators, as well as any new plants and incinerators built in the future. The regulations have reduced emissions of a number of HAPs, including mercury, by approximately 145,000 tons per year. The regulations have resulted in about a 90 percent reduction in mercury emissions from domestic municipal waste combustors from 1990 emission levels (57 tons per year of mercury emitted from domestic municipal waste combustors in 1990 versus 2.3 tons per year in 2005). In 2000, EPA promulgated NSPS and emission guidelines establishing similar requirements for small municipal waste combustor units (units with a capacity of 35 to 250 tons per day) (see 65 FR 76,355 [December 6, 2000], codified at 40 CFR part 60, subparts AAAA and BBBB).

8.3.2 Hospital, medical, and infectious waste incinerators

Hospital/medical/infectious waste incinerators (HMIWIs) are used by hospitals, health care facilities, research laboratories, universities, and commercial waste disposal companies to dispose of hospital waste and/or medical/infectious waste. EPA adopted regulations controlling mercury and other emissions from HMIWIs on September 15, 1997 (62 FR 48,348, codified at 40 CFR part 60, subparts Ce and Ec). All existing HMIWIs were required to comply with the regulations by September 15, 2002. EPA estimated that the regulations would reduce mercury emissions from HMIWIs at existing facilities by 93–95 percent (from 16.5 to 0.9-1.2 tons per year). In fact, the actual mercury emission reductions achieved as a result of implementing the regulations were approximately 98 percent. At the time the regulations were issued, EPA expected that 50 to 80 percent of the 2,400 then-existing HMIWIs would close in response to the rule. EPA's rule resulted in a significant change in medical waste disposal practices in the United States. Because of the increased cost of on-site incineration under the 1997 rule, approximately 98 percent of the 2,400 HMIWIs operating at health care facilities in 1997

have shut down or obtained exemptions, and few facilities have installed new HMIWIs (5 new HMIWIs at 4 facilities). Instead, many facilities have switched to other methods of waste treatment and disposal, such as autoclaving and off-site commercial waste disposal. There are currently 57 existing HMIWIs operating at 52 facilities. EPA adopted revised regulations for HMIWIs on October 6, 2009 (74 FR 51,368). The revisions were issued in order to respond to a court remand of the 1997 rule and to satisfy the Clean Air Act section 129(a)(5) requirement to conduct a review of the standards every 5 years. EPA estimates that the revised regulations will reduce mercury emissions at existing HMIWIs by 89 percent (from 0.3 to 0.04 tons per year). The revised mercury standards are estimated to impact 20 HMIWIs, which are expected to employ mercury control technology (e.g., installing activated carbon injection systems or increasing current use of activated carbon). All existing HMIWIs are required to comply with the revised regulations by October 6, 2014.

8.3.3 Chlor-alkali plants

On December 19, 2003, EPA issued final regulations to reduce mercury emissions from chlorine production plants that rely on mercury cells (see 68 FR 70,904, codified at 40 CFR part 63, subpart IIIII). These air regulations have reduced mercury air emissions from existing chlor-alkali plants by approximately 50 percent since the compliance date of December 19, 2006. The regulation requires a combination of controls for point sources, such as vents, and BMPs to address fugitive air emissions, that are more stringent work practices than those required by a preexisting regulation that covered this source category. Today, there are four (4) such plants in the United States, compared to 20 when work on the rule began. In addition, EPA completed a study of fugitive mercury emissions at existing chlor-alkali plants and found the levels of elemental mercury emissions much lower than previously thought. Current total emissions from the four plants are estimated to be approximately 0.3 tons per year of mostly (>98%) elemental mercury.

8.3.4 Hazardous waste combustors

In 2005, EPA published standards under Section 112(d) of the CAA for hazardous waste combustors (HWCs)--incinerators, cement kilns, lightweight aggregate kilns, liquid fuel boilers, solid fuel boilers, and hydrochloric acid production furnaces that burn hazardous waste (70 FR 59402 (October 12, 2005)). The mercury standards for existing and new sources, respectively, are under 40 CFR 63.1216(a)(2) and (b)(2) for solid fuel boilers, 40 CFR 63.1217(a)(2) and (b)(2) for liquid fuel boilers, 40 CFR 63.1218(a)(2) and (b)(2) for hydrochloric acid production furnaces, 40 CFR 63.1219(a)(2) and (b)(2) for incinerators, 40 CFR 63.1220(a)(2) and (b)(2) for cement kilns, and 40 CFR 63.1221(a)(2) and (b)(2) for lightweight aggregate kilns. Approximately 200 HWCs are complying with these standards.

EPA will be reviewing these standards as a result of the D.C Circuit Court of Appeals' approval in June 2009 of EPA’s motion for voluntary remand of the emission standards. Any revised standards would be no less stringent than the current standards.

8.3.5 Coal-fired power plants

At present, the largest single source of anthropogenic mercury emissions in the country is coal-fired power plants. Mercury emissions from U.S. power plants are estimated to account for about one percent of total global mercury emissions (70 FR 15994; March 29, 2005). EPA has initiated a rulemaking effort to develop emission standards under Clean Air Act section 112(d) for emissions of hazardous air pollutants (including mercury) from coal- and oil-fired electric utility steam generating units. Consistent with a Consent Decree, the Agency intends to issue final emission standards for these units by the end of 2011.

8.3.6 Other

In addition to EPA's regulatory efforts under the CAA, in 1996 the United States eliminated the use of mercury in most batteries under the Mercury Containing and Rechargeable Battery Management Act. This action reduces the mercury content of the waste stream, which further reduces mercury emissions from waste combustion. In addition, voluntary measures to reduce use of mercury-containing products, such as the voluntary measures to which the American Hospital Association has committed, will contribute to reduced emissions from waste combustion.

Appendix A. Methylmercury/Mercury Ratio Exhibited in Muscle Tissue of Various Freshwater Fish Species

Source	Ecosystem type	Fish species	MethylHg/ total Hg ratio
Hammerschmidt et al. 1999	Freshwater lakes in Wisconsin, USA	Yellow perch (*Perca flavescens*)	mean: 0.95 range: 0.84 to 0.97
Becker and Bigham 1995	Onondaga Lake, a chemically contaminated lake in New York, USA	Gizzard shad (*Dorosoma cepedianum*) White perch (*Morone americana*) Carp (*Cyprinus carpio*) Channel catfish (*Ictalurus punctatus*) Bluegill (*Lepomis macrochirus*) Smallmouth bass (*Micropterus dolomieui*) Walleye (*Stizostedion vitreum*)	> 0.90 Note: Authors did not provide specific percentages for individual species.
Grieb et al. 1990	Lakes in the Upper Michigan Peninsula, USA	Yellow perch (*Perca flavescens*) Northern pike (*Esox lucius*) Largemouth bass (*Micropterus salmoides*) White sucker (*Catostomus commersoni*)	0.99 Note: Authors did not provide data for each species separately—only mean value observed over all species.
Bloom 1992	Freshwater fish species collected from remote midwestern lakes and one mercury contaminated site USA	Yellow perch (*Perca flavescens*) Northern pike (*Esox lucius*) White sucker (*Catostomus commersoni*) Largemouth bass (*Micropterus salmoides*)	0.99 1.03 0.96 0.99
Lasorsa and Allen-Gil 1995	3 lakes in the Alaskan Arctic, USA	Arctic grayling Lake trout Arctic char Whitefish	1.00 all for species Note: Authors did not provide species-specific information on MeHg/total Hg ratio.
Kannan, et al. 1998	Estuaries in South Florida	Hardhead catfish (*Arius felis*) White grunt (*Haemulon plumieri*) Sand perch (*Diplectrum formosum*), Lane snapper (*Lutjanus synagris*) Gafftopsail catfish (*Bagre marinus*) Pinfish (*Lagodon rhomboides*) Spot (*Leiostomus xanthurus*) Pigfish (*Orthopristis chrysoptera*) Sand seatrout (*Cynoscion arenarius*) Brown shrimp (*Penaeus aztecus*)	0.90 0.91 0.91 0.97 0.71 0.78 0.75 0.82 0.85 0.72 Note: Author sampled the 10 fish species at 20 locations.
Jackson 1991	Lakes and reservoirs in northern Manitoba, Canada	Walleye (*Stizostedion vitreum*) Northern pike (*Esox lucius*) Lake whitefish (*Coregonus clupeaformis*)	range: 0.806% to 0.877% range: 0.824% to 0.899% range: 0.781% to 0.923% Note: Author sampled the 3 fish species at 4 lake locations.

Source	Ecosystem type	Fish species	MethylHg/ total Hg ratio
Wagemann et al. 1997	Sampling location not provided; presumed to be from Canadian waters	Walleye (*Stizostedion vitreum*)	mean 1.00 Note: Authors did not provide more specific information.

For trophic level assignments for specific fish species, refer to tables 6-4 and 6-6 of the 2000 Human Health BAF guidance (USEPA 2003). Additional information on trophic level assignments is in the appendix of that guidance (http://www.epa.gov/waterscience/criteria/humanhealth/method/tsdvol2.pdf).

Appendix B. Tables from Methylmercury Criteria Document

This appendix contains several tables taken directly from the 2001 methylmercury criteria document. They are repeated here to help the reader understand the development of the 2001 criterion.

Table B1. Exposure parameters used in derivation of the water quality criterion.

(References cited in this table can be found in the 2001 methylmercury criterion document.)

Parameter	Population			Source
	Children (0-14 years)	Women of Childbearing Age (15-44 years)	Adults in the General Population	
Body Weight, kg	30	67	70	USEPA (2000f)
Drinking Water Intake, L/day	1.0	2.0	2.0	USEPA (2000f)
Freshwater/Estuarine Fish Intake, g/day	156.3[a]	165.5[a]	17.5[b,c]	USEPA (2000f)
Inhalation, m^3/day	10.4	11	20	USEPA (1994, 1997d)[d]
Soil Ingestion, g/day	0.0001, 0.01[e]	0.00005	0.00005	USEPA (1997d)
Mean Marine Fish Intake, g/day	74.9[a]	91.04[a]	12.46[b]	USEPA (2000a)
Median Marine Fish intake, g/day	59.71[a]	75.48[a]	0[b]	USEPA (2000a)
90th Percentile Marine Fish Intake, g/day	152.29[a]	188.35[a]	49.16[b]	USEPA (2000a)

Notes:

[a] For children and women of childbearing age, intake rates are estimates of "consumers only" data (as described in USEPA 2000a).

[b] For adults in the general population, intake rates are estimates of all survey respondents to derive an estimate of long-term consumption (USEPA).

[c] This is the 90th percentile freshwater and estuarine fish consumption value.

[d] Inhalation rates for children and women of childbearing age from USEPA, 1997d. Inhalation rates for adults in the general population from USEPA (1994).

[e] Pica child soil ingestion.

Table B2. Average mercury concentrations in marine fish and shellfish[a]

(References cited in this table can be found in the 2001 methylmercury criteria document.)

Species	Concentration[b] (µg Hg/g Wet Wt.)	Species	Concentration (µg Hg/g Wet Wt.)
Finfish			
Anchovy	0.047	Pompano*	0.104
Barracuda, Pacific	0.177	Porgy*	0.522[d]
Cod*	0.121	Ray	0.176
Croaker, Atlantic	0.125	Salmon*	0.035
Eel, American	0.213	Sardines*	0.1
Flounder*[,c]	0.092	Sea Bass*	0.135
Haddock*	0.089	Shark*	1.327
Hake	0.145	Skate	0.176
Halibut*	0.25	Smelt, Rainbow*	0.1
Herring	0.013	Snapper*	0.25
Kingfish	0.10	Sturgeon	0.235
Mackerel*	0.081	Swordfish*	0.95[e]
Mullet	0.009	Tuna*	0.206
Ocean Perch*	0.116	Whiting (silver hake)*	0.041
Pollock*	0.15	Whitefish*	0.054[f]
Shellfish			
Abalone	0.016	Oysters	0.023
Clam*	0.023	Scallop*	0.042
Crab*	0.117	Shrimp	0.047
Lobster	0.232	Other shellfish*	0.012[d]
Molluscan Cephalopods			
Octopus*	0.029	Squid*	0.026

Notes:

*Denotes species used in calculation of methylmercury intake from marine fish for one or more populations of concern, based on existence of data for consumption in the CSFII (USEPA 2000a).

[a] More current information on commercial fish and shellfish is provided by the Food and Drug Administration at http://www.cfsan.fda.gov/%7Efrf/sea-mehg.html.

[b] Mercury concentrations are from NOAA (1978) as referenced in the NMFS database, as reported in USEPA (1997c) unless otherwise noted, measured as micrograms (µg) of mercury per gram (g) wet weight of fish tissue.

[c] Mercury data for flounder were used to estimate mercury concentration in marine flatfish for intake calculations.

[d] Mercury concentration data are from Stern et al. (1996) as cited in USEPA (1997f).

[e] Mercury concentration data are from U.S. FDA Compliance Testing as cited in USEPA (1997f).

[f] Mercury concentration data are from U.S. FDA (1978) compliance testing as described in the NMFS database, as cited in USEPA (1997f).

Table B3. Exposure estimates for methylmercury and percent of total exposure based on adults in the general population

Exposure Source	Exposure Estimate (mg/kg-day)	Percent of Total Exposure	Percent of RfD
Ambient water intake	4.3×10^{-9}	0.0047	0.004
Drinking water intake[a]	5.6×10^{-8}	0.0605	0.006
Nonfish dietary intake	0	0	0
Marine fish intake	2.7×10^{-5}	29.33	27
Air intake	4.6×10^{-9}	0.005	0.005
Soil intake	1.3×10^{-9}	0.0014	0.001

Note:

[a] This represents the high-end of the range of estimates. Because the contribution of ambient water or drinking water intake to total exposure is so negligible in comparison to the sum of intake from other sources, there is not difference in the total exposure estimated using either of these two alternatives.

Appendix C. Analytical Methods

Table C1. Analytical methods for determining mercury and methylmercury in tissue

Method	Form/species and applicable matrices	Quantitation Level or ML[a]	Technique	Known studies or literature references using the techniques in this method
Method 1630, with draft modifications for tissue (Recommended method – see section 4.1.3)	Methylmercury in tissue	0.001 mg/kg 0.002 mg/kg	Tissue modification: digest tissue with acid solution, neutralize with acetate buffer, and analyze as per Method 1630, i.e., distillation with heat and N_2 flow to separate methylHg from sample, ethylation with sodium tetraethyl borate, N_2 purging of methylethylHg onto graphite carbon (Carbotrap) column, thermal desorption of methylethylHg and reduction to Hg^0, followed by CVAFS detection.	• EPA Cook Inlet Contaminant Study • Lake Michigan fish and invertebrates, Mason and Sullivan 1997 • Northeastern Minnesota lake plankton, Monson and Brezonik 1998[b] • Method performance testing in freshwater and marine fish, Bloom 1989
Method 1631, draft appendix A (Recommended method – see section 4.1.3)	Total mercury in tissue, sludge, and sediment	0.002 mg/kg	Digest tissue with HNO_3/H_2SO_4. Dilute digestate with BrCl solution to destroy remaining organic material. Analyze digestate per method 1631: Add BrCl to oxidize all Hg compounds to Hg(II). Sequentially pre-reduced with hydroxylamine hydrochloride to destroy the free halogens and reduced with $SnCl_2$ to convert Hg(II) to Hg(0). Hg(0) is purged from solution onto gold-coated sand trap and thermally desorbed from trap for detection by CVAFS.	• EPA National Fish Tissue Study (>1,000 samples over 4-year period) • EPA Cook Inlet Contaminant Study • Lake Michigan fish and invertebrates, Mason and Sullivan 1997 • Northeastern Minnesota lake plankton, Monson and Brezonik 1998[b] • Method performance testing in freshwater and marine fish, Bloom 1989
Method 245.6	Total mercury in tissue	0.020 mg/kg	Sulfuric and nitric acid digestion, oxidation with potassium permanganate and potassium persulfate, $SnCl_2$ reduction, CVAAS detection	Unknown
Draft method 7474 (SW-846)	Total mercury in sediment and tissue	40 mg/kg	Microwave digestion of sample in nitric and hydrochloric acids, followed by cold digestion with bromate/bromide in HCl. Hg purged from sample and determined by CVAFS.	Reference materials cited in method. Niessen et al. 1999.

Notes:

[a] Quantitation level or minimum level (ML) is considered the lowest concentration at which a particular contaminant can be quantitatively measured using a specified laboratory procedure for monitoring of the contaminant.

[b] Used similar techniques but used a methylene chloride extraction instead of the distillation.

Table C2. Analytical methods for determining mercury and methylmercury in water, sediment, and other nontissue matrices

Method	Forms/species and applicable matrices	Quantitation Level or ML	Sample preparation	Known studies or literature references using the techniques in this method
EPA 1630[a] (Recommended method – see section 4.1.3)	Methylmercury in water	0.06 ng/L	Distillation with heat and N_2 flow, addition of acetate buffer and ethylation with sodium tetraethyl borate. Purge with N_2 onto Carbotrap. Thermal desorption and GC separation of ethylated mercury species, reduction to Hg^0 followed by CVAFS detection.	• USEPA Cook Inlet Study • USEPA Savannah River TMDL study • Northern Wisconsin Lakes, Watras et al. 1995 • Lake Michigan waters, Mason and Sullivan 1997 • Anacostia River Study, Mason and Sullivan 1998 • Northeastern Minnesota lakes, Monson and Brezonik 1998[b] • Poplar Creek, TN CERCLA Remedial Investigation of surface water, sediment, and pore water, Cambell et al. 1998[c] • Scheldt estuary study of water, polychaetes, and sediments, Baeyens et al. 1998
UW-Madison SOP for MeHg Analysis[a]	Methylmercury in water	0.01 ng/L	Distillation with heat and N_2 flow, with potassium chloride, sulfuric acid, and copper sulfate. Ethylation with sodium tetraethyl borate. Purge with N_2 onto Carbotrap. Thermal desorption and GC separation of ethylated mercury species, reduction to Hg^0 followed by CVAFS detection.	• Lake Michigan tributaries to support GLNPO's LMMB Study • Fox River, WI, waters and sediments, Hurley et al. 1998
USGS Wisconsin - Mercury Lab SOPs 004[a]	Methylmercury in water	0.05 ng/L	Distillation (heat), APDC solution, N_2 flow, potassium chloride, sulfuric acid, and copper sulfate. Ethylation with sodium tetraethyl borate. Purge with N_2 onto Carbotrap. Thermal desorption and GC separation of ethylated species, reduction to Hg^0, and CVAFS detection.	Aquatic Cycling of Mercury in the Everglades (ACME). cofunded by USGS, EPA, and others
USGS Open-File Report 01-445[a]	Methylmercury in water	0.04 ng/L	Distillation (heat) and N_2 flow, HCl and copper sulfate. Addition of acetate buffer and ethylation with sodium tetraethyl borate. Purge with N_2 onto Carbotrap. Thermal desorption and GC separation of ethylated mercury species, reduction to Hg(0) followed by CVAFS detection.	Formalized USGS method version of USGS Wisconsin Lab SOP 004. Report title is Determination of Methyl Mercury by Aqueous Phase Ethylation, Followed by GC Separation with CVAFS Detection.

Table C2. Analytical methods for determining mercury and methylmercury in water, sediment, and other nontissue matrices *(continued)*

Method	Forms/species and applicable matrices	Quantitation Level or ML	Sample preparation	Known studies or literature references using the techniques in this method
EPA 1631, revision E[d] (CVAFS) (Recommended method – see section 4.1.3)	Total or dissolved mercury in water	ML = 0.5 ng/L (MDL = 0.2 ng/L)	Oxidize all Hg compounds to Hg(II) with BrCl. Sequentially pre-reduce with hydroxylamine hydrochloride to destroy the free halogens and reduce with $SnCl_2$ to convert Hg(II) to Hg(0). Hg(0) is purged from solution with N_2 onto gold coated sand trap and thermally desorbed from trap for detection by CVAFS.	• USEPA Cook Inlet Study • State of Maine studies • USEPA Savannah River TMDL study • USEPA/U.S. Navy study for development of Uniform National Discharge Standards • Watras et al. 1995 • Anacostia River Study, Mason and Sullivan 1998 • Northeastern Minnesota lakes, Monson and Brezonik 1998 • Poplar Creek, TN, CERCLA Remedial Investigation Study, Cambell et al. 1998 • Scheldt Estuary Study, Baeyens et al. 1998
EPA 245.1[d] (CVAAS)	Total or dissolved mercury in wastewater	200 ng/L	H_2SO_4 and HNO_3 digestion, $KMnO_4$, $K_2S_2O_8$ oxidation + heat, cool +NaCl-$(NH_2OH)_2{\cdot}H_2SO_4$, $SnSO_4$, aeration. Detection by CVAAS.	Effluent guideline development studies for the Meat Products Industry, Metal Products and Machinery Industry, and Waste Incinerators
EPA 245.2[d] (CVAAS)	Total or dissolved mercury in wastewater and sewage	200 ng/L	H_2SO_4 and HNO_3 added, $SnSO_4$, NaCl-$(NH_2OH)_2{\cdot}H_2SO_4$, $KMnO_4$, $K_2S_2O_8$, heat. Detection by CVAAS.	MPM Industry effluent guideline development study
EPA 245.5 (CVAAS)	Total or dissolved mercury in soils, sludge and sediment	200 ng/L	Dry sample, aqua regia, heat, $KMnO_4$ added, cool +NaCl-$(NH_2OH)_2{\cdot}H_2SO_4$, $SnSO_4$, aeration. Detection by CVAAS.	Pharmaceutical industry effluent guideline development study
EPA 245.7[d] (CVAFS) (Recommended method – see section 4.1.3)	Total or dissolved mercury in water	ML = 5 ng/L; (MDL = 1.8 ng/L) [e]	HCl, $KBrO_3$ /KBr, $NH_2OH{\cdot}HCl$, $SnCl_2$, liquid-vapor separation. CVAFS detection	Interlaboratory validation completed
EPA 7470A (CVAAS)	Total or dissolved mercury in liquid wastes and ground water	200 ng/L (IDL)	H_2SO_4 and HNO_3 added, $KMnO_4$ added, $K_2S_2O_8$ added + heat, cool +NaCl-$(NH_2OH)_2{\cdot}H_2SO_4$, $SnSO_4$, aeration of sample. CVAAS detection.	Method is similar to and cites performance data given in EPA 245.5.

Table C2. Analytical methods for determining mercury and methylmercury in water, sediment, and other nontissue matrices *(continued)*

Method	Forms/species and applicable matrices	Quantitation Level of ML	Sample preparation	Known studies or literature references using the techniques in this method
EPA 7471B (CVAAS)	Total or dissolved mercury in solid wastes and semisolid wastes	200 ng/L (IDL)	H_2SO_4 and HNO_3 added, $KMnO_4$ added, $K_2S_2O_8$ added + heat, cool +NaCl-$(NH_2OH)_2{\cdot}H_2SO_4$, $SnSO_4$, aeration of sample. CVAAS detection.	Method is similar to and cites performance data given in EPA 245.5.
EPA 7472 (Anodic stripping voltametry)	Total or dissolved mercury in water	100-300 ng/L	Acidify and chlorinate sample, GCE electrode	Unknown
EPA 7473 (Thermal decomposition, amalgamation, and CVAA)	Mercury in water, soil, and sediment	estimated to be as low as 20 ng/ L or 20 ng/kg	Sample aliquot decomposed at 750°C in oxygen atmosphere. Decomposition products carried into catalytical furnace for completed oxidations, then to algamated trap. Mercury is thermally desorbed and determined by CVAA.	Unknown
Draft Method 7474 (SW-846)[f]	Total mercury in sediment and tissue	20 ng/g	Microwave digestion of sample in nitric and hydrochloric acids, followed by cold digestion with bromate/bromide in HCl. Hg purged from sample and determined by CVAFS.	Reference materials cited in method. Niessen et al. 1999.
EPA 1620 (CVAAS)	Mercury in water, sludge, and soil	200 ng/L	H_2SO_4 and HNO_3 added, $KMnO_4$, $K_2S_2O_8$ + heat, cool +NaCl-$(NH_2OH)_2{\cdot}H_2SO_4$, $SnSO_4$, aeration. CVAAS detection.	Industry effluent guideline development studies
SM 3112B (CVAAS)	Total or dissolved mercury in water	500 ng/L	H_2SO_4 and HNO_3 added, $KMnO_4$ added, $K_2S_2O_8$ added + heat, cool +NaCl $(NH_2OH)_2{\cdot}H_2SO_4$, $SnCl_2$ or $SnSO_4$, aeration. CVAAS determination.	Unknown
ASTM D3223-97, 02 (CVAAS)	Total or dissolved mercury in water	500 ng/L	H_2SO_4 and HNO_3 added, $KMnO_4$ added,$K_2S_2O_8$ added + heat, cool +NaCl $(NH_2OH)_2{\cdot}H_2SO_4$, $SnSO_4$, aeration. CVAAS determination.	Unknown
AOAC 977.22 (Atomic absorption spectrometry)	Total or dissolved mercury in water	200 ng/L	H_2SO_4 and HNO_3 added, $KMnO_4$ added, $K_2S_2O_8$ added + heat, cool +NaCl $(NH_2OH)_2{\cdot}H_2SO_4$, $SnSO_4$, aeration. Determine mercury by CVAA.	Unknown

Notes: (1) CVAAS = cold vapor atomic absorption spectrometry.

(2) CVAFS = cold-vapor atomic fluorescence spectrometry.

(3) ASTM and AOAC analytical methods are available from the respective organization.

[a] All four methylmercury methods above are based on the work of Bloom 1989, as modified by Horvat et al. 1993, and are virtually identical as a result.

[b] Used similar techniques but used a methylene chloride extraction instead of the distillation.

[c] Used similar techniques but omitted the distillation procedure.

[d] Promulgated and approved under 40 CFR part 136, Table 1B.

[e] The method detection level (MDL) is the minimum concentration of an analyte (substance) that can be measured and reported with a 99 percent confidence that the analyte concentration is greater than zero as determined by the procedure set forth in appendix B of 40 CFR part 136.

[f] Provided for reference purposes only. EPA recommends using method 1631 for analyzing mercury for water and fish tissue.

Appendix D. Synopsized Mercury TMDLs Developed or Approved by EPA

I. Ochlockonee Watershed, Georgia

II. Arivaca Lake, Arizona

III. McPhee and Narraguinnep Reservoirs, Colorado

IV. Clear Lake, California

V. Cache Creek, California

VI. Minnesota Statewide Mercury Total Maximum Daily Load

I. Ochlockonee Watershed, Georgia

Description of the Applicable Water Quality Standards

TMDLs are established to attain and maintain the applicable narrative and numerical water quality standards. The State of Georgia's *Rules and Regulations for Water Quality Control* do not include a numeric criterion for the protection of human health from methylmercury, but they do provide a narrative "free from toxics" water quality standard. Because mercury can cause toxicity in humans, Georgia has used a numeric "interpretation" of its narrative water quality standard for toxic substances to ensure that a TMDL will protect human health. The numeric interpretation of its narrative water quality standard is a concentration of no more than 0.3 mg/kg methylmercury in fish tissue. This numeric interpretation protects the "general population," which is the population that consumes 17.5 g/day or less of freshwater fish.

This approach is consistent with EPA's recommended water quality criterion for the protection of human health from methylmercury, described in the document *Water Quality Criterion for the Protection of Human Health: Methylmercury* (USEPA 2001a). The methodology uses a "weighted consumption" approach. When only trophic level 3 and 4 fish have been collected, the methodology assumes that 8 g/day (58.4 percent) of the total fish consumption is trophic level 3 fish (e.g., catfish and sunfish) and 5.7 g/day (41.6 percent) is trophic level 4 fish (e.g., largemouth bass). EPA collected site-specific data from the Ochlockonee River on ambient mercury in fish tissue and in the water column in the summer of 2000 and in March and April 2001 at two locations. Using a weighted consumption approach, site-specific fish tissue concentration data collected in the Ochlockonee River yields a weighted fish tissue concentration of 0.6 mg/kg, which is greater than the state's current applicable water quality criterion of 0.3 mg/kg. This was calculated as

Weighted fish tissue concentration = (avg. trophic 4 conc. x .416) + (avg. trophic 3 conc. x .584)

where:

average trophic level 3 concentration = 0.2 mg/kg
average trophic level 4 concentration = 1.0 mg/kg
weighted fish tissue concentration = 0.6 mg/kg

To establish the TMDL, EPA determined the maximum allowable concentration of mercury in the ambient water that will prevent accumulation of methylmercury in fish tissue above the applicable water quality standard, 0.3 mg/kg. To determine this concentration, EPA used the *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (USEPA 2000b). EPA also used the recommended national values from the *Methodology*, including the reference dose of 0.0001 mg/kg-day methylmercury, a standard average adult body weight of 70 kg, and the consumption rate for the general population of 17.5 g/day. For the other factors in the calculation, bioaccumulation and fraction of methylmercury, EPA used site-specific data from the Ochlockonee River collected in summer 2000 and March and April 2001. From this site-specific data, EPA determined a representative weighted BAF. The BAF was calculated

by taking the average calculated BAF from each of the two trophic levels. The BAF calculation also used 0.17 as the measured fraction of the total mercury as methylmercury. Using this approach, an allowable concentration of mercury in the ambient water of Ochlockonee River for the protection of human health is 1.6 ng/L. This concentration was calculated as

$$WQS = \frac{((\text{reference dose} - RSC) \times \text{body weight} \times \text{units conversion})}{(\text{consumption rate} \times \text{weighted BAF} \times \text{fraction MeHg})}$$

Where:

WQS = water quality standard = 1.6 ng/L
reference dose = 0.0001 mg/kg-day MeHg
RSC = relative source contribution from other fish species = 0.000027 mg/kg-day MeHg
body weight = 70 kg
units conversion = 1,000,000 mg/kg
consumption rate = 0.0175 kg/day fish
weighted bioaccumulation factor = 1,063,270 l/kg
fraction of the mercury as methylmercury = 0.17 as measured

Source Assessment

A TMDL evaluation must examine all known potential sources of the pollutant in the watershed, including point sources, nonpoint sources, and background levels. The source assessment was used as the basis of development of a model and the analysis of TMDL allocation options. This TMDL analysis includes contributions from point sources, nonpoint sources, and background levels. Sixteen water point sources in the Ochlockonee River watershed could have mercury in their discharges.

According to a review of the *Mercury Study Report to Congress* (USEPA 1997c), significant potential air emission sources include coal-fired power plants, waste incinerators, cement and lime kilns, smelters, and chlor-alkali factories. In the report, a national airshed model (RELMAP) was applied to the continental United States. This model provides a distribution of wet and dry deposition of mercury as a function of air emissions and global sources, and it was used to calculate wet and dry deposition rates for south Georgia.

The MDN includes a national database of weekly concentrations of mercury in precipitation and the seasonal and annual flux of mercury in wet deposition. EPA reviewed the MDN data for a sampling station near south Georgia. The MDN data were compared with the RELMAP deposition predictions and the MDN data were found to be substantially higher. Using the MDN data, the average annual wet deposition rate was determined to be 12.75 µg/square meter. The dry deposition rate was determined to be 6.375 µg/square meter on the basis of the RELMAP results.

Loading Capacity—Linking Water Quality and Pollutant Sources

The link between the fish tissue endpoint and the identified sources of mercury was the basis for the development of the TMDL. The linkage analysis helped estimate the total

assimilative capacity of the river and any needed load reductions. In this TMDL, models of watershed loading of mercury were combined with a model of mercury cycling and bioaccumulation in the water. This approach enabled a translation between the endpoint for the TMDL (expressed as a fish tissue concentration of mercury) and the mercury loads to the water. The loading capacity was then determined by the linkage analysis as a mercury loading rate that was consistent with meeting the endpoint fish tissue concentration.

Watershed-scale loading of water and sediment was simulated using the WCS. The complexity of this loading function model falls between that of a detailed simulation model (which attempts a mechanistic, time-dependent representation of pollutant load generation and transport) and simple export coefficient models (which do not represent temporal variability). The WCS provides a mechanistic, simplified simulation of precipitation-driven runoff and sediment delivery, yet it is intended to be applicable without calibration. Solids load, runoff, and ground water can then be used to estimate pollutant delivery to the receiving waterbody from the watershed. This estimate is based on pollutant concentrations in wet and dry deposition, processed by soils in the watershed and ultimately delivered to the receiving waterbody by runoff, erosion, and direct deposition. The WCS-calculated loads for each subbasin are shown in table D1.

Table D1. Annual average mercury load from each subbasin

Watershed	Total Hg load (mg)	Areal load (mg/ha)	Impervious area (mg/yr)	Sediment (mg/yr)	Runoff (mg/yr)	Deposition on water (mg/yr)
Barnett Creek	786098.4	25.6	116614.69	422879.88	177553.9	68850
Middle/Lower Ochlocklonee	307965.8	21.24	125771.73	89440.3	54786.29	37867.5
Tired Creek	827172.8	22.03	252386.89	317969.16	194751.7	61965
Lower Ochlockonee	359317.5	15.62	100125.11	130407.68	97802.16	30982.5
Little Ochlockonee	873773.4	19.89	140023.69	433136.75	219614.2	80898.75
Bridge Creek	454417.5	23.11	53496.45	261042.44	98468.66	41310

WASP5 (Ambrose et al. 1988) was chosen to simulate mercury fate in the Ochlockonee River. WASP5 is a general, dynamic mass balance framework for modeling contaminant fate and transport in surface waters. Environmental properties and chemical concentrations are modeled as spatially constant within segments. Each variable is advected and dispersed among water segments and exchanged with surficial benthic segments by diffusive mixing. Sorbed or particulate fractions can settle through water column segments and deposit to or erode from surficial benthic segments. Within the bed, dissolved variables can migrate downward or upward through percolation and pore water diffusion. Sorbed variables can migrate downward or upward through net sedimentation or erosion.

The toxics WASP model, TOXI5, combines a kinetic structure adapted from EXAMS2 with the WASP5 transport structure and simple sediment balance algorithms to predict dissolved and sorbed chemical concentrations in the bed and overlying waters. TOXI5 simulates the transport and transformation of chemicals as a neutral compound and up to four ionic species, as well as particulate material. Local equilibrium is assumed so that the distribution of the chemical among the species and phases is defined by distribution or partition coefficients. The predicted mercury concentrations are shown in table D2.

Table D2. Predicted mercury for annual average load and flow

Calculated concentrations	River reach					
	1	2	3	4	5	6
Total Hg: water column (ng/L)	6.33	5.84	5.55	5.76	5.65	5.17
Total Hg: sediment (ng/g)	7.05	9.07	9.81	8.17	7.63	6.97
Methyl Hg: water column (ng/L)	0.90	0.82	0.77	0.79	0.77	0.71

Allocations

To determine the total maximum load that can enter the Ochlockonee River, the current loading conditions were evaluated and the instream concentration was determined using the modeling approach described above. This allowed the development of a relationship between load and instream mercury concentrations. Using this developed relationship, the total maximum load could be determined. Because the water column mercury concentration response is linear with respect to changes in load, a proportion could be developed to calculate the total maximum mercury load from the watershed that would achieve the derived water quality target of 1.6 ng/L. The TMDL was calculated as the ratio of the water quality target to the highest segment concentration (1.6 ng/L divided by 6.3 ng/L) applied to the current annual average load of 5.00 kg/yr. This gave a TMDL load of 1.22 kg/yr mercury, which represents a 76 percent reduction from the current annual average load.

In a TMDL assessment, the total allowable load is divided and allocated to the various pollutant sources. The calculated allowable load of mercury that can come into the Ochlockonee River without exceeding the applicable water quality target of 1.6 ng/L is 1.22 kg/yr. Because EPA's assessment indicates that over 99 percent of the current loading of mercury is from atmospheric sources, 99 percent of the allowable load is assigned to the load allocation and 1 percent of the allowable load is assigned to the wasteload allocation. Therefore, the load allocation and the wasteload allocation for the Ochlockonee River are:

Load allocation (atmospheric sources) = 1.16 kilograms/year
Wasteload allocation (NPDES sources) = 0.06 kilograms/year

EPA estimates that atmospheric deposition contributes over 99 percent of current mercury loadings to the river; therefore, significant reductions in atmospheric deposition will be necessary if the applicable water quality standard is to be attained. On the basis of the total allowable load of 1.22 kg/year, a 76 percent reduction of mercury loading is needed to achieve the applicable water quality standard. EPA believes that an estimated

31 percent to 41 percent reduction in mercury deposition to the Ochlockonee River watershed can be achieved by 2010 through full implementation of existing CAA requirements. In addition, a number of activities to address remaining sources of mercury are planned or under way, and EPA expects that further reductions in mercury loadings will occur over time as a result of those activities. EPA is not able to estimate the reductions in mercury deposition to the Ochlockonee River watershed that will be achieved from future activities. As contemplated by CWA section 303(d)(1)(C), however, this TMDL quantifies the water quality problem facing the Ochlockonee River watershed and identifies the needed reductions in loadings from atmospheric deposition—by CAA initiatives or under other authorities—for the watershed to achieve applicable standards for mercury. In addition, as EPA collects additional data and information for the Ochlockonee River watershed and as new legal requirements are imposed under the CAA, EPA will continue to evaluate the effectiveness of regulatory and nonregulatory air programs in achieving the TMDL's water quality target.

The analysis of NPDES point sources in the watershed indicates that the cumulative loading of mercury from these facilities is less than 1 percent of the total estimated current loading. Even if this TMDL allocated none of the calculated allowable load to NPDES point sources (a wasteload allocation of zero), the waterbody would not attain the applicable water quality standards for mercury because of the very high mercury loadings from atmospheric deposition. At the same time, however, EPA recognizes that mercury is an environmentally persistent bioaccumulative toxic with detrimental effects on human fetuses even at minute quantities and that it should be eliminated from discharges to the extent practicable. Taking these two considerations into account, this TMDL provides a wasteload allocation applicable to all Georgia NPDES-permitted facilities in the watershed in the amount of 0.06 kg/year. The TMDL was written so that all NPDES-permitted facilities will achieve this wasteload allocation by discharging mercury only at concentrations below the applicable water quality standard, 1.6 ng/L, or by implementing a pollutant minimization program.

In the context of this TMDL, EPA believes it can reasonably offer the choice of the two approaches to the permitting authority for the following reasons. First, on the basis of EPA's analysis, the Agency expects either wasteload allocation option, in the aggregate, to result in point source mercury loadings lower than the wasteload allocation. Second, EPA believes this flexibility is the best way of ensuring that the necessary load reductions are achieved without causing significant social and economic disruption. EPA recognizes that NPDES point sources contribute a small share of the mercury contributions to the Ochlockonee River. EPA also recognizes, however, that mercury is a highly persistent toxic pollutant that can bioaccumulate in fish tissue at levels harmful to human health. Therefore, EPA has determined, as a matter of policy, that NPDES point sources known to discharge mercury at levels above the amount present in their source water should reduce their loadings of mercury using appropriate, cost-effective mercury minimization measures to ensure that the total point source discharges are at a level equal to or less than the wasteload allocation specified in this TMDL. The point sources' waste load allocation will be applied to the increment of mercury in their discharge that is above the amount of mercury in their source water. EPA recommends that the permitting authority make this choice between the two options in consultation with the affected dischargers

because EPA is not able to make the case-by-case judgments in this TMDL that EPA believes are appropriate.

II. Arivaca Lake, Arizona

Description of the Applicable Water Quality Standards

Authorities develop TMDLs to meet applicable water quality standards. These standards may include numeric water quality standards, narrative standards describing designated uses, and other associated indicators supporting designated uses (beneficial uses apply only to California). A numeric target identifies the specific goals or endpoints for the TMDL that equate to attainment of the water quality standard. The numeric target may be equivalent to a numeric water quality standard (where one exists), or it may represent a quantitative interpretation of a narrative standard.

The applicable numeric targets for the Arivaca TMDL are the Arizona water quality standard of 0.2 µg/L mercury in the water column and the Arizona Fish Consumption Guideline criterion of 1 mg/kg mercury concentration in fish tissue. Arizona has adopted water quality standards for mercury that apply to a number of the designated uses specified for Arivaca Lake, including protection of aquatic life and wildlife and protection of human and agricultural uses. Of these numeric criteria, the most stringent is the chronic aquatic life criterion of 0.01 µg/L dissolved mercury (see table 7 on page 15 in the TMDL). Arizona has also issued a fish consumption advisory for this lake because mercury concentrations in fish tissue exceed 1 mg/kg.

Mercury bioaccumulates in the food chain. Within a lake fish community, top predators usually have higher mercury concentrations than forage fish, and tissue concentrations generally increase with age class. Top predators (such as largemouth bass) are often target species for sport fishermen. Arizona bases its Fish Consumption Guideline on average concentrations in a sample of sport fish. Therefore, the criterion should not apply to the extreme case of the most-contaminated age class of fish within a target species; instead, the criterion is most applicable to an average-age top predator. Within Arivaca Lake, the top predator sport fish is the largemouth bass. The selected target for the TMDL analysis is an average tissue concentration in 5-year-old largemouth bass of 1.0 mg/kg.

Source Assessment

A TMDL evaluation must examine all known potential sources of the pollutant in the watershed, including point sources, nonpoint sources, and background levels. The source assessment is used as the basis for developing a model and analyzing TMDL allocation options. There are no permitted point source discharges and no known sources of mercury-containing effluent in the Arivaca watershed. External sources of the mercury load to the lake include natural background load from the watershed, atmospheric deposition, and possible nonpoint load from past mining activities.

Watershed background load. The watershed background load of mercury was derived from mercury in the parent rock and from the net effects of atmospheric deposition of mercury on the watershed. Some mercury is also present within the parent rock formations of the Arivaca watershed, although no concentrated ore deposits are known.

The net contributions of atmospheric deposition and weathering of native rock were assessed by measuring concentrations in sediment of tributaries to Arivaca Lake. EPA collected 25 sediment and rock samples from dry tributaries in the Arivaca watershed and analyzed them for mercury. These data show that most of the sediment samples from the Arivaca watershed were considered at or near background mercury levels.

Nonpoint loadings from mining. No known mining for mercury itself has occurred in the watershed. However, mining activities for minerals other than mercury, especially historical mining practices for gold, might contribute to mercury loading in the watershed. Gold and silver mining commonly occurred in the area surrounding Arivaca Lake but apparently not within the watershed itself. The U.S. Bureau of Mines identified only one exploratory prospect, for manganese and uranium, within the Arivaca watershed.

Ruby Dump. Ruby Dump is in the southern portion of Arivaca watershed at the very upstream end of Cedar Canyon Wash. The dump apparently served the town of Ruby and the Montana Mine. The waste is characterized by numerous mining artifacts (e.g., crucibles) but also includes many common household items like bottles and plates. Samples were taken at three different locations of the Ruby Dump: the top of the hill (just below the fire pit), the middle of the hill, and the base of the dump. The mercury results for these samples, from the top of the hill to the bottom, were 1,467 ppb, 1,244 ppb (blind duplicate was 495 ppb), and 486 ppb. The average of these four samples is 918 ppb, which is the number used in the watershed modeling to represent the mercury concentration in sediment eroding from this site.

Near-field atmospheric deposition. Significant atmospheric point sources of mercury often cause locally elevated areas of near-field atmospheric deposition downwind. A review of *Mercury Study Report to Congress* (USEPA 1997c) and a search of EPA's AIRS database of permitted point sources found no significant U.S. sources of airborne mercury within or near the Arivaca watershed. Also, the most nearby parts of Mexico immediately to the southwest (prevailing wind direction) of the watershed are sparsely populated. Because of the lack of major nearby sources, especially sources along the axis of the prevailing wind, EPA does not believe that near-field atmospheric deposition of mercury attributable to individual emitters is a major component of mercury loading to the Arivaca watershed. Because no significant near-field sources of mercury deposition were identified, mercury from atmospheric deposition onto the watershed is treated as part of a general watershed background load in this analysis.

Far-field atmospheric deposition. In May 1997 the MDN began collecting deposition data at a new station in Caballo, in the southwestern quadrant of New Mexico. This station is the closest MDN station to the Arivaca Lake and was used to estimate loads to Arivaca Lake. Because the climate at Arivaca is wetter than that at Caballo, the distribution of wet and dry deposition is likely to be different. Monthly wet deposition rates at Arivaca were estimated as the product of the volume-weighted mean concentration for wet deposition at Caballo times the rainfall depth at Arivaca. This approach was used because volume-weighted mean concentrations are usually much more stable between sites than wet deposition rates, which are sensitive to rainfall amount. Dry deposition at Arivaca was then calculated as the difference between the total deposition rate at Caballo and the estimated Arivaca wet deposition rate. The estimates

derived for Arivaca were 5.3 μg/m^2/yr by wet deposition and 7.1 μg/m^2/yr by dry deposition. In sum, mercury deposition at Arivaca is assumed to be equivalent to that estimated for Caballo, New Mexico, but Arivaca is estimated to receive more wet deposition and less dry deposition than Caballo because more of the particulate mercury and reactive gaseous mercury that contribute to dry deposition are scavenged at a site with higher rainfall.

Loading Capacity—Linking Water Quality and Pollutant Sources

The linkage analysis in a TMDL defines the connection between numeric targets and identified sources. The linkage is defined as the cause-and-effect relationship between the selected indicators, the associated numeric targets, and the identified sources. This linkage analysis provides the basis for estimating total assimilative capacity and any needed load reductions. Specifically, for the linkage analysis in the Arivaca TMDL, models of watershed loading of mercury were used together with a model of mercury cycling and bioaccumulation in the lake. This approach enabled a translation between the numeric target (expressed as a fish tissue concentration of mercury) and mercury loading rates. The loading capacity was then determined through the linkage analysis as the mercury loading rate that is consistent with meeting the target fish tissue concentration.

Watershed model, Watershed-scale loading of water and sediment was simulated using the Generalized Watershed Loading Function (GWLF) model. The complexity of this loading function model falls between that of detailed simulation models (which attempt a mechanistic, time-dependent representation of pollutant load generation and transport) and simple export coefficient models (which do not represent temporal variability). GWLF provides a mechanistic, simplified simulation of precipitation-driven runoff and sediment delivery, yet it is intended to be applicable without calibration. Solids load, runoff, and ground water seepage can then be used to estimate particulate and dissolved-phase pollutant delivery to a stream, on the basis of pollutant concentrations in soil, runoff, and ground water. Applying the GWLF model to the period from October 1985 through September 1998 yielded an average of 11.0 cm/year runoff and 2,520,000 kg sediment yield by sheet and rill erosion. The sediment yield estimate is likely to be less than the actual yield rate from the watershed because mass wasting loads were not accounted for; however, mass wasting loads are thought to be of minor significance for loading of bioavailable mercury to the lake.

Estimates of watershed mercury loading were based on the sediment loading estimates generated by GWLF by applying a sediment potency factor. These estimates are shown in table D3. A background loading estimate was first calculated and then combined with estimates of loads from individual hot spots. Most of the EPA sediment samples showed no clear spatial patterns, with the exception of the hot spot area identified at Ruby Dump. Therefore, background loading was calculated using the central tendency of sediment concentrations from all samples excluding Ruby Dump. The background sediment mercury concentrations were assumed to be distributed lognormally, as is typical for environmental concentration samples, and an estimate of the arithmetic mean of 70.9 ppb was calculated from the observed geometric mean and coefficient of variation. Applying this assumption to the GWLF estimates of sediment transport yields an estimated rate of mercury loading from watershed background of 178.9 g/yr.

Table D3. Annual total mercury load to Arivaca Lake

Watershed year	Mercury loading to lake (g/year)			
	From watershed	From Ruby Dump	From direct atmospheric deposition to lake	Total
1986	170.16	0.65	4.208	175.018
1987	184.34	0.7	4.208	189.248
1988	205.61	0.79	4.208	210.608
1989	70.9	0.27	4.208	75.378
1990	198.52	0.76	4.208	203.488
1991	99.26	0.38	4.208	103.848
1992	163.07	0.62	4.208	167.898
1993	233.97	0.89	4.208	239.068
1994	141.8	0.54	4.208	146.548
1995	219.79	0.84	4.208	224.838
1996	170.16	0.65	4.208	175.018
1997	191.43	0.73	4.208	196.368
1998	276.51	1.06	4.208	281.778
Grand total	2,325.52	8.88	54.704	2,389.10
Annual average	178.89	0.68	4.21	183.78

Loading from the Ruby Dump was calculated separately, but it was also based on the GWLF estimate of sediment load generated per hectare of rangeland (the land use surrounding the hot spots), as reduced by the sediment delivery ratio for the watershed. The extent of the hot spot was observed to be 200 feet by 50 feet. The mercury concentration assigned to surface sediments at the dump was the arithmetic average of the four EPA samples taken in October 1997, or 918 ppb. From these assumptions, less than 1 percent of the watershed mercury load to Arivaca Lake appears to originate from Ruby Dump, which is the only identified hot spot in the watershed.

The direct deposition of mercury from the atmosphere onto the Arivaca Lake surface was calculated by multiplying the estimated atmospheric deposition rates times the lake surface area, resulting in a load of 4.2 g/yr.

Lake hydrology model. The water level in Arivaca Lake is not actively managed, and releases occur only when storage capacity is exceeded. Therefore, lake hydrology was represented by a simple monthly water balance. Applying the water balance model requires pan evaporation data as an input, in addition to the watershed meteorological data. Because no evaporation data were available at the local Cooperative Summary of the Day meteorological station, pan evaporation data for Tucson were used. Pan evaporation data for 1980 through 1995 were obtained from the BASINS 2.0 Region 9 data files. Later pan evaporation data were not available for Tucson, so monthly averages were used for the 1996 through 1998 water balance. The water balance model was run for the period 1985 through 1998. This water balance approach provides a rough approximation of the seasonal cycle of changes in volume and surface area of Arivaca

Lake and of the amount of water released downstream over the spillway. It cannot capture daily or event-scale movement of water in and out of the lake.

Mercury cycling and bioaccumulation model. Cycling and bioaccumulation of mercury within the lake were simulated using the D-MCM (EPRI 1999). D-MCM predicts the cycling and fate of the major forms of mercury in lakes, including methylmercury, Hg(II), and elemental mercury. D-MCM is a time-dependent mechanistic model, designed to consider the most important physical, chemical, and biological factors affecting fish mercury concentrations in lakes. It can be used to develop and test hypotheses, scope field studies, improve understanding of cause/effect relationships, predict responses to changes in loading, and help design and evaluate mitigation options.

Because strong anoxia in the hypolimnion is a prominent feature during summer stratification for the Arizona lakes simulated in this study, D-MCM was modified to explicitly allow significant methylation to occur in the hypolimnion. In previous applications of D-MCM, the occurrence of methylation was restricted to primarily within surficial sediments. That the locus of methylation likely includes or is even largely within the hypolimnion is supported by (1) the detection of very high methylmercury concentrations in the hypolimnia of Arivaca Lake and (2) almost complete losses of sulfate in Arivaca Lake in the hypolimnion resulting from sulfate reduction. An input was added to the model to specify the rate constant for hypolimnetic methylation, distinct from sediment methylation.

The results of the model calibration are shown in table D4. The model calculations are the predicted annual ranges after the model has reached steady state. The observed concentrations are from July 1997.

Table D4. Predicted and observed mercury for annual average load and flow

	Predicted	Observed
Methyl Hg: Water column (ng/L)	0.00–12.07	14.3
Hg II: Water column (ng/L)	0.00–6.28	1.46–8.3
Methyl Hg: 5-year-old largemouth bass (mg/kg)	1.18	1.18

Allocations

A TMDL represents the sum of all individual allocations of portions of the waterbody's loading capacity. Allocations may be made to point sources (wasteload allocations) or nonpoint sources (load allocations). The TMDL (sum of allocations) must be less than or equal to the loading capacity; it is equal to the loading capacity only if the entire loading capacity is allocated. In many cases, it is appropriate to hold a portion of the loading capacity in reserve to provide a margin of safety (MOS), as provided for in the TMDL regulation. The allocations and MOS are shown in table D5. These allocations, from the best currently available information, predict attainment of acceptable fish tissue concentrations within a time horizon of approximately 10 years. A delay in achieving standards is unavoidable because time will be required for mercury to cycle through the lake and food chain after load reductions occur.

Table D5. Summary of TMDL allocations and needed load reductions (in g-Hg/yr)

Source	Allocation	Existing load	Needed reduction
Wasteload allocations	0.0	0.0	0.0
Load allocations			
Atmospheric deposition	4.2	4.2	0
Ruby Dump	0.7	0.7	0
Watershed background	111.2	178.9	67.7
Total	116.1	183.8	67.7
Unallocated reserve	38.7		
Loading capacity	154.8		

The model was used to evaluate the load reductions necessary to meet the numeric target. The response of concentrations of mercury in 5-year-old largemouth bass to changes in external mercury loads is nearly linear. This is because the sediment burial rates are high and sediment recycling is low, with most of the methylmercury that enters the food chain being created in the anoxic portion of the water column. The model calculates that the numeric target of 1 mg/kg in 5-year-old largemouth bass is predicted to be met with a 16 percent reduction in total watershed loads to Arivaca Lake, which results in a loading capacity of 154.8 g/year of mercury.

There are uncertainties associated with mercury sources and the linkage between mercury sources and fish tissue concentrations in Arivaca Lake. As a result, the TMDL reserves 38.7 g-Hg/yr (25 percent of the loading capacity) for the MOS and allots the remaining load of 116.1 g-Hg/yr for sources. Because no permitted point source discharges occur within the Arivaca watershed, the wasteload allocation is zero and the load allocation is 116.1 g-Hg/yr.

The load allocation provides loads for three general sources: direct atmospheric deposition onto the lake surface, hot spot loading from Ruby Dump, and generalized background watershed loading, including mercury derived from parent rock and soil material, small amounts of residual mercury from past mining operations, and the net contribution of atmospheric deposition onto the watershed. Direct deposition to the lake surface is a small part of the total load and is believed to derive from long-range transport of global sources, which are not readily controllable. The load from Ruby Dump is also small. As a result, the TMDL does not require reductions from these sources, and their load allocations are their existing loads.

Background watershed loading appears to be the major source of mercury to Arivaca Lake. The intensive watershed survey conducted for this TMDL did not identify any significant terrestrial sources of mercury. Regarding air deposition to the watershed land surface, insufficient data were available to calculate reliable estimates of the proportion of mercury deposited from the air that actually reaches Arivaca Lake. Therefore, a load allocation of 111.2 g-Hg/yr was established for overall background watershed loading. This requires a 38 percent reduction from existing estimated loads from this source. This reduction is believed feasible for several reasons.

Potential for erosion control. Reduction of mercury loading from the watershed to Arivaca Lake depends on reduction in sediment erosion rates. Improved livestock management practices could obtain significant reductions in erosion rates. As a side benefit, implementation of livestock BMPs could result in significant reductions in loadings of DOC and nutrients to the lake. The availability of high levels of DOC and nutrients in the lake appears to affect the methylation process. Reduction of DOC and nutrient levels should reduce the efficiency of the methylation process at Arivaca Lake, effectively increasing the lake's mercury loading capacity.

Reductions in atmospheric deposition of mercury. Although no reliable estimates are available, new mercury air emissions to the environment appear to be declining. U.S. mercury emissions have declined significantly since 1990 and are expected to decline further upon implementation of new emission limits on incinerators as required by recent EPA regulations. Reductions in air deposition in Arivaca Lake watershed would eventually result in decreases in mercury loading to the lake itself.

Potential location and remediation of undiscovered mercury sources. Although investigation of the watershed did not reveal any significant localized sources of mercury in the watershed (with the possible exception of Ruby Dump), additional site investigation is warranted to ensure that no significant sources were missed. From past experience with mine site remediation in similar circumstances in Arizona, newly discovered sites could be effectively eliminated as ongoing mercury sources.

Alternative management strategies. Any alterations in rates of methylation or in rates of mercury loss to deep sediments will change the relationship between external mercury load and fish tissue concentration and would thus result in a change in the loading capacity for external mercury loads. The loading capacity could be increased by management intervention methods that decrease rates of bacterial methylmercury production within the lake or increase rates of burial and sequestration of mercury in lake sediment. Selection of such an approach would require further research and feasibility studies. Some alternative strategies that might be suitable for further investigation include the following:

- Hypolimnion aeration or mixing
- Sulfur chemistry modification
- Alum treatment
- Reduction of DOC and nutrient levels
- Dredging of lake sediments

III. McPhee and Narraguinnep Reservoirs, Colorado

Description of the Applicable Water Quality Standards

The TMDL for McPhee and Narraguinnep Reservoirs in southwestern Colorado was based on the Fish Consumption Advisory action level of 0.5 mg/kg mercury concentration in fish tissue. Colorado Department of Public Health and the Environment listings are based on the risk analysis presented in the May 6, 1991, Disease Control and

Epidemiology Division position paper for *Draft Colorado Health Advisory for Consumption of Fish Contaminated with Methylmercury.* This paper, using a toxicity value RfD of 0.3 µg/kg/day, establishes a fish tissue concentration of 0.5 mg/kg as the approximate center of the range at which the safe consumption level is four meals per month for nonpregnant adults and one meal per month for women who are pregnant, nursing, or planning to become pregnant and children nine years of age or younger. The criterion is applied to an average-age top predator. In McPhee Reservoir, the top predator among sport fish regularly taken is the smallmouth bass (19 percent of the total catch in 1993); the top predator sport fish in Narraguinnep Reservoir is the walleye. The lake water quality model D-MCM (EPRI 1999) is capable of predicting mercury concentrations in fish tissue for each age class at each trophic level. Average mercury concentrations in fish tissue of target species are assumed to be approximated by the average concentration in 15-inch smallmouth bass in McPhee and the 18-inch walleye in Narraguinnep. Therefore, the selected target for the TMDL analysis in McPhee Reservoir is an average tissue concentration in 15-inch smallmouth bass of 0.5 mg/kg or less. The selected target in Narraguinnep Reservoir is the 18-inch walleye of 0.5 mg/kg or less.

Source Assessment

McPhee and Narraguinnep reservoirs have several sources of mercury. The sources external to the reservoirs separate into direct atmospheric deposition onto the lakes (from both near- and far-field sources) and transport into the lakes from the watershed. The watershed loading occurs in both dissolved and sediment-sorbed forms. Ultimate sources in the watershed include mercury in parent rock, mercury residue from mine tailings and mine seeps, point source discharges, and atmospheric deposition onto the watershed, including deposition and storage in snowpack. A summary of the mercury load estimates for McPhee Reservoir is presented in table D6.

Table D6. Summary of mercury load estimates for McPhee Reservoir

Reservoir	Water-shed runoff (g/yr)	Water-shed sediment (g/yr)	Inter-basin transfer (g/yr)	Atmos. deposition (g/yr)	Total (g/yr)	Load per volume (mg/ac-ft)	Load per surface area (mg/m^2)
McPhee	2,576	222		251	3,049	4.66	0.098
Narraguinnep	2.7	22.7	15.9	36.8	78.1	4.59	0.035

Past mining activities likely provide an important source of mercury load to the McPhee and Narraguinnep watershed. There are large mining districts in the Dolores River watershed, the LaPlata, the Rico, and the area around Dunton on the West Dolores River. The quantity of mercury loading from mining operations has been estimated through a combination of observed data in the water column and sediment coupled with the watershed linkage analysis.

Significant atmospheric point sources of mercury often cause locally elevated areas of near-field atmospheric deposition downwind. Two large coal-fired power plants are in the Four Corners area within about 50 miles of the McPhee and Narraguinnep reservoirs. The plants in the Four Corners area (2,040 megawatt (MW) capacity) and the Navajo plant (1,500 MW capacity) are upwind of McPhee and Narraguinnep reservoirs. It is likely that the

mercury emitted from these plants contributes to the mercury loading of the two reservoirs. Because no direct measurements of atmospheric deposition of mercury are available, EPA cannot assess the significance of this loading and must await further investigation, including the establishment of a mercury deposition monitoring site in the area.

Loading Capacity—Linking Water Quality and Pollutant Sources

Models of watershed loading of mercury are combined with a model of mercury cycling and bioaccumulation in the lake to translate the numeric target, expressed as a fish tissue concentration of mercury, to mercury loading rates. The coupled models estimate mercury loading to the reservoirs and predict mercury cycling and speciation within the reservoir. An estimated load reduction of 52 percent is needed for long-term average mercury concentrations in a standardized 15-inch smallmouth bass to drop to 0.5 mg/kg wet muscle.

Allocations

The loading capacity for McPhee Reservoir was estimated to be 2,592 g/year of mercury. Narraguinnep Reservoir's loading capacity was estimated at 39.1 g/year of mercury. This is the maximum rate of loading consistent with meeting the numeric target of 0.5 mg/kg in fish tissue. Because of the uncertainties regarding the linkage between mercury sources and fish tissue concentrations in McPhee and Narraguinnep reservoirs, an allocation of 70 percent of the loading capacity was used for this TMDL. The TMDL calculated for McPhee Reservoir is equivalent to a total annual mercury loading rate of 1,814 g/yr (70 percent of the loading capacity of 2,592 g/yr), while that for Narraguinnep Reservoir is equivalent to a total annual mercury loading rate of 27.3 g-Hg/yr (70 percent of 39.1 g-Hg/yr). Summaries of the TMDL allocations and needed load reductions for the McPhee and Narraguinnep Reservoirs are presented in tables D7 and D8, respectively.

Table D7. Summary of TMDL allocations and needed load reductions for McPhee Reservoir

Source	Allocation	Existing load	Needed reduction
Atmospheric deposition	63	251	188
Rico/Silver Creek mining area	507	1030	523
Dunton mining area	348	708	360
La Plata mining area	69	141	72
Watershed background	827	919	92
Total	1,814	3,049	1,235
Unallocated reserve	778		
Loading capacity	2,592		

Note: Measurements in g/year of mercury.

Table D8. Summary of TMDL allocations and needed load reductions for Narraguinnep Reservoir

Source	Allocation	Existing load	Needed reduction
Atmospheric deposition	9.2	36.8	27.6
Interbasin transfer from McPhee Reservoir	9.5	15.9	6.4
Watershed background	8.6	25.4	16.8
Total	27.3	78.1	50.8
Unallocated reserve	11.8		
Loading capacity	39.1		

Note: Measurements in g/year of mercury.

IV. Clear Lake, California

Description of the Applicable Water Quality Standards

EPA promulgated the California Toxics Rule (CTR) in May 2000 (65 FR 31682). The CTR contains a water quality criterion of 50 ng/L total recoverable mercury for water and organism consumption and is intended to protect humans from exposure to mercury in drinking water and through fish and shellfish consumption. This criterion is enforceable in California for all waters with a municipal or domestic water supply designated use and is applicable to Clear Lake. However, the state of California does not consider this criterion sufficiently protective of the consumers of fish from Clear Lake.

The water quality management plan or Basin Plan for the Central Valley Regional Water Quality Control Board adopted new water quality standards for mercury for Clear Lake at the same time it adopted mercury TMDLs for Clear Lake. The state's water quality criteria are for fish tissue and are intended to protect designated uses for fishing and wildlife habitat. The applicable criteria are 0.09 mg/kg and 0.19 mg/kg of mercury in fish tissue for trophic levels 3 and 4 fish, respectively. These levels were recommended by the U.S. Fish and Wildlife Service to protect wildlife, including osprey and bald eagles, at Clear Lake; these levels allow adults to safely consume about 3.5 fish meals per month (26 grams/day) if eating mainly trophic level 4 fish such as catfish and bass. The 26 grams/day assumes a diet composed of 70 percent trophic level 4 fish and 30 percent trophic level 3 fish. The 90th percentile consumption rate of a small group of residents of Clear Lake, primarily members of the Elem Pomo Indian Tribe, is 30 grams/day of Clear Lake fish, as reported in 1997.

Source Assessment

Clear Lake is in Lake County in northern California. It is a shallow, eutrophic waterbody that consists of three basins—the Upper, Lower, and Oaks Arms. It is the largest natural lake entirely within California's boundaries. Tourism and sport fishing are important sectors of the local economy. Five American Indian tribes use the resources of the lake and its watershed.

The Clear Lake watershed lies within a region naturally enriched in mercury. The Sulphur Bank Mercury Mine (SBMM) site, on the shores of Oak Arm, was a highly productive source of mercury between 1872 and 1957. Similar smaller mines were

present in the Clear Lake watershed, all of which are now inactive. Levels of mercury in Clear Lake sediments rose significantly after 1927, when open-pit operations became the dominant mining method at SBMM. EPA declared the SBMM a federal Superfund site in 1991, and since then several remediation projects have been completed, including regrading and vegetation of mine waste piles along the shoreline and construction of a diversion system for surface water runoff. EPA is conducting a remedial investigation to fully characterize the SBMM site to propose final remedies.

Inorganic mercury loads entering Clear Lake come from ground water and surface water from the SBMM site; tributaries and other surface water that flows directly into the lake; and atmospheric deposition, including atmospheric flux from SBMM. Some mercury deposited historically in the lake due to mining operations or erosion at SBMM might also contribute to mercury concentrations in fish today.

Ground water and surface water from the SBMM site. SBMM covers approximately 1 square mile on the east shore of the Oaks Arm of Clear Lake. The site contains approximately 120 acres of exposed mine overburden and tailings (referred to as waste rock). Two small unprocessed ore piles are also on the site. Mercury in samples of mine materials ranged from 50 to 4,000 mg/kg. All piles of mine materials exhibit the potential to generate acid rock drainage. The abandoned mine pit, the Herman Impoundment, is filled with 90 feet of acidic water (pH 3) and has a surface area of about 20 acres. The average concentrations in the Herman Impoundment of water and sediment are around 800 ng/L and 26 mg/kg, respectively. A geothermal vent at the bottom of the impoundment continues to discharge gases, minerals (including mercury), and fluids into the pit.

A large pile of waste rock, known as the waste rock dam (WRD), stretches about 2,000 feet along the shore of the western side of the SBMM site. The WRD lies between Herman Impoundment and Clear Lake. The surface water in the impoundment is 10–14 feet above the surface of Clear Lake, which creates a gradient of ground water flow toward the lake. Surface runoff from the northern side of the site is bounded by a wetland that drains to Clear Lake. Surface runoff from the northern waste rock piles is directed through culverts into the northern wetland. In 1990 rock and geofabric barriers were installed at the culverts to reduce the transport of suspended solids. The northern wetland is used for cattle grazing and as a source of fish, tules, and other resources used by the members of the Elem Pomo Tribe. Waste rock piles extend into the wetlands.

Inputs of mercury from SBMM are estimated to be between 1 and 568 kg/year. EPA Superfund program's estimate of mercury transported in ground water from the WRD is used as the lower-bound input. Regional Board staff estimate that 568 kg/year is the maximum upper-bound estimate of all inputs from SBMM, including past and continuing contributions to the active sediment layer. This is approximately 96.5 percent of total sources.

Ground water from SBMM appears to contribute mercury that is readily methylated, relative to mercury from other inputs. Ground water flow from the mine site has been detected entering Clear Lake by subsurface flow through lake sediments. Mercury in ground water from the WRD is solubilized and likely in chemical forms that are easily taken up by methylating bacteria. Acidic drainage from the mine site also contains high

sulfate concentrations that enhance the rates of methylation by sulfate-reducing bacteria. This assertion is supported by data showing that methylation rates near the mine site are significantly higher than those in other parts of Clear Lake. In contrast to the mercury in SBMM ground water, the mercury in lakebed and tributary sediments originates primarily as cinnabar, which has low solubility in water.

Tributaries and other surface water flowing directly into the lake. Mercury entering Clear Lake from its tributaries originates in runoff from naturally mercury-enriched soils, sites of historical mining activities, and mercury deposited in the watershed from the atmosphere. Geothermal springs might contribute to tributary loads, especially in the Schindler Creek tributary to Oaks Arm. Tributary and watershed runoff loads of mercury range from 1 to 60 kg/year, depending on flow rates. Loads in average water years are 18 kg/year, approximately 3 percent of the total sources.

Geothermal springs and lava tubes that directly discharge to Clear Lake do not appear to be significant sources of mercury. Mercury concentrations in surficial sediment samples collected near lakebed geothermal springs were not elevated relative to levels in sediment away from geothermal springs.

Atmospheric deposition, including flux from the SBMM site. Small amounts of mercury deposit directly on the surface of Clear Lake from the global atmospheric pool and potentially from local, mercury-enriched sources. Atmospheric loads to the lake surface from the global pool were estimated using data from MDN monitoring stations in Mendocino County and San Jose. Estimates ranged from 0.6 to 2.0 kg/year, approximately 0.3 percent of the total sources.

Loading Capacity—Linking Water Quality and Pollutant Sources

The Regional Board staff assumes that there is a directly proportional relationship between methylmercury in fish and mercury in the surficial sediment. This is a simplification of a highly complex process. Many factors, such as sulfide and sulfate concentrations, temperature, and organic carbon, affect methylation or concentrations of methylmercury. Factors that affect accumulation of methylmercury in fish include species, growth rate, prey availability, and the like. To reduce levels of methylmercury in fish, loads of mercury to the lake must be reduced. Section 5.3.1 of the Staff Report provides examples of remediation projects demonstrating that removal of inorganic mercury from a range of aquatic environments has been effective in reducing concentrations of mercury in fish.

A set of first-order relationships, each controlled by a single variable of concentration of mercury or methylmercury, provide the basis for the assumption of a directly proportional relationship between mercury in fish and in surficial sediment in Clear Lake. Concentrations of methylmercury in water and methylmercury in biota are related by BAFs. Relationships between methylmercury in the water column and in sediment can be described as a flux rate of methylmercury from sediment. Concentrations of methylmercury and mercury in sediment are related through calculation of a methylation efficiency index (ratio of methylmercury to mercury in surficial sediment).

In each of these steps in the linkage analysis, one variable is related to another by a simple ratio or linear equation. For example, BAFs are calculated by dividing the

concentration of methylmercury in fish by the concentration of methylmercury in the water. Data are available to determine BAF and methylation indices that are specific for Clear Lake. With the current understanding of the transport, methylation, and uptake processes in Clear Lake, the Regional Board staff was unable to refine these relationships to incorporate the effects of other factors. The end result was that methylmercury in biota was related linearly to mercury in surficial sediment.

Meeting the recommended water quality standards would require reducing existing fish tissue concentrations by 60 percent. Using the linear relationship, the linkage analysis indicates that overall mercury loads to Clear Lake sediment must be reduced by 60 percent to reduce methylmercury concentrations in fish tissue by the proportional amount. The Regional Board is establishing the assimilative capacity of inorganic mercury in Clear Lake sediments as 70 percent of existing levels to include a margin of safety of 10 percent to account for the uncertainties in the linkage analysis.

Allocations

The strategy for meeting the fish tissue criteria is to reduce the inputs of mercury to the lake from tributaries and the SBMM site, combined with active and passive remediation of contaminated lake sediments. The load allocations for Clear Lake will result in a reduction in the overall mercury sediment concentration by 70 percent of existing concentrations. The load allocations are assigned to the active sediment layer of the lakebed, the SBMM terrestrial site, the tributary creeks and surface water runoff to Clear Lake, and atmospheric deposition. Table D9 summarizes the load allocations. The load allocation to the active sediment layer is expressed as reducing concentrations of mercury in the active sediment layer to 30 percent of current concentrations. The load allocation to the SBMM terrestrial site is 5 percent of the ongoing loads from the terrestrial mine site. The load allocation for the mine also includes reducing mercury concentrations in surficial sediment to achieve the sediment compliance goals for Oaks Arm, shown in table D10. The load allocation to tributary and surface water runoff is 80 percent of existing loads. These load allocations account for seasonal variation in mercury loads, which vary with water flow and rainfall. The analysis includes an implicit margin of safety in the reference doses for methylmercury that were used to develop the fish tissue objectives. It also includes an explicit margin of safety of 10 percent to account for uncertainty in the relationship between fish tissue concentrations and loads of mercury. The reductions in loads of mercury from all sources are expected to result in attainment of water quality objectives.

Table D9. Summary of mercury load allocations

Source	Existing load (kg/year)	Needed reduction
Clear Lake sediment	695	70% of existing concentration
Sulphur Bank Mercury Mine		95% of existing load
Tributaries	18	20% of existing load
Atmosphere	2	no change

Table D10. Sediment goals for mercury in Clear Lake

Site designation	Location	Sediment mercury goal (mg/kg dry weight)[a]
Upper Arm UA-03	Center of Upper Arm on transect from Lakeport to Lucerne	0.8
Lower Arm LA-03	Center of Lower Arm, north and west of Monitor Point	1.0
Oaks Arm		
OA-01[b]	0.3 km from SBMM 0.3 km from SBMM	16[c]
OA-02[b]	0.8 km from SBMM	16[c]
OA-03[b]	1.8 km from SBMM	16
OA-04[b]	3.0 km from SBMM	10
Narrows O1	7.7 km from SBMM	3

Notes:

[a]Sediment goals are 30 percent of existing concentrations. Existing concentrations are taken as the average mercury concentrations in samples collected in 1996–2000 (Clear Lake Basin Plan Amendment Staff Report).

[b]Sediment goal is part of the load allocation for SBMM.

[c]Due to the exceptionally high concentrations existing at the eastern end of Oaks Arm, sediment goals at OA-01 and OA-02 are not 70 percent of existing concentrations. These goals are equal to the sediment goal established for OA-03.

Clear Lake sediment. Reducing mercury concentrations in surficial sediment by 70 percent is an overall goal for the entire lake. To achieve water quality objectives, extremely high levels of mercury in the eastern end of Oaks Arm near SBMM must be reduced by more than 70 percent. To evaluate progress in lowering sediment concentrations, the following sediment compliance goals are established at sites that have been sampled previously.

Sulphur Bank Mercury Mine. Current and past releases from SBMM are a significant source of mercury loading to Clear Lake. Ongoing annual loads from the terrestrial mine site to the lakebed sediments occur through ground water, surface water, and atmospheric routes. Loads from ongoing releases from the terrestrial mine site should be reduced to 5 percent of existing inputs. Because of its high potential for methylation relative to mercury in lakebed sediments, mercury entering the lake through ground water from the mine site should be reduced to 0.5 kg/year.

Past releases from the mine site are a current source of exposure through remobilization of mercury that exists in the lakebed sediments as a result of past releases to the lake from the terrestrial mine site. Past active mining operations, erosion, and other mercury transport processes at SBMM have contaminated sediment in Oaks Arm. The load allocation assigned to SBMM includes reducing surficial sediment concentrations in Oaks Arm by 70 percent (more at sites nearest the mine site) to meet the sediment compliance goals in table D10.

EPA anticipates implementing additional actions to address the ongoing surface and ground water releases from SBMM over the next several years. These actions are expected to lead to significant reductions in the ongoing releases from the mine pit, the mine waste piles, and other ongoing sources of mercury releases from the terrestrial mine

site. EPA also plans to investigate what steps are appropriate under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) to address the existing contamination in the lakebed sediments from past releases from SBMM. The Regional Board will continue to work closely with EPA on these important activities. In addition, the Regional Board will coordinate monitoring activities to investigate other sources of mercury loads to Clear Lake. These investigations by EPA and the Regional Board should reduce the uncertainty that exists regarding the annual load of mercury to the lake, the contribution of each source to that load, and the degree to which those sources lead to methylmercury exposure of and mercury uptake by fish in the lake. This information should lead to more refined decisions about what additional steps are appropriate and feasible to achieve the applicable water quality criteria.

Tributaries and surface water runoff. Past and current loads of mercury from the tributaries and direct surface water runoff are also a source of mercury loading to the lake and to the active sediment layer in the lakebed. This section excludes loads from surface water runoff associated with SBMM, which are addressed separately above. The loads of mercury from the tributaries and surface water runoff to Clear Lake should be reduced by 20 percent of existing levels. In an average water year, existing loads are estimated to be 18 kg/year. Loads range from 1 to 60 kg/year, depending on water flow rates and other factors. The load allocation applies to tributary inputs as a whole, instead of to individual tributaries. Efforts should be focused on identifying and controlling inputs from hot spots. The U.S. Bureau of Land Management, U.S. Forest Service, other land management agencies in the Clear Lake Basin, and Lake County will submit plans for monitoring and implementation to achieve the necessary load reductions. The Regional Board will coordinate with those agencies and other interested parties to develop the monitoring and implementation plans. The purpose of the monitoring is to refine load estimates and identify potential hot spots of mercury loading from tributaries or direct surface runoff into Clear Lake. Hot spots can include erosion of soils with concentrations of mercury above the average for the rest of the tributary. If significant sources are identified, the Regional Board will coordinate with the agencies to develop and implement load reductions. The implementation plans will include a summation of existing erosion control efforts and a discussion of feasibility and proposed actions to control loads from identified hot spots. The agencies will provide monitoring and implementation plans within five years after the effective date of this amendment and implement load reduction plans within five years thereafter. The goal is to complete the load reductions within 10 years of implementation plan approval.

The Regional Board will work with the American Indian tribes in the Clear Lake watershed on mercury reduction programs for the tributaries and surface water runoff. It will solicit the tribes' participation in developing monitoring and implementation plans.

Wetlands. The Regional Board is concerned about the potential for wetland areas to be significant sources of methylmercury. Loads and fate of methylmercury from wetlands that drain to Clear Lake are not fully understood. The potential for production of methylmercury should be assessed during the planning of any wetlands or floodplain restoration projects within the Clear Lake watershed. The Regional Board established a goal of no significant increases of methylmercury to Clear Lake resulting from such activities. As factors contributing to mercury methylation are better understood, the

Regional Board should examine the possible control of existing methylmercury production within tributary watersheds.

Atmospheric deposition. Atmospheric loads of mercury originating outside the Clear Lake watershed and depositing locally are minimal. Global and regional atmospheric inputs of mercury are not under the jurisdiction of the Regional Water Board. Loads of mercury from outside the Clear Lake watershed and depositing from air onto the lake surface are established at the existing input rate, estimated to be 1 to 2 kg/year.

V. Cache Creek, California

Description of the Applicable Water Quality Standards

EPA promulgated the California Toxics Rule (CTR) in May 2000 (65 FR 31682). The CTR contains a water quality criterion of 50 ng/L total recoverable mercury for waters designated for water and organism consumption, and it was intended to protect humans from exposure to mercury in drinking water and through fish and shellfish consumption. This criterion is enforceable in California for all waters with a municipal or domestic water supply designated use, and it is applicable to all waters in the Cache Creek watershed. The State of California, however, does not consider this criterion sufficiently protective of human and wildlife consumers of fish in the watershed.

The water quality management plan or Basin Plan for the Central Valley Regional Water Quality Control Board adopted new water quality standards for mercury for Cache Creek, Bear Creek, and Harley Gulch at the same time it adopted mercury TMDLs for those waterbodies. The state's water quality criteria are expressed as concentrations in fish tissue and are intended to protect designated uses, which include human and wildlife fish consumption. The applicable criteria are as follows: for Cache Creek and Bear Creek, the average methylmercury concentration shall not exceed 0.23 mg methylmercury/kg wet weight of muscle tissue in trophic level 4 fish 250–350 mm (piscivorous species, including bass and catfish), and 0.12 mg methylmercury/kg wet weight of muscle tissue in trophic level 3 fish 250–350 mm, or if not available, a minimum of 125 mm (bluegill, sunfish, and sucker); for Harley Gulch, the average methylmercury concentration shall not exceed 0.05 mg methylmercury/kg wet weight in whole, trophic level 2 and 3 fish 75–100 mm total length (hardhead, California roach, or other small resident species). Because Harley Gulch does not support larger, trophic level 3 and 4 fish, no water quality criteria for these larger fish were proposed in that waterbody.

These water quality standards permit safe consumption of about 22–40 g/day of Cache or Bear Creek fish (3 to 5.4 meals/month). In Cache and Bear creeks, the standards protect wildlife species, including bald eagle, peregrine falcon (state endangered), river otter, American mink, mergansers, grebes, and kingfishers. In Harley Gulch, the standards protect wildlife species, including small mammals, herons, and kingfishers.

Source Assessment

The Cache Creek watershed is impaired due to elevated levels of mercury in the water and in fish tissue. Because Cache Creek is a primary source of mercury to the Sacramento-San Joaquin Delta Estuary, lowering mercury levels in the Cache Creek watershed will assist in protecting human and wildlife health in the delta. The TMDL

encompasses the 81-mile reach of Cache Creek between Clear Lake Dam and the outflow of the Cache Creek Settling Basin, Bear Creek from its headwaters to its confluence with Cache Creek, and the 8-mile length of Harley Gulch.

Sources of mercury entering the watershed include waste rock and tailings from historical mercury mines, erosion of naturally mercury-enriched soils, geothermal springs, and atmospheric deposition. There are multiple inactive mercury mines in the Cache Creek watershed. The Sulphur Bank Mercury Mine contributes mercury to Cache Creek at the Clear Lake outflow. The Sulphur Creek mining district includes eight mines that drain predominately to Bear Creek via Sulphur Creek and four mines in the Bear Creek Basin. Harley Gulch receives inputs from the Turkey Run and Abbott mines. The Reed Mine drains to Davis Creek, a tributary to Cache Creek.

Historical mining activities in the Cache Creek watershed discharged and continue to discharge large volumes of inorganic mercury (termed total mercury) to creeks in the watershed. Much of the mercury discharged from the mines is now distributed in the creek channels and floodplain downstream from the mines. Natural erosion processes can be expected to slowly move the mercury downstream out of the watershed over the next several hundred years. However, current and proposed activities in and around the creek channel can enhance mobilization of this mercury. Activities in upland areas, such as road maintenance and grazing and timber activities, can add to the mercury loads reaching Cache Creek, particularly when the activities take place in areas that have elevated mercury levels. Mercury can be transformed to methylmercury in sediment by sulfate-reducing bacteria.

Cache Creek. In Cache Creek the watershed above Rumsey is the major source of methylmercury. The highest concentrations and production rates were observed below the mercury mines in Harley Gulch, in Sulphur and Bear creeks, and in the canyon above Rumsey. Lower methylmercury concentrations in water were measured in the North Fork and Cache Creek below Clear Lake Dam, which have lower inorganic mercury concentrations in sediment.

The sources of total mercury in Cache Creek largely parallel the sources of methylmercury. Most mercury derives from the watershed upstream of Rumsey. On a five-year average, mercury loads from the mine-related tributaries (Bear Creek, Harley Gulch, and Davis Creek), North Fork Cache Creek and Clear Lake contributed about 15 percent of the mercury loads measured in Cache Creek at Rumsey. In years with high degrees of runoff or extreme erosional events, inputs from the inactive mines would be much greater. The majority of the inorganic mercury loads were from unnamed sources, which include smaller, unmeasured tributaries and mercury in the Cache Creek bed and banks. Clean sediment entering the watershed below Rumsey diluted sediment mercury concentrations.

Bear Creek. The Bear Creek watershed upstream of all mine inputs contributes less than 10 percent to each of the loads of methylmercury and total mercury in Bear Creek. Sulphur Creek contributes about half of each of the methylmercury and total mercury loads in Bear Creek. The remainder of the Bear Creek methylmercury likely comes from production within the channel and seepage of underground springs. The rest of the mercury load in Bear Creek likely derives from the remobilization of mine waste deposited in the floodplain.

Harley Gulch. Much of the methylmercury in Harley Gulch is likely produced in a wetland area in the West Branch Harley Gulch, downstream of the inactive mercury mines. Over 90 percent the total mercury load in Harley Gulch is estimated to come from the West Branch, where the mines are. Total mercury loads from the mines may be underestimated due to a lack of data collected during heavy rainfall events. An alluvial fan, likely containing mine waste, at the confluence of Harley Gulch and Cache Creek, might contribute to the unknown source of mercury in the Cache Creek canyon.

Loading Capacity—Linking Water Quality Pollutant Sources

Total mercury in the creeks is converted to methylmercury by bacteria in the sediment. The concentration of methylmercury in fish tissue is directly related to the concentration of methylmercury in the water. The concentration of methylmercury in the water column is controlled in part by the concentration of total mercury in the sediment and the rate at which the total mercury is converted to methylmercury. The rate at which total mercury is converted to methylmercury varies from site to site; some sites (wetlands and marshes) having greatly enhanced methylation rates.

The linkage analysis describes the relationship between methylmercury concentrations in water and in large fish. Data collected in 2000 and 2001 show statistically significant relationships between concentrations of aqueous unfiltered methylmercury in water and large trophic level 3 and 4 fish. In Cache Creek, large trophic level 3 fish tissue concentrations (Sacramento sucker), normalized to 290 mm (from Slotten et al. 2004), were regressed against aqueous unfiltered methylmercury concentrations ($Y= 584.8X + 30.2$; $P < 0.001$, $R2 = 0.98$). In Cache Creek, large trophic level 4 fish tissue concentrations (largemouth bass, small mouth bass, and pikeminnow, depending on site), normalized to 305 mm (from Slotton et al. 2004), were regressed against aqueous unfiltered methylmercury concentrations ($Y = 2970.8X – 180.6$; $P < 0.01$, $R2 = 0.9$). Using these relationships, staff determined concentrations of unfiltered methylmercury in water that correspond to the proposed criteria for trophic levels 3 and 4 fish (0.12 mg/kg and 0.23 mg/kg, respectively). These concentrations are 0.15 ng/l for trophic level 3 fish and 0.14 ng/L for trophic level 4 fish. To ensure meeting both fish tissue criteria, staff selected 0.14 ng/L as the aqueous unfiltered methylmercury goal for Cache Creek.

For Bear Creek, the methylmercury goal of 0.06 ng/L represents the best estimate of the annual, median aqueous (unfiltered) concentration of methylmercury needed to attain the target of 0.23 mg/kg wet weight in trophic level 4 fish. Harley Gulch has no trophic level 4 fish, so the above relationships could not be used. Based on bioaccumulation factors specific to Harley Gulch, the aqueous methylmercury goal for Harley Gulch is 0.09 ng/L.

Allocations

The TMDL presents a plan to reduce mercury and methylmercury loads. Reducing the methylmercury loads will require a multi-faceted approach that includes controlling inorganic mercury loads and limiting the entry of inorganic mercury into sites with high rates of methylmercury production. Inorganic mercury loads may be controlled through remediation of mercury mines, erosion control, removal of highly contaminated sediment, and other activities. In addition to addressing inorganic mercury loads, the TMDL discusses limits to the production of methylmercury in constructed

impoundments, such as gravel pits and water storage facilities. Identification and evaluation of the unknown mercury source(s) in the upper basin are essential to attain the Cache Creek methylmercury targets in fish tissue and to help reduce mercury in sediment of the Sacramento-San Joaquin Delta Estuary.

Since methylmercury in the water column is directly related to mercury levels in fish, the following methylmercury load allocations are assigned to tributaries and the main stem of Cache Creek.

Methylmercury Load Allocations. Tables D11 and D12 provide methylmercury load allocations for Cache Creek, its tributaries, and instream methylmercury production. Allocations are expressed as a percent of existing methylmercury loads. The methylmercury allocations will be achieved by reducing the annual average methylmercury (unfiltered) concentrations to site- specific, aqueous methylmercury goals, which are 0.14 ng/L in Cache Creek, 0.06 ng/L in Bear Creek, and 0.09 ng/L in Harley Gulch. The allocations in tables D11 and D12 apply to sources of methylmercury entering each tributary or stream segment. In aggregate, the sources to each tributary or stream segment must have reductions of methylmercury loads as shown below.

Table D12 provides the load allocation within Bear Creek and its tributaries to attain the allocation for Bear Creek described in table D11. The inactive mines listed in the implementation summary are assigned a 95 percent total mercury load reduction. These mines include mines in the Harley Gulch Sulphur Creek and Bear Creek watersheds. Reductions in mercury loads from mines, erosion, and other sources in the Sulphur Creek watershed are expected to reduce in-channel production of methylmercury to meet the Sulphur Creek methylmercury allocation.

Table D11. Cache Creek methylmercury allocations

Source	Existing annual load (g/yr)	Acceptable annual load (g/yr)	Allocation (% of existing load)
Cache Creek (Clear Lake to North Fork confluence)	36.8	11	30%
North Fork Cache Creek	12.4	12.4	100%
Harley Gulch	1.0	0.04	4%
Davis Creek	1.3	0.7	50%
Bear Creek at Highway 20	21.1	3	15%
Within-channel production and ungauged tributaries	49.5	32	65%
		7[a]	10%[a]
Total of loads	122	66	54%
Cache Creek at Yolo[b]	72.5	39	54%
Cache Creek Settling Basin Outflow[c]	87	12	14%

Notes:

[a]The allocation includes a margin of safety, which is set to 10% of the acceptable loads. In terms of acceptable annual load estimates, the margin of safety is 7 g/yr.

[b]Cache Creek at Yolo is the compliance point for the tributaries and Cache Creek channel for meeting the allocations and aqueous goals. Agricultural water diversions upstream of Yolo remove methylmercury (50 g/yr existing load).

[c]The Settling Basin Outflow is the compliance point for methylmercury produced in the Settling Basin.

Table D12. Bear Creek methylmercury allocations

Source	Existing Annual Load (g/yr)	Acceptable Annual Load (g/yr)	Allocation (% of existing load)
Bear Creek at Bear Valley Road	1.7	0.9	50%
Sulphur Creek	8	0.8	10%
In-channel production and ungauged tributaries	11.4	1	10%
		0.3[a]	10%[a]
Total of loads	21.1	3	15%
Bear Creek at Highway 20[b]	21.1	3	15%

Notes:

[a]The allocation includes a margin of safety, which is set to 10% of the acceptable loads. In terms of acceptable annual load estimates, the margin of safety is 0.3 g/yr.

[b]Bear Creek at Highway 20 is the compliance point for Bear Creek and its tributaries.

To achieve the water quality objectives and the methylmercury allocations listed in tables D11 and D12, the following actions are needed: (1) reduce loads of total mercury from inactive mines; (2) where feasible, implement projects to reduce total mercury inputs from existing mercury-containing sediment deposits in creek channels and creek banks downstream from historical mine discharges; (3) reduce erosion of soils with enriched total mercury concentrations; (4) limit activities in the watershed that will increase methylmercury discharges to the creeks and, where feasible, reduce discharges of methylmercury from existing sources; and (5) evaluate other remediation actions that are not directly linked to activities of a discharger. Because methylmercury is a function of total mercury, reductions in total mercury loads are needed to achieve the methylmercury load allocations. Methylmercury allocations will be achieved in part by natural erosion processes that remove mercury that has deposited in creek beds and banks since the start of mining.

The proposed Basin Plan Amendment for mercury in San Francisco Bay assigns a reduction in total mercury loads from the Sacramento–San Joaquin River Delta of 110 kg/yr. Cache Creek is a major source of mercury to the Delta. To attain the San Francisco Bay reduction, loads of total mercury exiting Cache Creek should be reduced. Reductions in total mercury loads to the inactive mines in Harley Gulch and the Bear Creek watershed assigned by this TMDL and proposed changes to the Cache Creek Settling Basin, which would increase the mass of mercury retained in the basin, would create significant reductions in loads from Cache Creek.

VI. Minnesota Statewide[27] Mercury Total Maximum Daily Load

Description of the Applicable Water Quality Standards and TMDL Target

Minnesota Rules Chapters 7050.0222 and 7052.0100 set forth chronic numeric water quality standards based on total mercury concentrations in the water column. The wildlife-based standard applicable to only the waters of the Lake Superior Basin is 1.3 ng/L, while the human health-based standard applicable to waters outside the Lake Superior Basin is 6.9 ng/L. In addition to these numeric standards, Chapter 7050.0150, subpart 7, provides a narrative standard for assessing the contaminants in fish tissue. The narrative standard states that a waterbody is impaired when the Minnesota Department of Health recommends a consumption frequency of less than one meal per week for any member of the population.

To establish the two regional TMDLs, Minnesota selected a target of 0.2 mg/kg fish tissue mercury concentration. Fish tissue mercury concentration was selected as the water quality target for the TMDLs because it was consistent with EPA's 2001 methylmercury fish tissue criterion. In the 2001 guidance, EPA chose to express the water quality criterion as a fish tissue concentration rather than as a water column value because fish consumption is the primary route of human exposure. Two aspects of EPA's criterion are toxicity and exposure. Minnesota relied on EPA's assessments of toxicity to humans but selected a more state-specific exposure rate. For purposes of calculating its recommended human health-based fish tissue criterion, EPA assumes that people consume 17.5 g/day of fish. Minnesota selected a higher consumption rate, 30 g/day of fish, based on several surveys of the fish-eating habits of upper-Midwest recreational fishers.

Since Minnesota's water quality standards are water column chronic standards for total mercury, not fish tissue concentration standards, Minnesota demonstrated a link from the fish tissue mercury concentration TMDL target to the numeric water column water quality standards. Bioaccumulation factors for 14 lakes representing agricultural areas, urban areas, and forested areas were used to calculate the water column concentration that would be equivalent to the 0.2 mg/kg fish tissue mercury concentration target.

Source Assessment

Sources that Minnesota considered in developing the two regional TMDLs included atmospheric deposition, wastewater treatment plants, non-municipal waste discharges, and stormwater. Atmospheric deposition was the only significant nonpoint source of mercury identified by Minnesota. The state identified 99 percent of the total mercury load to the state as coming from atmospheric deposition. Both natural and anthropogenic

[27] As described in Section 6 of this guidance, Minnesota divided the state into two regions, a northeast region and a southwest region, and developed a TMDL for each region. Although Minnesota's report is called a "statewide TMDL," the two regional TMDLs do not address all the mercury impairments in the state. The TMDLs address 511 of the lake and river reach impairments in Category 5 of Minnesota's 2006 Integrated Report.

sources contribute to the atmospheric deposition mercury load. Minnesota identified natural sources as contributing 30 percent to the atmospheric deposition mercury load, while the remaining 70 percent is from worldwide anthropogenic sources. Point sources that Minnesota considered included wastewater treatment plants, pulp and paper mills, taconite mines, coal-fired power plants, and one refinery. The state recognized that stormwater is considered a point source and therefore subject to wasteload allocations; however, for purposes of estimating a baseline mercury load (referred to in the TMDL report as the total source load), the mercury loadings from stormwater were included in the estimate of loadings from atmospheric deposition. Using data from two studies in Minnesota, the state concluded that the primary source of mercury to stormwater is atmospheric deposition rather than specific anthropogenic sources.

Loading Capacity

Minnesota established a loading capacity for each of the two regional TMDLs. Each loading capacity was calculated by multiplying a regional reduction factor[28] needed to achieve the fish tissue mercury concentration target by the total source load[29] for each region, thus calculating a regional load reduction goal.[30] The load reduction goal was subtracted from the total source load to arrive at the loading capacities.

The total source load was considered the baseline condition from which reductions would be needed to achieve water quality standards. Minnesota selected the year 1990 as the baseline to which reductions would be applied. Minnesota selected 1990 as the baseline for three reasons. First, the total source load is the sum of the point source load and the nonpoint source load. The nonpoint source load is represented by total (wet and dry) mercury deposition. Minnesota's estimate of both wet and dry deposition is from lake sediment cores collected in a study conducted from 1988 to 1990. The second reason for selecting 1990 was to remain consistent with other mercury reduction baselines. The state uses 1990 as its mercury emission inventory baseline, and other state and federal plans, such as the Great Lakes Binational Toxics Strategy and the Lake Superior Lakewide Management Plan, use 1990 as a baseline for assessing mercury reductions. Minnesota selected a baseline year that was consistent with other reduction goals and targets. Last, Minnesota selected 1990 because prior to 1990 mercury use was relatively high, and then beginning in around 1990, mercury use dropped precipitously as mercury was removed from many products. For this reason Minnesota concluded that 1990 represents the end of a period when mercury emissions and fish tissue concentrations were in a steady state.

The sum of the point source load and nonpoint source load are the total source load for each region. The total source load for each region simply defines the 1990 baseline condition for the region to which the applicable reduction factor is applied.

The existing point source contribution to the total source load was calculated based on the sum of design flows for point sources within each region and mean effluent mercury concentrations. The design flows were current-day design flows, while the mean effluent

[28] The northeast regional reduction factor is 65 percent, and the southwest regional reduction factor is 51 percent.

[29] The baseline load for the northeast region is 1153 kg/yr, and the baseline load for the southwest region is 1628 kg/yr.

[30] The load reduction goal for the northeast region is 749 kg/yr, and the load reduction goal for the southwest region is 830 kg/yr.

mercury concentrations were "typical" mercury concentrations unless actual facility effluent concentrations were available. Actual facility effluent concentrations were used for the coal-fired power plants, the one refinery, and the Metro and Western Lake Superior Sanitary District wastewater treatment plants. For all other point sources, typical mercury concentrations were used. A typical effluent concentration of 5 ng/L was used for wastewater treatment plants. It was based on a study by the Association of Metropolitan Sewerage Agencies, a state study of 37 NPDES facilities, and the Mercury Maps report. Minnesota relied on the Mercury Maps report in support of the mean effluent mercury concentration of 13 ng/L for pulp and paper mills, although effluent reports from one Wisconsin and one Minnesota facility show effluent concentrations in the range of 1.6 ng/L to 2 ng/L. Minnesota used its discharge monitoring database to calculate 1.5 ng/L as the mean mercury effluent concentration for taconite mines.

The existing nonpoint source contribution to the total source load was based on total mercury deposition to the state. Minnesota used sediment cores from Minnesota lakes to estimate total statewide mercury deposition as 12.5 g km^{-2} yr^{-1}. Minnesota used the regional surface areas for each of the two regions, along with the total mercury deposition, to estimate the nonpoint source contribution to the total source load.

The reduction factor for each region is the percent reduction in total mercury load needed to achieve the fish tissue target of 0.2 mg/kg for the 90th percentile of the standard-length fish. Fish tissue data were reviewed for the standard-size top predator fish in each region. The 90th percentile fish tissue mercury concentration and median concentrations were calculated for each region for top predator fish (walleye and northern pike). Minnesota used the difference between the 90th percentile mercury concentration in top predator fish within each region and the 0.2 mg/kg target to calculate the reduction factors. Minnesota used fish tissue data from 1988 to 1992 to establish the reduction factors. The state looked at fish tissue data from 1970 to 2002; however, to be consistent with the baseline year of 1990, fish tissue data from 1988 to 1992 were selected. Multiyear data better represent real conditions over time because they account for year-to-year variability in weather, fish populations, and sampling locations. Data for the standard-size top predator fish were used to calculate the reduction factor. Mercury bioaccumulates in fish; therefore, mercury concentrations are typically highest in the top predator fish. To account for temporal and spatial comparisons of mercury concentrations in these top predator fish, Minnesota used the standard-size top predator fish.[31] Top predator fish that are collected for fish tissue analysis vary in size and age. Because mercury concentrations vary with the size of fish and age of fish, it is difficult to make comparisons regarding mercury concentrations in fish without establishing a standard of comparison. Use of the standard-size fish accounted for differences in mercury concentrations due to age and size and allowed Minnesota to compare mercury concentrations across waterbodies.

[31] Minnesota uses a standard size of 40 cm (approximately 22 inches) for walleye and 55 cm (approximately 16 inches) for northern pike.

Allocations

Consistent with the regional approach used to establish the loading capacities, Minnesota did not assign waterbody-specific allocations; rather, the state established gross allocations for each region.

Minnesota assigned 1 percent of the loading capacity to point sources as the wasteload allocation for each regional TMDL. Minnesota chose 1 percent of the loading capacity based on an approach used in the Mercury Maps report to screen watersheds for significant point source impacts to identify waterbodies impaired primarily by atmospheric mercury (see appendix E on Mercury Maps). The northeast region wasteload allocation was set at 1 percent of the loading capacity, while the southwest region's wasteload allocation was set equal to the point source load portion of the total source load. The state set the southwest region's wasteload allocation equal to the point source load portion of the total source load because it was slightly less than 1 percent of the southwest region's loading capacity and the state chose the more restrictive allocation.

Load allocations for each region were established by subtracting the wasteload allocation and any explicit margin of safety from the established loading capacity. The remaining load within each region was assigned to the load allocation. The approved loading capacity and allocations for both regional TMDLs are shown in table D13.

Table D13. Approved northeast and southwest mercury TMDLs

Region	Loading capacity	Load allocation	Wasteload allocation	Margin of safety
Northeast	1.10 kg/day	1.09 kg/day	0.01 kg/day	Implicit
Southwest	2.18 kg/day	1.55 kg/day	0.02 kg/day	0.61 kg/day

Appendix E. Model Descriptions

This appendix describes currently available models discussed in this guidance. These models aid in developing bioaccumulation factors and modifying fish tissue criteria (see chapter 3), making assessments (see chapter 4), developing total maximum daily loads (TMDLs) (see chapter 6), and in carrying out related programs such as 319 Nonpoint Source Program activities, watershed management, stormwater permits, and National Pollutant Discharge Elimination System (NPDES) discharge evaluations. This appendix provides a description of each model, some examples of how or where it has been used, and a Web site for further information about each model.

BASS (Bioaccumulation and Aquatic System Simulator)

The Bioaccumulation and Aquatic System Simulator (BASS) is a model that simulates the population and bioaccumulation dynamics of age-structured fish communities. Although BASS was specifically developed to investigate the bioaccumulation of chemical pollutants within a community or ecosystem context, it can also be used to explore population and community dynamics of fish assemblages that are exposed to a variety of non-chemical stressors such as altered thermal regimes associated with hydrological alterations or industrial activities, commercial or sports fisheries, and introductions of non native or exotic fish species.

BASS is being used to investigate methylmercury bioaccumulation in the Florida Everglades and to predict population and community dimensions of "fish health" for a regional analysis of the ecological sustainability of the Albemarle Pamlico drainage basin in North Carolina and Virginia.

Information on BASS can be found at: http://www.epa.gov/athens/research/modeling/bass.html.

Community Multi-Scale Air Quality (CMAQ) Model

The CMAQ modeling system is a comprehensive, three-dimensional, grid-based Eulerian air quality model designed to estimate pollutant concentrations and depositions over large spatial scales (Byun and Ching 1999; Byun and Schere 2006; Dennis et al. 1996). The CMAQ model is a publicly available, peer-reviewed, state-of-the-science model consisting of a number of science attributes that are critical for simulating the oxidant precursors and nonlinear chemical relationships associated with the formation of mercury. Version 4.3 of CMAQ (Bullock and Brehme 2002; Byun and Schere 2006) reflects updates to earlier versions in a number of areas to improve the underlying science and address comments from peer review. The updates in mercury chemistry in version 4.3 from that described in Bullock and Brehme (2002) are as follows:

1. The elemental mercury (Hg^0) reaction with H_2O_2 assumes the formation of 100 percent reactive gaseous mercury (RGM) rather than 100 percent particulate mercury (Hg_P).

2. The Hg^0 reaction with ozone assumes the formation of 50 percent RGM and 50 percent Hg_P rather than 100 percent Hg_P.

3. The Hg^0 reaction with OH assumes the formation of 50 percent RGM and 50 percent Hg_P rather than 100 percent Hg_P.

4. The rate constant for the Hg^0 + OH reaction was lowered from 8.7 to 7.7 x 10^{-14} cm^3 $molecules^{-1}s^{-1}$.

CMAQ simulates every hour of every day of the year and requires a variety of input files that contain information pertaining to the modeling domain and simulation period. These include hourly emissions estimates and meteorological data in every grid cell and a set of pollutant concentrations to initialize the model and to specify concentrations along the modeling domain boundaries.

Meteorological data, such as temperature, wind, stability parameters, and atmospheric moisture content influence the formation, transport, and removal of air pollution. The CMAQ model requires a specific suite of meteorological input files to simulate these physical and chemical processes. For recent CMAQ modeling, meteorological input files were derived from a simulation of the Pennsylvania State University's National Center for Atmospheric Research Mesoscale Model (Grell et al. 1994) for the entire year of 2001. This model, commonly referred to as MM5, is a limited-area, nonhydrostatic, terrain-following system that solves for the full set of physical and thermodynamic equations that govern atmospheric motions. For this analysis, version 3.6.1 of MM5 was used. A complete description of the configuration and evaluation of the 2001 meteorological modeling is provided by McNally (2003).

These initial and boundary concentrations were obtained from the output of a global chemistry model, Harvard's GEOS-CHEM model (Yantosca 2004), to provide the boundary concentrations and initial concentrations. The global GEOS-CHEM model simulates atmospheric chemical and physical processes driven by assimilated meteorological observations from NASA's Goddard Earth Observing System (GEOS). This model was run for 2001 with a grid resolution of 2 degrees x 2.5 degrees (latitude-longitude) and 20 vertical layers.

The CMAQ modeling domain encompasses all the lower 48 states and extends from 126 degrees west longitude to 66 degrees west longitude and from 24 degrees north latitude to 52 degrees north latitude. The modeling domain is segmented into rectangular blocks referred to as grid squares. The model predicts pollutant concentrations and depositions for each grid cell. For this application the horizontal domain consisted of 16,576 grid cells that are roughly 36 km by 36 km. The modeling domain contains 14 vertical layers, with the top of the modeling domain at about 16,200 meters, or 100 millibar. The height of the surface layer is 38 meters.

A CMAQ modeling run was performed to estimate the impact of global sources on U.S. deposition estimates. For this analysis, all non-U.S. mercury input species to the model were set to zero. By comparing the results of this analysis with the 2001 Clean Air Mercury Rule (CAMR) base case run, which included all U.S. and global mercury species, the percent of total mercury deposition attributable to global sources can be

estimated.[32] The model estimated that over 80 percent on average of total mercury deposition in the United States is attributable to global sources.

Due to the evolving nature of mercury modeling science, such deposition estimates have associated uncertainties. For example, it remains difficult to distinguish between the natural emissions of mercury and the re-emission of previously deposited anthropogenic mercury and there remains uncertainty in the scientific community concerning the atmospheric processes that control the oxidation state of atmospheric mercury. Thus, further advances in the current understanding of mercury chemistry could potentially lead to changes in the modeling parameters and assumptions governing the mercury chemistry in the models and therefore, changes in the estimate of the fraction deposited in the U.S. attributable to global sources.

For more information on CMAQ, see http://www.epa.gov/asmdnerl/CMAQ.

D-MCM (Dynamic Mercury Cycling Model)

D-MCM is a food web simulation of mercury accumulation in lakes. It predicts the cycling and fate of major forms of mercury in lakes, including methylmercury, Hg (II), elemental mercury, and total mercury. It is a time-dependent mechanistic model which considers the most important physical, chemical, and biological factors affecting fish mercury concentrations in lakes. D-MCM is meant for lotic (lake) systems, and is not meant to be used for lentic (streams, rivers, etc.) systems.

D-MCM can be used to develop and test hypotheses, scope field studies, improve understanding of cause and effect relationships, predict responses to changes in loading, and support design and evaluation of mitigation options. It was used in the development of mercury TMDLs for McPhee and Narraguinnep Reservoirs in Colorado and for the TMDLs for Arivaca and Pena Blanca Lakes in Arizona. The Everglades Mercury Cycling Model (E-MCM) was developed off of D-MCM and added vegetation processes and the ability to simulate multiple sediment layers for wetlands.

Information on D-MCM can be found at: http://rd.tetratech.com/DraftHgBrochurev2.pdf.

EXAMS2 (Exposure Analysis Modeling System)

EXAMS2 is a model for creating aquatic ecosystem models which can evaluate the fate, transport, and exposure concentrations of chemicals. Chemicals include synthetic organic chemicals like pesticides, industrial materials, and leachates from disposal sites. EXAMS2 core is a set of modules that link chemical properties to limnological characteristics that control the fate and transport of chemicals in aquatic systems. This model allows for both long-term analysis of chronic chemical discharges at constant release and varying release over time, and short-term analysis of chemical releases.

EXAMS2 has commonly been used to predict pesticide fate in water and soil. This model has been used to evaluate the role of hydroxyl radicals in degrading pesticides by

[32] On February 8, 2008, the D.C. Circuit Court of Appeals vacated the Clean Air Mercury Rule and remanded portions of it to EPA, for reasons unrelated to the technical analyses cited in this guidance.

researchers at the University of Georgia. EXAMS2 was also used to simulate mercury fate in the Withlacoochee River watershed and the Ohoopee River watershed in Georgia.

Information on EXAMS2 can be found at: http://www.epa.gov/ceampubl/swater/exams/.

GBMM (Grid Based Watershed Mercury Model)

EPA's Grid Based Watershed Mercury Model (GBMM) is a continuous grid-based watershed mercury loading model using the latest ArcGIS platform. It simulates the spatial and temporal dynamics of mercury from both point and non-point sources on a daily basis. The model calculates the water balance, sediment generation and transport, and mercury dynamics within a watershed. The mercury transport and transformation module simulates the following key processes:

- Mercury input from atmospheric deposition.
- Mercury assimilation and accumulation in forest canopy and release from forest litter.
- Mercury input from bedrock weathering.
- Mercury transformation in soils.
- Mercury transformation in lakes and wetlands including reduction and net methylation.
- Mercury transport through sediment and runoff.
- Mercury transport in stream channels.

GBMM accepts input data from atmospheric deposition, point sources, and natural background in time series or in digital spatial maps. By using the grid-based technology, flow and mercury dynamics can be examined at any of several points in the watershed.

The software has been peer reviewed and tested on two watersheds in Georgia, where it was used to calculate mercury TMDLs. GBMM has been used to investigate the mercury fate and transport in Brier Creek watershed located in the coastal plain of Georgia. GBMM was used to investigate detailed watershed mercury processes. The findings of this study were presented in Eighth International Conference on Mercury as a Global Pollutant (August 2006), Madison, Wisconsin, USA.

For more information on GBMM please visit: http://www.epa.gov/athens/research/modeling/mercury/gbmm.html.

GEOS-CHEM Model

The Global GEOS-CHEM model simulates physical and chemical atmospheric processes driven by observations by NASA's Goddard Earth Observing System (GEOS). This model is managed and supported by the atmospheric chemistry modeling group at Harvard University. This model is used as a tool for atmospheric composition problems.

This model was run for the 2001 CMAQ model with a grid resolution of 2 degree x 2.5 degree (latitude-longitude) and 20 vertical layers. GEOS–Chem is a major contributor to

the NASA Global Model Initiative (GMI). GEOS–Chem has been interfaced with the NASA/GISS general circulation model to investigate the effects of climate change. This work contributes to the multi-institutional Global Change and Air Pollution (GCAP) project. GEOS–Chem provides chemical modules for data assimilation of tropospheric composition at the NASA GMAO.

For more information on GEOS-CHEM please visit: http://www-as.harvard.edu/chemistry/trop/geos/geos_overview.html.

GWLF (Generalized Watershed Loading Function)

GWLF simulates mixed land use watersheds to evaluate the effect of land use practices on downstream loads of sediment and nutrients (N, P). As a loading function model, it simulates runoff and sediment transport using the curve number (CN) and Universal Soil Loss Equation (USLE), combined with average nutrient concentration, based on land use. Recently, a GIS-interface has been integrated which can use national land use and soil GIS data. Also GWLF models in-stream routing using the Muskingum-Cunge method and simulates three particle classes of sediment transport.

GWLF has been used in studies and TMDL development nationally. It is suitable for application to generalized watershed loading, source assessment, and seasonal and interannual variability. It has been extensively used in northeast and mid-Atlantic regions. It has been adopted by Pennsylvania as state system for TMDL development and agricultural land management. GWLF was used to calculate mercury load from the watershed to a lake in several TMDLs in Arizona (e.g., TMDL for Pena Blanca Lake, Arizona). GWLF is also applied in West Virginia TMDL projects by Tetra Tech, Inc.

Information on GWLF can be found at: http://www.epa.gov/nrmrl/pubs/600r05149/600r05149gwlf.pdf and http://www.vims.edu/bio/models/basinsim.html.

Mercury Maps screening analysis

A simple screening-level analysis of the mercury sources affecting a waterbody or waterbodies can assist in determining what type of approach to TMDLs is most appropriate. EPA's Mercury Maps (USEPA 2001b) is a geographic information system (GIS)-based analysis using national data coverage for watersheds, fish tissue concentrations, and non-air deposition source locations.

Mercury Maps uses a simplified form of the IEM-2M model applied in EPA's *Mercury Study Report to Congress* (USEPA 1997a). By simplifying the assumptions inherent in the freshwater ecosystem models described in the report to Congress, Mercury Maps showed that these models converge at a steady state solution for methylmercury concentrations in fish that are proportional to changes in mercury inputs from atmospheric deposition (e.g., over the long term, fish concentrations are expected to decline proportionally to declines in atmospheric loading to a waterbody). This analytical approach applies only to situations where air deposition is the only significant source of mercury to a waterbody and the physical, chemical, and biological characteristics of the ecosystem remain constant over time. To predict reductions in fish concentrations, Mercury Maps requires estimates of percent air deposition reductions by watershed, as

generated from a regional air deposition model, and georeferenced measurements of mercury concentrations in fish.

A state or authorized tribe can apply Mercury Maps on a state or watershed scale. For example, it could apply Mercury Maps on a statewide scale, using state- or tribe-defined watershed boundaries. The state might have its own data on point source effluent loads and more detailed information on other significant sources of mercury in the state, e.g., erosion of mine tailings or natural geology.

Because Mercury Maps is a simplified approach, it has several limitations.

1. The Mercury Maps approach is based on the assumption of a linear, steady state relationship between concentrations of methylmercury in fish and present-day air deposition mercury input. This condition might not be met in many waterbodies because of recent changes in mercury inputs and other environmental variables that affect mercury bioaccumulation. For example, the United States has recently reduced human-caused emissions, and international emissions have increased.

2. Environmental conditions might not remain constant over the time required to reach steady state inherent in the Mercury Maps methodology, particularly in systems that respond slowly to changes in mercury inputs.

3. Many waterbodies, particularly in areas of historical gold and mercury mining in western states, contain significant non-air sources of mercury. Mercury Maps' methodology should not be applied to such waterbodies.

4. Finally, Mercury Maps does not provide for a calculation of the time lag between a reduction in mercury deposition and a reduction in the methylmercury concentrations in fish.

Despite the limitations of Mercury Maps, for those watersheds where mercury comes almost exclusively from air deposition, Mercury Maps can be used as a simple screening tool to show the watersheds across a region where the current fish tissue concentration on average exceeds the new methylmercury fish tissue criterion and, thus, to estimate the atmospheric load reductions needed to meet the new criterion. Further information on Mercury Maps is at http://www.epa.gov/waterscience/maps and from the Office of Air Quality Planning and Standards at http://www.epa.gov/ttn/atw/utility/ria_final.pdf.

MOBILE

MOBILE is an EPA model for estimating air pollution from highway vehicles. MOBILE predicts emissions (grams/mile) of air pollutants from cars, trucks, and motorcycles under various conditions. MOBILE models emissions of several air toxics, hydrocarbons (HC), carbon monoxide (CO), oxides of nitrogen (NO_x), carbon dioxide (CO_2), and particulate matter (PM). MOBILE is based on emissions testing of tens of thousands of vehicles. The model accounts for the impact on emissions of factors such as legislative changes in vehicle emission standards, variation in local conditions such as temperature, humidity, and fuel quality, and changes in the types and use of the vehicles being driven.

MOBILE has been used to calculate national and local inventories of current and future levels of highway vehicle emissions. The inventories are used to inform decision-making

about air pollution policy and programs at the national, state and local level. Inventories based on MOBILE are also used to meet requirement of federal statutes like the Clean Air Act (CAA) and the National Environmental Protection Act (NEPA). MOBILE contributed to the creation of the National Emissions Inventory (NEI).

Information on MOBILE can be found at: http://www.epa.gov/otaq/mobile.htm.

NDMMF (National Descriptive Model of Mercury in Fish Tissue)

NDMMF is a statistical model which simulates mercury accumulation in varying species of fish. It simulates factors representing differences in species, size, and sampling method. This model has the ability to control for site factors specific to a location that influence mercury concentrations in fish tissue. For example, all fish tissue samples can be scaled to a standardized 14" bass for a specific location. The model works in association with a national dataset of over 30,000 samples of fish tissue for calibration.

NDMMF could be useful for evaluating spatial and temporal trends in fish mercury concentrations and developing fish-consumption advisories. The U.S. Geological Survey recently applied this model to study spatial variation in fish-tissue mercury concentrations in the St. Croix River Basin, Minnesota and Wisconsin.

Information on NDMMF can be found at: http://emmma.usgs.gov/fishHgAbout.aspx.

NONROAD

NONROAD is an EPA model for estimating air pollution from all engines, equipment, and vehicles that is considered "nonroad". This includes recreational vehicles, agricultural equipment, industrial equipment, residential equipment, and construction equipment. The NONROAD model is used to predict past, present, and future emissions of air pollutants like hydrocarbons (HC), oxides of nitrogen (NO_x), carbon monoxide (CO), carbon dioxide (CO_2), sulfur oxides (SO_x), and particulate matter (PM). It has been shown that "nonroad" sources contribute a significant amount of air pollutants to the environment.

Used in complement to MOBILE, NONROAD has been used to calculate national and local inventories of current and future levels of "nonroad" emissions. This model has become critical over the past several years in providing state and local pollution control agencies the ability to create accurate and consistent inventories of "nonroad" emissions to satisfy the requirements of the Clean Air Act Amendments of 1990. NONROAD contributed to the creation of the National Emissions Inventory (NEI). The Lake Michigan Air Directors Consortium (LADCO) used NONROAD to forecast emissions in their region and make appropriate policy recommendations.

Information on NONROAD can be found at: http://www.epa.gov/otaq/nonrdmdl.htm.

QEAFDCHN (Quantitative Environmental Analysis Food Chain) Model

The QEAFDCHN model is a tool for predicting chemical residues in aquatic organisms given the concentrations of chemicals in water and sediment. To predict chemical residues, the model requires information on the individual species (bioenergetic and physiological) and their diets. The model is designed to determine chemical residue in

aquatic organisms given varying chemical concentrations in both water and sediment over time.

The QEAFDCHN model can be used in a steady-state or dynamic application. The model allows the specification of complex food webs, e.g., fish preying on multiple species including smaller fish, and even age classes of fishes. The model treats individual segments of the greater ecosystem as individual ecosystems and the model has an aquatic organism migration feature. QEAFDCHN has been applied to the Lavaca Bay, Texas, chlor-alkali facility mercury contamination study by Quantitative Analysis, LLC.

Information on QEADFCHN can be found at: http://www.epa.gov/superfund//health/conmedia/sediment/pdfs/bsafissue.pdf.

Regional Modeling System for Aerosols and Deposition (REMSAD)

REMSAD is a three-dimensional grid model designed to calculate the concentrations of both inert and chemically reactive pollutants by simulating the physical and chemical processes in the atmosphere that affect pollutant concentrations (ICF International 2006). REMSAD has been peer-reviewed and is designed to support an understanding of the distributions, sources, and removal processes relevant to fine particles and other airborne pollutants, including soluble acidic components and several toxic species (mercury, cadmium, dioxin, polycyclic organic matter [POM], atrazine, and lead).

Mercury can be present in the atmosphere in both the gas and particulate phases. The mercury species included in REMSAD are Hg^0 (elemental mercury vapor), Hg^{2+} (divalent mercury compounds in gas phase), and Hg_P (divalent mercury compounds in particulate phase). These species represent the oxidation state of mercury, and the gas and particulate phases. The reactions in REMSAD, which are based on the studies of Lin and Pehkonen (1999) and other recently published studies, simulate the transfer of mercury mass from one of these states to another. REMSAD Version 8 uses the full Carbon Bond-V mechanism to simulate gas-phase photochemical processes in the atmosphere (micro-CB is still available as an option), and it also includes a chemical mechanism to calculate the transformations of mercury.

REMSAD simulates both wet and dry deposition of mercury. Wet deposition occurs as a result of precipitation scavenging. Dry deposition is calculated for each species based on land-use characteristics and meteorological parameters. REMSAD also includes algorithms for the reemission of previously deposited mercury (originating from anthropogenic and natural sources) into the atmosphere from land and water surfaces due to naturally occurring (e.g., microbial) processes.

REMSAD provides estimates of the concentrations and deposition of mercury and all other simulated pollutants at each grid location in the modeling domain. Post-processing can provide concentration averages and deposition totals for any subset of the time span of the simulation for any location within the domain.

The mercury treatment in REMSAD can be expanded to include additional, tagged mercury species. The Particle and Precursor Tagging Methodology (PPTM) feature allows the user to tag or track emissions from selected sources or groups of sources and

to quantify their contribution to mercury deposition throughout the modeling domain and simulation period.

The REMSAD model is capable of "nesting" one or more finer-scale subgrids within a coarser overall grid. This feature uses a fully interactive two-way nesting capability that permits high resolution over selected source and/or receptor regions of interest. The modeling system can be applied at scales ranging from a single metropolitan area to a continent containing multiple urban areas.

REMSAD has been used in identifying the sources contributing mercury deposition to a waterbody. In an EPA Wisconsin pilot project, REMSAD was used to input the air pollutant deposition results to aquatic models like the Mercury Cycling Model, to examine how mercury levels in fish might respond to potential changes in deposition. REMSAD has been used to develop TMDLs and determine strategies for addressing mercury and other air pollutant deposition. REMSAD was used in developing the mercury TMDL for the Coastal Bays and Gulf Waters of Louisiana (approved in 2005) and the mercury TMDLs for middle and south Georgia (approved in 2002).

Information on REMSAD can be found at: http://remsad.saintl.com/.

SERAFM (Spreadsheet-based Ecological Risk Assessment for the Fate of Mercury)

The SERAFM model is a spreadsheet-based risk assessment tool specifically designed for mercury contaminated ecosystems. SERAFM uses a steady-state simplifying assumption and includes a series of sequentially linked modules presented on separate spreadsheets. These modules include:

- Atmospheric deposition
- Watershed soil erosion
- Watershed mercury loading
- Waterbody solids balance
- Equilibrium partitioning (DOC complexation, solids partitioning)
- Mercury speciation
- Waterbody mercury calculations (historic sediment contamination, background, and remedial goal)
- Fish tissue concentrations
- Wildlife hazard quotients

The SERAFM model incorporates more recent advances in scientific understanding and implements an updated set of the IEM-2M solids and mercury fate algorithms that were described in the 1997 *Mercury Study Report to Congress* (USEPA 1997c).

For more information on SERAFM please visit: http://www.epa.gov/athens/research/modeling/mercury/serafm.html and http://www.epa.gov/nerl/news/forum2005/knightes.pdf.

TOXI5

TOXI5 is one of two submodels of WASP (Water Quality Analysis Simulation Model), the other being EUTRO5, which deals with eutrophication. TOXI5 is a sediment transport model which can also simulate the transport and transformation of chemicals. The transport of up to three types of sediment and up to three chemicals can be simulated. The chemicals may react independently or they may be linked with reaction yields which predict the fate of the interaction. Dissolved and sorbed chemical concentrations in the waterbody bed and overlying waters can be predicted using TOXI5.

TOXI5 was used to simulate the fate of mercury in the Ochlockonee Watershed in Georgia, to help develop mercury TMDLs for the Southeast U.S., and to evaluate the feasibility of dam release of water on the Nakdong River in Korea to mitigate frequent accidental spills of toxic chemicals.

For more information on TOXI5 please visit: http://smig.usgs.gov/cgi-bin/SMIC/model_home_pages/model_home?selection=wasp.

WASP (Water Quality Analysis Simulation Program)

The Water Quality Analysis Simulation Program (WASP) is a dynamic compartment-modeling program for aquatic systems, including both the water column and the underlying benthos. It has detailed mercury transformation processes for the water column and benthic sediments. The mercury module simulates the following key processes:

- Volatilization of Hg^0 (aq) to Hg^0 (air)
- Oxidation of Hg^0 → Hg^{II}
- Reduction of Hg^{II} → Hg^0
- Methylation of HgII → MeHg
- Demethylation of MeHg → Hg^{II}
- Photoreduction of MeHg → Hg^0

WASP has been used to examine eutrophication of Tampa Bay, Florida; phosphorus loading to Lake Okeechobee, Florida; eutrophication of the Neuse River Estuary, North Carolina; eutrophication of the Coosa River and Reservoirs, Alabama; PCB pollution of the Great Lakes; eutrophication of the Potomac Estuary; kepone pollution of the James River Estuary; volatile organic pollution of the Delaware Estuary; heavy metal pollution of the Deep River, North Carolina; and mercury in the Savannah River, Georgia.

Information on WASP can be found at: http://www.epa.gov/athens/research/modeling/wasp.html.

WCS (Watershed Characterization System) Mercury Loading Model

The WCS Mercury Loading model is a GIS-based (ArcView 3.x) extension of the WCS model based on a soil-mercury mass balance model (IEM v 2.05). The soil-mercury mass balance model calculates surface soil concentrations in dissolved, sorbed, and gas phases.

The model accounts for three routes of contaminant entry into the soil:

- Deposition of particle-bound contaminant through dry fall
- Deposition through wet fall
- Diffusion of gas phase contaminant into the soil surface

The model also accounts for four dissipation processes that remove mercury from the surface soils:

- Volatilization (movement of gas phase out of the soil surface)
- Runoff of dissolved phase from the soil surface
- Leaching of dissolved phase through the soil horizon
- Erosion of particulate phase from the soil surface

The model assumes that the diffusion and volatilization processes are roughly balanced on an annual basis. The WCS Mercury Loading model was used to develop many TMDLs in EPA Region 4 including a mercury TMDL for the Middle and Lower Savannah River.

Information on the WCS model can be found at: http://www.epa.gov/athens/wwqtsc/WCS-toolbox.pdf.

Example of Linking Models

Since there is no single model that can simulate all processes involved in TMDLs, some TMDLs for mercury have linked together models of atmospheric deposition, watershed loading, and mercury cycling with bioaccumulation. For example, a watershed mercury model such as GBMM, or the watershed module within SERAFM could be linked to a receiving water mercury model such as WASP, and a bioaccumulation model such as BASS.

GBMM is a spatially discrete, dynamic watershed mercury loading model which was designed for direct linkage to the EPA receiving waterbody model, WASP. GBMM can simulate mercury fate and transport within the watershed landscape and transport mercury and soils to the receiving waters through the tributaries. WASP can in turn simulate mercury dynamics in the receiving water. To predict bioaccumulation of the resulting mercury concentrations into fish tissues, WASP can then be linked to BASS. SERAFM is a more simplified approach and captures the processes from watershed to waterbody to fish bioaccumulation; however, it makes simplifying assumptions such as the waterbodies are steady state and it uses the national BAFs presented by EPA for trophic level fish.

Linkage of such models may be a workable solution in some situations. One of the limitations of the GBMM-WASP-BASS approach is that it is not an "off-the-shelf" model and a high level of expertise might be required to link the models together.

Appendix F. Examples of National Deposition Monitoring Networks

A number of national deposition monitoring networks might be useful for developing TMDLs. The networks include the National Atmospheric Deposition Program–National Trends Network (NADP/NTN) and the Mercury Deposition Network (MDN, a subset of the NADP network). The NADP/NTN is a nationwide network of precipitation monitoring stations. Operating since 1978, it collects data on the chemistry of precipitation for monitoring of geographic patterns and temporal long-term trends. NADP/NTN measures weekly average concentrations of sulfate, nitrate, ammonium, base cations, and acidity at approximately 230 monitoring stations across the United States. The MDN measures concentrations of total mercury in precipitation at approximately 45 monitoring stations across the United States and Canada. NADP/NTN results for 2003 are shown in figure F-1. For more information about NADP, see http://nadp.sws.uiuc.edu.

Used in conjunction with NADP/NTN, the Clean Air Status and Trends Network (CASTNET) is the nation's primary source of atmospheric data on the dry deposition component of total acid deposition, ground-level ozone, and other forms of atmospheric pollution that enters the environment as particles and gases. CASTNET measures weekly average atmospheric concentrations of sulfate, nitrate, ammonium, sulfur dioxide, and nitric acid, as well as hourly concentrations of ambient ozone levels in rural areas. Dry deposition rates are calculated using the measured atmospheric concentrations, meteorological data, and information on land use, surface conditions, and vegetation. Seventy-nine monitoring stations operate across the United States. For more information about CASTNET, see http://www.epa.gov/castnet and http://nadp.sws.uiuc.edu.

Note that these national monitoring networks generally provide only estimates of wet deposition; estimates of dry deposition can be obtained from the literature. For more information on deposition monitoring networks, see *Deposition of Air Pollutants to the Great Waters: Third Report to Congress* (USEPA 2000h) (http://www.epa.gov/oar/oaqps/gr8water/3rdrpt) and the Air-Water Interface Plan (http://www.epa.gov/ttn/caaa/t3/reports/combined.pdf).

Technical Report Series

The Biological Resources Division publishes scientific and technical articles and reports resulting from the research performed by our scientists and partners. These articles appear in professional journals around the world. Reports are published in two report series: Biological Science Reports and Information and Technology Reports.

Series Descriptions

Biological Science Reports ISSN 1081-292X

This series records the significant findings resulting from sponsored and co-sponsored research programs. They may include extensive data or theoretical analyses. Papers in this series are held to the same peer-review and high-quality standards as their journal counterparts.

Information and Technology Reports ISSN 1081-2911

These reports are intended for publication of book-length monographs; synthesis documents; compilations of conference and workshop papers; important planning and reference materials such as strategic plans, standard operating procedures, protocols, handbooks, and manuals; and data compilations such as tables and bibliographies. Papers in this series are held to the same peer-review and high-quality standards as their journal counterparts.

Copies of this publication are available from the National Technical Information Service, 5285 Port Royal Road, Springfield, Virginia 22161 (1-800-553-6847 or 703-487-4650). Copies also are available to registered users from the Defense Technical Information Center, Attn.: Help Desk, 8725 Kingman Road, Suite 0944, Fort Belvoir, Virginia 22060-6218 (1-800-225-3842 or 703-767-9050).

An electronic version of this report is available on-line at: http://www.cerc.usgs.gov/pubs/center/pdfdocs/BSR2001-0009.pdf

Front cover: The U.S. map shows 20 USGS National Water Quality Assessment (NAWQA) basins sampled in this study, categorized by geometric mean of mercury concentration in fish fillet samples. Basins shaded in gray delineate NAWQA study units not sampled.

A National Pilot Study of Mercury Contamination of Aquatic Ecosystems Along Multiple Gradients: Bioaccumulation in Fish

Abstract: Water, sediment, and fish were sampled in the summer and fall of 1998 at 106 sites from 20 U.S. watershed basins to examine relations of mercury (Hg) and methylmercury (MeHg) in aquatic ecosystems. Bioaccumulation of Hg in fish from these basins was evaluated in relation to species, Hg and MeHg in surficial sediment and water, and watershed characteristics. Bioaccumulation was strongly (positively) correlated with MeHg in water ($r = 0.63$, $\rho < 0.001$) but only moderately with the MeHg in sediment ($r = 0.33$, $\rho < 0.001$) or total Hg in water ($r = 0.28$, $\rho < 0.01$). Of the other measured parameters, pH, DOC, sulfate, sediment LOI, and the percent wetlands of each basin were also significantly correlated with Hg bioaccumulation in fish. The best model for predicting Hg bioaccumulation included MeHg in water, pH of the water, % wetlands in the basin, and the AVS content of the sediment. These four variables accounted for 45% of the variability of the fish fillet Hg concentration normalized (divided) by total length; however, the majority was described by MeHg in water. A MeHg water concentration of 0.12 ng/L was on average, associated with a fish fillet Hg concentration of 0.3 mg/kg wet weight for an age-3 fish when all species were considered. For age-3 largemouth bass, a MeHg water concentration of 0.058 ng/L was associated with the 0.3 mg/kg fillet concentration. Based on rankings for Hg in sediment, water, and fish, sampling sites from the following five study basins had the greatest Hg contamination: Nevada Basin and Range, South Florida Basin, Sacramento River Basin (California), Santee River Basin and Coastal Drainages (South Carolina), and the Long Island and New Jersey Coastal Drainages. A sampling and analysis strategy based on this pilot study is planned for all USGS NAWQA study units over the next decade.

Key Words: Mercury, methylmercury, bioaccumulation, fish, water, sediment

INTRODUCTION

Methylmercury (MeHg) is a potent neurotoxin that is among the most widespread contaminants affecting our Nation's aquatic ecosystems. Human fish-consumption advisories for Hg in fish have been issued in more than 40 states and account for more than eighty percent of all such advisories in the Nation (USEPA, 1998). While the threat to humans is very real, there is potentially a more serious threat to piscivorous wildlife, which consume relatively large quanitities of fish (Wiener and Spry, 1995). In Part One of this study (Krabbenhoft and others, 1999), Hg methylation efficiency was evaluated in sediment and water from watersheds that were sampled concurrently with the fish described by this report. Among other findings, MeHg production efficiency was highest in Eastern coastal basins containing high wetland densities. Nationwide, MeHg production was highest in sub-basins characterized as mixed agriculture and forested. In this report, relationships among Hg and MeHg in sediment and water are compared with bioaccumulation in fish axial muscle (the dominant repository for MeHg in fish) for 20 basins nationwide. The importance of total Hg load, methylation efficiency, MeHg in sediments and water, and selected watershed characteristics in determining the bioaccumulation of Hg in fish is assessed.

The USGS National Mercury Pilot Study

This study was conducted jointly by the National Water Quality Assessment (NAWQA) program, Toxic Substances Hydrology program, Wisconsin District Mercury Laboratory (WDML), and Columbia Environmental Research Center (CERC) of the U.S. Geological Survey. The overall objective was to identify ecosystem characteristics that favor the production and bioaccumulation of MeHg and to compare bioaccumulation rates on a national basis. Bioaccumulation of Hg in fish is a complex function of total Hg load, methylation efficiency, fish size, and the food chain dynamics in a given water body (Kidd and others, 1995). Consequently, aquatic ecosystems with high loads may have only moderate bioaccumulation in fish if methylation efficiency is low and conversely, significant bioaccumulation may result when loading is low if methylation efficiency is high. Regional- and national-scale fish surveys have been conducted in the past for Hg and other bioaccumulative contaminants. However, this is the first national-scale study in which water, sediment, and fish were sampled together with low-level Hg speciation analysis.

EXPERIMENTAL SECTION

Study Design

The major design characterics of this study were (1) national scope, (2) sampling of water, sediment, and predator fish muscle, (3) consistent use of ultra-trace clean sampling methods, (4) ultra-trace total and methyl-mercury analytical procedures, and (5) analysis of all routine water and sediment quality parameters. Sampling was conducted from June to October, 1998 at 3 to 8 sites from 20 of the 59 study units (front cover and Table 1) of the USGS NAWQA program (http://water.usgs.gov/nawqa). Nationally, these basins span the dominant east-to-west mercury deposition gradient (USEPA, 1997) and represent a wide range of environmental settings. Individual study basin teams were asked to choose sites within a basin which spanned gradients of wetland density, surface water pH, sulfate, total organic carbon, and suspected or known Hg loading. Most sampling sites were on streams. Some of the sites had high Hg loading from known Hg point sources.

Field crews were asked to focus on largemouth bass (*Micropterus salmoides*) or other black bass (*Micropterus sp.*) of age 3 years (estimated from regional growth rate data, when available) and to collect five individuals per site for compositing. Although collection objectives were not always met, all fish samples submitted were analyzed. In some cases, fish were analyzed individually to avoid creating composites of multiple species or ages. Axial muscle (fillet) was targeted for Hg analysis because it is generally the dominant and most stable repository in fish (Goldstein and others, 1996). Only total Hg was determined in the fish because virtually all of the Hg in the fillet is present as MeHg (Bloom, 1992). Black bass were targeted as ubiquitous predator fish which could facilitate inter-basin comparisons. Also, they might be expected to correlate well with localized sediment and water conditions because they normally inhabit relatively small ranges as compared to nomadic predators such as walleye (*Stizostedion vitreum*) or white bass (*Morone chrysops*), (Carlander, 1977). However, if black bass species were expected to be absent at one or more sites within a basin, samplers were advised to collect a predator species common to the entire basin so that gradients within each basin could be examined.

Age-3 fish were targeted because: (1) they should be relatively plentiful and of reasonable size for sampling fillets, (2) differences in Hg accumulation between males and females of the same size should be small, i.e., sexual growth dimorphism for largemouth bass is reportedly minimal up to this age (Lange and

Table 1. Basins, number of sites, and number of fish samples analyzed.

[a] Samples per basin, each consisting of either a homogenized composite or an individual depending on size and species submitted.

others, 1994) and (3) age-3 fish should be old enough to exhibit significant bioaccumulation of Hg. Older fish generally bioaccumulate higher concentrations of Hg but would be more difficult to capture in a consistent age class. Also, concentrations of Hg in older fish might be less representative of recent conditions contributing to the observed concentrations of Hg in the sediment and water.

Sample Collection and Preparation

Sampling and analysis of sediment and water was described in Part One of this study (Krabbenhoft and others, 1999). Of note, surface water was not filtered and sediments were taken from the top 2 to 4 cm. Ultra-trace protocols were followed for the sampling of water for Hg. Fish samples were collected by the most efficient means available, usually by electroshocking or gill-netting. Each fish was rinsed in stream water, measured for length and weight, double bagged in zip-seal plastic, and placed on dry ice as soon as possible. Samples from the ACAD and SANT basins were filleted by field crews, who also determined the ages of their specimens. Most samples were shipped within 48 hours of collection, but some were stored frozen for 1 to 2 weeks before shipment. Once received by CERC, they were stored at –20 °C for 3 to 6 months before the fillets were prepared for analysis.

Before removing fillets, individual fish from each site were thawed at room temperature for 1 to 2 hours, depending on size. Several scales were removed from behind the gill cover for aging. Each fish was then rinsed with laboratory-grade deionized (DI) water (> 10 Mohm-cm) and placed on a polypropylene cutting board situated in a polypropylene bin. Fillet knives with either ceramic (ZrO) or titanium-aluminum alloy (for larger fish) blades were used to remove a skinless, boneless (belly flap removed) fillet from the left side of each specimen. Each fillet (including those removed by field crews) was chopped into 2-cm square sections, placed in a heavy-duty polyethylene zip-seal freezer bag, rinsed twice with ultra-pure (UP) water (18 Mohm-cm), drained thoroughly and returned to the freezer. Between samples, the knife and cutting board were scrubbed with tap water and detergent, then rinsed with DI water, 1% (v/v) ultra-pure nitric acid, and HPLC-grade methanol. Equipment and cleaning procedures used for the few samples filleted by field crews were not necessarily as described above. However, we assume that potential surface contamination of all fillets was minimized by rinsing twice with UP water before

analysis.

For each site, fillets of the same species were composited for all fish of a similar size (assumed to be of similar age). However, for many sites the sampled fish varied greatly in size and apparent age, consequently some individuals were analyzed separately to avoid compositing fish of differing ages. For a few sites, the fish collected were too small (< 50 g) to conveniently remove a fillet; these specimens were chopped and processed either whole or whole, less heads. After all samples were filleted, the frozen muscle sections were placed into an acid-washed borosilicate glass jar and lyophilized (freeze-dried) to a constant dry weight at -5°C with a vacuum of about 100 mtorr. Lyophilization facilitates sample manipulation and storage but does not cause loss of biologically-incorporated Hg from tissue (LaFleur, 1973; Lasorsa and Allen-Gil, 1995). The dry product was briefly blended with a hand-held high-speed bio-homogenizer having a polystyrene bowl fitted with a stainless steel cutting blade. The base and blade assembly were washed between samples with detergent and hot water, rinsed with UP water, and dried with filtered compressed air. A representative portion of each homogenate was immediately transferred to a borosilicate glass vial fitted with a telfon-lined cap for storage in a desiccator.

Hg Determination

Tissue samples were digested before determination of Hg with microwave heating in sealable tetra-fluorinated ethylene (TFE) pressure vessels. Five mL of HNO_3 and 0.5 mL of HCl (each sub-boiled in quartz and stored in a TFE bottle) were added to a 0.5-g dry tissue sample and the vessel was sealed and placed overnight in a water bath at 70°C. The vessel was cooled, vented, then heated with a 3-step microwave program. After cooling, 1 mL of ultra-pure 30% H_20_2 was added, the vessel was sealed, and the 3-step heating program was repeated. The vessel was again cooled and the liquid contents were quantitatively transferred and diluted to 100 mL with 1% (v/v) HCl in an acid-cleaned polyethylene bottle. After briefly mixing, a 30-mL portion of the digestate was immediately transferred to a borosilicate glass tube and capped until analysis.

Analysis for Hg was conducted by cold-vapor atomic absorption spectrophotometry with flow injection sample introduction and stannous chloride reduction. Standards used for calibration included solutions containing 0.0, 5.0, 10.0, and 20.0 ng Hg/mL. Quality assurance samples analyzed included method (digestion) blanks, reference tissues, replicate samples, pre-digestion spikes (MeHg), post-digestion spikes (Hg^{2+}), and calibration and blank verification solutions. Sample results were blank-corrected based on the mean of three method blanks processed with each digestion set.

Age Determination

Age was estimated by scale analysis (Jearld, 1983) except for fish from SOFL and ACAD study units, for which sagittal otiliths were analysed (Porak and others, 1988). Scales were soaked in 70% ethanol to clean debris, increase transparency and soften them for flattening. Annuli were determined by two separate readers with the aid of a microfiche reader. A third reader was used in the case of discrepancies. All scale samples (about 10 per fish) were examined for each fish; the scale with the clearest markings was then used by all readers. Because samples were collected in late summer and fall, numerical ages of individuals that were spring spawners were assigned increments of 0.5 yr, whereas fall spawners (e.g., Salmonidae) were assigned increments of whole years. For example, a largemouth bass determined to be age-0 or age-1 was assigned a value of 0.5 or 1.5 yr, respectively. Due to resource limitations, not all individuals for composite samples were aged. Rather, the average for two representative individuals was used to estimate the age for each composite. Consequently, the age assigned for each composite was either a whole number or an increment of 0.5.

Statistical Analysis and Modelling

Linear regression and correlation analysis was conducted using the following variables: Hg concentration (µg/g wet wt.) in fish (Hg_{fish}), fish age (yr), fish length (m), fish weight (kg), methylmercury concentration (ng/g dry wt.) in sediment ($MeHg_{sed}$), total mercury concentration (ng/g dry wt.) in sediment ($HgTot_{sed}$), methylmercury concentration (ng/L) in water ($MeHg_{water}$), total mercury concentration (ng/L) in water ($HgTot_{water}$), percent methyl mercury in sediment, acid-volatile sulfide (AVS) in sediment (µmol/g dry wt.), sediment percent loss on ignition (LOI - an estimate of organic matter), dissolved organic carbon (DOC) in water (mg/L), sulfate concentration in water (wat_{sulf}), water pH (wat_{pH}), and % wetlands (of basin). We examined both Hg_{fish} and Hg_{fish} divided by weight, length, or age, as the dependent variable. Statistical analysis did not include results for fish determined to be less than one year of age, nor the results from the NBVR basin because of the extraordinarily high concentrations. For the multiple regression, residuals and partial plots were used to determine whether transformations were needed to meet the assumptions

of a good regression model (Helsel and Hirsch, 1992). The natural logarithm was used for Hg_{fish}, $MeHg_{water}$, $HgTot_{water}$, $HgTot_{sed}$, and $MeHg_{sed}$, and a cube root transformation for AVS, to obtain approximately normally-distributed residuals with constant variance. Several reasonable candidate regression models were selected using the adjusted R^2 (coefficient of determination) statistic. From this list, the one with the best predictive power (lowest PRESS statistic) was chosen. For principal components analysis (PCA), all data were processed using SIMCA-P (ver 8.0, Umetrics AB). The models and principal components were evaluated using pattern recognition of score (sample) plots and loading (variable) plots. As with the regression models, NVBR data was excluded from the analysis. Additionally, a subset consisting of sites where largemouth bass (LMB) were collected was modeled and evaluated in the same manner as the complete data set. For PCA only, the full data set and the LMB subset were also analyzed with the three size variables (age, length, weight) excluded so that influences of the remaining independent variables on Hg_{fish} could be more clearly examined.

Quality Assurance

Quality control results for the fish determinations of Hg were as follows: recovery of pre-digestion spikes of MeHg averaged 102.3 % (s.d. 4.2, n = 16); mean recovery for post digestion spikes of Hg^{2+} was 98.5 % (s.d. 5.1, n = 25). The measured values for three reference fish samples were in good agreement with certified or control ranges (Table 2). Precision for triplicate determinations (including digestion and analysis) averaged 2.6 % relative standard deviation (RSD) and ranged from 0.6 to 7.5% RSD (n = 8). The method detection limit, calculated for each of the three digestion blocks based on three times the pooled standard deviation of the method blanks (three per block) and a low-level sample analyzed in triplicate, ranged from 0.004 to 0.020 µg/g wet wt. Overall, eight of the nine method blanks were near or below the instrument detection limit (about 0.05 µg/L). The one elevated blank (0.3 µg/L) resulted in a higher reporting method detection limit (0.020 µg/g wet wt.) for samples determined in the same digestion block. However, virtually all sample concentrations were considerably above this highest blank. Consequently, the potential error associated with this worst-case blank was relatively small and it would affect the accuracy of only the very lowest sample concentrations. Overall, the results for quality assurance samples indicated good accuracy and precision for the study samples.

RESULTS AND DISCUSSION

Complete sample site information, species, weights, lengths, ages, and mercury concentrations in fish samples are listed in the Appendix; summary statistics are given in Table 3. For fish greater than 0.5 yr in age, the arithmetic means for total length, weight, and age were as follows: all species – 260 mm, 324 g, 3.2 yr; largemouth bass – 280 mm, 420 g, 3.2 yr; smallmouth bass – 261 mm, 299 g, 3.2 yr. For all fish samples (n = 159) the following statistics for Hg concentration (µg/g wet wt.) were obtained: arithmetic mean, 0.478; geometric mean, 0.218; median, 0.206; minimum, 0.018; maximum, 5.84. For largemouth bass (n = 50) these same statistics were 0.510, 0.329, 0.292, 0.045 and 4.22; for smallmouth bass (n = 37) the values were 0.244, 0.195, 0.205, 0.042 and 1.05, respectively. In comparison, the nationwide geometric mean for 27 largemouth bass composites sampled as part of the 1984 National Contaminant Biomonitoring Program (NCBP, Schmitt and Brumbaugh, 1990) is estimated at 0.31 µg/g wet weight for the fillet based on a conversion equation from whole fish (Goldstein and others, 1996). Thus, in general the national mean concentration of Hg in largemouth bass from our study (0.33) is similar to samples collected 15 years previously for the NCBP. Of course, this comparison does not account for possible differences in age or size of the samples, or differences in watershed coverage.

Mean Fish Concentration by Basin

The geometric means of fish Hg concentrations for each of the 20 study unit basins are presented in Figure 1. Because Hg concentrations in fish from a given body of water are usually a function of size or age (Wiener and others, 1990, Lange and others, 1994) and various sizes and species of fish were collected, the geometric means for the Hg concentrations normalized (divided) by weight, length, and age are also presented in Table 4. All age-0 fish (n = 7) were excluded for this comparison due to the high relative uncertainty associated with the assignment of a fractional age of less than one. For comparing Hg in fish between waterbodies, it would be preferable to conduct an analysis of covariance between concentration and size and adjust each treatment (site) mean to a uniform size variable (Sorenson and others, 1990; Lange and others, 1993). However, for most of our sites we had insufficient observations for this approach. As indicated in Table 4, NVBR, SOFL, SANT, and SACR basins consistently ranked high by any of four measures of Hg bioaccumulation in fish. The YELL, ACAD, NECB, and LINJ basins also ranked high or moderately high by these measures. The extraordinarily high concentration for NVBR fish compared with the other basins (Figure 1) is striking. Indeed, sections of the Carson River Basin are reported to be among the most severely Hg-contaminated in the world (Bonzongo and others, 1996). However, our data from this basin as a whole are greatly skewed relative to the other basins because all samples came from one severely contaminated site (Lahontan Reservoir). Similarly, fish samples from the SOFL unit were limited to two rather contaminated sites, which probably yielded a somewhat elevated mean for that study unit basin, although Hg contamination there is widespread. Means among the other 18 basins varied by a factor of about 20. The wide variety of fish species that were sampled probably factored into this range. Whereas over 65% of our samples were either largemouth-, smallmouth-, spotted-, or white bass, at least 16 other species were also represented. Also, sampling sites were selected to represent a gradient of environmental conditions and Hg levels, but they do not necessarily represent a systematic coverage of each entire basin. Nevertheless, the rankings listed in Table 4 give a reasonable guide as to the relative Hg contamination in fish among the basins sampled.

Ranking of basins for fish concentrations normalized by either length or age tended to mirror the rankings for non-adjusted concentrations. However, normalization by weight yielded some differences in rankings when compared to rankings by other means. For example, fish from the NECB and COOK study units ranked much higher for weight-normalized data as compared to length- or age-normalized data. However, samples from each of these two study units were quite small in size and were of a species that was uncommon for the data set (mixed sunfish and dolly varden, respectively). Also, the fillet data for some of the samples from these two study units were actually estimated from whole-body analysis based on a conversion equation derived from larger species (Goldstein and others, 1996). In the case of length-adjusted data, the largest specimens might have been favored due to the fact that as most fish age they have diminished increases in length relative to weight (Carlander, 1977). On the other hand, normalization by weight may have favored fish samples that were very small because regression equations for Hg concentration with fish weight tend to have a higher positive y-intercept for Hg contaminated systems relative to length-normalized data (Lange and others, 1994). These combined factors might explain why small sunfish from the NECB ranked highest by the weight-normalized criteria, but ranked fourth or lower by other measures (Table 4). Regardless of the fish ranking method chosen, the MeHg concentrations

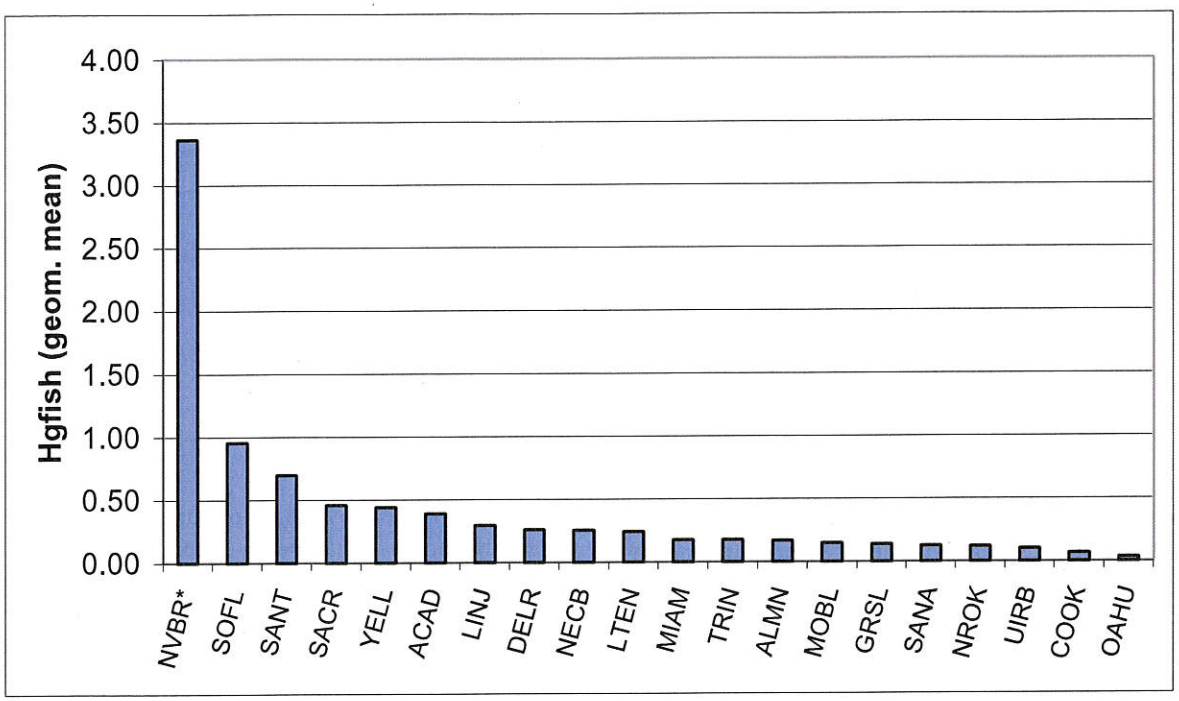

Figure 1. Geometric mean of Hg concentration in fish fillet samples collected for each of the 20 basins. *Samples from NVBR represent only one site (Lahontan Reservoir).

in both the sediment and water from the NECB basin were relatively high (Krabbenhoft and others, 1999), therefore, a high ranking for the fish is not surprising. But the comparison of bioaccumulation for NECB samples with the other basins must be viewed with caution because sunfish do not bioaccumulate Hg as rapidly as larger predator species and the fillet concentrations were estimated from the whole body measurements. In any event, a statewide Hg advisory is presently in effect for Massachusetts (where all of the NECB samples were collected).

Basins of Concern for Human Health

Our study was not designed to address the safety of consuming fish from the various participating study units, or to assess Hg exposure risks to fish and wildlife. Most, if not all of the basins of concern have already been identified by state and other federal agencies. Assessing the toxicological significance of Hg concentrations in fish with respect to populations of fish and fish-consuming wildlife is a complex matter that would be difficult to address from our data considering the the limited number of samples collected for each basin. Sensitivity to MeHg exposure can vary greatly among species and the rate of accumulation in fish apparently affects the toxicity (Wiener and Spry, 1996). Furthermore, the concentration of Hg in tissues other than the axial muscle, such as the brain or in the eggs, would generally be more useful for assessing potential impacts on fish (Wiener and Spry, 1996), whereas whole-body concentrations might be more meaningful for assessing impacts to piscivorous waterfowl and mammals (Wolfe and others, 1998). In order to address human health risks from fish consumption, we would have targeted fish older than 3 years, which typically contain higher concentrations of Hg and are more commonly sought by anglers. But because human health issues invariably arise when nation-wide fish residue data is examined, this aspect is briefly addressed.

Fish from our study that had Hg concentrations above 0.50 µg/g wet weight are listed in Table 5. Historically, 0.50 µg/g was a commonly reported human health advisory Hg fish concentration applicable to consumers of "high risk" categories, e.g., children, expectant mothers, and sub-populations whose diets include large percentages of fish (U.S. EPA, 1998). Recently, the U.S. EPA reduced the human health Hg fish criteria to 0.30 µg/g wet weight (U.S. EPA, 2001). Our results document that Hg contamination in U.S. freshwater fish is a widespread problem. One or more samples from nine of the 20 basins exceeded the 0.50 ug/g wet weight criteria and 15 of the basins had at least one sample above the 0.30 criteria. State fish

consumption advisories for Hg are currently in effect for most sites in the nine basins that exceeded the 0.50 criteria; exceptions include the SACR, MIAM, and MOBL basins. In addition, five states not included in our study (VT, MI, NH, IN, MO) currently have statewide advisories in effect for consumption of one or more species of freshwater fish due to Hg. Two other states not covered (MN and WI) have Hg advisories on a large number of water bodies.

Sources and Factors Enhancing Bioaccumulation of Hg in Fish

Among the primary basins of concern, the geographic and land-use categories varied greatly for the sub-basins from which fish above advisory concentrations were sampled. However, fish from our study with concentrations above 0.50 µg/g were most commonly from coastal or lowland primary basins, e.g. SOFL, SANT, LINJ, ACAD, SACR, MOBL. Presumably, the relatively high percentages of wetlands in these lowland basins enhance methylation rates and in turn, bioaccumulation rates of Hg in fish (St. Louis and others, 1994; Hurley, 1995: Krabbenhoft and others, 1999). The sources of Hg among these basins varies widely.

In the NVBR and SACR basins, nearby cinnabar (HgS) deposits and elemental Hg in streambeds resulting from past gold mining amalgamation practices continue to contribute to elevated Hg concentrations in fish (Bonzango and others, 1996; Domagalski, 1998). In the YELL basin, elevated Hg concentrations in reservoir fish have been associated with coal and phosphate deposits of Wyoming and Montana (May and McKinney, 1981). In a detailed study of that basin, it was concluded that elevated Hg in reservoir fish resulted primarily from weathering of soils and rocks upstream and that reservoirs furthest upstream

[e]Advisory in effect for state of Montana but not Wyoming (April 1999).

exhibited higher bioaccumulation rates because of greater susceptibility to flood events (Phillips and others, 1984). Flooding results in greater scouring of Hg from soils but more importantly methylation of waterborne Hg is enhanced when terrestial vegetation is inundated for extended periods of time (which increases the dissolved organic carbon in the water) as is the case when new reservoirs are filled (Bodaly and others, 1997).

There may be localized point sources of Hg in the ACAD basin associated with Hg-charged manometers used with natural gas wells; however, this is primarily a problem in northeast Louisiana (Facemire and others, 1995). The state of Louisiana and the USGS have been engaged in a statewide assessment of Hg contamination in fish since 1993 (Louisiana Department of Environmental Quality, 1999). Selected water bodies in the SANT and MOBL basins may still be impacted by past uses of mercury in the chloralkali and paper mill industries (May and McKinney, 1981). However, widespread elevation of Hg in fish from the SANT basin has generally not been traceable to specific industrial or wastewater discharges (South Carolina Department of Health and Environmental Control, 1999).

Overlaying the numerous point sources is a broader contribution from atmospheric deposition of mercury originating primarily from emissions associated with waste incineration and coal combustion (Hanisch, 1998). Atmospheric deposition rates of mercury are generally greatest in Florida and the northeastern U.S. (USEPA, 1997). However, many lakes in the upper Midwest have also apparently been affected by atmospheric deposition and those with low buffering capacity (and depressed pH) are likely to have high Hg accumulations in fish (Sorenson and others, 1990; Wiener and others, 1990). There is currently debate as to how localized the effects of atmospheric deposition of Hg are with respect to the emission sources and ultimately, if proposed U.S. atmospheric emission controls for Hg would be effective in reducing Hg burdens in fish (Hanisch, 1998). An index of atmospheric Hg accumulation (AHA) developed in part one of this study indicated that among the study units examined, the NVBR, NROK, GRSL, COOK, and SACR basins are most influenced by ground-based Hg sources, whereas the ALMN, DELR, LINJ, SANT, and SOFL basins are most influenced by atmospheric sources of Hg.

Ranking of Basins by Hg in Fish, Sediment, and Water

The six basins with the greatest contamination, as determined by ranking of individual sites for selected fish, sediment, and water Hg measures, are presented in Table 6. Only the highest ranking site from each study unit was considered for this comparison, i.e., for some criteria multiple sites from one study unit may have ranked above sites from other study units, but only one site from each study unit is presented. The seven Hg criteria evaluated included 1) concentration (µg/g wet) of Hg in fish (Hg_{fish}), 2) Hg_{fish} divided by fish age (yr), 3) Hg_{fish} divided by fish length (m), 4) methylmercury concentration (ng/g dry wt.) in sediment ($MeHg_{sed}$), 5) total mercury concentration (ng/g dry wt.) in sediment ($HgTot_{sed}$), 6) methylmercury concentration (ng/L) in water ($MeHg_{water}$), and 7) total mercury concentration (ng/L) in water ($HgTot_{water}$). For the ranking of sites based on Hg_{fish} normalized by age, age-0 fish (n = 7) were excluded due to the large relative error in asssigning a fractional age.

Based on the three fish criteria the following study units had samples that ranked at least twice in the top six: NVBR, SOFL, SACR, LINJ, and SANT (Table 6). Basins with sites ranking once in the top six included ACAD, YELL, MOBL, and NECB. Study unit basins having a site that ranked in the top six for both sediment and fish criteria included NVBR, SOFL, NECB, SANT, and LINJ. Conversely, basins with a site in the top six for sediment criteria but not for fish included: GRSL, COOK, and OAHU. The NROK basin contained a sampling site that was among the highest for HgTot and MeHg in sediment (S. Fork Coeur d'Alene R), but fish were not collected there because impacts of mining activity has made them scarce. Despite relatively high HgTot and MeHg in sediments at the Weber R. (GRSL) site, mountain whitefish (*Prosopium williamsoni*) collected there were below the median Hg concentration (0.206) for all samples in this study. However, this species feeds primarily on aquatic insects (Carlander, 1977) and therefore may not bioaccumulate Hg as rapidly as piscivorous fishes. The Deshka R. (COOK) and Lake Wilson (OAHU) sites were notable because despite having elevated concentrations of Hg in the sediments, each was among the very lowest for the concentration of Hg in fish (albeit for sculpin and tilapia, respectively). The Deshka R. site had an unusually high concentration of MeHg in the sediment (5.1 ng/g) considering the HgTot was only 21 ng/g, whereas sediment from the Lake Wilson site was relatively high in HgTot but only moderate in MeHg.

Basins having a site ranking high for Hg in water as well as for fish included NVBR, SOFL, SANT, SACR, and LINJ. Essentially all of the highest ranking sites for $MeHg_{water}$ also ranked high for Hg_{fish}. However,

Table 6. Top six study units based on ranking of individual sites according to various Hg criteria. Values for fish are means of up to 7 individuals; sediment and water data are single samples from each site. Only the highest site from each study unit was considered in the overall rankings for each criteria.

three basins had sites that ranked high for $HgTot_{water}$ but not for Hg_{fish}. These included OAHU (Nuunanu Res.), SANA (Santa Ana R.), and GRSL (Weber R.).

Correlation of Water and Sediment Parameters with Hg Bioaccumulation

A summary of the correlation of each measured variable (transformed as necessary to meet linearity requirements) with length-normalized mercury concentrations in fish is given in Table 7. Based on the initial analysis of our data, weight and length were about equally correlated with Hg_{fish} concentrations. But because of possible anomalies previously mentioned for rankings normalized by weight, we normalized by length for the correlation analysis. The correlation for age was significantly lower than for either length or weight, perhaps because the sample age was by design confined to a relatively narrow range and the resolution was limited to 0.5 units. Had our dataset consisted of samples of more widely varying ages, perhaps age would have been more useful. As indicated in Table 7, all of the measured parameters except $HgTot_{sed}$ and AVS_{sed} were significantly correlated with Hg bioaccumulation. The relative strength for correlation of bioaccumulation in fish with measures of Hg in water and

sediment was: $MeHg_{water} > MeHg_{sed} > HgTot_{water} >> HgTot_{sed}$ (no significant correlation). The correlation between $MeHg_{water}$ and $MeHg_{sed}$ was significant but relatively weak ($r = 0.306$, $\rho = .0009$). With the exception of DOC, all variables that were correlated with bioaccumulation exhibited stronger relationships for largemouth bass than for all species combined.

The positive relationship of Hg bioaccumulation with % wetlands, DOC, and sediment LOI (a proxy for organic matter) is widely documented (St. Louis and others, 1994, McMurtry and others, 1989, Mason and Lawrence, 1999). Higher MeHg production is generally associated with increases in organic matter in either the water column or in sediments because of enhanced microbial activity. But whereas low to moderate levels of DOC usually correlate with enhanced methylation rates of Hg (especially if the DOC is from terrestrial sources), high levels may act to reduce methylation and bioaccumulation (Winfrey and Rudd, 1990, Grieb and others, 1990, Driscoll and others, 1995). For reasons that are unclear, our Hg_{fish} data exhibited a significant positive correlation with DOC for all species combined, but not for largemouth bass. The bioacumulation of mercury in fish usually increases in waters of low pH (Wiener and others, 1990, Cope and others, 1990, Grieb and others, 1990, McMurtry and others, 1990) and the results from our nationwide sampling was no exception. In addition to other factors, lower water pH enhances Hg methylation and reduces loss of volatile Hg species from the water column by evasion (Winfrey and Rudd, 1990). Our data also exhibited a highly significant, negative correlation of Hg bioaccumulation with sulfate. The relationship was similar when either sites affected by mining, agriculture, or both were excluded from the analysis (ag and mining activity are often associated with elevated concentrations of sulfate in nearby drainges). At this time, the reason for the inverse relationship is unclear. Elevated levels of sulfate might be expected to correlate positively with Hg bioaccumulation rates because of the presence of sulfate in acidic precipitation (which has been associated with increased Hg bioaccumulation) and because of the role of sulfate-reducing bacteria that are directly involved in the methylation of mercury in water.

However, others have reported both positive and negative correlations of bioaccumulation with sulfate, depending on the watershed type (Grieb and others, 1990) and in general, most studies suggest that sulfate is not a determinant variable in the production of MeHg (Winfrey and Rudd, 1990).

Principal Components Analysis (PCA)

Factor loadings from the two most significant principal components of the PCA are presented graphically as vectors in Figures 2 (all species) and 3 (largemouth bass). Principal components 1 and 2 accounted for 44% and 54% of the variability for all species and for largemouth bass, respectively. From these plots, it is clear that a measure of fish size was the dominant variable influencing factor 2 (vectors in the positive y-direction) whereas the variables associated with the presence of organic matter (DOC, $MeHg_{water}$, LOI, % wetland, and $MeHg_{sed}$) each had a similar level of influence on factor 1 (vectors in positive x-direction). For largemouth bass only, there was a third statistically significant factor (not plotted in Figure 3) that accounted for an additional 14% of the variability. Therefore, a second PCA was conducted for largemouth bass only, but with the measures of length, weight, and age excluded, to allow for convenient examination of the first and third principal components. We expect that the exclusion of size factors may only be useful for data of a single fish species that are of relatively uniform size/age, as was the case for the largemouth bass in this study. With this plot (Figure 4), the importance of MeHg, especially in the water, on the fish Hg concentration is readily apparent because the Hg_{fish} and $MeHg_{water}$ appear as nearly identical vectors. In agreement with the simple regression analysis for largemouth bass (Table 7), DOC appears to correlate less strongly with the Hg_{fish} than many of the other parameters. It also appears that along with pH, sulfate, and AVS, DOC "counteracts" the influence of $TotHg_{water}$ on Hg_{fish} (vectors are opposite in the y-direction). However, the influence of DOC for the largemouth bass subset was probably greatly affected by the sites in the SOFL basin, which had the highest DOC values. And in fact, data for the SOFL sites fall near or outside the 95% confidence ellipse (interval) for PCA site score plots, indicating the SOFL sites were unique with respect to the variables analyzed in comparison to the other basins sampled.

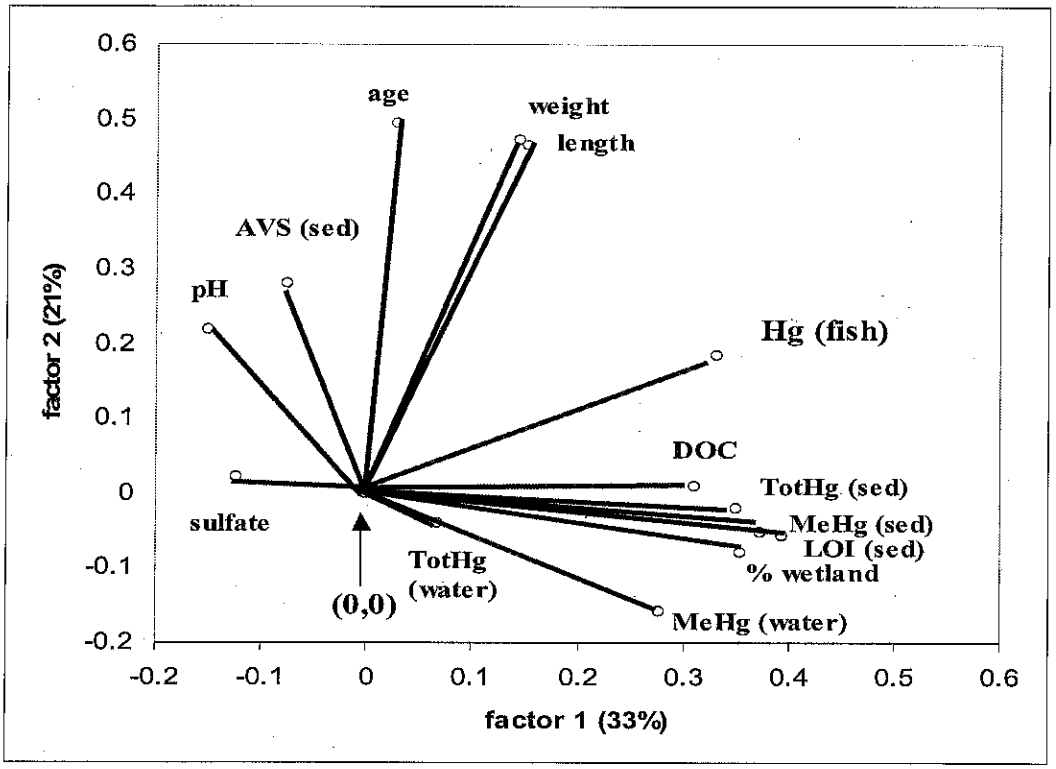

Figure 3. Principal Components Analysis - Factor Loadings for Hg Concentration in Largemouth Bass.

Model for the Bioaccumulation of Hg in Fish

An overall regression model for the bioaccumulation of Hg in fish was developed with the following candidate variables: fish weight (kg), fish total length (mm), fish age (yr), $MeHg_{water}$ (ng/L) , $HgTot_{water}$ (ng/L), $MeHg_{sed}$ (ng/g dry) $HgTot_{sed}$ (ng/g dry), DOC (mg/L), LOI (% dry wt), sediment AVS (µmol/g dry), water pH, and percent wetlands of each basin. Variables were transformed when necessary to meet the assumptions of linear regression. We also determined stable isotope ratios (C and N) in the fillets as a potential measure of trophic position (Kendall and others, 2000). However, the results were difficult to interpret (e.g., stable isotope ratios for the sediments would have been useful for adjusting for basin source differences) and consequently that data is not included in this report. For all fish combined, the following 4-variable model was deemed most useful based on the highest adjusted R^2 (44.6%) and lowest PRESS statistic (48.6):

$$\log_e(\text{Hg/length}) = -3.55 + 0.408 \log_e(MeHg_{water}) + 0.021\ (\%\text{wetland}) - 0.269\ pH - 0.121\ (AVS)^{1/3}$$

For our samples the $MeHg_{water}$ was by far the most useful predictor of Hg bioaccumulation "rate" (assuming fish length increases approximately linearly with time); it accounted for 30 of the 45% of the variability described by the model. Essentially, all of the other non-mercury parameters were measured because they were expected to influence the production MeHg. As it was correlated with several other of the explanatory variables, $MeHg_{sed}$ added no new explanatory power to the above regression equation. Many of our sampling sites were flowing (non-stratifying) waters in which the sediment-water boundary might be expected to be the most important Hg-methylation zone for the water body (Krabbenhoft and Gilmour, 1998). Also, because sediments act as a sink for most contaminants, the MeHg load in the sediment might be expected to provide a better indicator of the long term exposure for the age-3 fish that were targeted in our study. Poor correlation of Hg in fish with HgTot in sediments has been widely documented (Wiener and others, 1984; Harrison and Klaverkamp, 1990; Sorensen and others, 1990). However, relatively few studies have been conducted that directly compared MeHg in sediments with Hg in

fish. Our results suggest that on a national basis, MeHg in water is a much better predictor of concentrations in fish than is MeHg in the sediment, and that other sediment-related variables (e.g., AVS, %wetlands) probably replicate any ability of MeHg in sediment to predict Hg in fish. However, limnologic sampling conditions may greatly affect this relationship.

Presumably, fish tend to bioaccumulate a large percentage of their Hg burden during warmer months when rates of feeding and microbial methylation of Hg are highest. In waters that stratify, mixing of anoxic hypolimnetic water during fall "turnover" can result in rapid increases of mercury accumulation in zooplankton and young-of-year fishes (Slotten and others, 1995). Also, hypolimnetic tailrace water below stratified reservoirs may become enriched in MeHg during early fall (Canavan and others, 2000). We collected samples when water levels were generally at low flow - a condition that tends to favor an increase in concentrations of MeHg in the water. Because of these seasonal factors, our samples might have exhibited improved correlations with methylmercury concentrations in water relative to that in the sediment. Calculations presented by Mason and Lawrence (1999) suggest that both the sediment and water column can be significant contributors of MeHg to fish via food chain pathways. However, the greater importance of MeHg in the water relative to the sediment for our model indicates that MeHg production in surficial sediments may be of minimal consequence in some water bodies, perhaps because it is not effectively transported to the water column. Fluxes of MeHg from sediments to the water column are reported to be considerable only under anoxic conditions (Gill and others, 1999) because apparently, MeHg generated at the redox boundary is effectively trapped by sorption to solids in oxic sediment surface layers (Gagnon, and others, 1996). Therefore, for flowing, non-stratifying waters like most that were sampled in our study, effective transfer of MeHg to the water column from sediments might only occur for sediments that are prone to resuspension from wind or other factors (Bloom, and others, 1999).

The positive coefficient for % wetlands and the negative coefficient for pH with our model is in agreement with most other studies. Wetlands can be significant sources of MeHg and their presence can promote

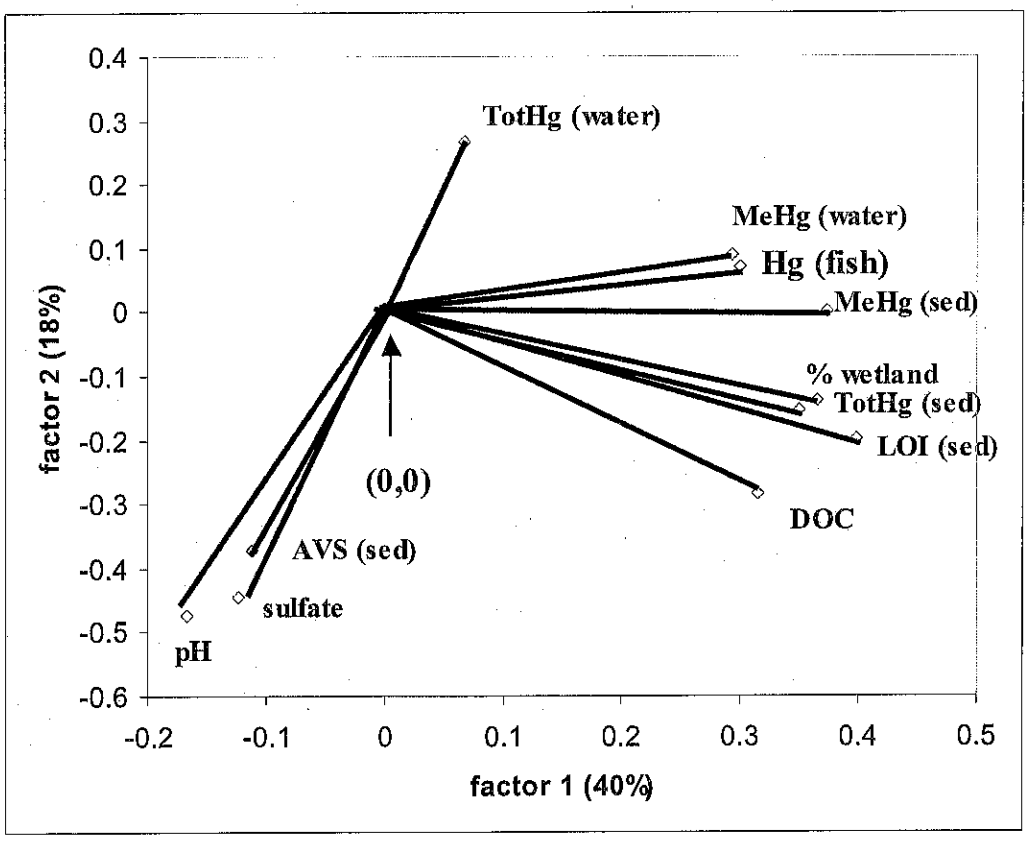

Figure 4. Principal Components Analysis - Factor Loadings for Hg Concentration in Largemouth Bass, excluding weight, length, and age.

MeHg production because, in addition to other factors, they provide DOC (and enhance microbial activity) to the watershed (Rudd, 1995). Bioaccumulation of Hg in fish usually increases in waters of low pH, primarily because the water column retains more Hg under acidic conditions (Winfrey and Rudd, 1990). A minor, but statistically significant factor with our bioaccumulation model, was the sediment acid-volatile sulfide (AVS), which exhibited a negative coefficient. Such a result might seem contradictory, because wetland sediments usually contain considerable AVS, yet Hg bioaccumulation rates are positively correlated with the presence of wetlands. It may be that highly anaeorbic wetlands, which typically contain very high AVS in the sediments, do not contribute to increased bioaccumulation of Hg in fish in the same way that more aerobic wetlands do. Also, it is possible that some of the MeHg in the water originated considerably upstream from our sampling sites. As discussed in Part One of this report, the methylation efficiency of Hg was found to decrease in sediments containing very high AVS, presumably because of the strong affinity of sulfides for Hg, which make it less available. Perhaps the small, but negative coefficient of AVS (as the cube root) for our model accounts for decreased methylation efficiency, or a net removal of MeHg from water, at very high AVS concentrations.

Regression plots of length-normalized fish concentrations for all species and for largemouth bass versus MeHg concentration in water are indicated in Figures 5 and 6, respectively. Based on these data, a water MeHg concentration of 0.12 ng/L was associated with a fish fillet Hg concentration of 0.30 µg/g for an age-3 fish when all species are considered. For age-3 largemouth bass a water MeHg concentration of 0.058 ng/L was, on average, associated with the 0.30 µg/g fillet concentration. In addition to fish species and age, other factors that might affect this relationship include seasonal and hydrologic conditions during water sampling, and prey availability and dietary pathways for the sampled fish. Although the diet is generally the dominant vector for bioaccumulation of MeHg in predator fish, the strong correlation with MeHg in water indicates that the water column was the primary source (at the base of the food chain) for the majority of our sites. It is important to note that our water samples were not filtered for the determination of Hg, although most were collected during low flow and consequently were relatively low in suspended solids. Additional studies are needed to define the limitations in estimating fish concentrations from MeHg concentrations in water, and to determine the sampling conditions that maximize the predictive power of water analyses.

Relation of Hg in Fish, Sediment, and Water to Land Use Patterns

All of the study basins were heterogeneous with respect to land cover and use. For the purposes of this

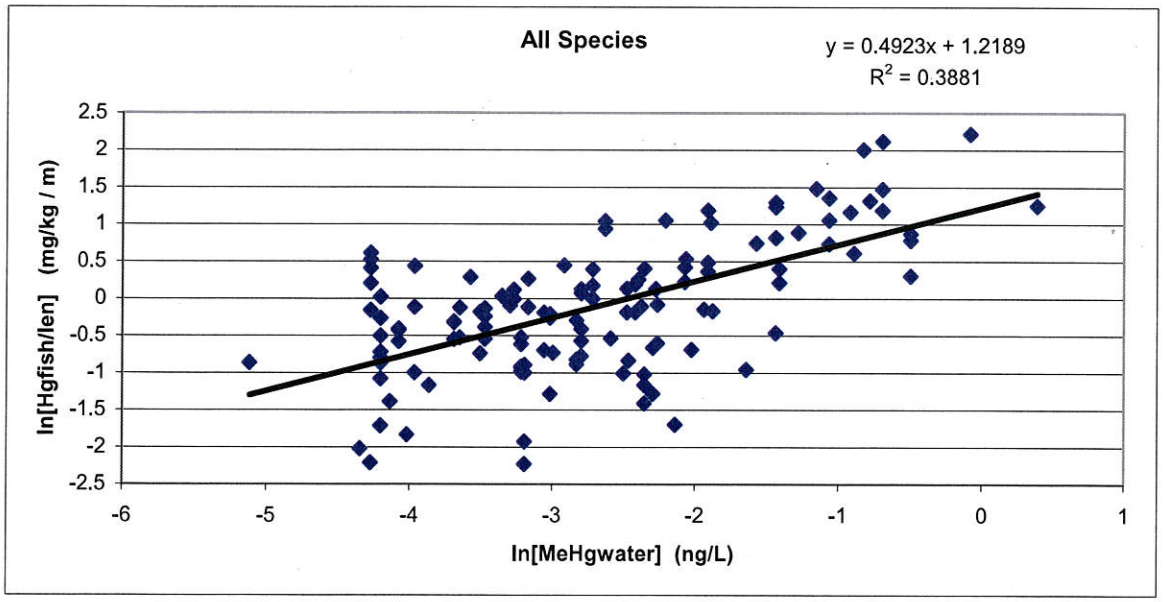

Figure 5. Length-normalized concentration of Hg in fish (all species) as a function of MeHg concentration in water. Excludes NVBR basin.

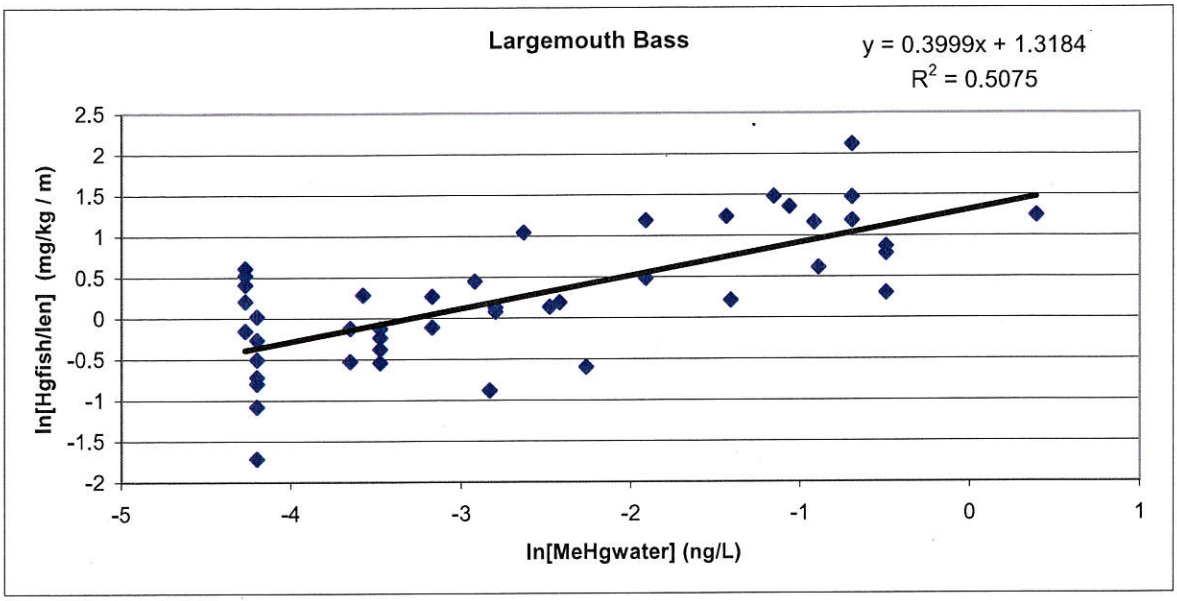

Figure 6. Length-normalized concentration of Hg in largemouth bass as a function of MeHg concentration in water.

analysis, the sub-basins above each of the sampling sites were categorized into one of the five following broad classes: agriculture dominant (Ag.); mixed agriculture and forest (A/F); background or reference site (Bkg.); current or abandonded mining activities near site (Mine); and urban or industrial activity near sampling site (Urb.). The land-use categories assigned to individual sites are listed in Part One of this report. The geometric means for each of the five Hg parameters and five land use catogories are depicted in Figure 7. Rankings for concentrations of Hg in fish were as follows: A/F >> Mine >Ag > Urb.≃ Bkd. Forested watersheds have been previously identified with high Hg methylation rates (Hurley and others, 1995). Also, A/F basins from our study often contained higher percentages of wetlands, which overall, contribute to higher methylation efficiency. Sub-basins characterized as mining-impacted ranked highest for HgTot in both sediment and water, and second in MeHg in water. As previously discussed, several of the mining basins sampled had past gold-mining operations where Hg amalgamation practices were used. Thus, although the methylation rates are not necessarily high in many of these basins, the overwhelming loads of HgTot in the watershed can yield relatively high concentrations of MeHg in the water and Hg in fish. Surprisingly, sub-basins categorized as urban had a comparatively low mean for Hg_{fish} but ranked fairly high for the HgTot and MeHg in sediment. At first glance, one might suspect that this discrepancy was due to a species bias, i.e., fewer top predators present in urban areas. But in fact, most of the fish sampled from urban sub-basins were either largemouth- or smallmouth bass. Interestingly, the correlation between $MeHg_{water}$ and $MeHg_{sed}$ was highly significant for urban sites ($r = 0.606$, $\rho = .0002$) but it was not significant for any other land-use category. The factors affecting the bioaccumulation of Hg in fish from urban settings deserves additional research.

The bioaccumulation factor (BAF) for MeHg in water to Hg in fish muscle (assumed to be all MeHg) is plotted in Figure 8 for each land-use category (and the SOFL basin) for either largemouth bass or all species combined. The SOFL unit was considered separately because of its unique character and because most other sites were flowing streams. There are no clear differences for BAFs among land-uses for all species combined. However, a trend opposite of that observed for fish concentrations (Figure 7) is apparent for BAFs for largemouth bass alone, i.e., the land-use categories with the highest fish and water concentrations (A/F and Mine) have the lowest BAFs, and vice-versa. Perhaps most striking is the comparatively low BAF for SOFL, where MeHg concentrations in water are generally high. A similar trend was observed for BAFs normalized by fish length, which indicates that overall, there was not a remarkable bias due to size differences of fish collected among land-use categories. The inverse relationship of BAF with the concentration of MeHg in water suggests that lower concentrations of MeHg in water are more efficiently biotransferred than are higher

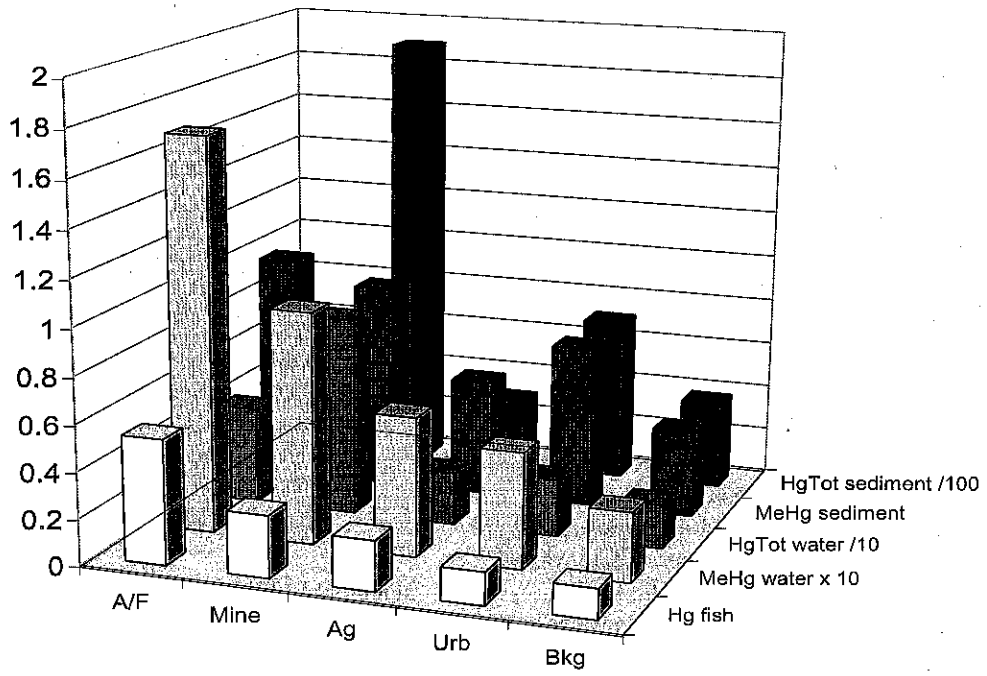

Figure 7. Geometric mean of Hg or MeHg in fish, water, and sediment for each land use category (see text for land use definitions). Number of observations = 13, 42, 23, 15, and 34, for A/F, Mine, Ag., Bkg, and Urb, respectively. Excludes South Florida basin.

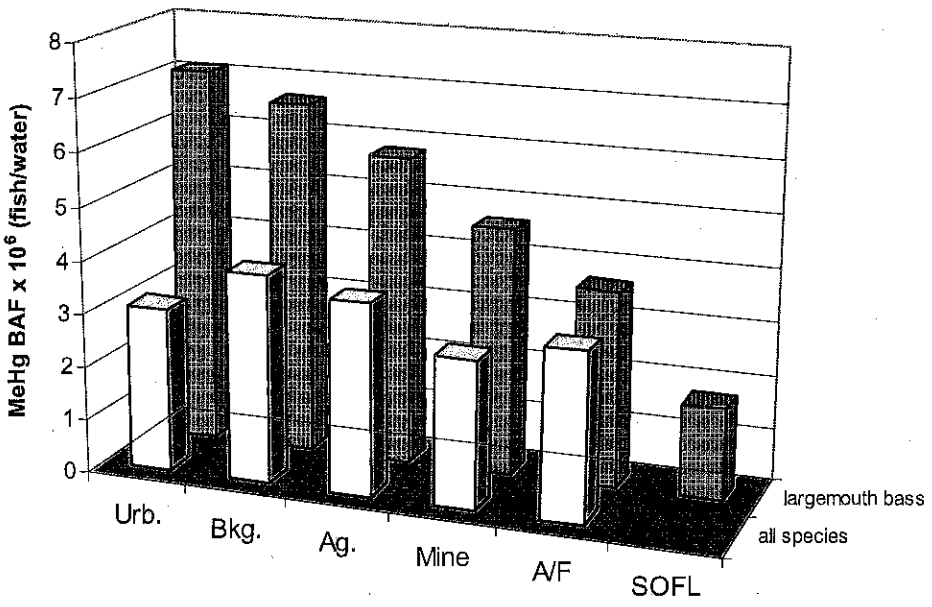

concentrations. This might result from lower assimilation (or greater elimination) by fish at higher MeHg concentrations. Or perhaps water quality factors that increase the MeHg production rate (like high DOC) also serve to reduce the relative bioavailablity and ultimately the BAF because of increased complexation of MeHg. These results warrant further investigation. But regardless of the water quality or type, high concentrations of MeHg in water will generally produce high concentrations in fish.

SUMMARY

Mercury contamination of waterways is a widespread problem and sources and accumulation rates in fish vary among basins. One or more fish fillet samples from nine of 20 basins examined in this pilot study had Hg concentrations above the historical advisory level of 0.50 µg/g wet weight and 15 of the basins had at least one sample above EPA's 2001 criteria of 0.30 µg/g wet weight. Based on rankings of selected water, sediment, and fish criteria, sampling sites from the following five basins exhibited the greatest Hg contamination: Nevada Basin and Range, South Florida, Sacramento Basin, Santee Basin and Coastal Drainages, and the Long Island and New Jersey Coast Drainages. The concentrations of Hg in fish were correlated strongly with MeHg in water, but only moderately with MeHg in sediment or HgTot in water. There was no correlation between Hg in fish and total Hg in sediment. The concentration of MeHg in water was by far the most useful variable for predicting the Hg bioaccumulation in fish. However, percent wetlands (+), pH of water (-) , and sediment AVS (-) also contributed significantly to the model. Based on our data, a MeHg water concentration of 0.12 ng/L was on average, associated with a fish fillet Hg concentration of 0.30 µg/g wet weight for an age-3 fish when all species were considered. For age-3 largemouth bass a MeHg water concentration of 0.058 ng/L was associated with the 0.30 µg/g fillet concentration. Additional studies are needed to define the limitations in estimating fish concentrations from MeHg concentrations in water, and to determine the sampling conditions that maximize the predictive power of water analyses.

Based on ranking criteria, sub-basins categorized as mixed agriculture/forest and mining-impacted had the most consistent contamination of Hg in all three sample matrices (water, sediment, and fish). The greatest discrepancy for rankings of Hg in fish and in sediments was for urban watersheds, where sediments often ranked high but fish usually ranked low. The bioaccumulation factor ($MeHg_{fish}$ / $MeHg_{water}$) was lowest for land-use categories having the highest concentrations of MeHg in water, which indicates that low concentrations of MeHg in water are more efficiently biotransferred than higher concentrations. Nevertheless, high concentrations of MeHg in water will generally produce high concentrations in fish. A sampling and analysis strategy based on this pilot study is planned for all USGS NAWQA study units over the next decade. We expect those results to provide a comprehensive national characterization of mercury contamination and bioaccumulation in our aquatic ecosystems.

ACKNOWLEDGEMENTS

The authors are indebted to all NAWQA study-basin teams who participated in the study and demonstrated great diligence, commitment, and enthusiam in the collection of the samples. We thank Jude Smith and coworkers with the U.S. Fish and Wildlife Service (Albuquerque, NM) for conducting age determinations and Dr. Ted Lange (Florida Fish and Game) for providing Hg measures in fish from South Florida. We acknowledge our colleagues Jesse Arms, Mike Walther, and Mark Olson for technical assistance, Robin Lipkin and Cory Stephens for assistance with manuscript preparation, and Chris Schmitt and Denny Buckler for helpful review comments.

Appendix. Concentrations of mercury in fish collected from USGS NAWQA Hg-Pilot Study basins, June through October, 1998. No. fish indicates number of fish in each composite sample. Sample species with [a] superscript were analyzed as whole-body less head; those with [b] superscript were analyzed as whole body. All others are fillet tissue. See text for assignment of age.. CERC = Columbia Environmental Research Center; -- = no data.

13. ABSTRACT (*Maximum 200 words*) Bioaccumulation of mercury (Hg) in fish sampled at 106 sites from 20 U.S. watershed basins was evaluated in relation to species, Hg and methylmercury (MeHg) in surficial sediment and water, and watershed characteristics. Bioaccumulation of Hg was strongly (positively) correlated with MeHg in water but only moderately with the MeHg in sediment or total Hg in water. The best model for predicting Hg bioaccumulation included MeHg in water, pH of the water, % wetlands in the basin, and the AVS content of the sediment; however, MeHg in water explained most of the model variability. Based on our data, a MeHg water concentration of 0.12 ng/L was on average, associated with a fish fillet Hg concentration of 0.3 mg/kg wet weight for an age-3 fish when all species were considered. For age-3 largemouth bass, a MeHg water concentration of 0.058 ng/L was associated with the 0.3 mg/kg fillet concentration. Based on rankings for Hg in sediment, water, and fish, sampling sites from the following five study basins had the greatest Hg contamination: Nevada Basin and Range, South Florida Basin, Sacramento River Basin (California), Santee River Basin and Coastal Drainages (South Carolina), and the Long Island and New Jersey Coastal Drainages.

U.S. Department of the Interior
U.S. Geological Survey

As the Nation's principal conservation agency, the Department of the Interior has responsibility for most of our nationally owned public lands and natural resources. This responsibility includes fostering the sound use of our lands and water resource; protecting our fish, wildlife, and biological diversity; preserving the environmental and cultural values of our national parks and historical places; and providing for the enjoyment of life through outdoor recreation. The Department assesses our energy and mineral resources and works to ensure that their development is in the best interests of all our people by encouraging stewardship and citizen participation in their care. The Department also has a major responsibility for American Indian reservation communities.

Methyl-Mercury Degradation Pathways: A Comparison among Three Mercury-Impacted Ecosystems

MARK MARVIN-DIPASQUALE,*,† JENNIFER AGEE,† CHAD MCGOWAN,† RONALD S. OREMLAND,† MARTHA THOMAS,‡ DAVID KRABBENHOFT,§ AND CYNTHIA C. GILMOUR#

U.S. Geological Survey, Water Resources Division/MS 480, 345 Middlefield Road, Menlo Park, California 94025, Department of Environmental Toxicology, University of California, Santa Cruz, California 95064, U.S. Geological Survey, Water Resources Division, 8505 Research Way, Middleton, Wisconsin 53562, and The Academy of Natural Sciences, Estuarine Research Center, 10545 Mackall Road, St. Leonard, Maryland 20685

We examined microbial methylmercury (MeHg) degradation in sediment of the Florida Everglades, Carson River (NV), and San Carlos Creek (CA), three freshwater environments that differ in the extent and type of mercury contamination and sediment biogeochemistry. Degradation rate constant (k_{deg}) values increased with total mercury (Hg_t) contamination both among and within ecosystems. The highest k_{deg}'s (2.8−5.8 d^{-1}) were observed in San Carlos Creek, at acid mine drainage impacted sites immediately downstream of the former New Idria mercury mine, where Hg_t ranged from 4.5 to 21.3 ppm (dry wt). A reductive degradation pathway (presumably *mer*-detoxification) dominated degradation at these sites, as indicated by the nearly exclusive production of $^{14}CH_4$ from ^{14}C-MeHg, under both aerobic and anaerobic conditions. At the upstream control site, and in the less contaminated ecosystems (e.g. the Everglades), k_{deg}'s were low ($\leq$0.2 d^{-1}) and oxidative demethylation (OD) dominated degradation, as evident from $^{14}CO_2$ production. k_{deg} increased with microbial CH_4 production, organic content, and reduced sulfur in the Carson River system and increased with decreasing pH in San Carlos Creek. OD associated CO_2 production increased with pore-water SO_4^{2-} in Everglades samples but was not attributable to anaerobic methane oxidation, as has been previously proposed. This ecosystem comparison indicates that severely contaminated sediments tend to have microbial populations that actively degrade MeHg via *mer*-detoxification, whereas OD occurs in heavily contaminated sediments as well but dominates in those less contaminated.

Introduction

Methylmercury (MeHg) is a heavy metal organo-toxin formed primarily by sulfate reducing bacteria in anoxic sediments (*1, 2*). Due to concerns regarding its bioaccumulation in aquatic food chains, much attention has been focused on factors controlling MeHg production under various environmental conditions (*3*−*8*). The balance of MeHg production and degradation ultimately controls MeHg concentration, yet comparatively little attention has been given to the degradation process (*9*), which may proceed by a number of abiotic and biotic pathways in the natural environment. Abiotic pathways include photodegradation (*10*) and the reaction with sulfide to form dimethylmercury (Me_2Hg) and HgS (*11*).

Biotic degradation also takes a number of forms. The most thoroughly researched involves mercury resistance in bacteria possessing genes of the *mer*-operon ((*12*−*14*) and references therein). This capacity appears widespread in nature and has been found for both gram negative and gram-positive bacteria and under aerobic and anaerobic conditions (*15*−*17*). The *mer*-operon can be carried on plasmids and other transposable elements and transferred among different bacteria species. "Broad-spectrum" resistance refers to the ability of bacteria to detoxify both inorganic Hg(II) and organomercurials, including MeHg. This contrasts with "narrow-spectrum" resistance, in which only Hg(II) detoxification occurs. The transcription of the specific detoxification and transport proteins is regulated by an organomercurial-responsive MerR protein in the first case and by a Hg(II) responsive regulatory MerR in the second case. Unique to broad-spectrum resistance is the *mer*-B gene that encodes for the organomercurial-lyase enzyme, which cleaves MeHg, forming CH_4 and Hg(II) as end-products. The associated *mer*-A gene, common in both resistance types, produces the enzyme mercuric reductase, which further reduces Hg(II) to volatile elemental Hg^0 (*18*). In this way, broad-spectrum mercury resistant microbes are able to detoxify MeHg by converting it to a form that may readily evade from the immediate environment.

An alternative anaerobic, non-*mer*-mediated, degradation pathway has been demonstrated for the sulfate reducing bacteria *Desulfovibrio desulfuricans* (*19*), where 2 mol of MeHg react with microbially produced sulfide to form an unstable dimethylmercury sulfide $(MeHg)_2S$ intermediate, which decomposes to Me_2Hg and HgS, as in the abiotic pathway above. Me_2Hg is then degraded to MeHg and CH_4. Thus, the production of CH_4 from MeHg is common to both of the above reductive demethylation (RD) pathways. It is unknown if the non-*mer* RD pathway is induced or regulated by ambient MeHg concentrations, as is *mer*-detoxification. However, genes regulating the production of sulfide and the degradation of MeHg were shown to be located on the same plasmid in *Clostridium cochlearium* T-2 (*20*), and it has been proposed that the MeHg degradation pathway in *C. cochlearium* and *D. desulfuricans* is one and the same (*21*).

Reports of CO_2 as a major bacterial end-product of MeHg degradation in anaerobic sediments led to the proposal of an oxidative demethylation (OD) pathway, which has since been demonstrated in freshwater, estuarine, and alkaline-hypersaline sediments (*22*−*24*). OD is thought to represent a cometabolism of MeHg analogous to the metabolism of other small organic substrates (e.g. C_1 compounds) by heterotrophic bacteria and as such does not represent an active detoxification response. Sulfate reducing, methanogenic, and aerobic bacteria have all been implicated in this pathway. While the production of CO_2 from MeHg is what defines OD, the production of both CO_2 and CH_4 via OD is also possible and would be analogous to the production of both end-products in the degradation of methanol or

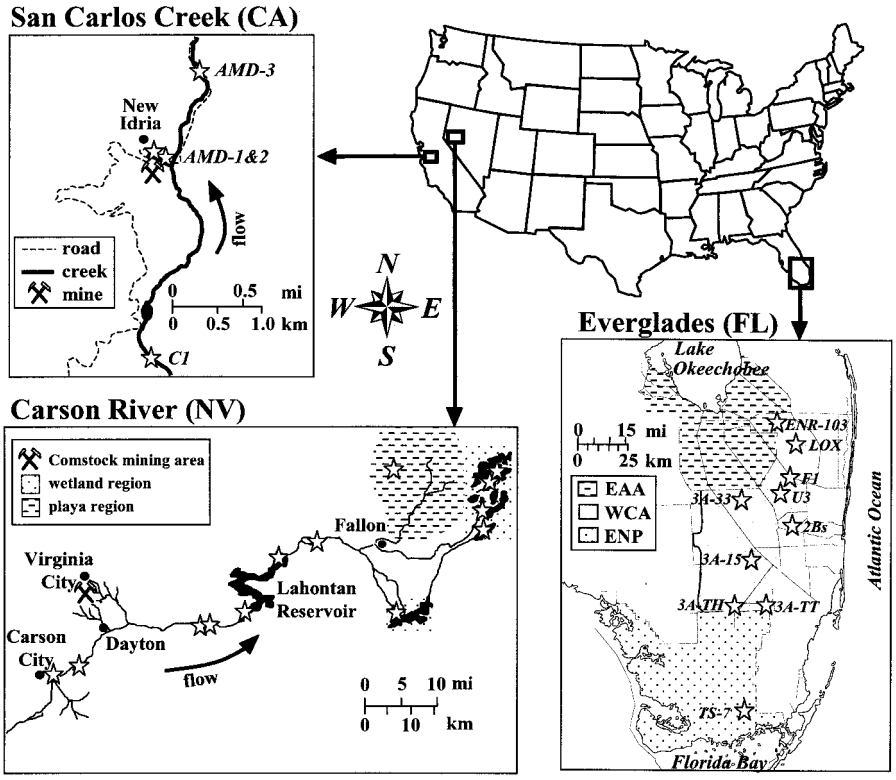

FIGURE 1. Maps of the San Carlos Creek (CA) [a], Carson River (NV) [b], and Everglades (FL) [c] ecosystems, with sampling sites given as (☆) and towns/cities as (●). Part [c] includes the Everglades Agricultural Area (EAA), Water Conservation Areas (WCA), and Everglades National Park (ENP).

monomethylamine by methanogens (*23*, *24*). In contrast, no CO_2 is formed from MeHg by either of the two RD pathways. Recently however, the evidence for OD has come into question. It has been suggested that the formation of $^{14}CO_2$ from ^{14}C-MeHg degradation experiments may simply reflect *mer*-detoxification followed by anaerobic $^{14}CH_4$ oxidation to $^{14}CO_2$ (*25*).

The specific environmental factors that control the relative importance of these biotic pathways in a particular system are largely unknown, although MeHg and/or Hg(II) concentration are likely important. Since *mer*-detoxification of MeHg is induced by the presence of the substrate, some threshold concentration is needed to induce transcription (*26*). A similar threshold concentration might not be necessary for OD to occur if this pathway represents a cometabolism of MeHg. We hypothesize that OD dominates at low in-situ MeHg concentrations, when induction of *mer*-degradation is minimal. It is also unknown if Hg(II) reduction to Hg^0 occurs under conditions favoring OD. If this capacity is lacking, an extended residence time for Hg might be predicted in systems where OD dominates. Thus, our limited understanding of the OD pathway and its potential importance in the global Hg cycle has led us to further investigate this process in various ecosystems throughout the past decade. We have observed OD in all systems investigated to date and focus here on the three most intensively studied. The Florida Everglades represents a moderately contaminated system with a nonpoint-source atmospheric Hg input, whereas San Carlos Creek (CA) and Carson River (NV) exhibit significantly higher Hg levels owing to ongoing point-source and historic regional contamination, respectively. Here we attempt to decipher the relative importance of these various microbial pathways under different environmental conditions by comparing MeHg degradation dynamics, in terms of CH_4 and CO_2 end-products, both within and among these three very different ecosystems. We also directly test the hypothesis that anaerobic CH_4 oxidation can account for the current and previous reports of OD.

Methods

Sites and Field Sampling. Mercury loading to the Florida Everglades is primarily in the form of atmospheric deposition (*27*), with sediment total mercury (Hg_t) concentrations typically 0.1−0.5 ppm (dry wt) (*28*). Surface sediment was collected from ten Everglades wetland sites (Figure 1) during December 1996, July 1997, January 1998, and June 1998, as part of the South Florida Aquatic Cycling of Mercury in the Everglades (ACME) project (*29*, *30*). Sample depth varied from the top 0−4 cm (July 1997 and June 1998) to the complete unconsolidated surface floc layer (top 4−10 cm; Dec 1996 and Jan 1998). These sites represent a 130-km north−south transect along an eutrophication gradient, stemming from high phosphate inputs from the Everglades Agricultural Area (EAA) (*31*). Sites were located in the Water Conservation Areas (WCA), the experimental Everglades Nutrient Removal (ENR) zone, and the more pristine Everglades National Park (ENP). Specific site descriptions have been given elsewhere (*24*, *32*, *33*).

The Carson River U.S. EPA Superfund site, in western Nevada, was originally contaminated during the mid- to late 1800s with elemental Hg^0 used in the processing of gold and silver ores associated with the Comstock load. The river flows northeast and drains into a desert/wetland evaporation basin at the terminus. Historic Hg inputs are from smaller tributaries originating near Virginia City and from a major amalgamation facility near Dayton. Due to the reworking and mobilization of these sediments over the past century, downstream locations currently have benthic Hg_t concentrations as high as several hundred ppm (*34*). Sediment samples (0−4 cm) were collected during October 1998 at 13 sites, over a 100-km stretch from Carson City to the wetlands

TABLE 1. Conditions Used for Methylmercury (MeHg) Degradation Measurement via $^{14}CH_3HgI$ Incubation and CT-LSC Detection of Gaseous ^{14}C End-Products

sample set	date	holding time prior to assay (d)	incubation duration (h)	^{14}C-MeHg added (nCi*cc sed^{-1})	total MeHg added (ng Hg*cc sed $^{-1}$)

San Carlos Creek (CA)	Jan 1999	30	23	2−3	7−11

region. Sites were categorized into five types depending on location and major features (*n* given in [ ]): river [5], Lahontan reservoir [2], agricultural drain [2], wetland [3], and playa [1]. Descriptions of the Carson River and associated wetlands are given elsewhere (*35*, *36*).

San Carlos Creek (SCC), located in the Diablo Mountain range of central California, intersects the former New Idria mercury mine, which operated for 118 years (1854−1972) and was the second largest producer of elemental Hg^0 in North America (*37*). The creek is impacted both by acid mine drainage (AMD) and mercury contamination from unprocessed cinnabar (HgS) ore and roasted-ore waste. Surface sediment (0−4 cm) was initially sampled in October 1997 at a non-AMD control site (C-1) located 3.2 km upstream of the mine and at an AMD site (AMD-3) located 1.2 km downstream of the mine. A second sampling in January 1999 included the two previous sites plus two additional sites associated with a short (<0.2 km) feeder stream from the New Idria mine flowing into SCC. AMD-1 was located directly in front of the mine, where subsurface AMD emerges as surface flow. AMD-2 was 0.1 km downstream, adjacent to a settling pond at the base of large roasted-ore waste pile. Detailed site descriptions are given elsewhere (*37*, *38*).

Sediment collection for microbial assays was conducted by hand with acid cleaned polycarbonate core tubes in all ecosystems. Holding times prior to the initiation of ^{14}C-MeHg incubations varied from <0.3 to 95 days (Table 1). When incubations were not initiated within a few hours of sample collection, sediment was stored at 5 °C in completely filled acid-cleaned mason jars until further analysis.

Sediment Assays. Sediment was subsampled (3 cm^3) into 13 cm^3 serum vials, which were crimp sealed and flushed with O_2-free N_2 gas. Radiolabeled MeHg (as $^{14}CH_3HgI$) was added (2−42 nCi*100 μL^{-1}) to each. The final ^{14}C-MeHg amendment levels (2−52 ng Hg*cm^{-3} wet sed or 15−2400 ppb dry wt, median = 134 ppb) were higher than in-situ MeHg (<10 ppb dry wt) for these systems (*28*, *39*). Samples were vortexed (30 s) and incubated in the dark at room temperature (17−22 °C) for 6 to 28 h (Table 1). Incubations were arrested with the addition of 1 mL of NaOH (3 N). Each site/depth sample set was replicated ($n = 2-3$) and included one autoclaved killed control. A high specific activity ^{14}C-MeHg stock (54 mCi*$mmol^{-1}$, Amersham Corp., Arlington Heights, IL) was used in all investigations, and ^{14}C-end-products were quantified by a CH_4 combustion and CO_2 trapping technique, followed by liquid scintillation counting (CT-LSC) (*24*). The serum bottle headspace was first flushed with commercial air (35−30 mL*min^{-1} for 15 min), while vortexing, to drive off $^{14}CH_4$. This end-product was combusted to $^{14}CO_2$ in an inline furnace (850 °C, using a CuO catalyst) and subsequently trapped in a solution of 8 mL of methanol and 3 mL of monoethanolamine. Nearly 100% $^{14}CH_4$ extraction efficiency achieved by twice amending the sample with 1 mL of pure unlabeled CH_4 during the flushing period. Samples were subsequently acidified with 1 mL of 6 M HCl to convert base-fixed aqueous $^{14}CO_3^{2-}$ to gaseous $^{14}CO_2$, which was then flushed from the bottle using N_2 and similarly trapped as above in a new CO_2-trap. Pure nonlabeled CO_2 was also twice added (1 mL) to samples during this second flushing step to facilitate the removal of $^{14}CO_2$ from the original sample. Scintillation cocktail (ScintiVerse II, Fisher Scientific) was added to all $^{14}CO_2$ traps, and samples were counted by LSC.

Pseudo-first-order MeHg degradation rate constant (k_{deg}) values were calculated as $k_{deg} = -\ln(1-f)*time^{-1}$, where f was the fraction of added ^{14}C-MeHg degraded to $^{14}CH_4 + {}^{14}CO_2$ (kill corrected). The relative amount of $^{14}CO_2$ produced was expressed as the percentage of total gaseous end-products recovered (henceforth called $\%^{14}CO_2$) and was calculated from kill-corrected data as $\%^{14}CO_2 = [{}^{14}CO_2/({}^{14}CH_4+{}^{14}CO_2)]*100$. While most ^{14}C-MeHg incubations consisted of only one time point (Table 1), multipoint time courses (20−120 h) were also conducted at selected sites from each ecosystem. In these cases, k_{deg} was calculated from the slope of the initial linear portion of each [%MeHg degraded versus time] curve. All determinations of statistically significant relationships were based on the $P < 0.05$ criteria for the slope of a linear model.

Methane ($^{14}CH_4$) oxidation was assessed in parallel with ^{14}C-MeHg degradation in all three ecosystems. Samples from SCC in 1997 were amended with $^{14}CH_4$ (5 nCi*250 μL^{-1}, sp. act. = 56 mCi*$mmol^{-1}$, purity = 97.5%, Amersham Corp.) and incubated 20 h, under both aerobic and anaerobic (static) conditions. Everglades (January 1998) sediment samples (3 cm^3) were amended with $^{14}CH_4$ (6 nCi*100 μL^{-1}, added to the gas phase of sealed vials) and incubated statically (no shaking) for 6−12 h, under both aerobic and anaerobic conditions. Carson River samples were slurried (3 cm^3 sediment plus 1 mL of anoxic DI water), amended with $^{14}CH_4$ (15 nCi*250 μL^{-1}), and incubated on a gyrating shaker table (150 rpm) under anaerobic conditions (only) for 45 h. Radiotracer $^{14}CH_4$ (sp. act. = 21.1 mCi*$mmol^{-1}$), used for Everglades and Carson River experiments, was obtained from and originally produced in the laboratory of B. Ward (UC Santa Cruz, CA) from methanogenic cultures incubated with $H^{14}CO_3^-$ (personal communication). $^{14}CH_4$ and $^{14}CO_2$ was subsequently quantified by the CT-LSC method in all cases.

Sediment Hg_t was quantified using acid digestion, Sn-reduction, gold trapping, and cold vapor atomic fluorescence spectrophotometry (CVAFS) detection (*40, 41*). MeHg was assayed by distillation (*42*), aqueous phase ethylation, G−C separation, and CVAFS detection (*43*). Assays were conducted at the following three institutions: Everglades samples—Academy of Natural Sciences (St. Leonard, MD), Carson River samples—USGS (Madison, WI), and New Idria samples—USGS (Menlo Park, CA). All institutions used similar equipment and assay conditions.

As measures of organic content, dry sediment samples were subject to weight loss on ignition (LOI) analysis (*44*) (all three systems) and to particulate carbon (PC) analysis (Carson River only) measured with a Carlo Erba elemental analyzer (Model 1500). Sediment pH was measured (Carson River and SCC only) by inserting a pH electrode (Cole-Parmer, model 59002-72) directly into homogenized sediment. Acid-volatile-

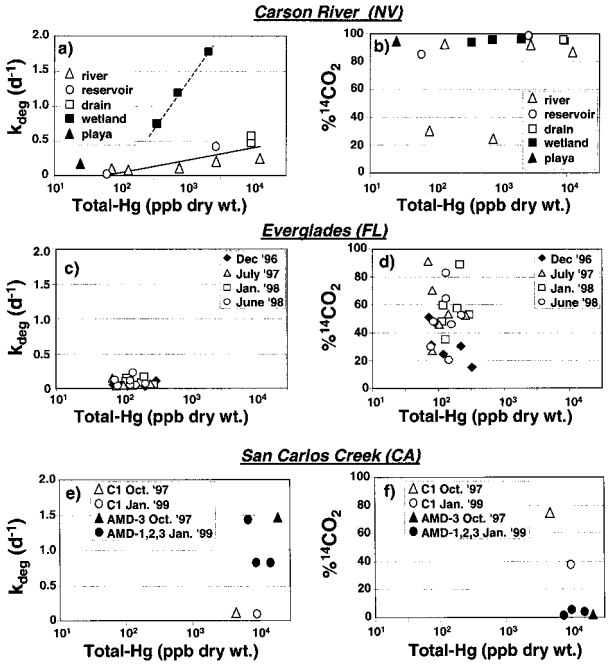

FIGURE 2. Log-linear plots of MeHg degradation rate constant (k_{deg}) [a,c,e] and $\%^{14}CO_2$ end-product [b,d,f] versus Hg_t concentrations in sediment from the Carson River (NV) 1998 [a,b], Everglades (FL) 1996−1998 [c,d], and San Carlos Creek (CA) 1997/1999 [e,f]. Carson River data is grouped by ecosystem zone, Everglades data by sampling date, and San Carlos Creek data by region and sampling date. Least-squares regression line and associated r^2 is given in [a] for data grouped by either wetlands or all other sites (excluding playa).

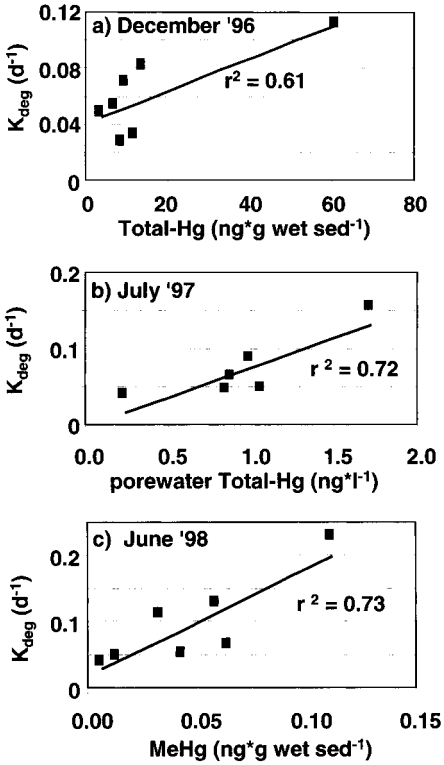

FIGURE 3. Significant linear regressions of MeHg degradation rate constant (k_{deg}) values versus various mercury pools in the Everglades data set. Depth intervals for k_{deg} data were variable (top 4 to 10 cm) during December 1996 and 0−4 cm during both July 1997 and June 1998. The corresponding mercury pool concentrations represent the 0−4 cm average depth interval in all cases.

sulfur (AVS) in Carson River samples was determined spectrophotometrically (*45*) after zinc-acetate trapping of H_2S from acidified whole sediment (*46*). AVS was determined similarly (*47*) in Everglades samples. Pore-water from Carson River sediment was collected under anaerobic conditions via centrifugation and was assayed for SO_4^{-2} via ion-chromatography (*48*) and for free sulfide (*45*). Everglades pore-water was collected by direct filtration of whole sediment or by using an in-situ interstitial pore-water sampler, with free sulfide analyzed using an ion-specific electrode (*28*). Methanogenesis in Carson River samples was measured as the net CH_4 production, over 7 days, quantified by gas chromatography with flame ionization detection. Methanogenesis in Everglades (1997) samples was measured as the conversion of radiolabeled $H^{14}CO_3^-$ (spec. act. = 54.4 mCi*mmol^{-1}; ICN Biomedicals, Irvine, CA) to $^{14}CH_4$, quantified via gas chromotography with gas proportional counting detection (*22*).

Results

Values of k_{deg} increased with increasing Hg_t (20−12 700 ppb dry wt) in the Carson River (Figure 2a). Two distinct regional groupings were observed, with the wetland sites exhibiting a stronger MeHg degradation response to Hg_t than river, reservoir, and agricultural drain sites (combined). All sites exhibited >80% $^{14}CO_2$, except two river sites which were 20−30% (Figure 2b). Everglades Hg_t concentrations (Figure 2c−d) fell into a low and narrow range (70−320 ppb dry wt) compared to the Carson River. Everglades k_{deg}'s were consistently low (0.03−0.23 d^{-1}) and similar to previously measured values (*24*). The $\%^{14}CO_2$ ranged from 15 to 92%. Neither k_{deg} nor $\%^{14}CO_2$ varied as a function of log[Hg_t] in the complete Everglades data set. However, significant relationships between k_{deg} and specific mercury fractions (e.g. bulk sediment Hg_t and MeHg, pore-water Hg_t) were found when individual sampling dates were analyzed (Figure 3a−c), although, specific results were not consistent among all dates.

SCC Hg_t levels were very high at both the control site (4800−9600 ppb dry wt) upstream and AMD sites (4500−21 300 ppb dry wt) downstream of the New Idria mercury mine (Figure 2e−f). A consistent spatial trend of low k_{deg} (≤0.1 d^{-1}) and high $\%^{14}CO_2$ (37−74%) upstream of the mine, and high k_{deg} (0.8−1.5 d^{-1}) and minimal $\%^{14}CO_2$ (1−4%) below the mine, was observed for both sampling dates.

Time course k_{deg}'s (Figure 4a−g) ranged from 0.017 d^{-1} for the modestly contaminated Everglades ENR-103 site, to 5.8 d^{-1} for the severely contaminated SCC AMD-3 site. This latter value was significantly larger than 1.5 d^{-1} depicted in Figure 2e for the same site and date. The lower value was calculated using the single 20-h data point so as to be comparable with the k_{deg} for January 1999 SCC, which was based on a single-point (22 h) incubation. The nonlinear time courses (Figure 4a,e,g) point out the potential for the underestimation of k_{deg} when calculated from a single time point, particularly from a prolonged incubation. MeHg degradation was slow (<0.1 d^{-1}) and increased linearly with time for both Everglades sites and SCC site C1. In contrast, after an initial rapid rate (0.45 d^{-1}), MeHg degradation slowed over time at Carson River site F1. A similar, but more pronounced, rapid initial degradation followed by a much slower rate was observed for SCC AMD-3 sediment, under both oxic and anoxic incubation conditions. The $\%^{14}CO_2$ was high (≥40%) and remained relatively constant over time for Carson River F1, Everglades ENR-103, and SCC C1 (anaerobic). There was a distinct decrease in $\%^{14}CO_2$ with time at both Everglades 3A-15 and SCC C1 (aerobic). Very little (<0.05%) $^{14}CO_2$ was produced in both aerobic and anaerobic SCC AMD-3 time courses.

Carson River k_{deg}'s increased with a number of biogeochemical parameters associated with the transition from

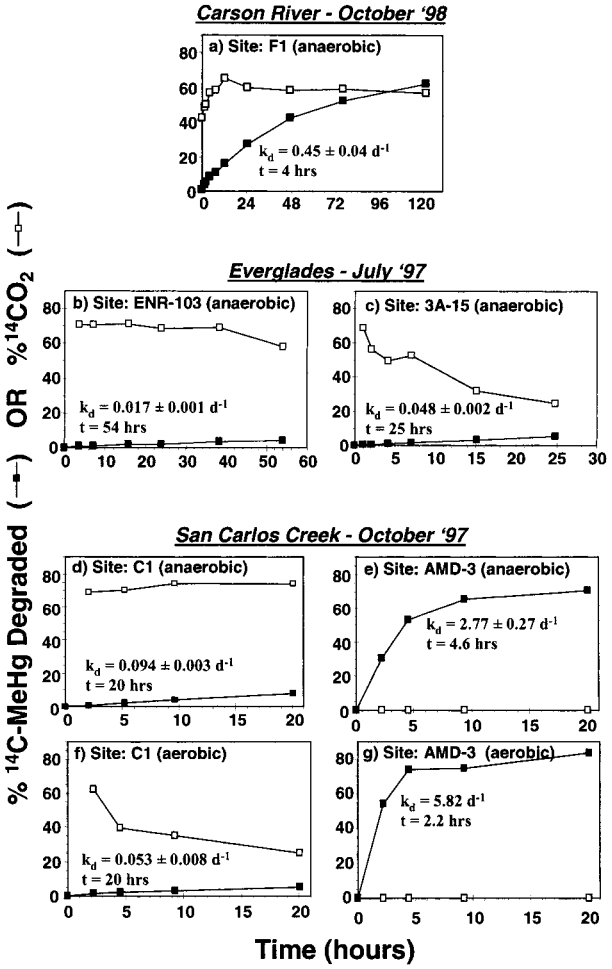

FIGURE 4. Time course experiments: percent MeHg degraded (closed square) and percent $^{14}CO_2$ end-product (open square) versus time for Carson River (NV), site F1 [a]; Everglades (FL), sites ENR-103 and 3A-15 [b,c]; and San Carlos Creek (CA), sites C1 and AMD-3 [d−g]. Degradation rate constants (k_{deg}'s) are calculated from the initial linear portion of each % degradation versus time plot. The maximum time point used for each regression is noted in each case, as are aerobic or anaerobic incubation conditions.

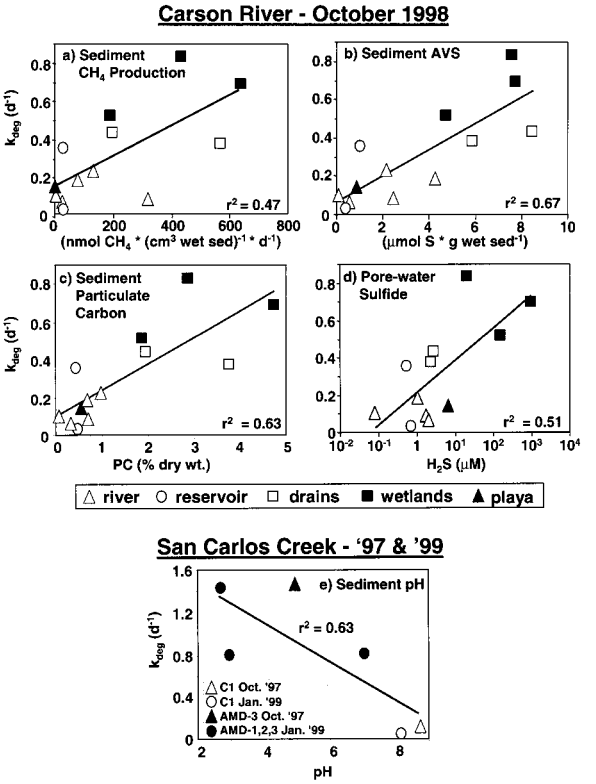

FIGURE 5. Significant linear regressions of biogeochemical variables (CH_4 production, acid-volatile-sulfur (AVS), particulate carbon (PC), pore-water sulfide (H_2S), and sediment pH) versus MeHg degradation rate constants (k_{deg}) for 0−4 cm depth interval sediment in the Carson River (NV) 1998 [a−d], and San Carlos Creek (NV) 1997/1999 [e].

low-organic river to comparatively high-organic wetland sediments, including methanogenesis rate, sediment PC and AVS, pore-water sulfide (Figure 5a−d), and LOI (not shown, similar to PC graph 5c). These parameters did not covary with Hg_t (data not shown). In contrast, no significant relationships were found between k_{deg} and methanogenesis, AVS, or sulfide in the Everglades data (no PC data). A weak negative relationship with LOI was seen for July 1997 but was heavily weighted by a single data point (not shown). No relationship between k_{deg} and LOI was seen for SCC (not shown), although degradation increased with decreasing sediment pH, which ranged from 8.1 to 8.7 at C1 and from to 2.6 to 7.1 at the AMD sites (Figure 5e). No significant relationship between pH and k_{deg} was observed for the Carson River data, where pH varied over a much narrower range (6.9−8.2).

Methane oxidation was investigated to determine if this microbial process could account for any of the $^{14}CO_2$ production routinely observed for ^{14}C-MeHg degradation experiments. In four Everglades sediments, 48−69% $^{14}CO_2$ was produced from ^{14}C-MeHg under anaerobic conditions, whereas only 0−4% $^{14}CO_2$ was produced from $^{14}CH_4$ during contemporaneous incubations (Table 2). In contrast, 9−23% $^{14}CH_4$ oxidation was observed in aerobic samples from the two sites. A corresponding increase in the $\%^{14}CO_2$ from ^{14}C-MeHg was also observed under aerobic conditions, although the total amount of MeHg degraded decreased slightly in both cases. In a similar set of parallel incubations (anaerobic only), no $^{14}CO_2$ was produced from $^{14}CH_4$ (detection limit ca. 0.1%) at any of 13 Carson River sites (not shown), while end-product $\%^{14}CO_2$ from ^{14}C-MeHg ranged from 24 to 98% (Figure 2b). Finally, no $^{14}CH_4$ oxidation was observed at either SCC (1998) site under either aerobic or anaerobic conditions, during a 20-h incubation (not shown). A positive relationship between $\%^{14}CO_2$ and pore-water SO_4^{2-} was observed in three of the four Everglades sampling dates (Figure 6), although, a similar relationship was not evident in the Carson River data.

Discussion

The positive relationship between k_{deg} and log[Hg_t] in the Carson River data set (Figure 2a) reconfirms earlier findings for this system in which the demethylation rate increased among three sites with increasing Hg contamination (*23*). The two distinct spatial groupings in the current data indicate that MeHg degrading bacteria in the wetlands were more responsive to Hg contamination than bacteria in other regions. This may reflect differences in the composition, abundance or activity of the respective microbial communities, and/or differences in the MeHg availability. The $\%^{14}CO_2$ data suggests that OD dominated MeHg degradation even at the most contaminated sites. This appears in contrast to results from the earlier investigation noted above, in which $\%^{14}CO_2$ decreased with increasing Hg contamination and demethylation rate. Such a trend would suggested a shift in microbial populations, from those invoking OD at low Hg levels to those invoking RD at higher contamination levels. The natural selection of bacteria, able to invoke *mer*-detoxification of both inorganic and organic mercury, has been shown in other Hg contaminated sediments (*18*, *49*). The lack of any clear relationship between $\%^{14}CO_2$ and Hg_t in the current study may indicate that the long sediment holding time (>90 days), prior to ^{14}C-MeHg incubation, impacted the original community composition so as to obscure this relationship. Alternatively, the apparent trend in the earlier report may have been spurious due to the limited number of observations ($n = 3$) or because *mer*-detoxification was inadvertently stimulated in contaminated sediments due to the high ^{14}C-MeHg amendment levels used (1800 ng Hg*cm^{-3}) compared to the current study (2−52 ng Hg*cm^{-3}).

The positive relationship between k_{deg} and various mercury pools evident in the Everglades data (Figure 3) further illustrates the potential for increased degradation with increasing contamination within an ecosystem. The inconsistency in the types of significant regressions observed among sampling dates partially reflects the fact that while sediment for both MeHg degradation assays and Hg-speciation analysis was collected at the same site and date, these samples were collected by two different groups of researchers, often tens of meters apart and not always at the same depth intervals (see Figure 3 legend). Thus, the analysis of k_{deg} and Hg-speciation relationships is less than optimal for this data set. However, since within-site variation in k_{deg} and Hg-species concentrations was presumably smaller than regional (among-site) variations (not directly tested), significant trends were detected in some cases. Further, since the range of Hg_t concentrations is much smaller in the Everglades compared to the Carson River, the expected response of the microbial community to increasing Hg contamination in the Everglades is expected to be more subtle and significant relationships more difficult to decipher. Finally, other geochemical factors assuredly influence k_{deg} values and thus partially obscure the direct influence of increased contamination in the Everglades.

Comparisons among systems further confirm the positive relationship between k_{deg} and Hg_t. In the Everglades, where Hg_t values were comparatively low, k_{deg}'s were likewise consistently low **(**Figure 2c**)**. In SCC, where Hg_t was very high both above and below the New Idria mine, k_{deg}'s were high at all AMD sites and low at the control site (Figure 2e). Mercury bioavailability likely accounted for this among-site difference within SCC. The source of Hg upstream is primarily recalcitrant and insoluble weathered cinnabar (HgS) abundant throughout the local area, whereas the downstream source includes particle-bound Hg(II) liberated by acidic conditions within the mine and the leaching of roasted-ore waste adjacent to the mine (*37*, *38*). Thus, the higher levels of bioavailable Hg_t at sites downstream of the mine would be more prone to select for bacterial populations that actively degrade MeHg.

As with the 1998 Carson River data, the lack of any clear relationship between $\%^{14}CO_2$ and log[Hg_t] in the Everglades (Figure 2d) indicates that something other than Hg_t alone influences MeHg degradation pathways or stoichiometric end-product ratios. The positive relationship between $\%^{14}CO_2$ and pore-water SO_4^{2-} (Figure 6) suggests that this anion plays a role in MeHg degradation pathway, although it is unclear if this role is biological (e.g. mediating sulfate reduction) or abiotic (e.g. affecting MeHg-complex formation). In either case, the consistent production of $^{14}CO_2$ at all sites demonstrates that OD was active, if not dominant. We infer that in-situ Hg was not high enough to induce a strong RD response in the Everglades sites. The situation appears altogether different in SCC sediments, where the lack of significant $^{14}CO_2$ production in AMD sites indicates that RD dominated degradation, as might be predicted under severely contaminated conditions. Abundant $^{14}CO_2$ production observed upstream of the mine (at C-1) supports the hypothesis that a strong RD response is invoked when Hg is not only very high in concentration but also bioavailable in form.

Time course experiment results (Figure 4) for Carson River site F1 and SCC site AMD-3 indicate that the ^{14}C-MeHg amendment was sequestered into at least two pools; one readily available to the resident microbial community and one less available. This was apparent from the initial rapid degradation rates followed by a slowing or cessation of degradation and was in contrast to the slow linear degradation seen in both Everglades sites and SCC site C1. Variations in substrate availability, due to refractory MeHg-complex formation with dissolved and/or particulate phases, may partially account for these spatial differences. Carson River site F1 had low organic content (4% LOI) compared to the two Everglades sites (80−91% LOI), suggesting that very organic-rich sediments may sequester a larger fraction of MeHg into slowly degrading refractory pools. We conclude that sediment organic content was not responsible for the large spatial differences in k_{deg} observed for SCC because LOI percentages were similar for SCC sites C1 and AMD-3 (11% and 17% LOI, respectively) and no significant relationship between k_{deg} and LOI was observed for SCC data. However, large differences in solid-phase composition were evident, with the AMD sites primarily composed of orange colored flocculent material, presumably iron(III)-oxy-hydroxy sulfate precipitate, typical of acid mine drainage (*50*). The distribution of ^{14}C-MeHg between organic and inoganic solid phases was not directly assessed. However, since 55−75% of the ^{14}C-MeHg amendment was readily degraded within 5 h at AMD-3 (Figure 4e,g), we speculate that much of the substrate was associated with the iron(III)-oxy-hydroxy sulfate fraction and that this portion was readily available to the MeHg degrading microbial population.

The nearly constant $\%^{14}CO_2$ produced in five of seven sites (Figure 4) indicates that one pathway dominated MeHg degradation in most cases. Specifically, OD is implicated in the case of Carson River F1, Everglades ENR-103, and SCC C1 (anaerobic), and *mer*-detoxification is implicated in the case of SCC AMD-3. We emphasize *mer*-detoxification in the latter case and not the alternative RD pathway (via reaction with H_2S), which would have been inhibited under aerobic conditions. Similarly for SCC C1, the change in the $\%^{14}CO_2$ trend, from constant and high under anaerobic conditions to decreasing with time under aerobic conditions, also suggests *mer*-detoxification may have been preferentially stimulated under aerobic conditions. The clear decrease in $\%^{14}CO_2$ with time at Everglades 3A-15 [anaerobic] and SCC C1 [aerobic] (Figure 4c,f) indicate that OD and RD were simultaneously active with RD dominating, since $\%^{14}CO_2$ would be expected to increase if OD dominated. An alternative explanation for decreasing $^{14}CO_2$ with time is that different microbial groups are capable of OD but with different stoichiometric end-product $^{14}CO_2/^{14}CH_4$ ratios and/or at different rates. It is important to emphasize that $\%^{14}CO_2$ end-product measurements alone do not indicate the relative importance of OD verses RD, particularly with single time point incubations, as some $^{14}CH_4$ may also be an OD end-product (*23, 24*). Only in cases where either $^{14}CH_4$ or $^{14}CO_2$ is the exclusive end-product can either RD or OD, respectively, be solely inferred. Then, only under aerobic conditions can the non-*mer* Me_2Hg intermediate pathway be ruled out and *mer*-detoxification surmised (e.g. SCC AMD-3).

Amendments with ^{14}C-MeHg, above ambient MeHg levels, may have stimulated RD to varying degrees at some sites (e.g. Figure 4c,f), which may partially account for the wide range of $\%^{14}CO_2$ values observed in Everglades samples (Figure 2d). It is noteworthy that when observed, the decrease in $\%^{14}CO_2$ was immediate and did not involve a lag time, suggesting that the bacterial community was preacclimated to MeHg (*18, 51*). Alternatively, the addition of ^{14}C-MeHg to organic-poor sediments may have stimulated heterotrophic bacteria capable of using MeHg as an organic substrate. If so, this would cause us to overestimate the importance of OD, as the rate of $^{14}CO_2$ produced would presumably be higher than that of nonlabeled CO_2 produced from in-situ MeHg levels. Previous experiments with Everglades sediment did show a significant increase in $\%^{14}CO_2$ produced with increasing ^{14}C-MeHg over a large amendment range (50−4000 ng MeHg*g dry sed^{-1}) but no significant increase in $\%^{14}CO_2$ over a much smaller range (2−18 ng MeHg*g dry sed^{-1}) (*24*). Amendment concentrations in the current work were varied over a wide range (in ng MeHg*g dry sed^{-1}: Everglades, 16-2600; Carson River, 68-270; SCC, 16-61), due to large variations in sediment porosity. While the corresponding amount of carbon added from ^{14}C-MeHg was small on a volumetric basis (0.01−0.25 nmol C*cm^{-3}), and only a fraction of the added radiolabel may be available for degradation, it is uncertain if the ^{14}C-MeHg amendment levels used in the current experiments resulted in a significant stimulation of heterotrophic activity. This possibility cannot be ruled, especially for some of the low organic sediments of the Carson River systems.

It is not surprising that a clear relationship between Hg_t and k_{deg} was not evident in all cases, as other environmental factors undoubtedly also impact observed MeHg degradation rates. The increase in k_{deg} with methanogenesis, sediment organic content (PC), and reduced S suggest that within-system regional differences in benthic microbiology and/or geochemistry are important in the Carson River (Figure 5a−d). It is difficult to assess the relative contribution and mechanism of each of these covarying parameters, as a control on microbial MeHg degradation, without conducting controlled experiments. Taken together, however, they depict a shift to higher k_{deg}'s going from organic-poor (river) to comparatively organic-rich and sulfidic (wetland and agricultural drain) sites with higher rates of anaerobic metabolism. These relationships were statistically independent ($P > 0.05$) of increases in k_{deg} due to increasing Hg_t. The increase in k_{deg} with increasing pore-water sulfide might suggest the non-*mer* RD pathway (via Me_2Hg formation), although the major end-product (>80%) was $^{14}CO_2$ and not $^{14}CH_4$ in most cases (Figure 3b). Thus, it would appear that it was OD, not RD, which dominated degradation. It is unknown if OD can also be carried out on $(MeHg)_2S$ or Me_2Hg, but such reactions could explain the spatial variation in the Carson River system.

The lack of positive relationships in the Everglades data set, similar to those noted above for the Carson River, may be due to the difficulty in detecting such relationships with such a comparatively low and narrow range of k_{deg}'s values. Alternatively, the relative influences of individual environmental controls on MeHg degradation may differ among systems. Specifically, the large difference in sediment organic content (as assessed by LOI) between the Everglades (33−91%, median = 80%, $n = 25$) and the Carson River (1−12%, median = 2%, $n = 13$) may partially account for the contrast in k_{deg} values among these ecosystems, for different reasons. The consistently low k_{deg} values in the organic-rich Everglades could reflect a high degree of MeHg-organic (or MeHg-reduced-S) complex formation, thereby decreasing MeHg availability to bacteria. While benthic anaerobic metabolism is presumably not carbon limited in the Everglades, organic substrate appears to limit microbial rates in the Carson River system, as evident from the increase in both methanogenesis and SR along a transect from organic-poor river sites to comparatively organic-rich wetland sites (data not shown). This increase in microbial rates parallels the increase in MeHg degradation for the Carson. Additional unpublished sequential extraction experiments conducted with ^{14}C-MeHg amended Carson River sediment indicates decreasing dissolved (water-extractable) and readily exchangeable (acid-extractable) MeHg pool size and an increase in MeHg-organic complex (base-extractable) pool size, with increasing organic content (data not shown). Assuming that the dissolved and readily exchangeable MeHg pools are more available for degradation than the MeHg-organic complex pool, then the increase in the overall activity of the MeHg degrading community more than compensates for the decrease in bioavailable MeHg pool size along the Carson River organic gradient.

The apparent increase in k_{deg} with decreasing pH in SCC sediments (Figure 5e) was not due to abiotic acid cleavage of the methyl group from MeHg, since the k_{deg}'s presented were kill corrected and represent microbial degradation only. Acidophilic bacteria were thus clearly involved in MeHg degradation at the AMD sites. To our knowledge, this is the first time that a significant MeHg degradation capacity has been suggested for this general bacterial group.

The lack of significant anaerobic $^{14}CH_4$ oxidation, in any of the three ecosystems, demonstrates that this process could not explain the $^{14}CO_2$ produced from anaerobic ^{14}C-MeHg degradation, as has been recently proposed (*25*). The fact that CH_4 oxidation was readily observed in Everglades samples incubated aerobically demonstrates our ability to detect this process. The corresponding increase in $\%^{14}CO_2$ from ^{14}C-MeHg, under aerobic conditions, indicates that some of this $^{14}CO_2$ could have been due to aerobic oxidation of $^{14}CH_4$ produced from either RD or OD.

A clear demonstration of OD in pure culture remains outstanding to date. The methylotrophic methanogen GS-16 (*22*), subsequently named *Methanolobus taylorii* sp. nov. (*52*), produced $^{14}CO_2$ from ^{14}C-MeHg ($\%^{14}CO_2$ = 29−46%) when grown on trimethylamine, although the total amount of ^{14}C-MeHg degraded was low (<3%). No anaerobic $^{14}CO_2$

production from ^{14}C-MeHg was detected for two sulfate reducing strains (*Desulfovibrio desulfuricans* LS and ND 132) and one methanogen (*Methanococcus maripaludis*), in a subsequent study (*25*). However, the high ^{14}C-MeHg amendment level used (500 ng/cm^3) was far in excess of typical environmental contamination levels and in excess of the levels used in the current study (2−52 ng/cm^3). Subsequently, *mer*-detoxification may have been induced, giving rise to detection of $^{14}CH_4$ only. It was not noted whether these bacteria were screened for the *mer*-operon. Further, previous work by Baldi et al. (*19*) demonstrated that *D. desulfuricans* degrades MeHg by the non-*mer* RD pathway (via reaction with H_2S), even under SO_4^{2-} limited conditions. While the above study (*25*) cites low SO_4^{2-} conditions for the culture media, it is also possible that low sulfide levels also existed in the sulfate reducing cultures and that the non-*mer* RD pathway was subsequently responsible for the detection of $^{14}CH_4$ as the sole gaseous end-product.

The current study demonstrates strong within-system and among-system differences in MeHg degradation rates and pathways. Systems or regions with low Hg contamination exhibited low k_{deg}'s and OD dominated the degradation pathway. A much wider range of k_{deg}'s was observed at higher contamination levels as other environmental factors become important, such as overall metabolic rates, sediment reduced S, organic matter concentrations, and substrate availability. The sequestering of MeHg by various solid phase fractions, as a key factor in mediating MeHg availability to bacteria, should be more fully investigated. Only under conditions of extreme contamination with bioavailable Hg was a strong RD pathway clearly dominant, and only then under aerobic conditions was *mer*-detoxification specifically implicated. While OD appears widespread in natural systems, its unambiguous demonstration in pure culture remains elusive, and the pathway specifics remain unknown. More work is needed to reconcile the results from the limited number of pure culture experiments with those from whole sediment field measurements.

Acknowledgments

This work was supported by the U.S. EPA (DW14955409-01-0) and the U.S. Geological Survey Place-Based Studies Program. The authors wish to thank S. Luoma (USGS, Menlo Park, CA) and C. Alpers (USGS, Sacramento, CA) for initial manuscript reviews; J. DeWild, S. Olund, and M. Olson (USGS, Madison, WI) for Carson River Hg_t and LOI analysis; C. Kendall and S. Silva for PC analysis; G. Riedel for Everglades Hg_t analysis; B. Ward (UC Santa Cruz, CA) for the $^{14}CH_4$; and three anonymous reviewers for their helpful comments. We extend special thanks to Priya Ganguli and Khalil Abu-Saba for introducing us to San Carlos Creek.

ABSTRACT: Mercury is one of the most hazardous contaminants that may be present in the aquatic environment, but its ecological and toxicological effects are strongly dependent on the chemical species present. Species distribution and transformation processes in natural aquatic systems are controlled by various physical, chemical, and biological factors. Depending on the prevailing environmental conditions, inorganic mercury species may be converted to many times more toxic methylated forms such as methylmercury, a potent neurotoxin that is readily accumulated by aquatic biota. Despite a considerable amount of literature on the subject, the behavior of mercury and many of the transformation and distribution mechanisms operating in the natural aquatic environment are still poorly understood. This review examines the current state of knowledge on the physicochemical behavior of mercury in the aquatic environment, and in particular the environmental factors influencing its transformation into highly toxic methylated forms.

KEY WORDS: methylmercury, speciation, environmental transformation, bioaccumulation.

I. INTRODUCTION

Mercury (Hg), a toxic element, is widely distributed in the environment and is naturally present in aquatic systems in very low concentrations. The extensive past industrial use of the metal and its compounds together with widespread agricultural application of organomercurials frequently has resulted in serious contamination of surface waters and sediments (e.g., Hosokawa;[147] Wilken and Wallschläger;[334] Heaven et al.[140]). Long-range atmospheric transport of Hg from fossil fuel combustion and other sources has led to increased concentrations in freshwater systems and biota even in remote areas that are free from direct anthropogenic influences (Rada et al.,[265]; Lindqvist[200]).

The chemistry of Hg is complex, making it difficult to predict the behavior of mercuric pollutants in the natural environment. Sediments act both as sinks and potential sources of Hg (Covelli et al.[81]) and once contaminated may pose a risk

* Corresponding author.

1064-3389/01/$.50

to aquatic life for many years (Kudo[187]). Depending on the prevailing physical, chemical and biological conditions, Hg compounds in aquatic systems can be interconverted and can be released from sediments to the water phase, taken up by aquatic biota, be lost to the atmosphere, or be transported with sediment particulate matter to new, previously uncontaminated locations.

The ecological and toxicological effects of Hg are strongly dependent on the chemical form (species) present (Clarkson[63]). Inorganic Hg forms may be transformed to organic, methylated species that are many times more toxic to aquatic organisms (WHO;[332,333] Boening[46]). The formation of methylmercury (MMHg), a potent neurotoxin, is of particular importance. Owing to its lipophilic and protein-binding properties, MMHg is readily accumulated by aquatic biota and may thus also pose a threat to humans and other fish-eating animals. Notorious incidents of mercury poisoning occurred in the 1950s and 1960s at Minamata Bay and on the Agano River in Japan (Takizawa[310]).

Many of the chemical and biological processes that control Hg methylation and bioaccumulation are still insufficiently understood, but if Hg pollution is to be effectively managed, we need to have a better understanding of the behavior of mercuric contaminants in the natural environment. This review discusses the behavior of Hg in aquatic systems and the factors that are thought to play a role in environmental MMHg formation. It also identifies areas in need of further research.

II. MERCURY IN THE AQUATIC ENVIRONMENT

A. Mercury Species in Aquatic Systems

Mercury occurs in three valence states (0, +1, and +2) and may be present in various physical and chemical forms in the natural aquatic environment. The nature and reactions of these species determine the solubility, mobility, and toxicity of Hg in aquatic ecosystems, as well as the potential for methylation. The main dissolved Hg species are elemental mercury (Hg^0), complexes of Hg(II) with various inorganic and organic ligands, and organic Hg forms, mainly methylmercury (MMHg) and dimethylmercury (DMHg). Between 10 to 30% of the dissolved Hg in the ocean is present as Hg^0 (Kim and Fitzgerald;[176] Mason and Fitzgerald[212]), and similar concentrations have been found for freshwaters (Vandal et al.;[313] Xiao et al.[341]). Hg^0 in surface waters occurs mainly from the reduction of Hg(II) compounds by aquatic microorganisms (Furukawa et al.;[111] Nelson et al.;[250] Mason et al.[216]) as well as from abiotic reduction by humic substances (Alberts et al.;[3] Miller;[237] Allard and Arsenie[4]), decomposition of organic Hg forms (Mason and Fitzgerald;[212] Mason and Sullivan[223]), and from anthropogenic discharges, a typical source being the chloralkali industry. Recent studies have shown that photoreduction of divalent Hg is another important mechanism of Hg^0 production in a wide

range of aquatic systems (Xiao et al.;[341,342] Schroeder et al.;[288] Amyot et al.;[5-9] Krabbenhoft et al.[181]), and that this process is mediated by humic material (Costa and Liss[79,80]). Hg^0 is relatively unreactive and is stable under mildly oxidizing or reducing conditions, but can be oxidized to Hg(II), particularly in the presence of chloride ions (Demagalhaes and Tubino;[89] Yamamoto[347]). Amyot et al.[5,6] have demonstrated the oxidation of Hg^0 in lake water and coastal seawater.

Most surface waters are supersaturated in Hg^0 relative to the atmosphere, especially in summer (Vandal et al.;[313] Fitzgerald et al.[104]). Due to its relatively high volatility, elemental Hg is readily lost from the aquatic environment at normal temperatures. The evasion of Hg^0 from water surfaces plays an important part in the global Hg cycle (Mason et al.;[214] Fitzgerald and Mason[105]). It has also been suggested that Hg^0 production is an important mechanism in aquatic systems for reducing the Hg(II) substrate used in the microbiological synthesis of MMHg (Fitzgerald et al.;[103,104] Mason et al.[215]).

Hg(I) is only stable as a dimer (Hg_2^{2+}) in aqueous solution and readily disproportionates into Hg^0 and Hg^{2+}, the most stable form in water. Until very recently, it was generally considered that the Hg^{2+} ion is the main species that is methylated in a bacterially mediated process (cf. Section III). Recent research, however, has shown that uncharged Hg complexes are much more likely to be taken up by bacteria (cf. Section III.B.1). Therefore, Hg speciation is a primary factor governing the methylation potential of a system.

The chemical form of Hg in aquatic systems is strongly influenced by redox (E_h) and pH conditions as well as by the concentrations of inorganic and organic complexing agents. Both the Hg^{2+} ion and the methylmercuric (CH_3Hg^+) cation have a high tendency to form complexes, in particular with soft ligands such as sulfur. Lindqvist[200] gives a list of potentially important inorganic and methylmercury complexes for fresh and sea water, and predominance diagrams showing the relative regions of stability of various soluble Hg species can be found in the literature (Hem;[90] Gavis and Fergusson;[118] Lockwood and Chen;[201] Beneš and Havlík;[24] Hudson et al.;[148] Stumm and Morgan[304]). In the absence of sulfide, the speciation of inorganic Hg in freshwaters is dominated by three uncharged complexes, $Hg(OH)_2$, HgOHCl, and $HgCl_2$ (cf. Figure 1). In the presence of increasing chloride ion concentrations, Hg^{2+} forms $HgCl^+$, $HgCl_2$, $HgCl_3^-$, and $HgCl_4^{2-}$ complexes, and in full-strength seawater (3.5% salinity), containing an average concentration of 0.56 *M* of Cl^-, it exists primarily as $HgCl_4^{2-}$ and $HgCl_3^-$ (Lockwood and Chen;[201] Hahne and Kroontje;[134] Stotzky and Babich[303]). Methylmercuric hydroxide, CH_3HgOH, is the most stable methylmercury species in the freshwater environment, whereas in seawater MMHg is present mainly as the chloride, CH_3HgCl (Craig;[82] Stumm and Morgan[304]). Equilibrium constants for MMHg and some of its complexes have been published, for example, by Stumm and Morgan.[304]

Predominance diagrams do not usually consider organic complexation due to a paucity of thermodynamic data on Hg and especially MMHg binding with polyfunctional natural ligands such as humic and fulvic acids. Hg speciation in

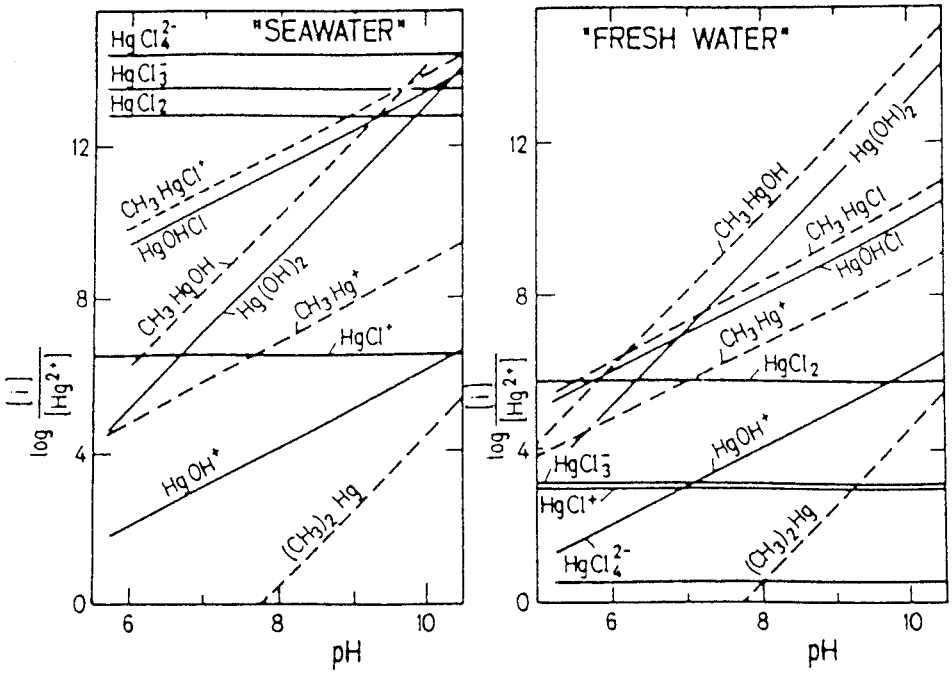

FIGURE 1. Concentration ratio diagrams illustrating the relative thermodynamic stability of mercury species in fresh water and sea water. Conditions: sea water [Cl^-] = 0.6 *M*, [$CH_{4(aq)}$] = 10^{-4} *M*: fresh water [Cl^-] = 2×10^{-4} *M* [$CH_{4(aq)}$] = 10^{-4} *M*. (Source: Stumm and Morgan.[304] Reprinted by permission of John Wiley & Sons, Inc.)

natural waters is largely dominated by organic rather than chloride or hydroxide complexes, however (Lövgren and Sjöberg;[202] Coquery et al.[71]). Particularly strong associations are formed with humic matter, where the Hg atom is most likely bound to thiol (-RSH) groups (Gavis and Fergusson;[118] Reimers et al.;[275] Beneš and Havlík;[24] Lindqvist[200]). Organic colloids comprise a substantial proportion of the traditionally defined dissolved Hg fraction (<0.45 μm) in freshwater, estuarine and marine environments (Mason et al.;[213] Watras et al.;[326] Leermakers et al.;[195] Stordal et al.;[302] Guentzel et al.[129]). In freshwaters more than 90% of Hg is complexed by organic matter (Mantoura et al.;[208] Meili[233]). Most MMHg (>70%) is probably also associated with dissolved organic carbon (DOC) in lake water (Lindqvist;[200] Hudson et al.[148]). Hudson et al.[148] have modeled the cycling of Hg in Wisconsin lakes and have calculated that 94 to 99+% of Hg(II) and 72 to 97% of MMHg in lakewaters is complexed by dissolved humic matter. In seawater, however, the proportion of Hg^{2+} bound to humics is decreased due to chloride ion competition (Lindberg and Harriss;[198] Mantoura et al.;[208] Leermakers et al.[195]). Hg complexation with humic matter also varies greatly depending on redox and pH conditions (cf. Section II.C), and the presence of sulfide ligands. Hudson et al.[148] calculated that in oxic waters sulfide may outcompete humic acid for Hg(II) and MMHg at a concentration of 10 μ*M*.

Although organic complexation is likely to dominate in oxic fresh water, under anoxic conditions the chemistry of Hg is mainly controlled by sulfide. In sediments Hg is mainly bound to sulfur as well as organic matter and inorganic particles (Morel et al.;[242] Lindberg and Harriss;[198] Dyrssen and Wedborg;[95] Fabbri et al.;[97] Mason and Lawrence[225]). Mercuric sulfide (HgS) is the main insoluble (L_{HgS} = 10^{-53} mol^2 l^{-2}) inorganic Hg compound in aquatic systems. Mercuric oxide (HgO), which is sparingly soluble (10^{-4} mol l^{-1}) is also commonly encountered in contaminated environments (Sakamoto et al.[283]). Hg compounds in the mud of Minamata Bay, for example, were mainly sulfides and oxides (Fujiki and Tajima[110]). HgS formation is generally favored at low pH and low sulfide concentrations. Under low E_h and high pH conditions, or if an excess of sulfide ions is present, HgS can be converted to soluble Hg-S complexes such as HgS_2^{2-}. Organic matter also enhances the solubility of HgS and may lead to a significant release of Hg into solution (Ravichandran et al.[270]), but other complexing agents do not appear to enhance HgS dissolution (Frimmel;[109] Ravichandran et al.[270]). Early work suggested that mercury in the HgS form is not available for bacterial methylation under anaerobic conditions, which was believed to be the reason for the generally lower MMHg concentrations encountered in sulfidic sediments, but recent research suggests that dissolved HgS^0 can in fact be methylated (Benoit et al.[26]), and that the mechanism of sulfide inhibition of Hg methylation is more complex (cf. Section III.B.6*)*.

At high sulfide concentrations, for example, in sulfidic marine waters and interstitial waters of bottom sediments, Hg forms soluble bi- and polysulfide complexes such as $HgSH^+$, $Hg(SH)_2$, $Hg(SH)S^-$, HgS_2^{2-}, $Hg(S_x)_2^{2-}$, or $Hg(S_x)OH^-$, depending on pH and E_h conditions and S^0/S^{2-} concentrations (Gardner;[117] Dyrssen and Wedborg;[95] Paquette and Helz;[257] Jay et al.[163]). Methylmercury also forms highly stable complexes with sulfur ligands (Zepp et al.[348]), but in contrast to Hg^{2+}, the chloride complex dominates at low concentrations (0.1 n*M*) of H_2S and thiols (Dyrssen and Wedborg[95]). The most important sulfide complex of methylmercury is CH_3HgS^-.

Organomercurials may be present in surface waters due to natural processes such as biomethylation of inorganic Hg or human activities. Many of these compounds have in the past been widely used, for example, as fungicides, slimicides, or industrial catalysts, but with most of these uses now banned in many parts of the world, transformation of inorganic Hg is the predominant source of methylated Hg compounds in aquatic systems (Craig[82]). Atmospheric deposition is the main source of inorganic Hg to oceanic waters (Mason et al.;[215] Mason and Fitzgerald[220]) and many lakes (Watras et al.[328]), but it is not a significant source of MMHg (Mason and Fitzgerald[210,211]). Precipitation and surface run-off can be important sources of MMHg to freshwaters besides internal methylation (Rudd[280]).

Only methyl- and dimethylmercury are thought to occur naturally in waters, where they can be formed from divalent inorganic Hg by various mechanisms (cf. Section III). MMHg is the most ubiquitous organomercury compound in freshwa-

ter and estuarine systems, while DMHg is not normally detected. MMHg is kinetically inert toward decomposition, which accounts for its remarkable stability in natural waters (Stumm and Morgan[304]). It is efficiently degraded by microbial action, however, and can also be decomposed photochemically (cf. Section III.A.4). Organomercury compounds other than MMHg decompose rapidly in the environment (Jensen and Jernelöv;[166] Craig[82]), with typical breakdown products being organic compounds such as ethane and inorganic Hg (Hg^0 and Hg^{2+}). Compounds such as dimethyl and diphenyl Hg are volatile, nonpolar, and very poorly soluble in water. Unlike MMHg, DMHg is readily lost from aquatic systems by evaporation (Talmi and Mesmer[311]) and is not considered to be available for accumulation by aquatic organisms (Morel et al.[243]).

In contrast to freshwater systems, DMHg is the dominant methylated species in deep ocean waters (Mason and Fitzgerald;[210,211] Cossa et al.;[75] Mason et al.;[218]), where it appears to be produced from labile inorganic Hg complexes predominantly, although not exclusively, in the low-oxygen region (Mason and Fitzgerald;[210,211,220] Cossa et al.;[77] Mason et al.[221]). Little or no methylated Hg species are found in oceanic surface waters (Mason and Fitzgerald[210,211]; Cossa et al.[75]; Mason et al.[218,221]; Mason and Sullivan[223]), with enhanced demethylation, evaporation, and/or photodegradation of DMHg, and particulate scavenging of MMHg from surface waters being suggested as potential loss mechanisms (Mason and Fitzgerald;[212] Mason et al.[218,221]).

B. Mercury Concentrations in the Aquatic Environment

1. Water

Mercury is naturally present in waters at very low levels. It should be noted that accepted background levels have fallen steadily in recent years following significant improvements in both sampling and analytical techniques (Horvat[146]), while previously reported high results are now believed to have resulted from sample contamination. Recently established Hg levels in aquatic systems in Antarctica have been suggested as global baseline values. Total Hg in surface waters of antarctic lakes and glacial streams ranged from 2.2 to 9.5 p*M*, dissolved Hg from 0.5 to 2.2 p*M* and MMHg from <0.4 to 2.1 p*M* (Vandal et al.;[314] Lyons et al.[206]). Uncontaminated freshwaters generally contain <5 ng l^{-1} (≅ 25 p*M*) total Hg (Bloom;[37] Craig[82]), although up to 10 or 20 ng l^{-1} can be found in humic lakes or rivers rich in particulate Hg (Meili[233]). Total Hg concentrations in the marine environment are much lower and were found to range between 0.5 and 4 p*M* in the Mediterranean and North Atlantic (Cossa et al.;[77] Mason et al.[221]). Mercury concentrations in contaminated waters can be in the μg l^{-1} range. Dissolved Hg concentrations in the River Nura in Central Kazakhstan were typically between 0.2 and 0.5 μg l^{-1}, for example, depending on season and suspended solids content

(Heaven et al.[140]). Considerably less data are available on organic Hg compounds in natural waters. Recommended water-quality criteria in the Netherlands give target values of 0.05 μg l^{-1} for total dissolved Hg and 0.005 μg l^{-1} for organic Hg (Stumm and Morgan[304] after Behra et al., 1993).

The proportion of MMHg to total Hg is usually higher in the water column than in sediments, and is higher in freshwater than in estuarine environments. In estuarine and marine waters, MMHg is typically less than 5% of total Hg content (Coquery et al.;[71] Mason and Sullivan[223]), whereas up to about 30% of total Hg can be found as MMHg in freshwater lakes and rivers (Kudo et al.;[186] Meili;[233] Leermakers et al.[196]). Elevated concentrations of both total Hg and MMHg are frequently found in anoxic waters. Bloom[37] reported MMHg concentrations in natural surface waters are typically in the range of 0.02 to 0.1 ng l^{-1} (0.1 to 0.5 p*M*), but found up to 4 ng l^{-1} (37% of total Hg) in the anoxic bottom waters of a stratified pristine lake. DMHg has not been detected in temperate freshwater lakes (e.g., Vandal et al.;[313] Cossa et al.[74]) but is the most common methylated species in the marine environment. Up to 280 f*M* MMHg and 670 f*M* DMHg were found below the thermocline in the equatorial Pacific (Mason and Fitzgerald[210]), and up to 0.29 p*M* DMHg were detected in the Western Mediterranean (Cossa et al.[75]); average DMHg concentrations in the North Atlantic were 0.08 p*M* (Mason et al.[221]).

2. Sediments

Sediments constitute the main reservoir of Hg in freshwater systems. Background levels of Hg in uncontaminated sediments are comparable to levels in unpolluted surface soils, with average concentrations in ocean sediments in the order of 0.02 to 0.1 μg g^{-1} (Lindqvist et al.[199]). Craig[82] reported concentration ranges of 0.2 to 0.4 μg g^{-1} total Hg for uncontaminated sediments, whereas sediments in urban, industrial, or mineralized areas can contain up to 100 μg g^{-1} total Hg and up to 100 ng g^{-1} MMHg. Methylmercury concentrations in sediments are typically only about 1 to 1.5% of total Hg content and tend to be lower (typically <0.5%) in estuarine and marine environments (Olson and Cooper;[251] Bartlett and Craig;[21] Craig and Moreton;[85] Craig;[82] Bubb et al.;[53] Gobeil and Cossa;[126] Gagnon et al.;[114] Benoit et al.[25]). Total Hg concentrations in sediment porewaters are usually much higher than in the overlying watercolumn, however (e.g., Gobeil and Cossa;[126] Cossa and Gobeil[78]), and the proportion of MMHg can reach between 30 and 85% (Gagnon et al.;[114] Covelli et al.;[81] Hines et al.[141]).

Contaminated sediments may exhibit extremely high total Hg concentrations. Mud from Minamata Bay contained up to 908 μg g^{-1} (d.w.) Hg (Fujiki and Tajima[110]). MMHg was mostly less than 0.005 μg g^{-1} (d.w.) with a maximum of 0.03 μg g^{-1} (Hosokawa[147]), however, possibly due to the high sulfide content of the sediment, or the inhibition of microbial activity at high Hg levels (Chen et al.[59]). The River Nura has average sediment concentrations between 150 and 240 μg g^{-1}

(d.w.) total Hg in the most polluted section (Heaven et al.[140]), and River Elbe sediments were found to contain 12 μg g^{-1} (d.w.) total Hg and 35 ng g^{-1} (d.w.) MMHg (Hintelmann and Wilken[142]). DMHg has rarely been detected to date, but Quevauviller et al.[263] reported 211 to 233 ng g^{-1} DMHg (d.w.) in subsurface mangrove sediments.

Sediment quality criteria for Hg have been set in some countries, but due to the uncertainties regarding the bioavailability of Hg, it has been suggested that these should be applied with caution and in concert with other site-specific data (Chapman et al.[58]). It is also important to note that there has been considerable controversy in recent years regarding the 'true' methylmercury content of environmental samples, in particular sediments, after it was found that MMHg may be artificially formed during the sample preparation process. Although methods have been devised since to overcome this problem (e.g., Hintelmann et al.[144]), MMHg values cited in the literature should be interpreted with caution, and it is now generally accepted that values in excess of ca. 1% of total Hg content are probably unrealistic.

3. Biota

Freshwater biota can accumulate detectable quantities of Hg even from natural sources, and most fish nowadays have analyzable levels in their tissues. Maximum background levels for Hg in uncontaminated freshwater fish are about 0.2 μg g^{-1}, although considerably more can be found in large predators and in fish from waters near geological sources. Craig[82] reported concentration ranges of 0.01 to 1.5 μg Hg g^{-1} and 0.14 to 0.75 μg Hg g^{-1} for unpolluted marine fish and shellfish, respectively, and 0.2 to 1 μg g^{-1} for uncontaminated freshwater fish. For comparison, fish and shellfish from the highly polluted Minamata Bay contained up to 15 μg Hg g^{-1} (w.w.) and 178 μg Hg g^{-1} (d.w.), respectively (Fujiki and Tajima[110]). Human exposure to mercury occurs mainly from the ingestion of contaminated fish and seafood (Myers et al.[245]), and quality criteria have been set by various regulatory bodies. EEC quality objectives state a limit value of 0.3 μg Hg g^{-1} (w.w.) in fish (Craig[82]), whereas WHO[332] and the U.S. Food and Drug Administration (FDA[101]) have suggested maximum permissible concentrations of 0.5 and 1 μg Hg g^{-1}, respectively.

C. Mercury Transport and Distribution in Surface Waters

Mercury has a high tendency to be sorbed on surfaces. Therefore, in natural waters it is mostly bound to sediments, and a large proportion of Hg in the water phase is attached to suspended particles (Andren and Harriss;[11] Craig;[82] Mason et al.;[213] Cossa et al.[76]). MMHg is also strongly sorbed (Craig;[82] Baeyens et al.;[14] Rytuba[282]), although usually to a lesser extent than inorganic Hg (e.g., Suchanek

et al.[305]) Thus, suspended matter plays an important role in the transport of Hg and MMHg in aquatic systems (Kudo et al.;[183,185] Baeyens and Leermakers;[13] Coquery et al.;[71] Mason and Sullivan;[222,223] Maurice-Bourgoin et al.;[230] Lawson et al.[191]). Particulate transport is more important in particle-rich fresh and coastal waters than in the open sea (Coquery and Cossa;[69] Coquery et al.;[71] Fitzgerald and Mason[106]). Particulate Hg consists of Hg bound to inorganic particles and particulate organic matter, as well as biogenic particles such as bacteria, algae, and phytoplankton. Inorganic Hg tends to bind more strongly to mineral particles and detrital organic matter, whereas MMHg is more strongly associated with biogenic particles (Hurley et al.;[150] Meili[233]). In freshwater lakes, the distribution of Hg and MMHg is largely controlled by particulate scavenging in surface waters and particulate dissolution at the redox boundary (Hurley et al.[149]). Settling of particulate matter is considered a major Hg delivery mechanism to the sediment/water interface, the main site for methylation, whereas (redox-driven) upward diffusion from sediment porewater is probably less important (Hurley et al.;[149,151] Watras et al.[323]). Similarly, vertical transport of particulate matter in the ocean is the main supplier of Hg to low-oxygen waters and thus is a major factor controlling Hg methylation (Mason and Fitzgerald;[212,220] Mason and Sullivan[223]).

Oxyhydoxides and organic matter are the main vectors controlling the mobility and transport of Hg in aquatic systems. Due to the high stability of Hg-humic complexes, a high percentage of Hg in natural waters is present in organically complexed form (cf. Section II.A), and Hg concentrations in lake water or in the interstitial waters of sediments are often significantly correlated with dissolved organic matter (Lindberg and Harriss;[198] Meili et al.;[232] Watras et al.[325,326]). Hg concentrations in sediments or suspended particles are also often closely related to organic content (Lindberg and Harriss;[198] Coquery et al.;[70] Benoit et al.;[25] Mason and Lawrence;[225] Harland et al.;[139] Lawson et al.[191]). Hg appears to be more strongly sorbed by humic substances than MMHg (Hudson et al.;[148] Sjöblom et al.[291]), which may be the reason why it is less easily mobilized from sediments than MMHg (Bloom et al.;[42] Gill et al.[119]). In watersheds, MMHg is also considered more mobile than inorganic Hg (Bishop and Lee;[33] Mason and Sullivan;[222] Hurley et al.;[152] Lawson et al.[191]). The strong association of Hg with humic matter has important implications for the watershed transport of Hg (Bishop and Lee[33]). Transport of terrestrial organic matter with surface runoff can be a major source of Hg and MMHg to lakes and rivers (Mierle and Ingram;[236] Verta et al.;[317] Hurley et al.;[152] Lee et al.[194]) and may even constitute the main source of MMHg in drainage lakes receiving high amounts of runoff (Lee and Hultberg[193]). In seepage lakes, on the other hand, the relative importance of atmospheric MMHg deposition and in-lake MMHg production is increased (Verta et al.[317]). Watershed characteristics such as catchment type, land use, and soil organic content play an important role in Hg and MMHg fate and transport (Bringmark[52]). Wetlands and peatlands are sites of active MMHg production and have been recognized as important sources of MMHg for freshwaters (St. Louis et al.;[301] Hurley et al.;[152] Branfireun

et al.;[49-51] Waldron et al.[330]). Soil erosion and increased mobilization of Hg by runoff is an important source of Hg to tropical aquatic ecosystems, especially during the rainy season (Roulet et al.;[278] Maurice-Bourgoin et al.[230]), and in arid regions storm-driven runoff following forest fires may lead to elevated sediment Hg levels while simultaneously providing a carbon source for microbial methylation processes (Caldwell et al.[54]).

Iron and manganese oxides play a particularly important role in the cycling and transport of Hg in aquatic systems. This is due to their large surface areas and high capacity to adsorb and co-precipitate Hg, and to rerelease it after their dissolution (Fagerström and Jernelöv[99]). Many workers have found the distribution and concentration of dissolved and particulate Hg species to be influenced, among other factors, by the redox cycling of Fe, and less frequently Mn (e.g., Mason et al.;[213] Hurley et al.;[151] Bonzongo et al.;[47] Gagnon et al.;[115] Regnell et al.;[274] Quemerais et al.;[262] Gobeil et al.;[127] Bloom et al.[41]). Bloom et al.[41] reported, for example, that the mobility of MMHg in estuarine surface sediments was linked to the Fe redox cycle, while the mobility of Hg(II) was controlled by the formation of soluble polysulfide or organic complexes. The formation and dissolution of Fe and Mn oxides is strongly controlled by the redox state and oxygen content of waters and sediments. In anoxic conditions, oxyhydroxides dissolve and release any associated Hg (Gobeil and Cossa;[126] Gagnon et al.;[115] Cossa and Gobeil[78]), which is thought to be one reason for the frequently observed Hg and MMHg enrichment in (seasonally) anoxic waters (Hurley et al.;[149] Cossa et al.;[74] Watras et al.[327]). Seasonal and diurnal trends in MMHg concentrations in sediment porewaters (Covelli et al.;[81] Gill et al.[119]) may also be linked with redox effects. Meili[233] noted that oxyhydroxides form labile complexes with organic matter and clay minerals, which may further increase their metal scavenging capacity. The formation and dissolution of oxyhydroxides and organic complexes may influence methylation by controlling the availability of inorganic Hg.

Sediments can act both as sinks and as secondary sources of Hg. Covelli et al.[81] estimated that in the Gulf of Trieste up to 25% of Hg may be released annually from sediments and recycled at the sediment/water interface, and Stein et al.[300] have reviewed the chemical and physical processes governing the distribution of Hg between environmental media. Partition coefficients describe the equilibrium partitioning of Hg between the solid and dissolved phases. Sediment-water partition coefficients (K_d = mg sorbed Hg per kg sediment/mg dissolved Hg per liter) vary widely both within and between systems but are broadly in the order of 10^4 to 10^6 for Hg and 10^3 to 10^5 for MMHg (Hurley et al.;[150] Watras et al.;[326] Stordal et al.;[302] Coquery et al.;[71] Lyon et al.;[205] Mason and Sullivan;[222] Bloom et al.;[41] Lawson et al.[191]). Sorption/desorption phenomena and precipitation reactions are also likely to affect Hg bioavailability (King et al.[177]) and need to be taken into account when estimating rates of MMHg production in the natural environment (Bisogni[35]).

D. Influence of Environmental Factors on Hg Partitioning

The cycling and distribution of Hg between the sediment and water phases may be physically, chemically, or biologically mediated, and hence may be affected by parameters such as pH, temperature, redox changes, availability of nutrients and complexing agents. This should be considered when evaluating the effect of environmental factors on Hg methylation. The degree of binding of MMHg by sediments, for instance, depends on sediment properties as well as pH and dissolved oxygen concentrations (Reimers et al.;[275] Kudo et al.;[182] Gambrell et al.[116]). Although the proportion of Hg in dissolved form may sometimes decrease under anoxic conditions due to the formation of reduced species such as HgS (Baeyens and Leermakers[13]), oxic conditions generally favor sediment uptake of Hg and MMHg, whereas anoxic conditions favor Hg release (Wang et al.;[320] Regnell and Tunlid;[272] Regnell et al.[273]). The observed effects are most likely linked to the precipitation and dissolution of Fe and Mn oxides and oxyhydroxides. The solubility of Hg and MMHg under anoxic conditions may also be increased due to the formation of soluble sulfide complexes (Regnell et al.;[273] Benoit et al.[25]). Apart from redox effects, seasonal variations in the partitioning of Hg and MMHg may also be related to changes in biotic particulate matter (Hurley et al.;[149] Watras et al.;[323] Coquery et al.[70]).

Methylmercury release from sediments also increases with increasing temperature and nutrient addition (Wright and Hamilton[339]) and decreasing pH. Miller and Akagi[238] reported that a change in pH from 7.0 to 5.0 doubles the release of MMHg from sediments, and Hintelmann et al.[143] found that the binding of MMHg to humic and fulvic acids decreases with decreasing pH. The observed pH-dependent changes in the partitioning of MMHg between the sediment and water phases may be partly responsible for the often noted increased Hg concentrations in fish from low-pH lakes (e.g., Lindqvist et al.[199]).

The presence of organic or inorganic complexing agents also affects the partitioning of Hg. The formation of soluble humic complexes may significantly increase the solubility and mobility of Hg in aquatic systems (Miller;[237] Reimers et al.;[275] Miskimmin;[239] Melamed et al.;[234,235] Ravichandran et al.[270,271]), especially above pH 5, while $HgCl_2$ is effectively sorbed at lower pH values (Stein et al.[300] after Bodek et al. 1988). The situation in sediments may be comparable to that in soils, where adsorption of Hg to humus predominates in acidic conditions, and Hg is preferentially sorbed to mineral particles (Fe oxides and clay minerals) in the neutral to alkaline pH range, due to formation of the more particle reactive $HgOH^+$ species (Bringmark[52]). High chloride concentrations appear to reduce the amount of Hg associated with suspended particulate matter and organic colloids, most likely due to competition of Cl^- for binding sites. Increased mobilization of Hg with increasing salinity was observed both in model experiments (Reimers et al.[275]) and in estuarine and marine environments (Cossa and Noel;[72] Cossa and Martin;[73] Leermakers et al.;[195] Guentzel et al.[129]).

E. Accumulation in Aquatic Biota

Mercury, and in particular methylmercury, is effectively taken up by aquatic biota, and bioconcentration factors in the order of 10^4 to 10^7 have been reported (WHO;[332] Stein et al.[300]). Accumulation in the aquatic food chain therefore can be high even at the generally very low environmental MMHg concentrations. While MMHg typically constitutes between 10 and 30% of total Hg in the water phase, more than 85 to 90% of Hg in fish is present in the MMHg form (Grieb et al.;[128] Bloom;[39] Southworth et al.[292]). Other organomercurials are also sometimes detected. Fish caught downstream of a source of phenylmercury effluent contained both methyl and ethylmercury (Ashby and Craig[12] after Frieberg 1971), and methylmercury methanethiol (CH_3HgSCH_3) has been found in shellfish (Ashby and Craig[12] after Kitamura 1963 and Lofroth 1969). The Hg content of aquatic organisms and the percentage present as MMHg usually increases with increasing size and increasing level in the food chain (Boudou and Ribeyre;[48] Meili;[233] Watras et al.;[329] Mason et al.[226]). Hg concentrations in fish often remain high for many years after Hg inputs have ceased or contaminated sediments have been dredged (Rada and Findley;[264] Kudo;[187] Francesconi et al.;[108] Southworth et al.[293]).

The precise factors controlling the accumulation of Hg in aquatic biota are poorly understood. The high tendency of MMHg for bioaccumulation is usually explained by its high stability and lipid solubility, and by its high tendency to bind to -SH groups associated with proteins. However, this alone cannot account for the predominance of MMHg in fish muscle tissue (Mason et al.;[217] Boudou and Ribeyre[48]). MMHg is taken up by fish mainly through their diet, while direct uptake from the water is of minor importance (Bodaly et al.;[45] Boudou and Ribeyre;[48] Meili[233]). Hg concentrations in fish thus are primarily determined by the accumulation of MMHg at the base of the food chain, that is, in phyto- and bacterioplankton (Mason et al.[217,219]; Watras et al.[329]). The predominance of MMHg in fish appears to be the result of its greater trophic transfer efficiency compared with inorganic Hg (Watras and Bloom;[322] Mason et al.[219]). Uptake into biota is influenced by the physicochemical form in which Hg exists in the water. Uncharged lipophilic chloride complexes ($HgCl_2$ and CH_3HgCl) appear to be most bioavailable (Mason et al.[217,219]; Laporte et al.[190]), whereas DMHg and Hg^0 are not bioaccumulated (Morel et al.[243]). A number of other factors such as temperature, DOC, alkalinity, and in particular pH may also influence Hg bioaccumulation as well as methylation (Watras and Bloom;[322] Boudou and Ribeyre;[48] Meili;[233] Watras et al.[329]). The accumulation of Hg in the aquatic food chain has been reviewed recently (Bodaly et al.;[45] Boudou and Ribeyre[48]).

III. METHYLATION OF MERCURY IN THE AQUATIC ENVIRONMENT

A. General Aspects

The methylation of inorganic Hg in waters and sediments constitutes a key step in the cycling of Hg in aquatic systems (Fitzgerald and Mason[106]) and takes place

in both remote and impacted environments (Cossa et al.[74]). It is important to note that since both methylation and demethylation processes occur, environmental MMHg concentrations reflect *net* methylation rather than actual rates of MMHg synthesis. It appears that the combined effect of MMHg production and degradation leads to a state of equilibrium with a near constant level of MMHg in sediments (Beijer and Jernelöv;[23] Pak and Bartha[256]) that rarely exceeds 1 to 1.5% of total Hg concentration (cf. Section II.B.2), whereas the proportion of MMHg in fish and other aquatic biota may be much higher (cf. Section II.E). On the basis of mass balance studies, estimated rates for MMHg production in temperate freshwater lakes currently range from 0.5 to 5 g MMHg per km^2 per year (Watras et al.[328]).

Methylation occurs predominantly in sediments and to a lesser extent in the water column (Olson and Cooper;[251] Robinson and Tuovinen;[277] Callister and Winfrey;[55] Korthals and Winfrey;[180] Xun et al.[343]), but it should be borne in mind that water column methylation is potentially more important, because the volume of water is typically much larger than the volume of surficial sediments. Maximum methylation rates usually occur at the redox boundary, which may vary seasonally and frequently coincides with the sediment-water interface, and decrease with increasing sediment depth (Rudd et al.;[279] Korthals and Winfrey;[180] Matilainen[227]). In tropical systems, the root zones of floating aquatic macrophytes are further important sites of methylation (Mauro et al.;[231] Guimarães et al.[130]).

The effects of environmental factors on MMHg formation and decomposition were studied in the past mainly by relating MMHg concentrations in sediments, water, and aquatic biota to changes in environmental conditions. In recent years the use of radiotracers and stable isotopes has made it possible to distinguish between the two opposing processes of MMHg formation and decomposition, but it must be borne in mind that rates measured after Hg additions may differ considerably from *in situ* rates. Gilmour and Henry[122] give an overview of the techniques that are typically employed for measuring MMHg concentrations and methylation/demethylation rates in aquatic systems, and their limitations.

The methylation of Hg requires the presence of a suitable methyl donor molecule. In the natural aquatic environment, a large variety of potential donor molecules are present, most of which are biologically synthesized. Whereas it had first been assumed that Hg methylation requires the presence of bacteria, both microbially mediated and abiotic methylation mechanisms are now known, although the latter is thought to be of only minor importance.

1. Biomethylation

Biological methylation of inorganic Hg was first observed in sediments from aquaria and lakes and in coastal waters in Sweden (Jernelöv;[167] Jensen and Jernelöv[165]) and has been studied since by many other workers. Hg methylation by organisms may be enzymatic or nonenzymatic. Enzymatic methylation requires the presence of actively metabolizing organisms, while nonenzymatic methylation

requires only the methylated products of active metabolism. Detailed mechanisms for Hg methylation were first proposed by Wood et al.[336] and Landner.[188] Wood et al.[336] suspected that methylcobalamin, a vitamin B_{12} derivative (methylcorrinoid) produced by many organisms, is involved in microbial Hg methylation and suggested that the process involves nonenzymatic transfer of the methyl group of methylcobalamin to the mercuric ion. DeSimone et al.[91] have shown that methyl transfer to Hg^{2+} is a carbanion (CH_3^-) process. Although there are many potential methyl donor molecules in the aquatic environment, methylcobalamin is thought to be the only natural methylating agent capable of transferring methyl groups as carbanions (Ridley et al.[276]). This together with its prevalence in anaerobic ecosystems and living organisms makes it the most likely methyl source for environmental Hg methylation.

Metabolically produced methylcobalamin can spontaneously methylate Hg^{2+} in aqueous solution (Bertilsson and Neujahr;[31] Imura et al.[154]), but little is known about the biochemistry of MMHg formation in the natural environment. Organisms capable of Hg methylation have been found among anaerobes, facultative anaerobes, and aerobes, but the potential for microbial methylation is generally thought to be higher under anaerobic conditions, and sulfate-reducing bacteria have been identified as the principal methylators of inorganic Hg in anaerobic sediments (Compeau and Bartha[66]). Methylation of Hg is generally thought to occur inside bacteria by transfer of a methyl group from a methylcorrinoid donor molecule, although Parkman et al.[258] suggested that methylation is an extracellular process that is enhanced by the activity of bacterial exoenzymes that also catalyze the microbial decompositon of organic matter. Choi and Bartha[60] demonstrated that methylcobalamin is the methyl group donor when divalent Hg is methylated by the LS strain of *Desulfovibrio desulfuricans*. Within the cell, Hg methylation appears to be an enzyme-catalyzed process rather than a spontaneous chemical reaction, with the rate of methylation at pH 7 being 600-fold higher than transmethylation by free methylcobalamin (Choi et al.[62]). The process is oxygen sensitive, with optimal methylation conditions at 35°C and pH 6.5. The enzyme responsible for transferring methyl groups from methylcorrinoid protein to Hg^{2+} has yet to be identified. As biological Hg methylation takes place within microorganisms, cellular uptake of Hg plays a key role in the methylation process. This is discussed in detail in Section III.B.1.

2. Abiotic Methylation

Purely chemical methylation of Hg is also possible if suitable methyl donors are present. DeSimone[90] showed that water-soluble methylsilicon compounds react with Hg^{2+} to form MMHg. Organosiloxanes and other silicone-related substances have also been considered as possible methylating agents (Nagase et al.[248,249]; Watanabe et al.[321]). Akagi et al.[1] demonstrated the photochemically induced alky-

lation of mercuric chloride with methanol, ethanol, acetic acid, and propionic acid. Sewage effluent and industrial wastewater have also been reported as methyl sources in the photochemical methylation of Hg. Hamasaki et al.[136] have summarized some of the available data on photochemical methylation.

Wood[337] suggested Hg methylation can also occur as a result of transmethylation reactions between Hg and lead and tin alkyls used as gasoline additives. Jewett et al.[171] demonstrated that both trimethyl lead chloride and trimethyltin chloride are able to transfer methyl groups to Hg^{2+}. Trimethyl lead was found to be a particularly effective methylator for Hg, and high MMHg concentrations in sediments of the St. Clair River were attributed to transmethylation reactions caused by alkyllead emissions (Beijer and Jernelöv[23] after Jernelöv et al., 1972). More recent investigations of Hg methylation by organolead, organotin, and organoarsenic compounds have been carried out, for example, by Ebinghaus et al.[96]

Humic matter may be another significant environmental methylating agent (Weber[331]). Abiological formation of MMHg by humic compounds has been demonstrated, for example, by Nagase et al.[246,247] The capacity for MMHg formation generally increased with increasing temperature and Hg concentration, but was low at naturally occurring temperatures and pH values. Falter and Wilken[100] have shown that small amounts of MMHg can be formed abiotically at environmentally relevant temperatures and pH values, however. More than 400 pg MMHg, corresponding to ca. 0.05% of the added $^{200}Hg^{2+}$ spike, were produced in the acetone extract of a river sediment within 2 h at 40ºC between pH 3 and 7. At 35ºC, up to 160 pg could still be formed. In the river sediment itself, however, methylation was only detected at 40ºC, with between 50 and 100 pg MMHg (0.005 to 0.01% of added $^{200}Hg^{2+}$) being formed.

Thus, mercury methylation may be biotic or abiotic, or may involve a mixture of biotic and abiotic processes, such as the bacterial methylation of tin (IV) species followed by abiotic methyl transfer to Hg. The relative importance of abiotic vs. biotic methylation mechanisms in the natural aquatic environment has not yet been established, but it is generally believed that Hg methylation is predominantly a microbially mediated process, and Berman and Bartha[30] demonstrated that in anoxic sediments MMHg levels resulting from chemical methylation were approximately one order of magnitude lower than those formed by biochemical Hg methylation. Ebinghaus et al.[96] reported that organo Pb, Sn, and As compounds are more effective methylators than biogenic methyl donors such as methylcobalamin, but this is probably not material in the natural environment, because *in vivo* Hg methylation is enzymatically catalyzed and is much faster than transmethylation by free methylcobalamin (Choi et al.[62]).

3. Methylation Products

MMHg may be formed from ionic Hg and many divalent Hg compounds (Yamada and Tonomura[344]), as well as from organic Hg compounds and metallic

Hg (Jernelöv;[168] Jacobs and Keeney[162]), possibly via formation of Hg^{2+}. DMHg can be synthesized from both methyl- and ionic Hg (Craig and Moreton;[85,86] Baldi et al.;[18] Filipelli and Baldi[102]). There is still considerable uncertainty, however, regarding the pathways of MMHg and DMHg formation. Filipelli and Baldi[102] have demonstrated that the initial product of the reaction between methylcobalamin and Hg^{2+} is MMHg, which is then further transformed into DMHg. The reaction is pH and temperature dependent and MMHg and DMHg formation rates are of similar magnitude at 20°C. Low pH values appear to favor the production of MMHg, while DMHg formation is favored under neutral and basic (pH>7) conditions (Jensen and Jernelöv;[165] Beijer and Jernelöv;[23] Fagerström and Jernelöv[99]). Below pH 5, DMHg is thermodynamically unstable and decomposes to form MMHg (Fagerström and Jernelöv;[99] Fitzgerald and Mason[106]), which may be one reason why DMHg has not been detected in freshwaters, where the pH is typically lower compared with estuarine and marine systems. Mason et al.[218] suggested that DMHg forms directly from Hg(II), but is rapidly decomposed to MMHg in freshwaters and hence does not accumulate to detectable levels. In deep ocean waters, on the other hand, the stability of DMHg might be enhanced by low-light, low-temperature, and high pH conditions (Fitzgerald and Mason;[106] Mason et al.[221]). Pongratz and Heumann[259,260] have also suggested that DMHg may be the primary biogenic methylation product in the ocean, and it appears that MMHg in the deep ocean is formed by decomposition of DMHg (Mason and Fitzgerald;[210,212] Fitzgerald and Mason;[105,106] Mason et al.;[221] Mason and Sullivan[223]). DMHg decomposition is thought to be primarily abiotic (Fitzgerald and Mason[106]), whereas MMHg decomposition is predominantly biologically mediated (see below). Because DMHg formation in the ocean also occurs in oxygenated environments (Mason et al.;[218,221] Cossa et al.[75]), it has been suggested that it may be formed by a different mechanism than in freshwaters (Mason et al.;[220,221] Fitzgerald and Mason[106]).

4. Demethylation

The biological and abiological decomposition of methylated Hg species is an important process regulating the organic Hg content of sediments and waters. MMHg degradation is thought to be predominantly microbially mediated (Robinson and Tuovinen[277]). Numerous bacterial strains capable of demethylating MMHg are known (Spangler et al.;[294,295] Billen et al.;[32] Robinson and Tuovinen;[277] Oremland et al.;[254] Matilainen and Verta[228]), including both aerobic and anaerobic species, but demethylation appears to be predominantly accomplished by aerobic organisms (cf. Section III.B.5). Bacterial demethylation has been demonstrated both in sediments (e.g., Billen et al.;[32] Oremland et al.[254]) and in the water column of freshwater lakes (Xun et al.;[343] Winfrey and Rudd;[335] Matilainen[227]). Degradation of methyl and phenyl mercury by fresh water algae has also been described (Beneš and Havlík[24] after Havlík *et al.,* 1979a,b).

Mercury demethylation by bacteria appears to be a predominantly reductive process (Furukawa et al.;[111] Spangler et al.;[294,295] Nelson et al.[250]). The commonly accepted mechanism of microbial MMHg decomposition involves cleavage of the carbon-mercury bond by the organomercurial lyase enzyme, yielding methane and Hg^{2+}, followed by the reduction of Hg^{2+} to Hg^0 by the mercuric reductase enzyme (Robinson and Tuovinen;[277] Summers;[309] Walsh et al.[319]). Synthesis of these enzymes is encoded by the *merB* and *merA* genes in bacteria possessing broad-spectrum Hg resistance. More recent work indicates that *mer* detoxification is not the only microbial degradation pathway, however. Oremland et al.[254] found that while methane was the sole product of MMHg degradation in aerobic estuarine sediments, aerobic demethylation in freshwater sediments and anaerobic demethylation in both freshwater and estuarine sediments produced primarily carbon dioxide, indicating the presence of an oxidative pathway. Oremland et al.[255] and Hines et al.[141] have since shown that oxidative demethylation is significant in both contaminated and uncontaminated river sediments and is most pronounced at sediment surfaces. Inhibitor studies suggest that both sulfate reducers and methanogens, and possibly other anaerobes, are involved in oxidative demethylation (Oremland et al.;[254,255] Marvin-Dipasquale and Oremland[209]). Marvin-Dipasquale and Oremland[209] recently have proposed specific mechanisms for the oxidative demethylation of Hg by sulfate-reducing bacteria and methanogens and have suggested that methanogens dominate MMHg degradation at *in situ* concentrations. Either process produces Hg^{2+}, but it is unclear whether the Hg^{2+} produced in oxidative demethylation is subsequently reduced to Hg^0 as has been demonstrated for the *mer*-mediated pathway (Robinson and Tuovinen[277]). Alternatively, it may be remethylated, bound by sulfur species, or volatilized as DMHg (Baldi et al.[16]). At present, it is also not known which of the abovementioned degradation pathways (i.e., organomercurial-lyase, or oxidative demethylation by sulfate reducers and/or methanogens) dominate under specific environmental conditions. The relative importance of these pathways has major implications for the fate of Hg in natural systems, however, and thus may ultimately determine its residence time in sediments.

Photolytic decomposition appears to be the only significant *abiotic* decomposition mechanism. DMHg in the atmosphere is photolytically decomposed to Hg^0 and hydrocarbons (Craig[82]). Phenylmercury and sulfur-bonded MMHg species (e.g., CH_3HgS^-) can undergo quite rapid photolytic decay, but photodegradation was thought to be insignificant for methylmercuric ion and methylmercuric hydroxide due to their low sunlight absorption rates (Baughman et al.[22]). Suda et al.[307] have shown that methyl- and ethylmercury are photodegraded by singlet oxgen in seawater, however, and recent work by Sellers et al.[289] demonstrates that MMHg is photolytically decomposed in surface waters, and that this process is potentially an important step in the aquatic Hg cycle. Mass-balance calculations show that microbial demethylation may not be the dominant removal mechanism for MMHg in epilimnetic freshwaters. Model simulations by Branfireun et al.[50] have since

confirmed the findings of Sellers et al.[289] The overall impact of photodegradation on the aquatic Hg cycle is still unclear, however, because the end products of MMHg photodegradation in natural waters have not yet been identified. Furthermore, although photolytic decay contributes to Hg demethylation in the water phase, it is unlikely to be significant in deeper sediments, where bacterial demethylation is more important (Xun et al.;[343] Ramlal et al.[268]).

The ability of microorganisms to degrade Hg can be employed in the treatment of sewage (Hansen et al.[138]) and Hg-contaminated liquid wastes (Baldi et al.[16,17]). Hansen et al.[138] reported that >98% of Hg present at a concentration of 70 mg l^{-1} can be removed from municipal sewage water by bacterial treatment. However, it should be noted that sewage treatment plants themselves can be sources of MMHg (Gilmour and Bloom;[124] Carpi et al.[57]). In the bioremediation field, efforts have been made to devise methods for reducing the amount of MMHg in contaminated aquatic ecosystems by stimulating the bacterial conversion of MMHg and Hg^{2+} to less harmful elemental Hg (Saouter et al.[284]). Very recently, transgenic plants have been specifically engineered to express bacterial *mer* genes (Rugh et al.;[281] Bizily et al.[36]). Such plants show a high resistance to inorganic Hg and organomercurials and may in the future be used to degrade MMHg at polluted sites and to accumulate Hg for later safe disposal.

B. Factors Affecting Methylation

The synthesis of MMHg in aquatic systems is influenced by a wide variety of environmental factors. The efficiency of microbial Hg methylation generally depends on factors such as microbial activity and the concentration of bioavailable Hg (rather than the total Hg pool), which in turn are influenced by parameters such as temperature, pH, redox potential, and the presence of inorganic and organic complexing agents. Total Hg concentrations generally are not useful in predicting MMHg concentrations (Kelly et al.[174]). While there is no simple relationship, it appears that enhanced rates of MMHg production are linked in particular with low pH, low salinity, and the presence of decomposable organic matter in reducing environments. The main factors known to affect methylation are discussed below; it should be borne in mind, however, that they cannot be viewed independently from each other, as they often interact, forming a complex system of synergistic and antagonistic effects.

1. Microbiology

Microorganisms play a pivotal role in aquatic Hg cycling and catalyze many of the inter-conversions between different forms of Hg, such as the conversion of Hg^{2+} to methyl and dimethyl Hg and the reduction of Hg^{2+} to Hg^{0} (Summers and

Silver;[308] Robinson and Tuovinen;[277] Silver[290]). Mercury compounds are acutely toxic to freshwater microorganisms, but many bacteria are known to have developed resistance mechanims (Baldi;[19] Hobman and Brown[145]), and positive correlations are often found in sediments between the distribution of Hg compounds and Hg-resistant microorganisms (Timoney et al.;[312] Bubb et al.[53]). Bacterial Hg resistance is inducible and is regulated by the *mer* operon (Baldi[19]). Hg volatilization is regarded as a detoxification mechanism, whereas Hg methylation appears to be an accidental process and not a detoxification mechanism as previously suggested.

A large number of organisms, including strict and facultative anaerobes as well as aerobes, have been shown to methylate Hg *in vitro* (Wood et al.;[336] Kitamura et al.;[179] Yamada and Tonamura;[344-346] Vonk and Sijpesteijn;[318] Robinson and Tuovinen[277]), but it is not certain whether these bacteria are responsible for Hg methylation in the natural aquatic environment. Several more recent studies have indicated that anaerobic sulfate-reducing bacteria (SRB) are the principal methylators of inorganic Hg in both freshwater and estuarine sediments (Compeau and Bartha;[66,67] Berman and Bartha;[29] Gilmour and Henry;[122] Gilmour et al.[123]). Contrary to earlier assumptions (e.g., Wood et al.[336]), methanogenic bacteria seem to play only a minor role in MMHg production. Interestingly, the same bacteria that are primarily responsible for MMHg production also appear to mediate MMHg degradation (Robinson and Tuovinen[277]). Both sulfate reducers and methanogens are important demethylators in estuarine and freshwater sediments (e.g., Oremland et al.;[254,255] cf. Section III.A.4). In pure culture, the formation of DMHg from MMHg is also mediated by SRB (Baldi et al.[16,18]). DMHg formation in the ocean is thought to be microbial (Pongratz and Heumann;[259,260] Mason and Sullivan[223]), but is is not known whether SRB or other organisms are the primary methylators (Mason et al.;[220,221] Fitzgerald and Mason[106]).

Hg methylation activity in sediments is often significantly correlated with sulfate-reduction rates (Choi and Bartha;[61] King et al.[177,178]) or with the distribution of SRB populations (Devereux et al.;[92] Macalady et al.[207]), but not all SRB are capable of Hg methylation. Many studies have focussed on *Desulfovibrio* populations (e.g., Baldi et al.;[16] Choi and Bartha;[60] Choi et al.[62]) but recently King et al.[178] have noted that SRB capable of acetate utilization (i.e., members of the family *Desulfobacteriaceae*) appear to methylate Hg more effectively than members of the *Desulfovibrio* group. Macalady et al.[207] also found that *Desulfobacter* populations are important methylators in lake sediments and that they were more abundant than *Desulfovibrio*.

The efficiency of microbial MMHg production appears to depend chiefly on the activity and structure of the bacterial community (Macalady et al.[207]), Hg availability, the availability of nutrients, and the abundance of electron acceptors such as sulfate (Choi and Bartha[61]). At low concentrations, sulfate stimulates both sulfate reduction and methylation (Compeau and Bartha;[66] Gilmour et al.[123]). The *in situ* addition of small amounts of sulfate thus may lead to increased MMHg production in freshwater environments when sulfate is limiting (Gilmour et al.;[123]

Branfireun et al.[51]). Although a sulfate concentration of <10 mg l^{-1} (0.1 m*M*) generally starts to become limiting for the activities of SRB (Ingvorsen et al.;[155] Lovley and Klug[203]), they can remain active even at the very low sulfate concentrations (ca. 3 mg l^{-1}, 0.03 m*M*) typically encountered in freshwater systems by successfully competing with methanogens for common substrates, that is, hydrogen and acetate (Lovley and Klug;[203] Matilainen[227]). Compeau and Bartha[66] reported that the methylating potential of SRB is highest when sulfate is limiting and other organic substrates are available that can be utilized in place of sulfate, which may be due to the inhibitory effect of sulfide on Hg methylation. At high sulfate concentrations, the accumulation of sulfide generated by sulfate respiration interferes with Hg methylation, thereby limiting MMHg production (e.g., Baker et al.;[15] Compeau and Bartha;[66,67] Winfrey and Rudd[335]). Sulfide inhibition was previously ascribed to HgS precipitation, but is now thought to be linked with charged Hg-S complexes (cf. Section III.B.6). Gilmour and Henry[122] proposed an optimal sulfate concentration range of 0.2 to 0.5 m*M* SO_4^{2-} for Hg methylation by SRB in sediments, above which methylation is inhibited, and below which sulfate becomes limiting for methylation and sulfate-reduction processes. For comparison, seawater has ca. 28 m*M* or 2.7 g l^{-1} SO_4^{2-} (Ingvorsen et al.[155]), which may explain the typically low MMHg levels encountered in estuarine and marine environments (cf. Section III.B.7). Methylation is only partly inhibited by sulfur chemistry, however. For example, King et al.[177] have observed active MMHg formation in the presence of 30 m*M* sulfate and millimolar concentrations of dissolved sulfide. The addition of amorphous Fe(III) oxyhydroxide to sediments may inhibit both sulfate reduction and methanogenesis (Lovley and Phillips[204]), probably due to iron-reducing bacteria suppressing hydrogen and acetate concentrations. Whether this might lead to lower Hg methylation rates in Fe(III)-rich sediments still needs to be determined, however.

Many researchers have noted that net MMHg production in methylation experiments is highest in the first few days or weeks of equilibration (depending on study), after which accumulation apparently stops, and in some cases MMHg concentrations decline, and some studies have noted a cyclical production pattern for MMHg (Jacobs and Keeney;[162] Spangler et al.;[295] Hamdy and Noyes;[137] Olson;[253] Furutani and Rudd;[112] Ikingura and Akagi[153]). It has been suggested that cyclical variations in the supply of bacterial substrates may be the cause (Stary et al.[297]), but changes in the bacterial population may be a more likely explanation. Bacterial life stages can also affect the speciation and fate of Hg, but the available data appear contradictory. Ramamoorthy et al.[266] found growing bacterial cells promote Hg^0 formation, whereas living but nongrowing cells cause demethylation, and dead cells lead to the formation of MMHg. This would appear to agree with Parkman et al.,[258] who suggested Hg methylation is an accidental process that does not require the presence of living bacterial cells. In contrast, Ebinghaus et al.[96] observed active methylation during the phase of exponential growth of sediment bacteria, whereas demethylation became dominant when the bacterial population

began to die off, and Pongratz and Heumann[260] reported methylated Hg species were preferably formed in the stationary period of bacterial growth.

Compeau and Bartha[65] reported MMHg concentrations approached a steady state after 8 to 12 days of incubation, but renewed addition of Hg^{2+} resulted in MMHg synthesis at the previous rate. The percentage of total Hg converted to MMHg declined significantly with increasing spiking levels, however, a phenomenon that has also been noted by other authors (Berdichevsky et al.;[28] Jeffries;[164] Lexmond et al.;[197] Robinson and Tuovinen[277]). Chen et al.[59] observed an increase in methylation rates when the $HgCl_2$ spike was less than or equal to 15.3 $\mu g\ g^{-1}$ d.w., whereas microbial methylation activity appeared to be inhibited at concentrations exceeding this value. Sediments containing high levels of Hg have also shown higher rates of demethylation compared with less-contaminated sediments (Gilmour and Henry;[122] Oremland et al.[255]). The results suggest that high concentrations of inorganic Hg may depress MMHg production or may favor demethylation. In water samples, on the other hand, an increase in specific methylation rates that was proportionally greater than the increase in added Hg^{2+} was observed, possibly due to increased availability of Hg following the saturation of binding sites (Xun et al.[343]). The above results may explain why the ratio of methyl : total Hg in sediments or waters is frequently found to increase with increasing distance from the pollution source (e.g., Suchanek et al.;[305], Hines et al.[141]). The apparent cyclical nature of the methylation process together with a possible inverse relationship of net MMHg production with total Hg concentrations may be one reason why MMHg levels in sediments rarely exceed a threshold value of 1%.

The availability of nutrients is an important factor controlling microbial Hg methylation in aquatic systems (Jernelöv;[169] Langley;[189] Wright and Hamilton[339]). Methylation and sulfate reduction rates therefore are generally highest in the upper layers of sediments, where microbial activity and nutrient supply are greatest, and on suspended organic material (Jernelöv;[169] Callister and Winfrey;[55] Korthals and Winfrey;[180] Jorgensen and Bak;[172] Bubb et al.;[53] Choi and Bartha;[61] Gilmour et al.;[125] Bloom et al.;[41] Hines et al.[141]). Microbial DMHg formation in the ocean is also driven by the supply of labile organic matter (Mason and Sullivan[223]). Many studies have found a positive correlation between sediment organic matter content and MMHg production (Callister and Winfrey;[55] Jackson;[158] Choi and Bartha;[61] Hadjispyrou et al.;[133] Pak and Bartha[256]). Macalady et al.[207] observed a correlation between microbial community structure and organic carbon content and suggested that organic-rich sediments support microbial communities with higher Hg methylation activity per unit of microbial biomass. Because of the generally stimulating effect of organic matter on microbial activity, bacterial demethylation rates may also be increased (Ramlal et al.;[268] Pak and Bartha[256]). Ramlal et al.[268] found net MMHg production in organic-rich soils from a recently flooded reservoir was always higher compared with clay sites, but the organic sites also had rapid demethylation rates.

The creation of new hydroelectric reservoirs and enlargement of lakes significantly increases MMHg production, leading to elevated Hg concentrations in fish that can remain high for several decades (Morrison and Therien;[244] Jackson;[161] Bodaly et al.;[45] Schetagne et al.[286]). Kelly et al.[175] found that MMHg production increased by almost 40 times following the experimental flooding of a boreal forest wetland. Recent data by Montgomery et al.[241] indicate that dissolved MMHg concentrations in flooded environments are on average about four times greater than in natural lakes. It is thought that the flooding of vegetation and soils releases associated inorganic Hg as well as large amounts of organic matter and nutrients, thereby stimulating microbial methylation activity (Porvari and Verta;[261] Bodaly et al.[45]). The effect is enhanced further by the prevailing anaerobic conditions, but it may be mitigated by the provision of additional Hg-binding sites when an excess of organic substrates is supplied (Jackson[161]). Surprisingly, reservoir creation does not appear to increase microbial demethylation rates (Bodaly et al.[45]).

The availability of Hg to methylating bacteria is frequently believed to be determined by the concentration of free Hg^{2+} ions. However, microbial uptake of Hg involves diffusive transport of Hg across bacterial membranes, which are known to have higher permeability for uncharged molecules than for ionic species (e.g., Gutknecht[131,132]). Whereas uncharged $HgCl_2$ may diffuse rapidly through lipid bilayers, charged chloride complexes HgOHCl and $Hg(OH)_2$ do not cross membranes at a significant rate under physiological conditions, for example (Gutknecht[131]). Recent studies (Mason et al.;[219] Barkay et al.;[20] Benoit et al.;[26] Wright and Mason[340]) therefore have suggested that Hg bioavailability is controlled by the concentration of neutral dissolved Hg complexes. $HgCl_2$ may be the key chemical species determining cellular uptake of inorganic Hg in oxic waters (Morel et al.[243]), while uncharged HgS^0, bisulfide $Hg(SH)_2^0$, or polysulfide HgS_n^0 complexes may be important for bacterial uptake in anoxic waters (Hudson et al.;[148] Benoit et al.;[26] Jay et al.[163]). Wright and Mason[340] speculated that there may be other mechanisms of uptake besides passive diffusion, because bioavailability is reduced but not inhibited by organic complexation (Barkay et al.[20]).

Other factors that may affect microbial Hg methylation and/or demethylation are discussed in the following. In many cases these parameters appear to affect methylation by controlling the bioavailability of inorganic Hg. Net MMHg production rates in natural aquatic systems appear to depend to a large extent on the environmental conditions that determine whether bacterial methylation or demethylation will dominate.

2. Temperature

It has been observed frequently that Hg methylation rates in aquatic systems peak during the summer months (Jackson et al.;[157] Callister and Winfrey;[55] Korthals and Winfrey;[180] Bubb et al.;[53] Hintelmann and Wilken;[142] Watras et al.[326]). Most

studies have shown maximum methylation activity occurs during mid or late summer, although Bloom et al.[41] found a sharp peak in sediment MMHg production in early spring, followed by a slow decrease throughout the remainder of the year. Seasonal variations in MMHg production and decomposition generally have been attributed to temperature effects, but are probably also linked with seasonal changes in productivity/nutrient supply and redox conditions (cf. Section III.B.5).

Temperature most likely affects methylation as a result of its effect on the overall microbial activity (Bisogni and Lawrence[34]). Wright and Hamilton[339] noted that MMHg release from sediments at 4°C was only 50 to 70% of that observed at 20°C, suggesting that net MMHg production may be significantly decreased in winter due to lower rates of growth and metabolic activity, and Callister and Winfrey[55] reported microbial Hg methylation in surficial river sediments had a temperature optimum of 35°C. Korthals and Winfrey[180] found that while both temperature and anoxic conditions were important factors influencing net methylation, temperature alone accounted for about 30% of the variation. The data suggested that increased net MMHg production was partly due to decreased demethylation rather than an increase in the actual methylation rate, however. Several other workers have also found that demethylation is favored by low temperatures, whereas higher temperatures favor methylation, leading to a large increase in net MMHg production in the summer (Bodaly et al.;[44] Ramlal et al.[269]). Abiotic methylation by humic substances has also been shown to gain in importance with increasing temperature (cf. Section III.A.2), but it is probably of little/minor significance compared with biotic methylation. In contrast to the findings of Ramlal et al.[269] and Bodaly et al.[44], Matilainen et al.[229] found that the highest rates of *both* methylation and demethylation in surficial lake sediments coincided with maximum temperatures. Similarly, Matilainen and Verta[228] found microbial demethylation rates in aerobic surface waters of small forest lakes (up to 13.2% d^{-1}) were decreased by low temperatures.

Temperature is clearly an important factor controlling both methylation and demethylation. It appears that moderately high temperatures have a stimulating effect on Hg methylation, which is most likely due to increased microbial activity. Together with seasonal changes in oxygen levels and organic content/primary production, this seems to account for the increased MMHg production rates usually observed in the summer. The results for Hg demethylation are somewhat contradictory, but most workers found demethylation is favored by lower temperatures. It may be that the rate of methylation increases faster than the rate of demethylation with increasing temperature.

3. pH

The effect of pH on the methylation of Hg has received considerable attention over the last 2 decades, in particular with regard to lakewater acidification caused

by atmospheric deposition. Many workers have noted elevated Hg levels in fish from acidified lakes (e.g., Scheider et al.;[285] Akielaszek and Haines;[2] Wren and McCrimmon;[338] Lindqvist et al.;[199] Håkanson et al.;[135] Spry and Wiener[296]), and there has been concern that low pH values may lead to an increase in the production and/or bioaccumulation of MMHg. Modeling results suggest that observed inverse correlations between lakewater pH and fish Hg content are due to a combination of generally higher MMHg concentrations at low pH and lower bioconcentration factors at high pH (Hudson et al.[148]). There are, however, many ways in which pH changes may influence MMHg concentrations in aquatic systems, and the effect of pH is not necessarily a direct effect on methylation rates. The solubility and mobility of Hg and MMHg is pH dependent, for example, and acid rain/snow may increase Hg inputs from watersheds (Lee and Hultberg[193]). Furthermore, the added sulfate may stimulate MMHg production (Gilmour et al.;[123] Branfireun et al.[51]). Acid mine drainage, which typically is high in sulfate, has also been linked to elevated MMHg concentrations in lake water (Suchanek et al.[306]).

Low pH conditions generally facilitate the release of heavy metals from sediments and particulate matter, but data on the partitioning and mobility of Hg are somewhat contradictory. Some workers have noted that the mobility of Hg is higher in the acidic pH range (Beijer and Jernelöv;[23] Duarte et al.[94]), but Jackson et al.[156] found that Hg was not leached from sediments by HCl, and Schindler et al.[287] reported that lakewater acidification caused a higher proportion of Hg to bind to particulates, thereby decreasing the solubility of Hg in the water column. The amount of dissolved Hg in sediment porewater was also found to decrease with decreasing pH (Ramlal et al.[267]). The available data on the pH-dependent partitioning of MMHg between the sediment and water phases and the transport of MMHg in watersheds (cf. Sections II.C and II.D) strongly suggest that the solubility of MMHg is increased at low pH values. Thus, lakewater acidification probably does not result in the release of Hg^{2+} from organic sediments, but affects the partitioning of MMHg.

Several studies have indicated that the volatilization of Hg^0 may be positively correlated with lakewater pH (Winfrey and Rudd[335] after Rada et al., 1987, Hudson et al.;[148] Watras et al.[326]), which may decrease Hg(II) substrate concentrations for methylation in high pH waters (Fitzgerald et al.[103]). Modeling calculations by Hudson et al.[148] predict an increase in the ratio of Hg^0/Hg(II) and Hg^0 evasion rates with increasing pH, whereas low pH values favor methylation over Hg(II) reduction. In agreement with this, Watras et al.[326] observed an increase in Hg^0 and a corresponding decrease in MMHg with increasing pH values. High pH values also favor the formation of volatile DMHg (cf. Section III.A.3). Neutral and slightly alkaline conditions thus may reduce MMHg concentrations, whereas low pH waters may contain a relatively higher share of MMHg. This would appear to agree with Swedish field studies that have shown that the treatment of lakes with lime to raise lakewater pH can help reduce the Hg content of fish (e.g., Andersson and Håkanson[10]).

The effect of pH on Hg methylation has been studied both in waters and sediments. MMHg concentrations in lake water generally have been found to increase with decreasing pH (e.g., Xun et al.;[343] Bloom et al.;[40] Miskimmin et al.[240]). Xun et al.[343] reported that net MMHg production in lake water was about seven times faster at low pH (ca. 4.5) than at high pH (ca. 8.5), although in samples that were artificially acidified the observed effect may have been partly due to sulfate stimulation. A pH decrease at the aerobic sediment-water interface resulted in a two- to threefold increase in MMHg production. Miskimmin et al.[240] also reported that a reduction in lakewater pH from 7.0 to 5.0 led to significant increases in net methylation rates. In anaerobic sediments, on the other hand, net MMHg production was generally found to be decreased at low pH values (Steffan and Winfrey;[298] Furutani et al.;[113] Ramlal et al.;[267] Steffan et al.[299]). The acidification of surficial lake sediments always resulted in a significant decrease in ^{203}Hg methylation rates. Ramlal et al.[267] reported that the decrease in ^{203}Hg methylation with decreasing pH appeared to be linked to a reduction of available inorganic Hg in the sediment porewater, which may have been due to increased sorption to particles at low pH. Aerobic methylation in surface sediments was also found to decrease with decreasing water pH (Matilainen et al.[229]).

Demethylation rates are also pH sensitive. Matilainen et al.[229] observed a decrease in anaerobic demethylation in surface sediments with decreasing water pH and speculated that high MMHg concentrations found in the anoxic bottom waters of stratified, low pH lakes may be partly the result of a decrease in demethylation rather than an increase in methylation. Other workers have also found a decrease in demethylation activity at low pH values, but in general demethylation rates in both sediments and lake water were found to be much less affected by pH than methylation rates (Ramlal et al.;[267] Xun et al.;[343] Steffan et al.[299]), indicating that the changes observed in net MMHg production are largely due to an effect of pH on methylation rather than demethylation. However, the results of Ramlal et al.[267] and Steffan et al.[299] show that in sediments demethylation may gain in importance at low pH values. Steffan et al.[299] found little change in demethylation over the pH range 8.0 to 4.5, but methylation decreased sharply with decreasing pH, leading to a substantial increase in the relative importance of demethylation vs methylation under acidic conditions. This may also explain why Ramlal et al.[267] did not observe methylation below pH 5.0.

One of the ways in which pH might affect methylation may be by decreasing microbial activity under acidic conditions, causing a corresponding decrease in bacterial methylation rates. The published literature indicates that microbial activity in lakes is not reduced after acidification, however. Furutani et al.[113] and Kelly and Rudd[173] reported that acidification did not affect general microbial activity (CO_2 + CH_4 production) in sediments, and Miskimmin et al.[240] found that microbial respiration rates had only a very small effect on net MMHg production in lake water and were insensitive to pH changes between pH 5 and 7. However, there are indications that the activity of sulfate-reducing bacteria may be significantly

decreased in the acidic pH range (Connell and Patrick[68]), and Furutani et al.[113] observed a decrease in sulfate reduction at low pH that was independent of general microbial activity. It may also be that pH affects the population distribution of methylating vs. demethylating bacteria in sediments such that demethylation processes dominate at low pH values. This would agree with the results obtained by Ramlal et al.[267] and Steffan et al.[299] and might merit further investigation. It is also possible that pH affects cellular uptake of Hg, but Gutknecht[132] found that the diffusion of Hg^{2+} through lipid bilayer membranes was only dependent on Cl^- concentrations and not on pH.

In summary, it appears that acidic conditions generally favor Hg methylation in lake water and at the sediment/water interface, whereas methylation in anoxic sediments is decreased, possibly due to increased demethylation activity at low pH values. Lakewater acidification thus may lead to increased methylation in the water phase, but it is unlikely to substantially affect methylation in deeper sediments. The observed differences in the effect of pH on Hg methylation in waters and sediments may be related to differences in redox conditions: whereas sediments were generally studied under anoxic conditions, the water samples appear to have been oxygenated to some degree.

It is not clear whether the stimulation of methylation in lake water is a direct effect of low pH on the methylation process, or whether it is related to other factors that are influenced by pH, such as the loss of volatile Hg species from water surfaces, or changes in Hg solubility and partitioning. Winfrey and Rudd[335] hypothesized that the likely decrease in DOC binding sites at low pH values resulting from the protonation of functional groups may stimulate methylation by promoting Hg binding directly onto microbial cells. Increased MMHg concentrations in the water phase at low pH are also likely to be partly attributable to increased desorption of MMHg from surficial sediments (Miller and Akagi;[238] Hintelmann et al.[143]), and thus do not necessarily reflect increased methylation.

It should be mentioned briefly that the abiotic methylation of Hg by organic substances is also pH dependent, but the data are somewhat contradictory (Nagase et al.;[246,247] Varshal et al.;[315] Falter and Wilken[100]). Nagase et al.[246] reported that MMHg formation in fulvic acid solution was strongly enhanced at pH 4 and declined at higher pH values, whereas Varshal et al.[315] found MMHg production increased with increasing pH, for example. While the relative importance of abiotic mechanisms in the methylation of Hg under natural environmental conditions is still unclear, it is generally thought to be low.

4. Organic Material

The role of organic matter in the methylation of Hg is not well understood. Conversion rates of inorganic Hg to MMHg are generally much higher when sediments contain organic substances and can be very high in or near sewage

treatment plants (Jernelöv;[168] Jackson[158]). Observed increases in MMHg concentrations in water, sediments, or fish tissue with increasing levels of organic carbon (Olson and Cooper;[252] Furutani and Rudd;[112] Wright and Hamilton;[339] Lee and Hultberg;[193] Fjeld and Rognerud[107]) generally have been attributed to a stimulating effect of organic nutrients on microbial methylation activity (cf. Section III.B.1), but in some cases transport of (methyl)mercury-DOC complexes to surface waters with runoff (Section II.C) is likely to be an additional factor. Direct abiotic methylation by humic and fulvic acids generally is considered to be of minor importance (cf. Section III.A.2), although it is possible that its influence is increased in organic-rich lakes. However, the data of Porvari and Verta[261] indicate that although humic substances are chiefly responsible for the transport of MMHg, they are not themselves active methylating agents. To date it is not clear to what extent abiotic methylation contributes to MMHg production in organic-rich sediments and lake waters.

Many workers have reported decreased methylation at high concentrations of organic matter, and several studies have suggested that dissolved organic carbon (DOC) may have a mitigating effect on the production and/or bioaccumulation of MMHg in natural waters (Grieb et al.;[128] Jackson;[161] Miskimmin et al.;[240] Driscoll et al.;[93] Watras et al.;[326] Barkay et al.[20]). Miskimmin[239] reported that natural levels of DOC had no effect on the production of MMHg in sediments, although they enhanced the water solubility of MMHg. However, Miskimmin et al.[240] demonstrated that MMHg production in lake water is reduced at high DOC concentrations, presumably as a result of complexation of inorganic Hg with organic matter. A reduction in pH from 7.0 to 5.0 significantly increased methylation rates at both low and high DOC concentrations (500 to 2600 μM), possibly due to competition of H^+ with Hg^{2+} for negatively charged binding sites and increased bioavailability of Hg. Using a bioindicator that responds exclusively to bioavailable Hg^{2+}, Barkay et al.[20] demonstrated that DOC affects the rate of MMHg synthesis by reducing the availability of the Hg^{2+} substrate to methylating bacteria. The exact nature of the Hg-DOC interaction remains unknown, however. The reduction in bioavailable Hg was more pronounced under neutral (pH 7) than under acidic (pH 5) conditions, which is in good agreement with the study by Miskimmin et al.[240]

The availability of Hg for methylation reactions may also be decreased by complexation with sulfur ligands (cf. Section III.B.6). The degradation of organic matter in aquatic environments leads to the production of low-molecular-weight S compounds (Cutter and Krahforst[88]) that can potentially form complexes with Hg^{2+}. On the other hand, increased oxygen consumption during the degradation of organic matter causes progressively more anoxic conditions at the sediment/water interface, which may lead to the mobilization and potential methylation of inorganic Hg (Gagnon et al.;[115] Cossa and Gobeil[78]). DOC also significantly enhances the solubility of HgS (Ravichandran et al.[270]) and may inhibit the precipitation and aggregation of HgS even at low concentrations (Ravichandran et al.[271]).

Humic substances are capable of reducing Hg^{2+} to Hg^0 in aqueous systems (e.g., Miller[237]), which may lead not only to reduced availability of Hg^{2+} for methylation, but potentially also to a reduction in the overall Hg content. Allard and Arsenie[4] suggested Hg^0 production is highest in anaerobic systems in the absence of chloride at a pH of about 4.5, but it is considerably reduced by the presence of competing ions. In contrast to the findings of Miskimmin et al.,[240] Watras et al.[326] observed an increase in the MMHg fraction in Wisconsin lakewaters with increasing levels of DOC, in particular at DOC concentrations >5 mg l^{-1}, whereas the Hg^0 fraction decreased. This is in agreement with modeling calculations by Hudson et al.,[148] which predict that as DOC increases, the fraction of Hg(II) that is reduced declines, while the fraction that is methylated increases. The relative importance of Hg^0 evasion is increased in humic-rich lakes, however, despite the observed decrease in the Hg^0 fraction. Watras et al.[328] hypothesized that high DOC conditions in lakes favor either methylation (at low pH) or evasion (at high pH), whereas low pH low DOC conditions favor sedimentation processes.

The role of humic matter in the methylation of Hg remains unclear. It seems that, on the one hand, organic carbon can enhance methylation by stimulating the activity of heterotrophic microorganisms, or through direct abiotic methylation of Hg by humic or fulvic substances. On the other hand, Hg methylation may be inhibited at high DOC concentrations due to increased complexation of Hg with organic ligands, reducing Hg bioavailability to bacteria, particularly in the neutral pH range. The observed differences may partly reflect different methylation mechanisms. Anaerobic methylation was found to be enhanced by high concentrations of organic matter, presumably due to stimulated microbial growth, whereas aerobic methylation frequently has been observed to be suppressed by high organic matter or particulate concentrations and does not appear to be microbially mediated (cf. Section III.B.5).

5. Redox Conditions

Mercury methylation occurs in both aerobic and anaerobic environments. Early work based on pure culture studies showed that methylation was faster under aerobic conditions (Bisogni and Lawrence;[34] Hamdy and Noyes;[137] Ramamoorthy et al.[266]), but in the natural environment, methylation rates are highest in anoxic sediments and waters, and it is now generally accepted that Hg methylation takes place mainly in anaerobic conditions (Olson and Cooper;[252] Compeau and Bartha;[65] Callister and Winfrey;[55] Craig and Moreton;[87] Jackson;[159] Rudd et al.;[279] Matilainen et al.[229]). Both methylation rates and the stability of MMHg in sediments appear to be enhanced under anaerobic conditions (e.g., Olson and Cooper;[252] Compeau and Bartha[65]), whereas methylation rates are low under aerobic conditions, probably because of the reduced activity of anaerobic sulfate-reducing bacteria. Compeau and Bartha[65] found that Hg methylation in estuarine sediments was strongly

favored at low (-220 mV) E_h, for example, and Callister and Winfrey[55] reported that the oxygenation of sediments inhibited microbial methylation activity. Regnell and Tunlid[272] used radiolabeled $HgCl_2$ in model aquatic systems to demonstrate that Hg methylation in freshwater sediments and water is significantly higher under anaerobic than under aerobic conditions. MMHg concentrations in anaerobically incubated water and sediment samples from a Hg-contaminated lake were also at least an order of magnitude higher than in aerobic incubation (Regnell et al.[273]); both the production and water solubility of MMHg appeared to be increased under anaerobic conditions.

On the other hand, the degradation of MMHg appears to be generally favored by aerobic conditions. Although some workers have found demethylation rates in freshwater sediments were similar under aerobic and anaerobic conditions (Billen et al.;[32] Matilainen et al.[229]), most studies have shown that MMHg degradation is faster under aerobic/high E_h conditions (Olson and Cooper;[252] Compeau and Bartha;[65] Ramlal et al.;[268] Oremland et al.;[254] Ebinghaus et al.[96]). Oremland et al.[254] found that demethylation in estuarine sediments was more rapid and extensive under aerobic conditions, but anaerobic sulfate reducers were also important demethylators, suggesting that there are multiple degradation pathways (cf. Section III.A.4).

It may be that different mechanisms are responsible for Hg methylation under aerobic and anaerobic conditions. Anaerobic methylation was found to be enhanced by high concentrations of organic matter, presumably due to stimulated microbial growth (Olson and Cooper;[252] Compeau and Bartha[65]). Aerobic methylation on the other hand is frequently observed to be suppressed by high organic matter or particulate concentrations, and does not appear to be microbially mediated (Matilainen et al.;[229] Matilainen;[227] Matilainen and Verta[228]). Matilainen[227] found, for example, that aerobic methylation was abiotic and was suppressed by humic compounds and particulate matter, whereas methylation in the anaerobic hypolimnion was microbial. Matilainen et al.[229] reported that aerobic methylation in organic-rich surficial lake sediments was abiotic and was slow compared with anaerobic methylation, but increased in importance with increasing sediment mineral content. Aerobic methylation and the methylation/demethylation ratio correlated positively with the Fe and Mn content of the sediment. The authors suggested that sediments with high metal content may have more bioavailable Hg, owing to the interaction of these metals with sulfur, which would appear to agree with more recent results by Gagnon et al.,[114] who found that high dissolved Fe concentrations in sediment porewaters seem to limit the amount of dissolved H_2S that may potentially interfere with the methylation process. A possible catalytic effect of Fe on Hg methylation can also not be ruled out. Lee et al.[192] reported that Hg methylation in lake waters in the presence of fulvic acid was increased by the addition of metal ions, and in particular Fe.

In most aquatic sediments, only the upper few millimetres are aerobic, while the rest of the sediment is in an anaerobic state. MMHg concentrations are usually highest in the moderately anaerobic surface sediments and rapidly decline with

increasing sediment depth (Korthals and Winfrey;[180] Bubb et al.;[53] Hintelmann and Wilken;[142] Bloom et al.;[41] Hines et al.[141]). In sediment porewaters, MMHg concentrations were very low in the oxic zone, but were high in anoxic layers (Gagnon et al.[114]). Bubb et al.[53] suggested that subsurface maxima of methylation activity just below the sediment/water interface are caused by increased MMHg production under moderately anaerobic conditions, whereas bacterial degradation of MMHg dominates in the oxygenated surface zone, and in deeper sediment layers where conditions are strongly reducing sulfide limits the availability of Hg for methylation (cf. Section III.B.6). MMHg concentrations in sediments are also influenced by the redox cycling of Fe and Mn oxides that partly control dissolved Hg concentrations in sediment porewaters (Gobeil and Cossa;[126] Gagnon et al.[115]), thereby influencing Hg bioavailability. In the oxidized surface layers of marine sediments, Hg was found to be primarily associated with fresh particulate organic matter and Fe and/or Mn oxyhydroxides, which was limiting dissolved Hg concentrations (Gagnon et al.[115]). High dissolved Hg concentrations were observed at the redox boundary, however, due to the accumulation and subsequent dissolution of oxyhydroxides (Gagnon et al.[115]). Similarly, Gobeil and Cossa[126] found that dissolved Hg and Fe concentrations increased below 2 cm from the sediment/water interface.

In the water column, MMHg (and DMHg) production is also related to zones of low oxygen concentration (e.g., Bloom et al.;[40] Hurley et al.;[149] Verta and Matilainen;[316] Mason and Fitzgerald;[211,212] Mason et al.[214]), whereas levels are typically low in the oxic zone, both in freshwater lakes (Bloom et al.;[40] Cossa et al.;[74] Watras and Bloom[323]) and ocean waters (e.g., Mason and Fitzgerald[210,211]). In stratified lakes and estuaries, MMHg concentrations are usually highest in the oxic/anoxic boundary layer and in anoxic water layers (Bloom et al.;[40] Mason et al.;[213] Cossa et al.;[74] Parkman et al.;[258] Verta et al.;[317] Watras and Bloom;[323] Watras et al.;[324] Matilainen[227]). High MMHg concentrations at the oxic/anoxic boundary do not necessarily reflect *in situ* MMHg production, but could result from the accumulation of settling particulate matter. For instance, Matilainen[227] found MMHg concentrations were elevated in the particle-rich oxic/anoxic boundary layer despite low methylation rates (<0.1% d^{-1}), apparently as a result of the settling of particle bound MMHg from the epilimnion. The low net methylation rates were attributed to the binding of Hg to particles and demethylation by heterotrophic bacteria. Cossa et al.[74] also observed a peak in particulate MMHg in the upper region of the redoxcline. The results suggest that methylation occurs mainly in the low oxygen region, but the concentration and distribution of MMHg are strongly influenced by the redox cycling of Fe and Mn at the oxic/anoxic boundary.

Seasonal variations in MMHg concentrations are also strongly linked to changes in redox state. MMHg levels in hypolimnetic waters of seasonally stratified lakes and reservoirs generally increase during summer stratification, and decrease again following fall turnover (Bloom and Effler;[38] Bloom et al.;[40] Watras and Bloom;[323] Watras et al.;[324] Driscoll et al.;[93] Regnell et al.;[274] Canavan et al.[56]). Similar trends

are observed in surface sediments (Korthals and Winfrey[180]). The increased decomposition of organic matter and primary production during the summer months renders sediments and hypolimnetic waters progressively more anoxic, which together with the generally higher temperatures is thought to have a stimulating effect on bacterial methylation activity. Hypolimnetic enrichment of MMHg and Hg in (seasonally) anoxic lake waters may also be due to redox-controlled release of Hg from bottom sediments or sedimenting particles (Hurley et al.;[149,151] Mason et al.[224]). Meili[233] suggested that the build-up of MMHg in anoxic waters may be due to suppressed demethylation rather than enhanced methylation, however. Passive uptake of neutral $Hg(SH)_2^0$ and HgS^0 complexes by methylating bacteria may be another reason for increased Hg methylation in anoxic waters (Hudson et al.;[148] Benoit et al.[26]). Demethylation processes are expected to dominate when hypolimnetic waters are reaerated during lake turnover.

In summary, it is clear that microbially mediated methylation is generally favored by anaerobic conditions, while demethylation is favored by aerobic conditions. On the other hand, abiotic methylation appears to be largely aerobic. Sediment redox state also affects the partitioning of Hg species between the sediment and water phases. Other environmental factors can interact significantly with redox effects, in particular organic matter and pH.

6. Sulfide

Hydrogen sulfide plays an important role in the chemistry of anaerobic sediments where it is produced as a result of bacterial sulfate reduction. Conditions of high sulfide typically develop in anoxic, organic-rich sediments that are high in sulfate, but can also occur in surface waters as a result of industrial or domestic wastewater discharges. Early studies noted that high sulfide concentrations appear to inhibit MMHg formation in soils, sediments, and bacterial cultures (Fagerström and Jernelöv;[98] Bisogni and Lawrence;[34] Yamada and Tonomura;[346] Jacobs and Keeney;[162] Talmi and Mesmer[311]), and significant reductions of MMHg in fish were achieved in aquarium experiments by adding sulfides as S^{2-}, FeS, or FeS_2 (Jernelöv and Åséll[170]). An inverse relationship between (dissolved) sulfide concentration and MMHg production or concentration in sediments or sediment porewaters has also been noted in many more recent studies (e.g., Craig and Moreton;[85] Compeau and Bartha;[64,67] Winfrey and Rudd;[335] Gilmour et al.;[125] Benoit et al.[25,26]). Craig and Moreton[85] found MMHg levels in sediments were initially in direct proportion to sulfide concentrations, but declined sharply beyond a sulfide concentration of about 1.8 mg g^{-1}, and Berman and Bartha[29] observed that Hg added to sediments containing 7.06 mg g^{-1} (d.w.) acid labile and 1.98 mg g^{-1} (d.w.) free sulfide became rapidly unavailable for methylation, whereas increasing amounts of MMHg were formed when the sediment was diluted with a low-sulfide control sediment, or when it was partially depleted of sulfide.

The presence of sulfide clearly decreases the availability of Hg^{2+} for methylation. However, although MMHg production is generally greatly reduced at high sulfide concentrations, it is not usually completely inhibited. Furutani and Rudd[112] found that $^{203}Hg^{2+}$ was actively methylated in anaerobic sediments even in the presence of about 30 μg g^{-1} of bound sulfide (d.w., as amorphous FeS), for example. Furthermore, MMHg levels in sediments are sometimes found to increase with increasing sulfide concentrations (Hintelmann and Wilken[142]), and in stratified lakes and estuaries high MMHg concentrations are frequently found in the sulfidic boundary layer (Bloom et al.;[40] Mason et al.;[213] Parkman et al.;[258] Verta et al.;[317] Watras et al.;[324] Matilainen[227]).

In the presence of sulfide, Hg forms insoluble HgS (cf. Section II.A). Several early reports indicated that mercury in the HgS form is not readily available for methylation under anaerobic conditions (Fagerström and Jernelöv;[98] Gillespie;[121] Yamada and Tonomura[344-346]). In aerobic conditions, the sulfide may be oxidized to sulfate, leading to increased solubility and greater availability of Hg^{2+} (Fagerström and Jernelöv;[98] Jensen and Jernelöv[166]), but aerobic methylation rates are several orders of magnitude lower compared to anaerobic conditions (Fagerström and Jernelöv;[98] Gillespie and Scott;[120] Jacobs and Keeney[162]). Nevertheless, exposure of contaminated sediments to aerobic conditions may lead to the remobilization and subsequent methylation of Hg (Berman and Bartha[29]).

It is commonly speculated that the inhibitory effect of sulfide on Hg methylation is the result of decreased solubility and bioavailability of Hg^{2+} due to HgS precipitation (e.g., Craig and Bartlett;[84] Gavis and Fergusson;[118] Blum and Bartha;[43]Compeau and Bartha;[64,67] Winfrey and Rudd;[335] Gilmour and Henry[122]). However, high dissolved Hg(II) concentrations in the porewater of sulfidic sediments (Gagnon et al.;[115] Benoit et al.;[25] Bloom et al.[41]) indicate that the solubility of Hg is actually increased in the presence of excess sulfide, most likely due to the formation of soluble sulfide complexes. Furthermore, the lack of a relationship between dissolved Hg(II) concentrations in porewater and MMHg production suggests that Hg^{2+} may not be the main species that is methylated (Benoit et al.[25]). The work of Benoit et al.[25-27] shows that sulfide affects the bioavailability of Hg by controlling Hg speciation. Benoit et al.[26] suggest that the bioavailability of Hg in sediments is determined by the concentration of neutral dissolved Hg complexes such as HgS^0, which may readily diffuse across bacterial cell membranes. Under sulfidic conditions, on the other hand, Hg methylation is inhibited due to the formation of charged disulfide complexes which are likely to be less bioavailable (Benoit et al.[27]). The formation of polysulfides (Paquette and Helz;[257] Jay et al.[163]) and complexes with dissolved organic matter (Ravichandran et al.[270,271]) may contribute to the solubility of Hg in sulfidic environments. Barkay et al.[20] have shown that DOC complexation reduces the availability of Hg to bacteria, but the effect of polysulfide formation on Hg methylation is not clear. Jay et al.[163] speculate that although the formation of charged polysulfide species may decrease the concentration of bioavailable HgS^0, bioavailability could potentially be increased

due to the formation of small concentrations of other lipid-soluble uncharged species such as HgS_5.

A number of studies have suggested that in the presence of high sulfide concentrations, MMHg may be converted to volatile DMHg (Craig and Bartlett;[84] Craig and Moreton;[86] Baldi et al.[16,18]). Craig and Bartlett[84] proposed that the reaction proceeds via the formation of an instable organomercury sulfide intermediate, $(CH_3Hg)_2S$, which decomposes into DMHg and HgS. The volatile hydrophobic DMHg produced may diffuse through the water column and be lost to the atmosphere, potentially leading to a significant reduction in the organic Hg content of sediments (Craig;[83] Craig and Moreton[85]). Craig and Moreton[86] demonstrated the evolution of DMHg from a sediment containing a natural unamended level of MMHg on exposure to sulfide. Baldi et al.[18] have shown that MMHg added to polluted sediments can also be converted to DMHg, but the study was performed under high sulfide and high MMHg conditions that would thermodynamically favor DMHg production. The formation of DMHg is considered a potentially important loss mechanism of MMHg from anaerobic sediments high in sulfide (Craig;[83] Baldi et al.[18]), but it is not clear to what extent it occurs in the natural environment.

7. Salinity

The methylating activity of marine and estuarine sediments is usually lower than that of freshwater sediments (e.g., Olson and Cooper;[251] Blum and Bartha;[43] Compeau and Bartha[67]), which generally has been attributed to salinity effects. Blum and Bartha[43] and Compeau and Bartha[67] observed a strong inverse relationship between the salinity of anaerobic sediments and their ability for Hg^{2+} methylation. High-salinity sediments methylated Hg at only 40% of the level observed in low-salinity sediments (Compeau and Bartha[67]). The inhibitory effect of salinity on Hg methylation is particularly pronounced under reducing conditions, and high-salinity conditions appear to promote demethylation processes (Compeau and Bartha[65]). Low-salinity coastal waters have also been found to contain a relatively higher proportion of MMHg (Coquery et al.[71]).

The negative effect of salinity on Hg methylation appears to be mainly linked with the microbial production of sulfide from sea salt sulfate. However, while MMHg production in sediments is often strongly reduced in the presence of sulfate (Baker et al.;[15] Compeau and Bartha;[67] Winfrey and Rudd[335]), methylation does not necessarily stop at high sulfate concentrations. Compeau and Bartha[67] reported that methylation still occurred at 2.4% salinity, corresponding to 19.5 m*M* sulfate per liter and 7.1 mg sulfide per gram of dry sediment, whereas the same level of sulfide had been found to almost completely inhibit methylation in a freshwater sediment (Berman and Bartha[29]). While it was previously believed that sulfide originating from sulfate-reduction processes limits the bioavailability of Hg in anaerobic

sediments due to HgS formation (Blum and Bartha;[43] Compeau and Bartha;[64,67] Winfrey and Rudd[335]), recent evidence suggests that methylation is inhibited at high sulfide concentrations due to changes in Hg speciation (cf. Section III.B.6).

Not only sulfate, but other sea salt anions may also affect Hg speciation and/or methylation in estuarine and marine environments. Compeau and Bartha[64] demonstrated that bicarbonate has a negative influence on Hg methylation under both aerobic and anaerobic conditions, possibly due to the formation of $HgCO_3$. The authors speculated that the availability of Hg for methylation may hence be higher in 'soft' than in 'hard' (i.e., bicarbonate rich) freshwater systems. Compeau and Bartha[64,67] found no noticeable effect of chloride on Hg methylation, but it has been suggested that the negative charge of mercuric chloride species may reduce their availability to methylating bacteria. Using a mercury-specific bioindicator, Barkay et al.[20] demonstrated that uncharged $HgCl_2$ is indeed more bioavailable than anionic forms. On the basis of the data available to date, it would appear that the formation of charged sulfide and chloride complexes offers the best explanation for the apparently reduced methylation activity in estuarine and marine environments.

IV. SUMMARY AND CONCLUSIONS

Mercury methylation is mainly a microbially mediated process with methylcobalamin being the most likely environmental methyl donor. Abiotic methylation appears to be of minor importance, although its influence may be increased in organic-rich lakes. The precise mechanism of MMHg and DMHg formation is still unclear. Although it is generally believed that DMHg is the final product of Hg methylation, MMHg in the ocean appears to be produced mainly by decomposition of DMHg, indicating that there may be more than one methylation mechanism. More research is also needed into the factors controlling bacterially mediated and abiotic demethylation processes.

Mercury methylation and demethylation rates in aquatic systems are clearly influenced by both the speciation and biochemical availability of Hg and by a large number of environmental variables, many of which are interrelated. Biological activity, nutrient availability, pH, temperature, redox potential, and the presence of inorganic and organic complexing agents all have significant effects, with the net rate of MMHg production being determined by their complex interaction. Which factors dominate is likely to differ from ecosystem to ecosystem. Furthermore, the distribution of Hg between the sediment and water phases as well as the gaseous evasion of volatile Hg species is also influenced by environmental factors. The interrelatedness of these processes has often hampered research into the factors controlling Hg methylation. Nevertheless, certain general trends are apparent. MMHg formation is generally favored under anaerobic conditions, whereas aerobic conditions promote demethylation processes. In stratified lakes and estuaries,

MMHg formation occurs primarily at the oxic/anoxic interface, whether this occurs in bottom waters or surface sediments. Methylation in the ocean is not confined to low-oxygen zones, however, which is another indicator that there may be more than one mechanism for MMHg/DMHg formation. Seasonal variations in MMHg production appear to be mainly related to temperature and redox effects, as well as seasonal changes in productivity and hence nutrient availability. Moderately high temperatures have a stimulating effect on methylation, whereas demethylation processes are favored by lower temperatures. Lakewater acidification may lead to increased methylation in the water column, but in sediments methylation is generally found to be decreased, which may be due to a reduction in the activity of sulfate-reducing bacteria, or increased demethylation. It may also be that different mechanisms are responsible for Hg methylation in waters and in sediments, and there are indications that methylation in the water column may be abiotic and linked to particles. Studies investigating the effect of pH on Hg methylation should consider that increased MMHg concentrations in the water phase are likely to be partly attributable to increased desorption of MMHg from sediments at low pH.

Sulfur chemistry is a particularly important factor controlling methylation. Sulfate-reducing bacteria are important methylators of Hg in anaerobic sediments, and sulfate stimulates microbial Hg methylation at the typically low sulfate concentrations prevailing in freshwater systems. However, at high levels in reducing conditions methylation is inhibited due to sulfide formation, which may be one reason why MMHg levels in sediments rarely exceed 1% of the total Hg concentration. Recent studies have shown that the inhibitory effect of sulfide on Hg methylation is not due to HgS precipitation, but that sulfide lowers the availability of Hg for bacterial methylation by formation of less bioavailable charged Hg-S complexes.

The role of organic matter in the methylation of Hg is not well understood. Humic matter is an important factor controlling the solubility and mobility of Hg in natural waters. Organic nutrients generally stimulate microbial activity and hence Hg methylation, although they may also have an effect on bacterial demethylation activity. Direct abiotic methylation of Hg by humic and fulvic acids has also been reported. On the other hand, high levels of dissolved organic carbon appear to have a mitigating effect on both the production and bioaccumulation of MMHg due to Hg complexation, particularly in the neutral pH range. The formation and dissolution of Hg-OM complexes is pH sensitive, with complexation being reduced at low pH.

Unfortunately, despite a vast body of literature on the subject, we are still unable to predict Hg methylation rates and the likely effects of environmental perturbations on methylation and demethylation processes in aquatic systems. Owing to the complexity of processes in the natural environment, it is difficult to directly compare the results of the studies that have been published to date. Future laboratory-based studies of methylation/demethylation rates that address not only

the direct effects of environmental variables but that place particular emphasis on understanding how these factors interact would be desirable. These studies should aim to quantify Hg transformation rates at environmentally relevant concentrations, thereby providing a more realistic assessment of *in situ* rates than the traditionally large Hg additions. The effect of pH under oxic compared with anoxic conditions should receive particular attention. Further research is also needed on the binding and partitioning of both inorganic and MMHg, which is also influenced by the above-mentioned factors and that may to a certain extent confound the primary effects of these variables on methylation/demethylation rates. This work is particularly important if we are to find more effective ways of minimizing the ecological risk of mercury in the aquatic environment.

ACKNOWLEDGMENTS

We are grateful to the European Union INCO-Copernicus programme and BG Group for funding this work. We would also like to thank the referees who reviewed the first draft of this paper and made a considerable number of suggestions for its improvement.

CATCHMENT AREA COMPOSITION AND WATER CHEMISTRY HEAVILY AFFECTS MERCURY LEVELS IN PERCH (*PERCA FLUVIATILIS* L.) IN CIRCUMNEUTRAL LAKES

LARS SONESTEN
Department of Limnology, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden (Present address: Department of Environmental Assessment, Swedish University of Agricultural Sciences, P.O. Box 7050, SE-750 07 Uppsala, Sweden, e-mail: Lars.Sonesten@ma.slu.se, Fax: +46 18 673156)

(Received 23 February 2000; accepted 5 August 2002)

Abstract. The environmental impact on the mercury level in perch (*Perca fluviatilis* L.) is examined using Partial Least Square regression (PLS) on 48 environmental descriptors assessing land use, various catchment area and lake characteristics, lake water chemistry, and fish stock. The lake specific intercepts of Hg content vs. fish length regressions are used to describe the Hg level in the fish. The Hg levels in perch from 78 circumneutral lakes were largely influenced by land use in the surroundings. Boreal forest lakes had the highest Hg burden in the fish, while fish from lakes heavily influenced by arable land possessed lower contents. The Hg levels also showed a negative relationship to the concentrations of dissolved ions and total nutrients in lake water, and to the perch growth rate, whereas the relationship was positive to the concentration of TOC/humic matter. Lake pH did not have any significant influence on the Hg content in perch in these circumneutral lakes. The Hg levels in perch from lakes surrounded by large amounts of wetland were less satisfactorily explained by the presently examined environmental descriptors, which suggests that the Hg burden in fish from these lakes are influenced by other factors.

Keywords: catchment area, fish, land use, mercury (Hg), partial least square regression (PLS), perch (*Perca fluviatilis*), pH, water chemistry

1. Introduction

High mercury levels in fish is a prolonged major concern for many areas in the boreal forest region of Sweden (Björklund *et al*., 1984; Lindqvist *et al*., 1984, 1991), Finland (Verta *et al*., 1986), Russia (Haines *et al*., 1995), Canada (Wren *et al*., 1991) and northern U.S.A. (Lathrop *et al*., 1989). The large reductions in Swedish Hg emissions during the 1970's and 1980's have still not resulted in any obvious decline in fish Hg levels. On the contrary, there might even have been a small increase in fish from lakes without any known direct Hg inputs (Håkanson *et al*., 1988; Lindqvist *et al*., 1991). This is probably caused by continued import of airborne Hg emissions from central Europe and Great Britain, and/or Hg leaching out from the catchment areas (Håkanson *et al*., 1990). Although the domestic Hg emissions are drastically reduced, Lindqvist *et al*. (1991) found that about 10 times more Hg was deposited on a typical Swedish forested catchment area than

Water, Air, and Soil Pollution **144:** 117–139, 2003.

what was reaching the lake. This net accumulation in catchment areas implies that high mercury levels in lakes and aquatic organisms might be an even more serious problem in the future (Bishop *et al*., 1995).

Enhanced analytical capabilities of different Hg compounds during the last decade have enabled more accurate Hg budgets (Rudd, 1995). Hence it was clarified that the major Hg sources to lakes without any point discharge of Hg, are dry and wet atmospheric deposition. Though, only a minor fraction of this atmospheric Hg is in methylated form (Downs *et al*., 1998). This implies that the (mono)methylmercury (MeHg), which is the most readily biomagnified Hg form in aquatic ecosystems and the most common form in fish (Westöö, 1967; Bloom, 1992), generally is produced within the lake ecosystems (including the catchment areas). Two major sites of methylation are recognised: (1) wetlands (St. Louis *et al*., 1994, 1996; Verta *et al*., 1994; Bishop *et al*., 1995; Branfireun *et al*., 1996; Kelly *et al*., 1997); and (2) lake sediments (Jensen and Järnelöv, 1969; Ramlal *et al*., 1993). Occasionally, significant methylation also is found in the water column, mainly in connection to suspended particles (Henry *et al*., 1995; Matilainen, 1995).

The catchment area affects the Hg bioavailability in aquatic ecosystems mainly by governing the Hg transport from terrestrial soils to lakes, and via altering the chemical properties of Hg and thereby changing its mobility. The Hg transport to lakes is largely governed by co-transport with humic matter (Meili *et al*., 1991; Mierle and Ingram, 1991; Johansson and Iverfeldt, 1994). Chemical alteration to more mobile forms, like MeHg, will increase the flux of Hg to lake ecosystems and thereby enhance the load of this highly bioavailable Hg form (Lee *et al*., 1994).

Mercury cycling studies in aquatic ecosystems has primarily been focused on areas affected by acidification, as such lakes have been found to exhibit high Hg levels in fish (Björklund *et al*., 1984; Lindqvist *et al*., 1984; Håkanson *et al*., 1990; Turunen and Alm, 1990). Only a few studies have been accomplished in circumneutral or alkaline lakes, notably in Canada and northern U.S.A. (MacCrimmon *et al*., 1983; Lathrop *et al*., 1989; McMurtry *et al*., 1989; Wren *et al*., 1991). In Sweden there seems to be a sampling bias towards acidic lakes (Sonesten, 2000, 2001), chiefly because the problem with high Hg levels in biota from circumneutral lakes are considered to be low (Andersson *et al*., 1987; Håkanson *et al*., 1988). In this study I test whether the assumed low Hg level in such lakes is true, and I make an assessment of the environmental impact on the Hg level in fish from circumneutral or slightly alkaline lakes. This study is focused on the basal Hg level in perch (*Perca fluviatilis* L.), but comparisons are also made to the level in roach (*Rutilus rutilus* L.) caught within the same survey (Sonesten, 2001). The perch is well known to change its food items during its lifetime. Principally, from being zooplanktivorous, it turns successively to feed on zoobenthos and finally becomes a piscivorous species when it is sufficiently large (Collette *et al*., 1977). Although, there are some recent studies that indicate piscivory, and especially cannibalism, to be important during the first months after the perch is hatched, at least in high fish abundancies in laboratory experiments and ponds (Brabrand 1995, 2001). The

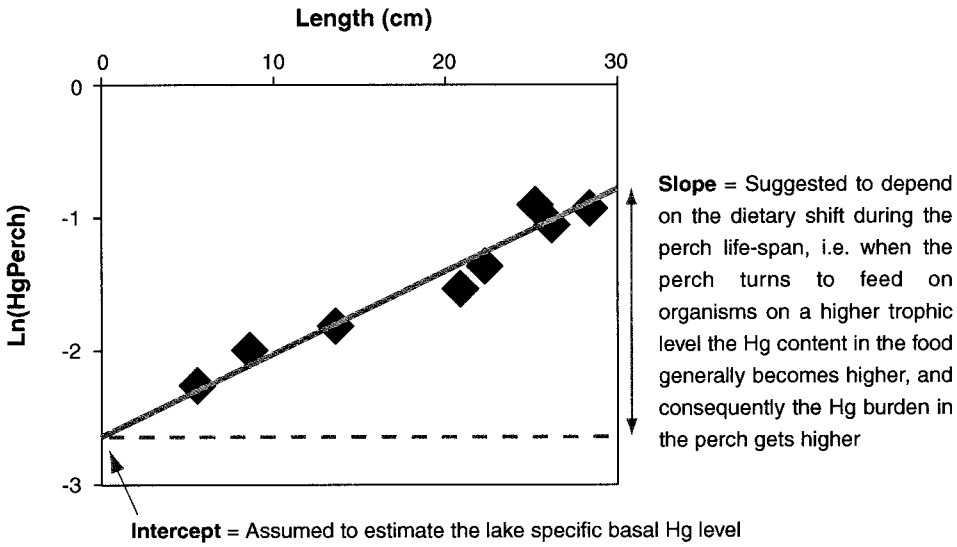

Figure 1. The linear regression on Hg content and fish length in perch from lake Vikasjön showing the separation into the intercept, which estimates the lakespecific basal Hg level in perch, and the regression slope that depends on the Hg bioaccumulation during the perch lifetime.

degree of this behaviour in lakes is not clear, as it has only been indicated by size-dependent mortality studies (op. cit.). Also, if this presumed early piscivory do have any effect on the Hg content in the perch larvae is still not shown, and no comparisons on the Hg content in perch larvae and other food items are known to have been published. However, by changing food items during its lifetime the perch successively feeds at different trophic levels and hence it is an exceedingly interesting link in the transfer of mercury within the food web. The lake specific basal Hg levels in perch used in this study are obtained by splitting lake specific linear regressions of Hg content in perch vs. fish length into intercepts and slopes, where the intercepts are estimates of the Hg level and the slopes are assessing the Hg bioaccumulation (Figure 1). The ontogenethic diet chift in perch has been suggested to be the main contributor to the Hg bioaccumulation, as there is no significant environmental impact on the regression slope of the Hg content vs. fish size (L. Sonesten, manuscript).

2. Material and Methods

Total mercury level in perch (*Perca fluviatilis* L.), from a regional survey of 78 lakes in the county of Uppsala, Sweden, is related to 48 environmental variables describing land use in the catchment area, lake morphometry, lake water chemistry, and fish landings from the fish survey (Table I).

TABLE I

Definitions[a] and statistics of environmental variables used to analyse the environment impact on the Hg levels in perch from 78 lakes in the County of Uppsala, Sweden, 1991–1993

Variable	Unit	Mean	Min	Max	Definition
HgPerch, ln(mg Hg kg^{-1} ww)			–4.98	–1.21	The intercept of the lineary regressed Hg content in perch vs. fish length
HgRoach, ln(mg Hg kg^{-1} ww)			–3.24	–1.17	The geometric lake mean Hg content in roach
X					X co-ordinate according to the Swedish National Grid
Y					Y co-ordinate according to the Swedish National Grid
Z					Distance from the NW–SE separator (cf. Figure 2)
m.a.s.l.	m	26	0.3	88	Meters above sea level
TotAltDiff	m	32	5	110	Altitude difference within the whole catchment area
AltDiff	m	27	5	75	Altitude difference within the catchment area (excl. subcatchments)
TotCatchArea	km^2	60	0.16	704	The surface of the whole catchment area
CatchArea	km^2	15	0.16	103	The surface of catchment area
TotCatch/lake		99	2.93	1842	The ratio between the whole catchment and lake areas
Catch/lake		26	2.93	205	The ratio between the catchment area and lake area
Forest%	%	76	34	95	Forest coverage of the catchment area
Arable land%	%	10	0	65	Arable land coverage of the catchment area
Wetland%	%	14	0	57	Wetland coverage of the catchment area
Urban%	%	1	0	11	Coverage of other kinds of land use of the area (mainly urban areas)
TotForest%	%	75	40	96	Forest coverage of the whole catchment area
TotArable%	%	105	0	48	Arable land coverage of the whole catchment area
TotWetland%	%	13	0	57	Wetland coverage of the whole catchment area
TotLakes%	%	2	0	12	Lake coverage of the whole catchment area

TABLE I
(continued)

Variable	Unit	Mean	Min	Max	Definition
TotUrban%	%	1	0	8	Coverage of other kinds of land use of the whole catchment area
Lake area	km^2	0.97	0.05	9.42	Lake area
Lake volume	Mm^3	2.08	0.03	26.5	Lake volume
Lake length	km	2.0	0.25	15	Maximum lake length
Lake width	km	0.69	0.12	2.6	Maximum lake width (perpendicular to max. length)
Max depth	m	3.7	1	12.5	Maximum lake depth
Mean depth	m	1.9	0.5	6.4	Average lake depth
VD		1.63	0.51	2.43	Volume development = 3 $*$ mean depth/max depth (describes lake shape)
Tr	days	189	1.6	1570	Theoretical lake water retention time
Ca	$\mu eq\ L^{-1}$	1110	170	2560	Total amount of Ca[b]
Mg	$\mu eq\ L^{-1}$	178	40	660	Total amount of Mg[b]
K	$\mu eq\ L^{-1}$	28	1	84	Total amount of K[b]
Na	$\mu eq\ L^{-1}$	243	77	765	Total amount of Na[b]
Fe	$\mu eq\ L^{-1}$	4.1	0.6	21	Total amount of Fe[b]
pH		7.7	6.5	8.8	pH[c]
Colour	mg Pt L^{-1}	92	13	260	Water colour measured on filtered water (Whatman GF/C) with comparator 1991–1992 and calculated from absorbances 1993 (420 nm)[c]
Conductivity	mS m^{-1}	19.3	4.4	49.3	Water conductivity[c]
TotP	$\mu g\ P\ L^{-1}$	34	3	275	Total amount of P in unfiltered deep frozen water. Molybdate reactive phosphate after $K_2S_2O_8$ oxidation
TotN	$\mu g\ N\ L^{-1}$	1020	405	2980	Total amount of N in unfiltered deep frozen water. Measured by second derivate spectroscopy
TOC	mg L^{-1}	18.5	5	39.8	Total amount of organic carbon after H^+ and aeration of unfiltered deep frozen water
Dec O_2	mg L^{-1}	8.1	0.2	12.6	O_2 content at 0.5 m depth in December 1988 (after 1 month of ice coverage as a measure on the capacity to withstand oxygen depletion)
TotCPUE	kg	3.7	0.33	17.0	Total fish catch per unit effort
TotNCPUE		86	8.8	384	Average total number of fish per unit effort

TABLE I
(continued)

Variable	Unit	Mean	Min	Max	Definition
CPUE roach	kg	0.8	0.0	2.7	Catch of roach (*Rutilus rutilus*) per unit effort
NCPUE roach		39	0.0	302	Average number of roach per unit effort
CPUE perch	kg	0.9	0.07	3.1	Catch of perch (*Perca fluviatilis*) per unit effort
NCPUE perch		31	1.0	215	Average number of perch per unit effort
Growth rate	mm yr^{-1}	39	24	53	Perch growth rate from linear regression of fish length vs. fish age
No. species		6.3	2	13	Number of fish species caught

[a] Distinction is made between 'whole catchment area', which includes subcatchment areas belonging to eventual upstream lakes, whereas 'catchment area' refers to the area exluding eventual subcatchments.
[b] Measured on unfiltered deep frozen water by atomic absorption spectrophotometry.
[c] Measured at 25 °C on cold stored water (<8 °C) within 48 hr.

2.1. AREA DESCRIPTION

The county of Uppsala is situated just north of Stockholm, Sweden (Figure 2). The area belongs to the boreal forest region, but in contrast to most other parts of the country, calcareous moraines heavily affects the soils (Ingmar and Moreborg, 1976). Consequently, even humic lakes are predominantly non-acidic, with high concentrations of dissolved ions. A comprehensive description of the area can be found elsewhere (Sonesten, 2001).

The county can be divided into three different physical geographic regions (CABU, 1986; SNA, 1992). The southern part is a fissure-valley terrain with clayey valleys, lakes and streams. Coniferous forests and arable land dominate the mosaic-like landscape. The eastern part of the county is an extension of the Stockholm and Roslagen archipelagos with a hilly fissure-valley landscape dominated by coniferous forests. The north and north-western part of the county is a plain, belonging to the transitional zone to the Taiga terrain, dominated by coniferous forests, large mires and eskers.

Two historically important point discharges of Hg emissions to the air are identified, the waste incineration and peat combustion plant in Uppsala and a chlor-alkali plant just north of the county (Figure 2). The waste incineration and peat combustion plant was responsible for large emissions to the air during the 1960's–1980's, resulting in raised Hg levels in terrestrial mosses in the main trajectory to Northeast (Skye and Lindman, 1997), which is an area virtually without lakes. The emissions were effectively reduced in the mid 1980's due to enhanced treatment of com-

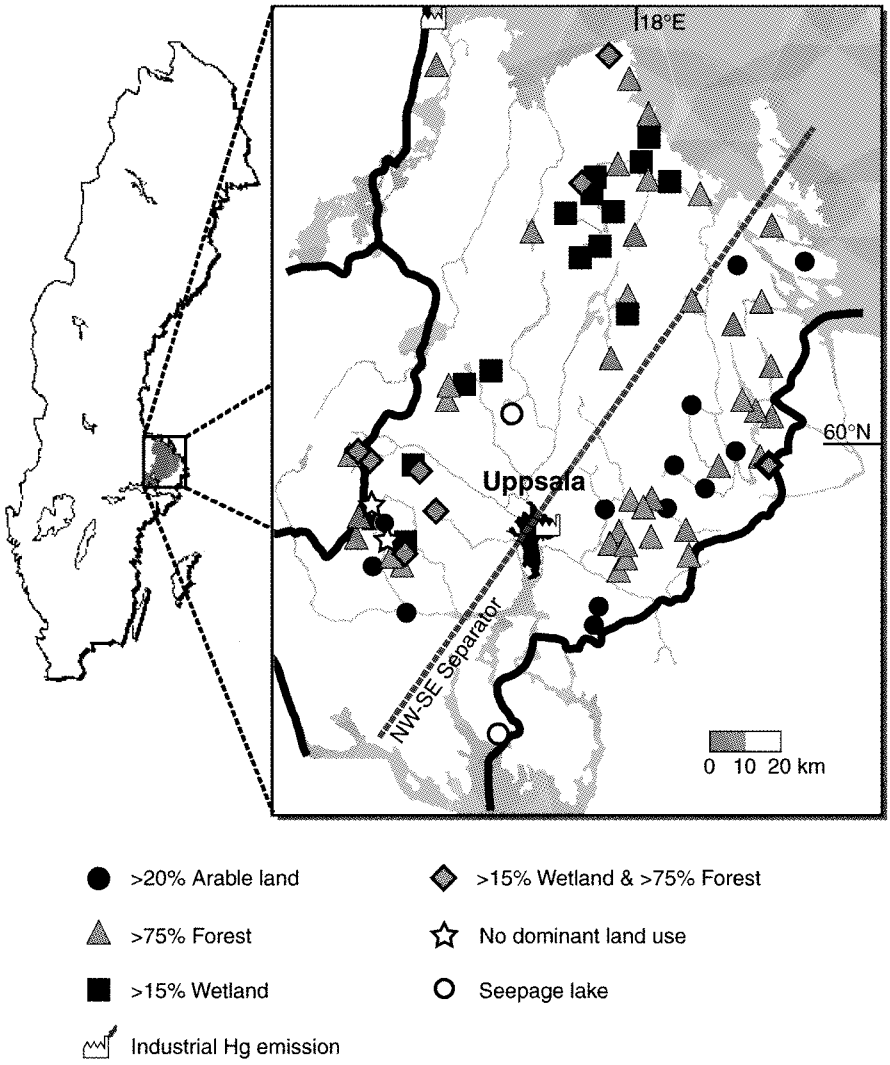

Figure 2. The geographic location of investigated lakes in the County of Uppsala, Sweden, 1991–1993. Lakes are marked according to main land use in their catchment areas. The NW–SE separator, used to separate between two geologically distinct areas, is also shown.

bustion gases (op. cit.). The chlor-alkali plant has been responsible for large Hg emissions to the air as well as to the Baltic sea (Lindqvist *et al.*, 1984). As the dominant winds in the area are from the Southwest (Skye and Lindman, 1997), most of these emissions ought to have blown out over the Baltic Sea. Additionally, the effect of these two local Hg sources on the investigated lake ecosystems are believed to be fairly small, since the impact from comparable sources generally have been detectable only in the close vicinity of the outlets (<5–10 km), even

though the major part of the emitted Hg precipitated far away from the outlets (Lindqvist *et al*., 1984; Lodenius, 1994).

2.2. Fish samples

Perch were caught by means of a standardised fishing during 1991–1993, starting in the end of July and continuing to the beginning of September each year (Nyberg, 1999). The fishing effort was standardised in relation to lake morphometry to give comparable landings, and benthic multi-mesh gillnets were used to get representative specimens of varying size (Nyberg and Degerman, 1988). The fish were handled, and skin-free dorsal muscle samples were taken and analysed for Hg content by CV-AAS, according to Sonesten (2000, 2001). The Hg analyses were made on lyophilised samples, but the Hg contents were back-calculated to wet weights (w.w.) before use. Additionally, the opercula of all specimens were used for age determination, which was later used to calculate perch growth rate.

2.3. Environmental data

Data on land use and lake morphometry is taken from the literature (Brunberg and Blomqvist, 1998 and ref. therein), with some minor additions and corrections. Distinction is made between the whole catchment area and the part closest to the lakes, which is defined as the catchment area excluding eventual sub-catchments of upstream lakes. This distinction is done because the immediate surroundings potentially have the largest influence on lakes, especially in headwater lakes, and lakes with long water retention time. The lake water chemical composition was measured on subsurface samples (0.5 m) collected concomitantly to the fishing. The capacity to withstand oxygen depletion during winter time is assessed by using the dissolved oxygen content in the lakes, after one month of ice cover, from a survey in 1988 (Sonesten, 1989). The chemical analyses were done according to Swedish Standard Methods or similar methods described in Goedkoop and Sonesten (1995).

The amount of fish caught per unit effort (CPUE) in the standardised fishing is used as an estimate on fish biomass. The landings are given as the total number and weight of all species, as well as separate measures for perch and roach (*Rutilus rutilus* L.). The roach biomass is included because small specimens are important as food for large perch and the roach biomass is also an estimate of lake eutrophication (Persson *et al*., 1991).

The lake X and Y co-ordinates within the Swedish National Grid, as well as its distance (Z) to the NW–SE separator (Figure 2), describes its geographical location. The separator divides the county into two geologically distinct areas (Sonesten, 2001). One area is the hilly fissure-valley landscapes of the southern and eastern parts of Uppsala County, and the other area is the plain with coniferous forest, mires and eskers in the north and north-western part of the county. The separator also describes the lake ontogenesis in the area, as the northwestern part

emerged from the Litorina Sea, a predecessor to the Baltic Sea, substantially earlier than the southeastern area (cf. Segerberg, 1999).

2.4. LAKE SPECIFIC MERCURY ESTIMATE

In this study, the lake specific intercept of the (linear) regression line of mercury content in perch vs. fish length, is used as a typical lake specific estimate of the basal Hg level in the perch. Some fish species, particularly carnivorous species like perch, possess a prominent Hg and fish-size covariation, which has to be taken into account during the evaluation process. Most frequently the Hg content in fish is normalised to some arbitrary fish size or the size is treated as a covariate in an analysis of covariance (ANCOVA), to circumvent the fish-size effects. In some occasions, fish within a narrow size range (usually age 0^+ or 1^+) is used to avoid the size covariation effects (e. g. Nilsson and Håkanson, 1992; Post *et al.*, 1996). The practice of normalising the Hg content or using ANCOVA's have been criticised, since the fish size covariation may not be completely removed (Somers and Jackson, 1993; Tremblay *et al.*, 1998; Sonesten, 2000; L. Sonesten, manuscript). The remaining size dependency after normalisation is an effect of non-parallel regression slopes of Hg content vs. fish size when different lakes are compared. This has the serious implication that the outcome of the study might merely be an artifact depending on the fish size used (op. cit.). It is assumed that the intercepts used in this study are good estimates of the basal Hg levels in the fish and they are believed to estimate the Hg content in age 0^+ perch (Sonesten, 2000; L. Sonesten, manuscript).

2.5. STATISTICAL EVALUATION

The impact of the different environmental variables on the mercury level in perch are statistically investigated by applying Partial Least Square regression models (also called Projections on Latent Structures or simply PLS) to the data set. PLS is a biased multivariate regression method similar to Principal Component Regression (PCR) (Höskuldsson, 1988; Garthwaite, 1994). The PLS components are similar to the principal components used in the PCR-analysis. However, there is one principal difference between the two different kinds of latent components. The PLS is a biased method as it uses the information in the response variable(s) to extract only the useful variance among the explanatory variables to form its components, i.e. the PLS maximize the covariance between the explanatory and response variable(s). This has the implication that latent components of the PLS analysis are usually smaller that comparable PCA components, but on the other hand they gives a better relationship between the X-and Y-spaces. In contrast, the PCA components of the PCR method are formed, irrespective of the response variable, in a previous principal component analysis. This procedure might even obstruct the analysis if the first PCA components are irrelevant to the response variable. Furthermore, the PLS and the PCA methods also produce two similar plots, the X-score and the

loading plots, which are vital for model evaluation. These plots are complementary and superimposable on each other. The X-scores project the relationship between observations (lakes), i.e. observations close to each other in the plot are comparatively more similar than distant observations. The loadings show the relationship between the variables. In contrast to PCA, there are two kinds of loadings in PLS, the analogue to the PCA loadings and the PLS weights. Most frequently, the weights are used, as they summarize the correlation structure between the explanatory and response variables (environmental predictors and ^{137}Hg levels, respectively). In addition to the PLS weights there are two other possibilities for model interpretation, especially suited for complex models (op. cit.). The PLS regression coefficients are summarising the information over all PLS dimensions (components), which gives one vector of model information per response variable. The VIP (Variable Influence on Projection) gives a summary of the information in the PLS weights and regression coefficients, i.e. it is pooling the information over all Y-variables and PLS dimension, resulting in one VIP-value for every explanatory variable. In comparison, the PLS weights gives both the correlation structure (multi-dimensional) and the strength. The regression coefficients give the direction (one-dimensional) and strength of the influence, whereas the VIP only gives the strength of the relationship. The VIP might be used to find the most significant explanatory variables to the model. Unfortunately, no defined limit exists for the statistical significance, but limits of 0.7–0.8 or 1.0 are often used (Eriksson *et al.*, 1999). In this study significant explanatory variables is defined as having a VIP > 1.0, a moderately significant variable having VIP = 0.8–1.0, whereas VIP < 0.8 signifies low importance.

In the model presented here, the environmental predictors are kept untransformed, as transformations did not significantly improve the model. All statistical analyses are made on predictors that are mean centred and scaled to unit variance (autoscaled). This gives all the predictors the same weight in the analyses and thereby they have the same influence on the analyses, even though they are not measured on the same scale (Geladi and Kowalski, 1986). Predictive ability of the different PLS models are estimated by cross-validation (Eriksson *et al.*, 1995; Lindgren *et al.*, 1996). Permutation tests are used to avoid spurious results caused by serious inherent background correlation. In the permutation test, the data set is analysed for latent structures by randomised reordering the response variable 25 times and retesting the model with cross-validation on every new data set. The background correlation is given by the intercepts of the permuted R^2 and Q^2 (cross-validated R^2) regressed against the R^2 of the original Hg levels and the scrambled levels (Lindgren *et al.*, 1996). The PLS models are made using Simca-P® 7.0 (Umetrics AB) and SAS® (V612 for the Macintosh, SAS Institute Inc.).

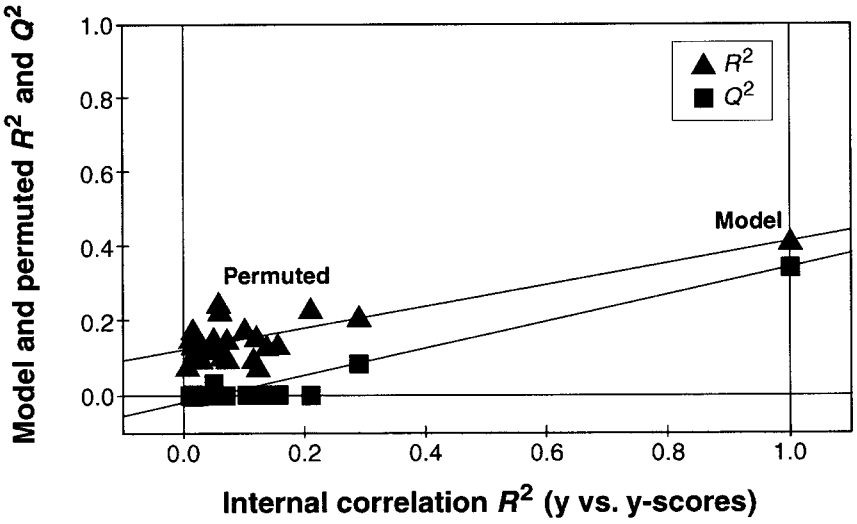

Figure 3. The PLS model on Hg levels in perch vs. 48 environmental variables is well separated from any eventual inherent background correlation, as measured by the intercepts of the permuted R^2's and Q^2's regressed against the observed Hg levels and the permuted levels (0.12 and –0.02, respectively).

3. Results and Discussion

In general, the Hg content in perch was found to be high. Out of the 78 lakes investigated, 51 lakes had at least one perch sample with a Hg content exceeding 0.5 mg Hg kg^{-1} (w.w.). Hence, in a majority of lakes the Hg concentration exceeded the internationally most common food consumption advisory level, which is also the Swedish national limit for selling the perch (NFA, 1996). Samples exceeding the Swedish food consumption advisory level 1.0 mg Hg kg^{-1} (w.w.) were found in 19 of these lakes. The range of the 573 fish samples analysed was 0.02–2.42 mg Hg kg^{-1} (w.w.), with an average content of 0.31 mg Hg kg^{-1} (Table II). Generally the Hg levels were low, in this study 90% of the samples had a content within 0.05–0.69 mg Hg kg^{-1} (w.w.). Though, high Hg levels were often found in a few (large) specimens. The observed Hg levels in perch are well within the range of other studies on Hg content in perch in Northern Europe (Table II). Great care should though be taken when comparing different data sets because of the strong covariation of the Hg content with fish size, implying that comparisons have to be made between fish of similar size.

3.1. PLS MODELS EVALUATING THE ENVIRONMETAL IMPACT ON Hg LEVELS IN PERCH

The environmental impact on the mercury level in the perch (as measured as the intercept of the lake specific linear regression of Hg content in perch vs. fish

TABLE II

Mercury content in perch (*Perca fluviatilis* L.) in European lakes and reservoirs, including the present study

Hg content (mg kg^{-1} ww)		Fish size	No. of lakes	Country	Reference	Comments
Lake average	Sample range					
0.35–1.4	0.12–2.6	?	20	Finland	Verta *et al.*, 1986	Acid and brownwater reservoirs
	0.04–0.4	'Small'	8	Sweden	Lindqvist *et al.*, 1991	Slightly acid brown water lakes

	0.02–2.42	1–1160 g	78	Sweden (County of Uppsala)	**Present study**	Circumneutral forest and plain country lakes
	0.02–0.66	<50 g	78			
	0.08–2.42	>200 g	78			

length) was analysed by several PLS models describing different features as spatial grouping and potential outliers. As all models were consistent regarding the major environmental influence in explaining the observed mercury levels in perch, only the simplest model will be presented here. All models were also consistent in explaining about 41–44% of the variation in Hg level in perch, using about 24% of the variation of the environmental variables (Table III). This illustrates how PLS uses only a limited but significant amount of information from the X-matrix, which is a great advantage in comparison to ordinary multiple linear regression techniques (MLR). The MLR would incorporate the remaining 76% of the variation in the x-matrix, which was found to be excessive in the PLS analysis. The result would be addition of 'noise' into the model and, consequently, it becomes 'overfitted'. This is indicated by the large difference of the MLR model R^2 and R^2_{adj} (0.77 and 0.42, respectively). On the contrary, the cross-validation of the PLS model, which gives the predictive ability and the stability of the model, agrees well with the explained variance ($R^2 = 0.41$, $R^2_{adj} = 0.40$ and Q^2 (i.e. cross-validated R^2) = 0.34). If more components are added to the model, the predictive ability and the model stability are drastically reduced (Table III), which indicates overfitting by noise addition. Actually, a full ranked PLS model, i.e. the same number of latent components as X-variables, would be the same as the MLR model. The model R^2 and Q^2 are also well separated from any spurious background correlation, caused by an inherent structure in the environmental data, as the intercepts of the permuted R^2's and Q^2's (0.12 and –0.02, respectively; Figure 3) are well separated from the model. Even though the model contains only one significant PLS component, two-dimensional plots of the X-scores and the PLS weights are used to increase the interpretability of the model. The significant first component is of course emphasized in the interpretation.

3.2. Land use effects on Hg in perch

Among the X-scores, a pattern showing the strong impact of land use in the lake catchment areas is eminent (Figure 4). All lakes but four have at least 50% of their catchment area covered by forests, but lakes that are comparatively more affected by arable land are generally found in the left part of the X-scores plot, whereas lakes highly influenced by wetlands in their surroundings are on the right side. Three lakes are detected as potential outliers by their X-scores (Figure 4), but as they do not have any exceptionally strong influence on the analysis, they are considered as lakes in the margin of the investigated lake types and therefore kept within the model. Lakes with high amounts of wetlands in their catchment areas deviates from the model, especially the lakes in the lower right corner of the X-scores plot (Figure 4). These lakes probably exert some particular properties that are not fully described by the presently investigated environmental variables. This phenomenon is also seen when the environmental impact on the Hg content in roach (*Rutilus rutilus* L.) is analysed (Sonesten, 2001). It also illustrates the

TABLE III

Percent variation explained (R^2) and predictive ability (Q^2) of the PLS model on Hg levels in perch vs. 48 environmental predictors (cf. Table I). The variation in the X-matrix (X) used by the model is also given

PLS	Percent variation			
component	X	R^2	R^2_{adj}	Q^2
1	24	41	40	34
2	29	59	58	22
3	36	65	63	<0
4	42	67	66	<0
5	48	69	67	<0
6	54	70	68	<0

importance of the surrounding soils on the Hg turnover in lake ecosystems, which warrants further studies, especially on the influence of different kinds of wetlands on Hg bioavailability.

3.3. Environmental influence on Hg level in perch

Five distinct functional groups of the most important environmental variables are apparent in the PLS weights plot (Figure 5) and the PLS regression coefficients (Figure 6). These groups describes:

(i) the spatial location (X and Y co-ordinates and Z [cf. Figure 2]);
(ii) the amount of dissolved ions in lake water (Conductivity, Ca, Mg, Na and K);
(iii) the lake nutrient status (Total P and N, and fish stock characteristics);
(iv) main land use (arable land, forests, wetlands and urban areas);
(v) the influence of humic matter (water colour, TOC and Fe).

The importance of the separate environmental variables are illustrated by the PLS regression coefficients for the first significant component (Figure 6). The major groups of explaining factors are the same groups as are found for the Hg content in roach (Sonesten, 2001). Also, the directions of their influence in the weights plot are virtually the same as in the Hg in roach model (cf. Sonesten, 2001), which strengthens the accuracy of the two different models, as well as the interpretation of the underlying causes to the observed Hg levels in the fish. Additionally, the most important single factor in explaining the Hg level in perch is the Hg content in roach

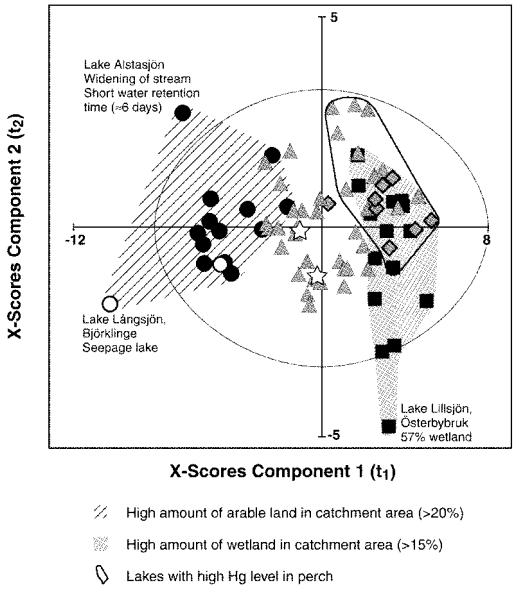

Figure 4. Similarities between the lakes, as given by the X-scores (t_1, t_2) for the 1st and 2nd latent PLS components of the model on Hg levels in perch vs. 48 environmental variables. The ellipse shows Hotelling's T^2 with significance level $p = 0.05$. Symbol explanations as given in Figure 21. Note! The figure is complementary to Figure 4.

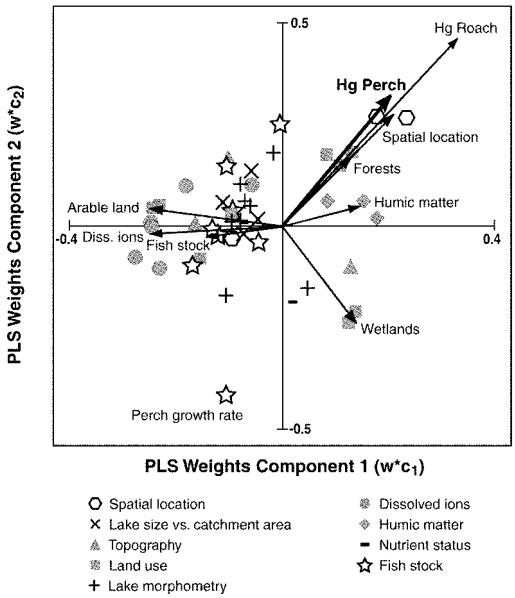

Figure 5. The correlation structure between environmental predictors and the observed Hg levels in perch, as given by the PLS weights (w^*c_1 vs. w^*c_2) for the 1st and 2nd latent PLS components. The most important environmental variables are subjectively grouped into functional groups (arrows) giving the direction and an approximation of the strength of the correlative relationship. Note! The figure is complementary and superimposable to Figure 4.

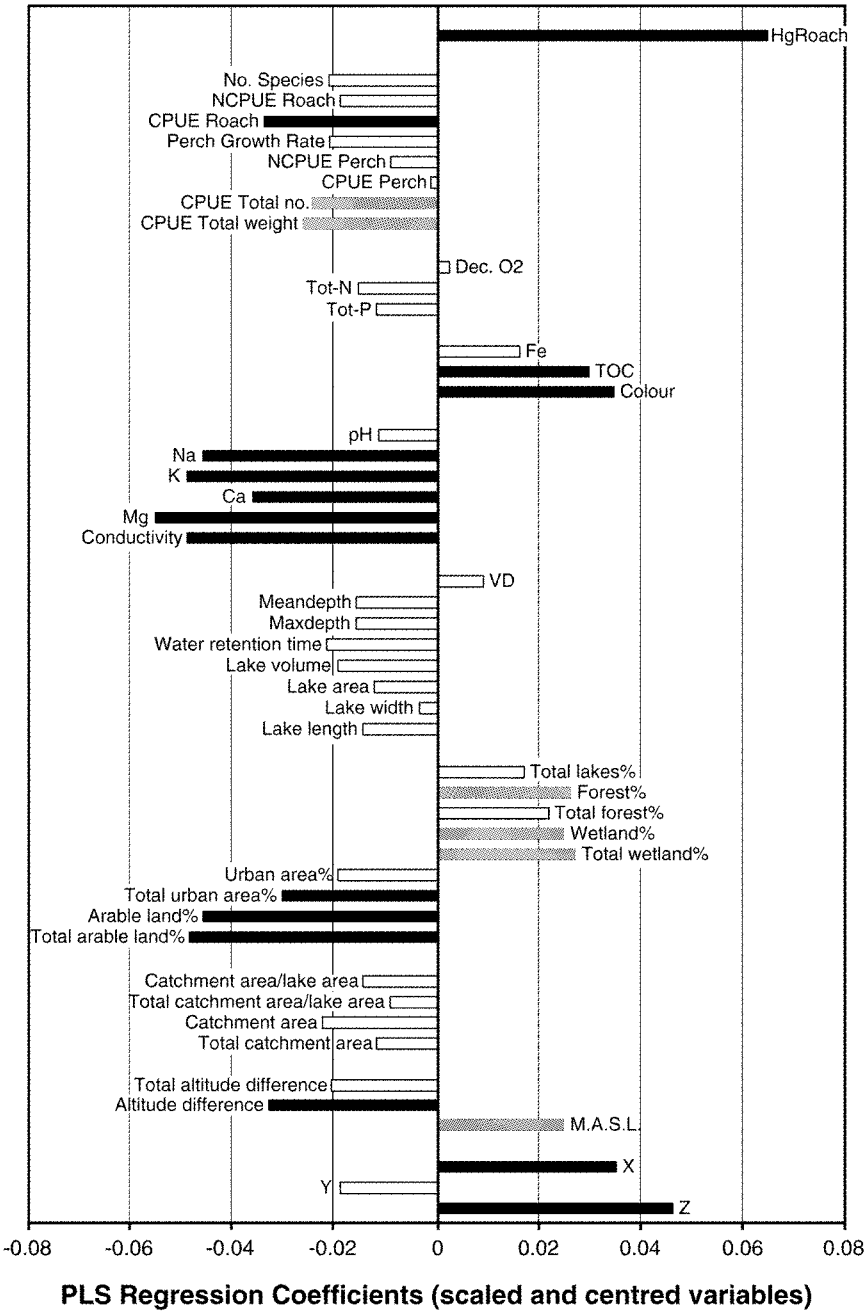

Figure 6. The PLS regression coefficients for the significant first PLS component of the Hg levels in perch vs. 48 environmental variables. The coefficients are on autoscaled variables for immediate comparison of influence. Black bars illustrates highly significant influence on the model (Variance Influence on Projection, VIP > 1.0); Gray bars shows moderate significant influence (VIP = 0.8–1.0); White bars indicates low influence (VIP < 0.8).

(Figures 5 and 6). Due to the similarities of the two models, this highly significant influence is interpreted to be a measure of the 'Hg burden within the lake biomass' and not necessarily, a measure of the Hg content in the perch food items. This is assumed as the investigated Hg levels (the intercepts of the Hg vs. length regressions) in perch are believed to estimate the Hg content in young-of-the-year specimens, which generally are believed to still have not turned to piscivory (Persson *et al.*, 2000).

High Hg level in fish is a common problem, especially in low productive (acidic) dystrophic softwater lakes, all over the boreal forest zone (Björklund *et al.*, 1984; Verta *et al.*, 1986; Meili, 1994; Wren *et al.*, 1991; Haines *et al.*, 1995; Sonesten, 1993, 1997, 2001). Due to the severe multicollinearity between the components in the humus, dissolved ions, pH, available nutrient complexes, it is difficult to reveal the causal effect(s) on the fate of Hg in lake ecosystems (Meili, 1994). A serious problem is the chelating properties of humic substances binding phosphorous and cations, e.g. Ca^{2+} and Mg^{2+} (cf. Hessen and Tranvik, 1998). An additional complication is the coagulative properties of Ca^{2+} and Mg^{2+} on humic substances, resulting in precipitation of the complexes (Stumm and Morgan, 1981). Altogether, these negative relationships between humic matter and P, Ca and Mg, makes dystrophic lakes generally have low amounts of dissolved ions (low salinity) and low amounts of easily bioavailable nutrients. Accordingly, it also makes high salinity lakes to be predominantly low in humic DOC (Stumm and Morgan, 1981). The deviant behaviour of wetland lakes in the present study, suggest that there are at least two, possibly three, co-occurring processes governing the observed Hg levels in fish. The two most plausible processes are the co-transport of Hg with humic substances from surrounding soils and biodilution. The Hg co-transport with humic substances is suggested to cause the high Hg level in fish from brownwater lakes (Mierle and Ingram, 1991) and biodilution of methylmercury is suggested to be the reason for the low levels in eutrophic lakes, due to the higher total biomass that the Hg is distributed within (Lindqvist *et al.*, 1984; Meili, 1994). A third possible process may be acting upon the wetland lakes. These lakes can be classified, by their PLS weights and regression coefficients (Figures 5 and 6), as being predominantly small, shallow lakes at comparatively high altitude with small altitude differences within the catchment areas. As mentioned before, these lakes are not completely modelled by the present study, and needs to be investigated further.

In dystrophic ecosystems, an overall high Hg transfer from the surroundings results in a high total amount of Hg in the lakes. A major part of this Hg is inorganic, but potentially available for methylation and bioaccumulation. In many recent studies wetlands *per se* have been found to be a major source of methylmercury, especially in headwater lakes with comparatively short turnover time (St. Louis *et al.*, 1994; Verta *et al.*, 1994; Bishop *et al.*, 1995; Branfireun *et al.*, 1996; Kelly *et al.*, 1997), but there are large differences in methylmercury output from different kinds of wetlands (St. Louis *et al.*, 1996). These studies also have revealed the importance of the methylating and demethylating capabilities of wetlands in changing the

Hg bioavailability within the systems. Consequently, the final amount of Hg that reaches the biota will depend on the Hg bioavailability, which in turn is dependent on the net methylation capacity within the whole system. Additionally, both the bioavailability and the methylating/demethylating capacity are also intricately affected by the amount of dissolved organic matter (DOC) in the lake water, but this subject is not completely revealed and beyond the scope of this study.

The organic-rich topsoils of arable land in this region contains on average more Hg (10–15 kg Hg km^{-2}; SCB, 1990; Klang and Eriksson, 1997), than do the corresponding mor layer of forested soils (2–2.5 kg Hg km^{-2}; Nilsson *et al.*, 1989). This suggests that Hg to a larger extent is retained in cultivated soils, whereas the Hg is more readily leached out from forested soils. This finding, together with the strong impact of land use on the basal Hg level in fish, suggests that the transport of Hg from the catchment area is crucial to the observed high Hg levels in fish in boreal forest lakes. At the moment, no data is available on Hg concentrations in water or various parts of the catchment areas. Instead, this study reflects the net effects of the different processes that affect the Hg levels in perch. Altogether, this strengthens the earlier postulation that more research is needed to elucidate the influence of surrounding catchment areas, and especially the wetlands, on Hg levels in fish. Such an investigation should preferably be made in a few typical catchment areas, and should include bioavailable Hg concentrations in water and Hg fractions in surrounding land.

3.4. Lack of lake pH effect on Hg in perch

Interestingly, lake pH is shown to have only a limited impact on the Hg level in perch (Figure 6). The possible effects of lake acidity on Hg in living organisms are exhaustively investigated in other studies, but with very divergent results (cf. Richman *et al.*, 1988; Winfrey and Rudd, 1990; Downs *et al.*, 1998). The causal impact of lake pH on Hg turnover in lakes is therefore questioned and a plausible explanation to the occasionally observed relationship might be the covariation of pH with lake water colour and productivity (Meili, 1994). Possibly, the very divergent results could be due to the fact that, in most studies correlations or (stepwise) multiple linear regressions (MLR) are used to analyse the environmental impact on the Hg content in biota. These methods are very sensitive to intercorrelations between the variables and causal effects are hard to reveal. MLR is even improper to use, as the method does not permit serious interdependencies among the x-variables (Draper and Smith, 1981). This is likely to result in spurious conclusions about causal relationships, especially if stepwise selection of the variables is used (Eriksson *et al.*, 1995).

4. Conclusions

This study on Hg in perch from circumneutral hardwater lakes demonstrates that:

(i) The Hg level is comparable to levels found in other studies on perch, mainly in more acidic softwater lakes, in Northern Europe.
(ii) The Hg level in the perch is greatly affected by the catchment area composition and land use.

The lowest Hg levels in perch are observed in lakes strongly influenced by arable land and having high concentrations of dissolved ions in the lake water. Lakes dominated by forests in the catchment area have, on the other hand, generally high Hg levels in fish. Lakes predominantly affected by wetlands are found to possess deviating properties, which could not be explained in this study and warrants for further studies.

Additionally, some lake water characteristics are found to have a high influence on the Hg level in perch. Especially important are:

(iii) The negative influence of dissolved ions (Conductivity, Ca, Mg, Na and K).
(iv) The negative influence of lake trophic status (Total P and N, fish stock characteristics).
(v) The positive influence of the TOC/humic matter complex. On the contrary, lake pH does not seem to have any large influence on the Hg level in perch from circumneutral lakes.

(*Received* 31 *March* 1998; *Accepted* 20 *October* 1998)

Abstract—The sediment, water, and three species of fish from 24 of Massachusetts' (relatively) least-impacted water bodies were sampled to determine the patterns of variation in edible tissue mercury concentrations and the relationships of these patterns to characteristics of the water, sediment, and water bodies (lake, wetland, and watershed areas). Sampling was apportioned among three different ecological subregions and among lakes of differing trophic status. We sought to partition the variance to discover if these broadly defined concepts are suitable predictors of mercury levels in fish. Average muscle mercury concentrations were 0.15 mg/kg wet weight in the bottom-feeding brown bullheads (*Ameiurus nebulosus*) (range = 0.01–0.79 mg/kg); 0.31 mg/kg in the omnivorous yellow perch (*Perca flavescens*) (range = 0.01–0.75 mg/kg); and 0.39 mg/kg in the predaceous largemouth bass (*Micropterus salmoides*) (range = 0.05–1.1 mg/kg). Statistically significant differences in fish mercury concentrations between ecological subregions in Massachusetts, USA, existed only in yellow perch. The productivity level of the lakes (as deduced from Carlson's Trophic Status Index) was not a strong predictor of tissue mercury concentrations in any species. pH was a highly (inversely) correlated environmental variable with yellow perch and brown bullhead tissue mercury. Largemouth bass tissue mercury concentrations were most highly correlated with the weight of the fish (+), lake size (+), and source area sizes (+). Properties of individual lakes appear more important for determining fish tissue mercury concentrations than do small-scale ecoregional differences. Species that show major mercury variation with size or trophic level may not be good choices for use in evaluating the importance of environmental variables.

Keywords—Mercury Fish Perch Bullhead Bass

INTRODUCTION

During the past 10 years, a growing awareness of the problem of high mercury concentrations in freshwater fish has generated a proliferation of studies at the international [1–3], national [4,5], and state [6,7] levels.

Massachusetts has surveyed contaminants in freshwater fish since 1983 [8], focusing primarily on areas of known or suspected contamination or on areas where biological effects were observed. These studies have shown that the variation in fish mercury contamination is relatively high in surface waters. Concentrations have been sufficiently high in some species to warrant the issuance of Fish Consumption Advisories for specific water bodies as well as a statewide health advisory cautioning pregnant women of the possible health risk associated with eating fish from Massachusetts freshwater bodies (excluding stocked and farm-raised fish).

Many factors contribute to the dynamics of contaminant accumulation in fish populations. An ecoregional approach partially explained geographic variation in fish mercury concentrations [9]. Lake productivity and lake trophic status affect the accumulation of persistent pollutants in fish [10]. The complexity of the definitions of ecoregion and lake trophic status makes these concepts potentially apt descriptors for ecosystems, which are inherently complex systems.

* To whom correspondence may be addressed (michael.hutcheson@state.ma.us).

Two ecoregions and 13 ecological subregions have been delineated in Massachusetts [11]. Shared components of ecoregions included soils, vegetation, climate, geology, and physiography. Patterns of animal migration and land use were also used to delineate ecoregions. Lakes in Massachusetts are either glacial (~10,000 years old) or they date back to the last mountain-building episode, roughly 200 million years ago. Most lakes were altered in colonial times to increase their utility to industrious New Englanders. The ecoregion concept may prove to be an effective tool for statistical analysis, research, and assessment of environmental resources, because it characterizes relatively homogeneous geographic regions, incorporating more information than do individual physical or chemical measurements.

In this study, yellow perch (*Perca flavescens*), largemouth bass (*Micropterus salmoides*), and brown bullheads (*Ameiurus nebulosus*) were sampled for muscle mercury concentration determinations in 24 lakes not likely to have been affected by nonpoint sources (e.g., landfills, industrial facilities, hazardous waste sites, wastewater treatment facilities). We also attempted to determine the relative degrees of influence on these concentrations of geographic location as well as lake biological, physical, and chemical characteristics.

MATERIALS AND METHODS

Lake selection

The lakes chosen for sampling were identified on the basis of the region of the state in which they were located and the

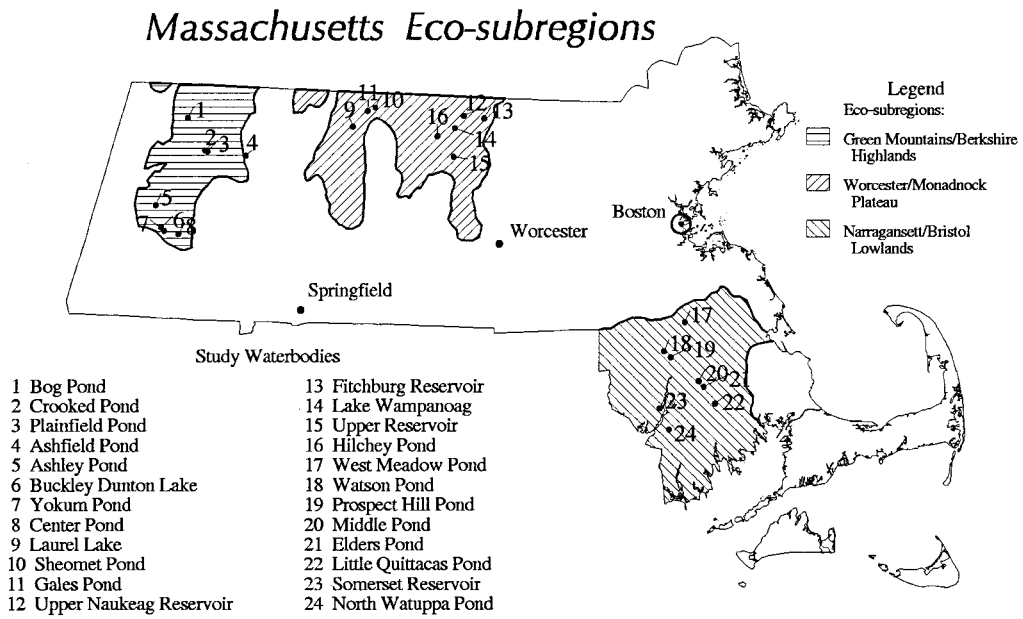

Fig. 1. Subecoregions of Massachusetts and study lake locations.

degree of development on or near the lakes. Eight lakes within each of three ecological subregions [11], representing contrasting environmental settings in Massachusetts, were selected (Fig. 1).

The Green Mountain/Berkshire Highlands subregion, located in northwestern Massachusetts, is characterized by relatively high elevations, which reach approximately 305 to 762 m above mean sea level. Metamorphic geology composed of schists, gneiss, and marbles creates a steep terrain that is overlaid by thin deposits of glacial till. Forest types include northern hardwoods (maple, beech, birch), spruce, and fir. Surface waters are generally low in phosphorus, with alkalinity under 200 μg/L [11].

The Worcester/Monadnock Plateau is located in the north-central part of the state at 152 to 457 m above sea level. The monadnocks are formed of granite plutons that dominate the surrounding geology of metamorphic schists and gneiss. Forest types include transition hardwoods (maple, beech, birch; oak, hickory) and some northern hardwoods. Surface waters are poorly buffered and acidic, with alkalinities generally between 50 and 100 μg/L [11]. Some surface waters exhibit moderate to high concentrations of dissolved organic compounds.

The Narragansett/Bristol Lowland is located in the southeastern part of the state. The landscape of this region consists of flat to rolling plains that seldom exceed 61 m above mean sea level, with numerous wetlands and bogs. Extensive deposits of glacial till and outwash material make up the soils and sediments. Central hardwoods (oak, hickory) are common, as are elm, ash, red maple, cottonwood, white pine, and red pine. Phosphorus in surface waters ranges widely, and alkalinities are in the 50 to 400 μg/L range [11].

The suitability of each lake identified in each ecosubregion on U.S. Geological Survey (USGS), 7.5′ series topographical maps was assessed using the following exclusion criteria in order to identify 24 lakes for study: surface area less than four hectares; proximity to concentrated urban, agricultural, or industrial areas; evidence of impact from human activities based on prior studies [12,13]; potential point or nonpoint sources of pollution.

Lake watershed areas were delineated based on USGS topographic quadrangles. Wetlands within the watersheds were delineated from U.S. Fish and Wildlife Service National Wetlands Inventory maps (1:24,000) and from stereoscopic analysis of high-altitude aerial photographs. Lake areas were calculated from digitized 1:25,000 coverages or from USGS topographic quadrangles.

Fish, water, and sediment sampling

The test species were selected principally because they encompass a range of fish trophic levels. Largemouth bass are fish-eating predators, although their diet also includes invertebrates and amphibians. The species did not occur in all of the study lakes. Yellow perch are omnivorous, consuming insects, invertebrates, and other fish, and brown bullhead are bottom-feeding omnivores [14].

Nine individuals of each species were targeted for collection from each lake. Fish sampling was conducted in the early fall after summer spawning. Total length criteria of 20 to 25 cm for yellow perch and brown bullhead and 30 to 36 cm for largemouth bass were established. The larger size was selected for largemouth bass because 30.5 cm is the legal minimum size limit for this species and may be representative of fish retained for consumption. Fish obtained by electrofishing, gill netting, and trot lines were rinsed in ambient water, chilled on ice, wrapped individually in aluminum foil, placed inside polyethylene zip-lock bags, and delivered to the laboratory on ice within 24 h of collection.

Water-quality sampling was conducted during midsummer, not coincident with fish sampling but during the period when lakes would be thermally stratified and when measures of degree of eutrophy might be strongest. In stratified lakes, a composite sample of water taken from the deepest part of the lake at 1.5 m below the surface, taken at mid-thermocline, and taken at 1.5 m above the bottom was prepared. The composite was then divided into three precleaned glass containers for chemical analyses. Single samples were taken from mixed lakes (non–thermally stratified) at 1.5 m below the surface. All water-quality sampling and handling was performed in accor-

dance with U.S. Environmental Protection Agency (U.S. EPA) protocols [15]. The following parameters were measured in the field using a Datasonde® Hydrolab (Hydrolab, Austin, TX, USA): pH, dissolved oxygen (DO), temperature, depth, and conductivity. Water clarity was measured using a Secchi disk. Chlorophyll *a* samples were taken at the deepest part of the lake, 1.5 m below the surface. The samples were filtered in the field following U.S. Environmental Monitoring and Assessment Program (EMAP) protocols [15].

Sediments were sampled using an Ekman dredge (GENEQ, Montreal, QC, Canada) at two locations in each body of water—at the deep hole and halfway to a shore. These samples were combined. In addition, a replicate sample was taken at the deep hole. Precleaned, wide-mouthed glass jars were inverted and pushed into the portion of sediment sample away from the sides of the dredge and were then capped with Teflon®-lined caps (VWR, Canlab, Mississauga, ON, Canada) and placed on ice for shipment to the lab. All sediment sampling and handling was performed in accordance with U.S. EPA protocols [15].

Laboratory methods

Fish specimens were processed for analysis in accordance with U.S. EPA procedures [16]. Dissection and tissue homogenization were conducted in a small, clean laboratory (not class 100) dedicated for fish processing.

Individual fish homogenates were analyzed for total mercury by cold-vapor atomic absorption spectrometry, using U.S. EPA method 245.6 [17], within their recommended holding-time limit for mercury (28 d) [16]. All handling of fish homogenates prior to analysis was conducted in a laminar airflow polypropylene fume hood for trace metal analysis that exceeds federal standard 209B for class-100 clean benches. Trace metal–grade sulfuric and nitric acids were used for fish sample digestions. The method detection limit (MDL) for mercury analysis in fish tissue of 0.020 mg/kg was experimentally determined using the conventional U.S. EPA procedure [18]. Accuracy for spiked fish samples and precision of the analyses were 104 ± 12.4 and 12.1 ± 9.7% (means ± 1 SD). The reference standard for mercury in fish tissue was freeze-dried oyster tissue (NBS 1566A). The accuracy of analyses of that standard was 101 ± 14.1%. Mercury in all laboratory reagent blanks was less than the MDL of 0.0002 mg/L.

Water-column samples were analyzed for chloride, using the argentometric method [19]; for calcium, using inductively coupled plasma–atomic emission spectrometry (ICP-AES) using U.S. EPA method 200.7 [20]; for sulfate, using turbidimetric nephelometry using U.S. EPA method 375.4 [21]; for ammonia-N (MDL = 0.02 mg/L), nitrate-N (MDL = 0.02 mg/L), and total phosphorus (MDL = 0.01 mg/L), using automated colorimetry on an autoanalyzer using U.S. EPA methods 350.1 [22], 353.1 [17], and 365.4 [17], respectively; and for dissolved organic carbon on glass-fiber–filtered samples, using ultraviolet (254-nm) absorbence, with potassium biphthalate as the standard [19].

Sediment samples were analyzed for total mercury and selenium. Sample aliquots for mercury analysis were digested in concentrated nitric and sulfuric acids and analyzed by cold-vapor atomic absorption spectrometry using U.S. EPA method 7471A [23]. For total selenium, the sediment samples were digested according to U.S. EPA method 3050A [23] and were analyzed by graphite furnace atomic absorption spectrometry using U.S. EPA methods 7060A and 7740 [23]. Accuracy for field sediments and precision for mercury determinations were 104 and 0.8%, respectively, and for selenium, they were 80.5 and 5.8%, respectively,. All reagent blanks were less than mercury and selenium MDLs of 0.0002 and 0.002 mg/L. The reference standard for sediments was dry river sediment (NBS 1645). Accuracies of analyses of that standard were 98 and 82% for mercury and selenium, respectively. Trace metal–grade acids were used for these analyses. Analyte concentrations were expressed as μg/g (dry weight).

Statistical methods

The number of each species of fish to be sampled in each lake in order to provide adequate statistical validity to the results was determined using fish mercury-concentration sampling variance from 10 years of monitoring in Massachusetts [8] and following consideration of available resources for fish collection and analysis.

Bivariate plots of all pairs of variables were also visually examined for outliers. Prior to statistical analyses of the raw tissue concentration data, the data were examined with linear regression analysis for correlations between mercury content and fish size (length or weight).

Lake trophic states were characterized with Carlson's Trophic State Index (TSI)[24], which gives a scaled measurement of water quality. Chlorophyll *a* measurements were used to calculate TSIs using the formula TSI = 30.6 ± 9.81 ln Chlorophyll *a* (mg/m^3) [25]. The TSIs of water bodies are scaled from 0 to 110, with oligotrophic lakes between 0 and 39, mesotrophic lakes between 40 and 50, and eutrophic lakes between 51 and 110. Lakes were grouped into these three categories. Because of their small number, mesotrophic lakes were grouped with eutrophic lakes for analyses of variance (ANOVA). The oligotrophic and eutrophic or mesotrophic categories were coded as 5 and 4 for statistical analyses. Subecoregions were numerically coded for analyses as follows: 1, Green Mountain/Berkshire Highlands; 2, Narragansett/Bristol Lowland; 3, Worcester/Monadnock Plateau.

The relative importances of the geographical locations of lakes (three subecoregion levels) and of their trophic states (two levels) were assessed with fixed-constants Model I ANOVA of mean lake tissue mercury concentrations, with replication for both yellow perch and brown bullhead. A separate analysis of covariance (ANCOVA) of mean lake tissue mercury concentrations across ecoregions and trophic states, using fish weight as a covariate, was performed for largemouth bass because of an observed relationship between weight (or total length) and mercury concentrations in this species [26]. Lake mean mercury values for each species were normally distributed (Kolmogorov–Smirnov test statistic with an α of 0.05 [26]); therefore, no data transformation was necessary to satisfy normality assumptions. We found unequal regression slopes [26] of tissue mercury on weight between lakes for largemouth bass and brown bullhead and equal slopes for yellow perch. These results were interpreted to mean that fish weight may have a differential effect on fish mercury concentrations between lakes for brown bullhead and largemouth bass. The effect of size may not have been removed from the data set for these two species even if ANCOVA was used to standardize mercury concentrations to a standard-sized fish [27]. Consequently, we chose to treat fish weight as an independent variable in all of our subsequent statistical procedures.

The multivariate data set was analyzed by factor analysis

[28] to assess which environmental parameters might influence regional differences associated with the bioaccumulation of mercury. Pearson's product moment correlation matrices for each species's mercury concentrations and environmental data were calculated. A varimax normalized rotation strategy was needed only with the bullhead data set to improve the separation of variables on factors. In factor analysis, the number of variables analyzed is limited to the number of cases. All species of fish were not available in every lake. We collected brown bullhead in 22 lakes, largemouth bass in 19 lakes, and yellow perch in 22 lakes. Stepwise multiple regressions were used to eliminate poorly correlated variables. Initially, the factor analysis was computed for two factors. The number of factors was increased iteratively until mercury in the species being analyzed scored high on only one factor. All statistical evaluations were performed with the Statistica/W, Version 5.0 software package (StatSoft, Tulsa, OK, USA).

RESULTS

Summary statistics for mercury concentrations in each species in the 24 lakes are presented in Table 1. Nine individuals of each species were not obtained in all water bodies. The results of physical and chemical sampling and measurement are contained in Tables 2 and 3. The pH value of 10.5 for Prospect Hill Pond (Table 2) was eliminated from further analysis as an outlier, since other chemical values for this pond suggested inconsistencies. Results for water ammonia-N, nitrate-N, and total phosphorus are not shown, as the majority of results were below method-detection limits.

Brown bullhead generally had the lowest muscle mercury concentrations, with mean tissue concentrations of 0.15 mg/kg wet weight (range = 0.01–0.79 mg/kg, 95th percentile concentration 0.32 mg/kg); yellow perch were intermediate, with 0.31 mg/kg (range = 0.01–0.75 mg/kg, 95th percentile concentration 0.57 mg/kg); and largemouth bass were highest, with 0.39 mg/kg (range = 0.05–1.1 mg/kg, 95th percentile concentration 0.91 mg/kg) (Table 1). The distribution of individual values of largemouth bass tissue mercury concentrations was somewhat similar to the log-normally distributed mercury concentration values in yellow perch and brown bullhead, in the concentration range of 0.2 to 0.6 mg/kg, but the bass distribution had a tail to the right beyond 0.6 mg/kg, with upper concentrations up to 1.1 mg/kg (plots not shown).

Largemouth bass are the only one of the three species in this study that exhibited a significant correlation ($r = 0.72$; p for H_0; $\rho = 0$ was 0.01) between fish length and mercury content for the combined data set. Similar relationships existed for weight (not shown). Correlation coefficients for regression equations of mercury on length for each species for individual lakes also generally exhibited the same pattern. The slopes of these regression lines were not equal among lakes for largemouth bass ($F_{16,116} = 4.74$; $p \leq 0.01$) and brown bullhead ($F_{17,125} \leq 3.59$; $p \leq 0.01$). They were equal for yellow perch ($F_{20,147} = 1.44$; $p = 0.11$).

The lake trophic-state indicator values ranged from 19 to 75, with 13 lakes falling in the oligotrophic range, 7 lakes in the mesotrophic range, and 4 lakes in the eutrophic range (Table 3). Analyses of variance showed no significant differences in tissue mercury concentrations ($p > 0.05$) between lakes of different trophic states for any of the three species. The ANOVA also determined that significant differences in fish mercury concentrations between subecoregions existed only in yellow perch ($p = 0.05$; $F_{2,16} = 3.62$) (Fig. 2). Regionally, the Narragansett/Bristol Lowlands subecoregion and the Green Mountain/Berkshire Highlands subecoregion have somewhat lower mercury in all species than does the Worcester/Monadnock Plateau.

Mercury concentrations in bass (Fig. 3a) were most strongly positively associated with the weight of the fish, lake size, and variables representing potential source area–contribution sizes (wetlands and watersheds). Mercury concentrations in this species did not correlate with either subecoregion or lake trophic state. Sediment mercury and selenium score high on an independent factor that also correlates with low DO. These two factors explained 46% of the variance in the data set. Mercury concentrations in yellow perch have a high negative correlation with factor 1 (Fig. 3b), while at the opposite end of the factor are high positive correlations for pH, conductance, and calcium, indicating inverse correlations between the tissue mercury and these lake chemistry variables. Variables loading orthogonal to this factor on factor 2 are primarily indicators of lake trophic status and are independent of the species' mercury concentrations. These two factors explained 43% of the total variance in the yellow perch data set. Mercury concentrations in brown bullhead tissue and pH had high opposite sign-factor scores on factor 6 (Fig. 3c). Trophic state indicator variables (DO, chlorophyll *a*) were independent of tissue mercury patterns, having high absolute value scores on factor 1. These two factors explained approximately 29% of the variance in the data set.

DISCUSSION

This study of the variation and possible determinants of fish tissue mercury in relatively non–source affected fresh water lakes in Massachusetts revealed that the order of species mercury concentrations, within the size ranges of fish sampled, was largemouth bass > yellow perch > brown bullhead. The largemouth bass sampled were primarily in the 4+ and 5+ year classes. Comparable mean concentrations to the 0.39 mg/kg for this data set for similarly aged fish in Michigan and Wisconsin data sets were 0.43 and 0.33 mg/kg [6], and they were 0.59 and 0.65 mg/kg in Lake Tohopekaliga, Florida [29]. The mean yellow perch mercury concentration of 0.31 mg/kg primarily represented fish in the 4+ and 5+ year classes. Comparable means for these year classes of yellow perch from other studies were 0.36 and 0.43 mg/kg in the Adirondacks of New York State [30] and 0.25 and 0.27 mg/kg in the Upper Peninsula of Michigan and in Wisconsin [6]. The majority of brown bullhead represented the 2+ through 4+ year classes. The interspecific differences in tissue mercury concentrations recorded in this study were consistent with observations from other studies using the same species or species representing the same trophic level [6,31,32]. They are also consistent with a priori considerations of the trophic level at which each species functions.

Variation in fish muscle mercury concentrations may be the result, in varying degrees, of biological variability associated with the species themselves (age, size, physiology, diet), of geological influences (bedrock and sediments), of chemical variability (water quality and mercury biogeochemistry), of physical variability (e.g., water temperature, lake and watershed size), and of other influences, such as climate and atmospheric deposition [33].

In our study design, we sought to control several sources of potential variation in tissue mercury concentrations. Seasonal influences on fish physiology and subsequently on fish

mercury concentrations were reduced by the choice of sampling time. Control of the influence of fish size and age on tissue mercury was accomplished by confining our sampling to restricted size ranges of fish. In practice, a wider size range of fish than intended was obtained. However, the lack of correlation, over all samples, between mercury concentration and size in yellow perch or brown bullhead suggests that our attempt to control for fish size by limiting the size range during

Table 1. Continued

capture was successful. The observed relationship with size and mercury in bass may be related to interspecific variation in the kinetics of mercury bioaccumulation [32]. Largemouth bass are long-lived and have the largest body sizes and probably the lowest rates of growth and metabolism at older ages [14]. They are also the only species studied here that had a positive, significant correlation between mercury and weight. Yellow perch and brown bullhead have smaller body sizes, shorter lifespans (in the case of perch), and, presumably, higher rates of growth and metabolism. The older, slower growing fish had longer times to accumulate and concentrate mercury (as a result of more uptake than excretion), because growth dilution of methylmercury is not sufficiently rapid to offset this effect. In the other two species, the higher growth rates may have resulted in growth dilution of their body burdens of mercury, thereby offsetting possible accelerated mercury uptake due to higher metabolic rates and age-dependent bioaccumulation.

A slight geographic gradient of fish mercury concentration for yellow perch was detectable in our analyses, even across the relatively narrowly defined differences between ecological subregions. Allen-Gil et al. [34] did not note spatial differences in fish species mercury concentrations across geographic regions delineated on the basis of ecological, geological, and climatic factors. Lathrop et al. [35] noted a west to east increase in walleye mercury concentrations across northeastern Minnesota, northern Wisconsin, and southeastern Ontario, Canada, which is possibly related to acidic deposition patterns. Ecoregional differences in Massachusetts are associated with pH differences and may also be overshadowed by other lake-specific factors.

Mercury concentrations in sediment samples ranged from 0.008 mg/kg to 0.425 mg/kg (Table 3). None of the species studied in this project showed a relationship between tissue mercury and sediment mercury or selenium concentrations. Figure 3a shows that sediment mercury and selenium vary independently from fish mercury. Selenium can form highly insoluble complexes with mercury and thereby reduce its biological availability [36]. Under low pH conditions, leaching of sedimentary metals into surface waters and subsequent availability of these metals for bioaccumulation may be facilitated in a complex relationship modulated by the amount and types of particulate and organic matter in the water column and by the pH and Eh of the sediment [37]. In brown bullhead, the source of mercury may not be confined to diet, given the bottom-dwelling habitat of the species and its scaleless, permeable skin. Underlying relationships between sedimentary mercury and selenium may have been obscured with our bulk mercury concentration determination, since mercury is probably preferentially associated with silts and clays, and a normalization to the mass of this size fraction might have been more useful.

Our analyses indicated a clear link between certain environmental characteristics and elevated mercury concentrations in fish. Low pH of the water body was a major correlate to tissue mercury concentrations in brown bullhead and yellow perch (Fig. 3b, c) but not in largemouth bass (Fig. 3a). The association between high mercury concentrations and low pH is clearly delineated by factor analysis. This environmental variable would also seem the most likely to represent subecoregion variability in our analyses. Some of the continuous variables measured in the field (e.g., Secchi disk depth, chlorophyll *a,* DO) represent measures of trophic status that are perhaps better suited for use in the correlation and other association tests than as a coded variable. The factor analysis provided complementary information, scoring mercury in perch highly negative on the same factor as pH. Suns and Hitchin [38] observed a similar relationship in yellow perch from 16 lakes situated on the Precambrian Canadian Shield north of Toronto, Canada.

Low pH has been most consistently documented as being responsible for elevated tissue mercury concentrations in freshwater fish in uncontaminated lakes [2,6]. Possible mechanisms associated with this relationship include [37] (1) mercury entering watersheds with atmospheric deposition; (2) mobilization of existing sediment-bound mercury and mercury present in the surrounding watershed by acidification of surface water runoff and lake water, leading to increases in the amount of mercury available for methylation and bioaccumulation; (3) differential production of the more bioavailable monomethylmercury form of mercury at lower pH; and (4) alteration of rates of mercury methylation and demethylation by microorganisms by acidic conditions. Having reviewed evidence for each of these mechanisms, Richman et al. [37] concluded that they were not mutually exclusive processes and that mercury cycling and uptake into fish tissues was governed

by an array of interrelated, variables, the relative importance of which can differ from lake to lake.

Our analyses did not show an association between fish tissue mercury concentrations and the lake TSI. Trophic status and variables associated with it are relatively independent of both fish mercury and pH (Fig. 3). For example, chlorophyll *a* and Secchi disk depth, both associated with lake trophic status, did not partition onto the same factor as species mercury values, indicating that variance in trophic state variables was independent of mercury concentrations in most fish tissue. Other reviews [37] and studies [9,39,40] on this specific relationship have noted that, while the general availability of mercury within aquatic ecosystems may be affected by trophic status, other abiotic factors interfere with and confound the issue.

The ratio of basin area to pond area was not a strong correlate of fish mercury concentrations in any of the species we studied in Massachusetts. The absence of such a relationship does not support the logic that where the basin (watershed) is much larger than the pond, there should be a tendency to have higher mercury concentration in fish tissue, reflective of mercury transport from the watershed [41]. In largemouth bass, however, we did find significant correlations between tissue mercury concentrations and the size of the watershed and the lake area as well as the area in the watershed occupied by wetlands (Fig. 3a). The relative importance of watershed-derived mercury to fish mercury is not consistent in various studies [2,6] and sometimes appears to be a function of the types of water inputs to the lakes. In cases where there has been little surface-water inflow into lakes [6,41], no relationship has been seen between fish mercury concentrations and watershed area to lake volume ratios, whereas positive relationships have been seen in lakes with greater surface-water inputs from drainage basins [38].

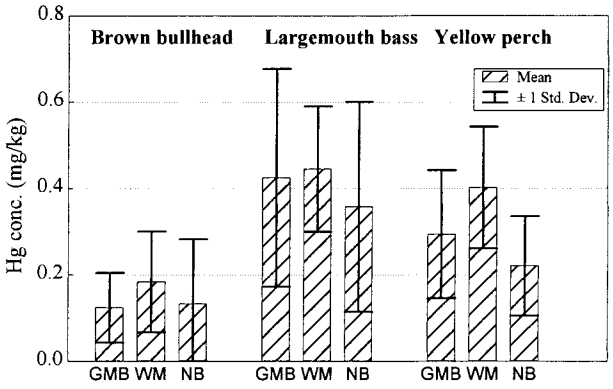

Fig. 2. Mean species mercury concentrations (mg/kg) in Massachusetts subecoregions. GMB = Green Mountain/Berkshire Highlands; WM = Worcester/Monadnock Plateau; NB = Narragansett/Bristol Lowland.

In addition to substantiating the recognized association between fish tissue mercury and acid waters, the principal contributions of the present study include insight into the relative importance of the various biologic, chemical, and geologic factors that may influence fish mercury bioconcentration patterns. Specifically, given that significant ecoregional differences in tissue mercury concentrations only existed in one species, the properties of individual lakes within these narrowly defined regions are more important than are regional variations in determining fish mercury concentrations. The results for largemouth bass, contrasted with those of yellow perch and brown bullhead, suggest that species whose mercury concentrations exhibit major variation associated with size or food-chain position may not be good choices for evaluating the effects of environmental variables. The additional variability introduced by using such species tends to obscure other

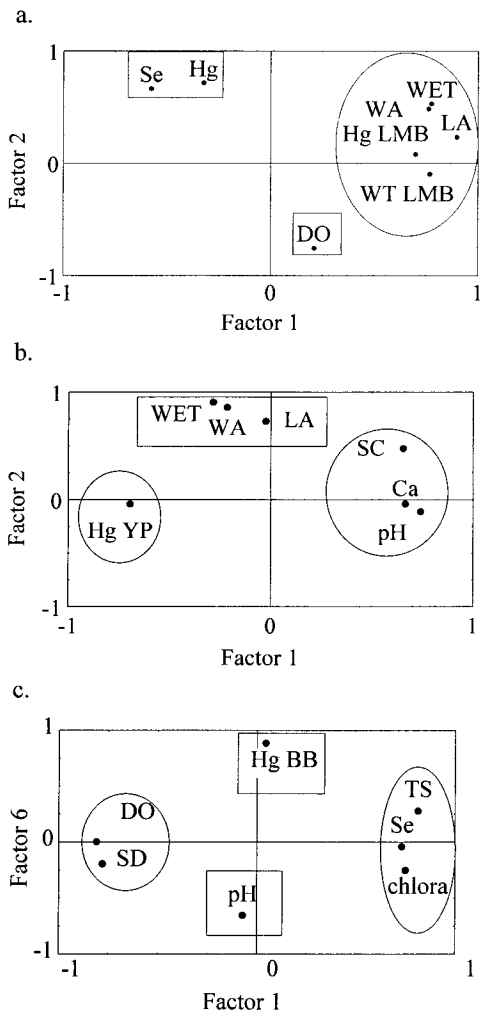

Fig. 3. Rotated factor score plots for: (**a**) largemouth bass, (**b**) yellow perch, and (**c**) brown bullhead. Only variables with scores >|0.65| are shown. Elipses and squares highlight variables grouping on factor 1 or on other factors, respectively. relationships. This study clearly shows the value of using a specified size range of species that exhibit little size to mercury ratio covariance.

Studies such as this, in which fine-scale ecoregional differences are not usually significant, do not indicate that ecoregional differences are not meaningfully related to fish mercury on larger geographic scales. Indeed, the variables measured in this study may well be important on larger geographic scales and may be beneficially examined in that context. Literature on mercury bioaccumulation is generally dominated by data from waters in regions where bioaccumulation has reached levels of concern, whereas data from areas where bioaccumulation has not been a concern has not been published in the open literature as frequently. Inclusion of this type of data in regional analyses would provide a broader spectrum of conditions for evaluating the importance of ecoregional differences.

Abstract

Current paradigms regarding the bioaccumulation of mercury are rooted in observations that monomethyl mercury (meHg) biomagnifies along pelagic food chains. However, mechanisms regulating the formation of meHg, its initial incorporation at the base of pelagic food chains, and its subsequent trophic transfer remain controversial. Here we use field data from 15 northern Wisconsin lakes, equilibrium aqueous speciation modeling, and statistical modeling to revisit several hypotheses about the uptake, distribution, and fate of inorganic Hg (Hg^{II}) and meHg in aquatic biota. Our field data comprise determinations of total Hg (Hg_T) and meHg in surface waters, sediments, microseston, zooplankton, and small fish in each of the study lakes. For these lake waters, strong positive correlations between DOC and aqueous concentrations of mercury along with negative correlations between DOC and the seston–water partitioning of mercury indicate that organic ligands bind Hg^{II} and meHg strongly enough to dominate their apparent aqueous speciation. In the microseston, zooplankton and fish, meHg concentrations and bioaccumulation factors (BAFs) increased with increasing trophic level while biotic concentrations of Hg^{II} decreased — indicating that meHg was indeed the biomagnified species of mercury. For all trophic levels, meHg concentrations varied positively with the calculated aqueous concentration of $meHg^{+}$ (free ion), especially when coupled with pH, or meHgOH (hydroxide) species but not with $meHgCl^{0}$, the neutral chloride complex. These findings suggest that: (1) the passive uptake of meHg does not control bioaccumulation at the base of aquatic food webs in nature (i.e. phyto- and bacterioplankton); (2) correlation with pH and DOC largely reflect the supply and bioavailability of meHg to lower trophic levels; and (3) meHg concentrations at higher trophic levels reflect uptake at low trophic levels and other factors, such as diet and growth. Low concentrations of meHg in surficial sediments indicate that the fates of biotic Hg^{II} and meHg are different. Most biotic meHg is demethylated rather than buried in lake sediments.

1. Introduction

The potential determinants of mercury bioaccumulation in natural aquatic ecosystems include environmental factors (such as mercury loading rates, pH, DOC, and temperature), ecological factors (such as productivity and trophic position), and physiological factors (such as respiration and assimilation). Although there is an extensive body of literature examining statistical relationships between such factors and mercury bioaccumulation in fish, large uncertainties remain (Spry and Wiener, 1991; Wiener and Spry, 1996). Survey data show that body size, pH, and DOC often correlate with mercury concentration, but in seemingly inconsistent ways. For example, some studies report a strong negative correlation with pH and a weak or non-significant correlation with DOC (e.g. Lathrop et al., 1989; Lange et al., 1993) while other studies report a strong correlation with DOC and only a weak or non-significant correlation with pH (e.g. McMurty et al., 1989; Fjeld and Rognerud, 1993). Reported correlation with DOC has been positive (e.g. Haines et al., 1994) and negative (Grieb et al., 1990). At least one fish survey reported no significant correlation with either pH or DOC (Driscoll et al., 1995). Such seeming inconsistency suggests a significant degree of interaction among controlling variables and/or multiple effects from single variables.

The opportunity for interaction and multiple effects is clear in Sunda's steady-state model of bioaccumulation (Sunda and Huntsman, 1998):

$$C_{\text{biota}} = V_{\text{net}}/\mu \quad (1)$$

where C_{biota} is the metal concentration in biota, V_{net} is the net metal uptake rate, and μ is the growth rate of the organism (or biodilution term). Although developed for phytoplankton, Sunda's law is a general paradigm for trace metal bioaccumulation across the board in aquatic ecosystems. It holds for phytoplankton, zooplankton, benthic invertebrates and fish — despite the substantial differences in uptake pathways and growth patterns. Various regulatory factors operate through processes related to V_{net}, μ, or both. Since V_{net} and μ comprise many processes, one would anticipate a complex set of dependencies for C_{biota}.

For mercury, DOC of terrestrial origin (i.e. humic matter) can hypothetically affect V_{net} in several ways. For example, co-transport with DOC from the terrestrial watershed can increase the supply of Hg^{II} and meHg to lakes; organic complexation can limit the bioavailability of either chemical form; and light attenuation in dark water lakes can inhibit the photo-destruction of meHg (Lee and Iverfeldt, 1991; Mierle and Ingram, 1991; Driscoll et al., 1995; Sellers et al., 1996). pH may also exert multiple effects on C_{biota}, potentially by depressing μ (since growth rates may be low in acidic waters) and by increasing V_{net} through effects on the net internal production of meHg or on the relative abundance of inorganic bioavailable aqueous species (Winfrey and Rudd, 1990; Gilmour and Henry, 1991; Meili, 1994; Mason et al., 1996).

In this paper, we focus on the relationships between DOC, pH, and the bioaccumulation of mercury by pelagic organisms in small Wisconsin lakes. We measured Hg and meHg in water, microseston (phytoplankton and bacterioplankton), zooplankton, fish, and sediments in lakes that were reasonably well defined hydrologically and that spanned relatively wide ranges of pH and DOC. Our mercury determinations were supported by data on mercury sources, water chemistry, and aquatic biology. Since current paradigms hold that meHg is the chemical species that biomagnifies through trophic transport (May et al., 1987; Meili, 1991; Watras and Bloom, 1992; Suedel et al., 1994; Mason et al., 1996), we emphasize the supply, bioavailability and uptake of meHg with respect to water chemistry and trophic position (i.e. V_{net}). We use field data, equilibrium aqueous speciation modeling of Hg^{II} and meHg, and statistical modeling to revisit several hypotheses.

$\mu g/m^2$ per year (Fitzgerald et al., 1991). However, interactions with riparian wetland varied between lakes and this likely affected loading to some lakes (e.g. Mierle and Ingram, 1991; St Louis et al., 1994). Yellow perch (*Perca flavescens*) were abundant in the study lakes, with one exception (Rose Lake). Unless otherwise indicated, our sampling platform was a non-metallic boat deployed at the deepest point in each lake during May 1994. Clean technique was followed during all phases of sample collection, storage and analysis.

2.2. Aqueous mercury speciation and water chemistry

All lakes were sampled for total and dissolved Hg, total and dissolved meHg, DOC, DIC, pH, suspended particulate matter (SPM), and Chl *a* during May 1994. Many of the lakes had been sampled previously for these and other analytes during 1992 and 1993 (Watras et al., 1995a,b). Where appropriate, these data have been pooled with the data for May 1994. Water samples were collected from a 2-m depth using a submersible, non-metallic centrifugal pump attached to a 3-m length of 1.3-cm i.d. C-Flex tubing. Unfiltered water for mercury analyses was pumped into 500-ml Teflon bottles through a 64-μm Nitex screen to remove zooplankton. Filtered water for mercury analyses was similarly collected after pumping through an acid-cleaned, Gelman Versaflow filtration capsule (0.45 μm). Samples for dissolved gaseous mercury (DGM) were collected using an overflow technique into 1-l or 2-l Teflon bottles through a narrow tube that extended to the bottom of the collection bottle. The DGM bottle was allowed to overflow for three full volumes before capping without headspace. All samples except those for DGM analysis were preserved with clean 6N HCl to 1% v/v.

Aqueous Hg and meHg were determined according to Bloom and Fitzgerald (1988) and Bloom (1989) as modified by Liang et al. (1994) to incorporate the meHg distillation protocol described by Horvat et al. (1993). Detection limits ranged from 0.03 to 0.18 ng/l for Hg and from 0.03 to 0.06 ng/l for meHg defined as 3 S.D. of reagent blanks. DGM was determined by sparging unfiltered lakewater with Hg-free N_2 gas for 20 min and trapping the liberated Hg vapor on gold (Vandal et al., 1991). DGM samples were sparged within 4 h of collection. The detection limit for DGM ranged from 4 to 20 pg/l defined as 3 S.D. of the sparging blank. Inorganic Hg^{II} was operationally defined as: $Hg^{II} = Hg_T - MeHg - Hg^0$. The aqueous Hg^{II} fraction includes $Hg(OH)_2$, $HgCl_2$, HgOHCl, humic-bound Hg, and potentially some organo-Hg species not quantitatively separated by the ethylation method of Bloom (1989).

Analytical methods for the determination of DOC, DIC, pH, ANC, conductivity, major cations (Ca, Mg, Mn, Na, Fe), and major anions (SO_4, NO_3-N, Cl) followed Watras et al. (1995b). Trace elements (Cd, Cu, Pb, Se, As) were measured using Zeeman-corrected GFAAS with pre-concentration via ultra-clean evaporation (Cd, Cu, Pb) or hydride generation and cryogenic trapping (As, Se).

2.3. Microseston

The microseston in these lakes is primarily phytoplankton, bacterioplankton, and cellular debris. Hg and meHg concentrations in microseston were estimated from the difference between filtered and unfiltered water concentrations ($Hg_P = Hg_T - Hg_D$, where $0.45\ \mu m \leq HgP \leq 64\ \mu m$). Since Hg_P is often small relative to Hg_T and Hg_D (Table 3), the validity of this approach depends, in part, on the precision with which total and dissolved mercury concentrations can be determined. One measure of precision, the CV for replicate analyses, averaged approx. 10% for aqueous Hg and meHg in Wisconsin lakewaters (Bloom et al., 1995).

2.4. Zooplankton

Roughly 100 zooplankton samples were analyzed for Hg and meHg. Zooplankton were collected in replicate vertical hauls of a 20-cm diameter, non-metallic, plankton net (153-μm mesh) at the deepest point in each lake during May 1994. The zooplankton were transported back to a clean laboratory in acid-washed 1-l Teflon jars that were sealed in double, zip-locked plastic bags

Note. Data are mean values for each lake from 1990 to 1994 with S.D. in parentheses. Lakes numbered as in Table 1.
Nomenclature. T, total; D, dissolved (0.45 μm filtered); Hg^0, dissolved gaseous Hg; $Hg^{II} = Hg - MeHg - Hg^0$. Note that the Hg^{II} pool is operationally defined and may also contain organo-Hg species that are not differentiated by the ethylation/GC-separation method of Bloom (1989).

and placed in a plastic cooler. Live zooplankton were then taxonomically sorted and monospecific samples containing 10–150 individuals (0.1–4 mg dry wt.) were put into Teflon micro-vials within 8 h of collection (Watras and Bloom, 1992; Back and Watras, 1995). The sorted live samples were immediately frozen and stored under clean conditions until homogenization and analysis for Hg, meHg and dry weight. Following the method of Back et al. (1995), sample homogenate was digested overnight at 65°C in HNO_3/H_2SO_4 and BrCl for Hg or in KOH/methanol for meHg. Hg digestates were pre-reduced with NH_2OH HCl for 20 min prior to analysis. Detection limits ranged from 4 to 12 pg Hg and from 0.8 to 4.3 pg meHg.

2.5. Fish

Yellow perch (*Perca flavescens*) and golden

shiners (*Notemigonus crysoleucas*) were collected during spring and summer 1994 primarily by mini-fyke net, but shore seining, angling, AC electroshocking, and gill netting were also used when fyke nets were unsuccessful. Fyke nets were set overnight and gill nets were tended every 2 h. Fish were weighed and measured and several scales were collected posterior to the left pectoral fin for age estimation. Because of the large number of fish involved (727 perch, 139 golden shiners, ages <1–7 years), it was not possible to estimate age from otoliths. Fish were individually placed in double zip-lock bags for freezing at -20°C. Individual thawed fish were processed whole, homogenized and analyzed for Hg according to Bloom (1992).

2.6. Sediments

Surficial sediment samples were collected during spring 1994 from six depths spaced along a transect extending from shore to the deepest point in each lake. An Ekman dredge was slowly lowered into the sediment, taking care to minimize disturbance on descent and retrieval. Roughly 30 cm^3 of sediment was removed from the center of the dredge by inserting a clean, plastic scoop to a depth of 3–4 cm. The sample was put into a zip-locked plastic bag and placed on ice in the dark for transport to the lab freezer. Ninety sediment samples were collected in total. Thawed sediment was analyzed for organic content (loss on ignition, LOI) and water content in addition to Hg and meHg. Hg concentrations were determined by the same method used for fish (Bloom, 1992). Methyl mercury concentrations were determined by aqueous distillation, ethylation and CVAFS (Horvat et al., 1993). Corrections for incidental methylation during distillation were not applied, so meHg concentrations in sediments may be over-estimated by 10–20% (Bloom et al., 1997).

3. Results and discussion

3.1. Aqueous mercury

Mean concentrations of Hg_T and $meHg_T$ in the study lakes ranged from 0.5 to 4.4 ng Hg/l and from 0.04 to 0.8 ng meHg/l (Fig. 1A, Table 3). On average, $meHg_T$ constituted approx. 15% of the Hg_T in surface waters, but the meHg fraction ($meHg_T/Hg_T$) was positively correlated with DOC. Dissolved gaseous mercury, largely Hg^0, represented approx. 1% of the total aqueous Hg pool (Table 3). Mercury concentrations were lower than the concentrations of other trace metals and minor elements by 1–2 orders of magnitude (Table 4). These results agree well with previous findings for this region and other temperate areas of North America (Driscoll et al., 1994; Kelly et al., 1995; Watras et al., 1995a,b).

Concentrations of dissolved Hg and meHg were strongly dependent on DOC (Fig. 1B). Linear regression analysis indicated that DOC accounted for 80–85% of the variability in dissolved mercury species. Neither Hg or meHg were correlated strongly with other aqueous constituents, except those trace metals and minor elements that co-varied with DOC (Table 5). Aluminum, copper, iron, Hg and meHg all exhibited strong, positive

Note. Lake numbers as on Table 1.

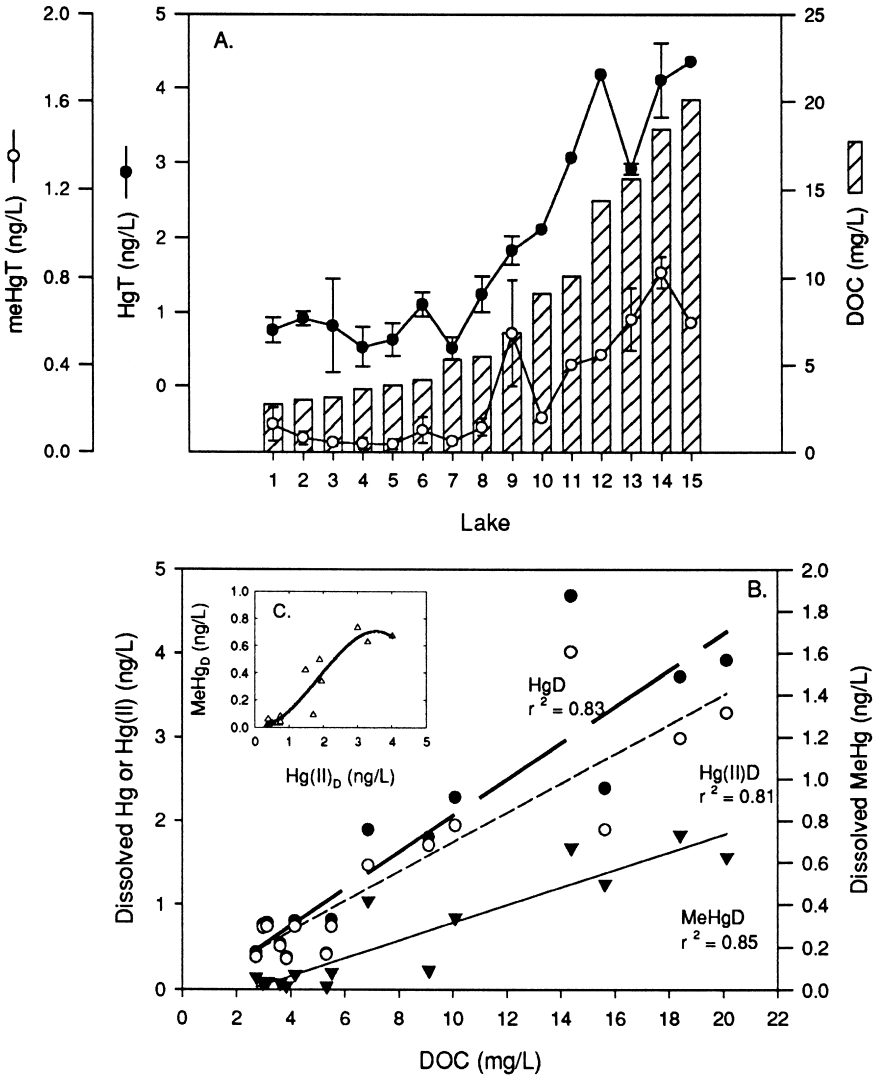

Fig. 1. Relationship between aqueous mercury concentrations and DOC in the 15 WI study lakes. (A) Total Hg and meHg: data are lake averages ± 1 S.D. (1992–1994). Lake numbers from Table 1. (B) Dissolved mercury: first order regression equations are $meHg_D = -0.01 + 0.04$ DOC (solid line, filled triangles); $Hg_D^{II} = -0.02 + 0.17$ DOC (short dashed line, open circles); $Hg_D = -0.12 + 0.22$ DOC (long dashed line, filled circles) — note that we fit a straight line to the meHg data even though there is evidence of curvature at low DOC. (C) Regression equation is $MeHg_D = 0.02 - 0.06\ Hg_D^{II} + 0.20\ Hg_D^{II2} - 0.04\ Hg_D^{II3}$, $r^2 = 0.89$.

DOC dependencies (Fig. 2). Weak negative correlation between aqueous mercury and pH were also observed (Table 5), consistent with previous observations for this region (Watras et al., 1995b).

The strong positive correlations between aqueous mercury and DOC suggest that most of the dissolved Hg^{II} and meHg in these lakewaters is organically complexed — given the relatively constant atmospheric loading of Hg to these lakes and lack of correlation with other aqueous analytes that signify geochemical control. This conclusion is in agreement with numerous field observations (e.g. Meili, 1991; Mierle and Ingram, 1991; Watras et al., 1995b,c; Driscoll et al., 1995), as well as the modeling results of Hudson et al. (1994) which indicated that organic complexes

made up more than 99% of the Hg^{II}_D in a set of seven lakes from this region. It also agrees with the experimental studies of Hintelmann et al. (1996) whose equilibrium constants for the complexation of meHg by dissolved humic matter indicate a similarly high degree of organic complexation.

MeHg increased with increasing Hg^{II}, but the relationship was best described by a third-order polynomial (Fig. 1C). In an earlier study, we concluded that a second-order expression described this relationship well because meHg was weakly dependent on Hg^{II} at low concentrations (Watras et al., 1995b). Our additional data suggest that meHg concentrations are relatively independent of Hg^{II} at both low and high concentrations. The biogeochemical mechanisms underlying this pattern are unclear. We note, however, that meHg concentrations in oxic surface waters rarely exceed 1 ng/l even in ecosystems that are grossly contaminated with inorganic Hg (Suchanek et al., 1993; Jacobs et al., 1995; Saouter et al., 1995).

Although the DOC in dark water lakes (5−>20 mg C/l) comprises humic material exported from riparian wetland, the observed relationship between Hg^{II} and DOC does not necessarily imply that wetlands are a major source of Hg^{II} to lakes. Given the magnitude and regional constancy of atmospheric Hg^{II} loading and the importance of sedimentation and gaseous evasion as Hg^{II} loss terms in seepage lakes (Fitzgerald and Watras, 1989; Fitzgerald et al., 1991; Watras et al., 1994, 1996), the concentration of inorganic Hg^{II} would reach a level where inputs exactly balanced outputs provided rates of loss were controlled by inorganically complexed Hg^{II} while the total Hg^{II} was dominated by organic complexes. At steady-state, the inorganic pool would remain unchanged with respect to DOC but the total Hg^{II} pool would rise in proportion to DOC — yielding a relatively constant ratio Hg^{II}:DOC across lakes, as we observed (170 ± 31 ng Hg/g C, 95% CI). Alternatively, if riparian wetland was a large source of Hg^{II} to lakes, the constant ratio

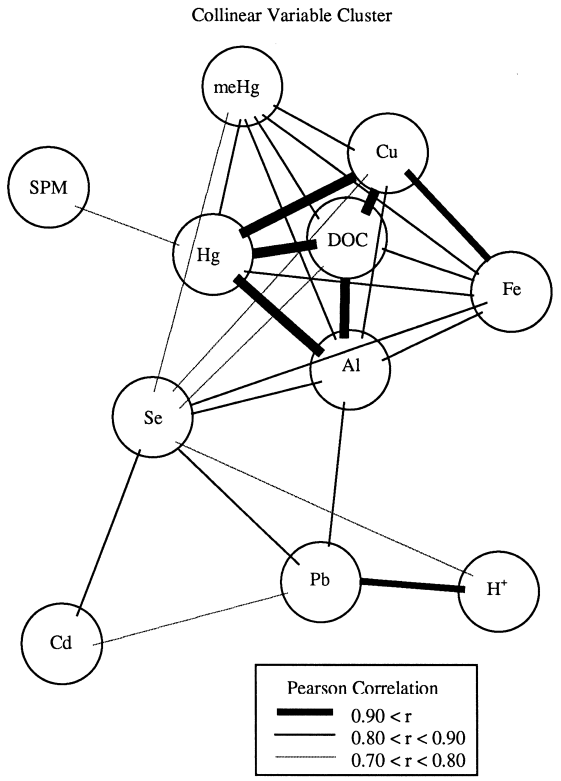

Fig. 2. Diagrammatic representation of the collinearity between Hg, meHg, aqueous metals, and other correlates in the water columns of the 15 WI study lakes. Data from Table 5.

Hg^{II}:DOC across lakes could be explained by similar cycling of carbon and Hg^{II}. In other words, the removal of Hg^{II} from lake water would be linked or parallel to the loss of allochthonous C — perhaps by co-sedimentation or by parallel evasion of Hg^0, CO_2 and CH_4.

A different balance of processes is needed to explain why the ratio meHg:DOC in lake water varied positively with DOC. Although the element Hg is conserved, meHg is produced and destroyed within ecosystems. There is evidence that net meHg input could be affected by DOC in several ways: (1) by the production and export of meHg from riparian wetlands (e.g. Lee and Iverfeldt, 1991; St Louis et al., 1994; Pettersson et al., 1995); (2) by enhanced microbial methylation in-lake due to additional carbon or Hg^{II} substrate (Hudson et al., 1994); and (3) by reduced photodestruction in dark water lakes (Sellers et al., 1996). A variety of mechanisms might be consistent with our observation.

3.2. Microseston

The concentration of Hg^{II} and meHg in microseston averaged 170 ± 44 ng/g dry wt. and 33 ± 14 ng/g dry wt. (95% CI), respectively, across lakes. The concentration of Hg^{II} and meHg in microseston varied independently of DOC (Fig. 3). However, the log K_ds [ratio of Hg in seston (ng/kg dry wt.) to Hg in water (ng/l)] for both Hg^{II} and meHg were negatively correlated with DOC, as expected for strongly complexed metals (Fig. 3). Seston–water partition coefficients were roughly twofold higher for meHg than for Hg^{II} when averaged across all lakes. Without an independent measure, it is unclear whether this difference in K_ds reflects a higher plankton affinity or a lower DOC affinity for meHg. However, conditional stability constants calculated for thiols suggest that DOC has a lower affinity for meHg than for Hg^{II} (Dyrssen and Wedborg, 1991).

Assuming most of the small particulate matter in these lakes consists of living phytoplankton and bacterioplankton, the log K_d may approximate the bioaccumulation factor (BAF) for microplankton. For meHg, we note that detrital organic matter would likely depress observed K_ds below true BAFs since meHg concentrations are low in organic sediments (Watras et al., 1994, 1995d; this paper). Furthermore, even though Fe-oxides have a significant affinity for meHg and Hg^{II}, we estimate that they do not contribute significantly to K_d in the presence of DOC at the levels found in these lakes (Hudson and Watras, in preparation). Assuming that most of the suspended mercury is in living cells and that half of the seston is live biomass, 'true' BAFs would be elevated by roughly 0.3 log units — ranging from 4.7 to 5.9 for Hg^{II} and from 4.8 to 6.2 for meHg. In any case, the magnitude of these BAFs clearly indicate that uptake by the microplankton is a major step in the bioaccumulation process. As shown below, BAFs for higher trophic levels increase further by only a factor of 2–4.

Sestonic meHg increased slightly with decreas-

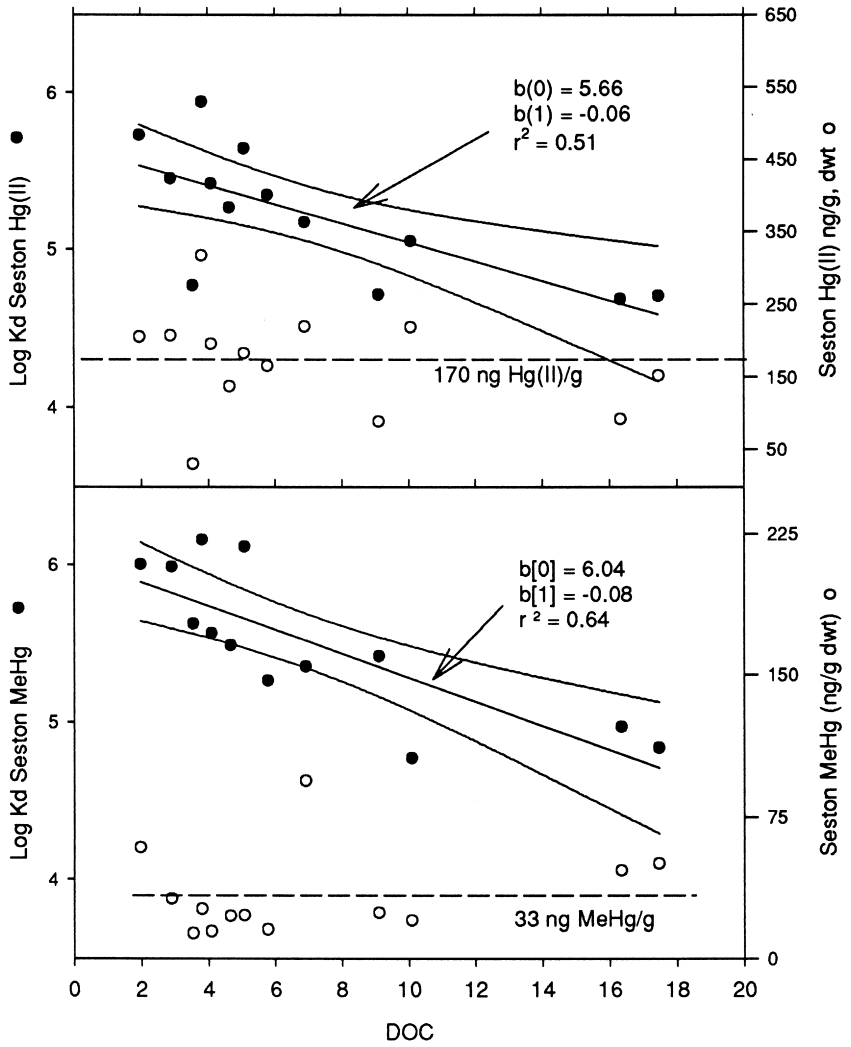

Fig. 3. Dependence of seston–water partition coefficients (log K_d) and sestonic concentrations of Hg^{II} (top) and meHg (bottom) on DOC in the 15 WI study lakes. Solid lines indicate linear regression of DOC vs. log K_d with 95% CI. Regression parameters: $b(0)$ = slope; $b(1)$ = intercept. Dotted lines indicate mean sestonic concentration for all lakes.

ing pH, paralleling the change in dissolved meHg (Fig. 4A,B). This observation is consistent with at least two hypotheses regarding the uptake of meHg at the base of aquatic food webs. Based on earlier field data and modeling results, we previously hypothesized that meHg was bioaccumulated in proportion to supply and that pH affected the supply of meHg to aquatic ecosystems (Bloom et al., 1991; Watras and Bloom, 1992; Hudson et al., 1994). However, the recent experimental data of Mason et al. (1996) suggest an alternative hypothesis: i.e. that meHg uptake by microseston is governed by the passive uptake of neutrally charged $meHgCl^0$ species which increase in concentration as pH decreases — all other things being equal.

Although the passive uptake of $meHgCl^0$ by phytoplankton is indisputable, our field data are not consistent with the hypothesis that passive uptake controls bioaccumulation in nature. For

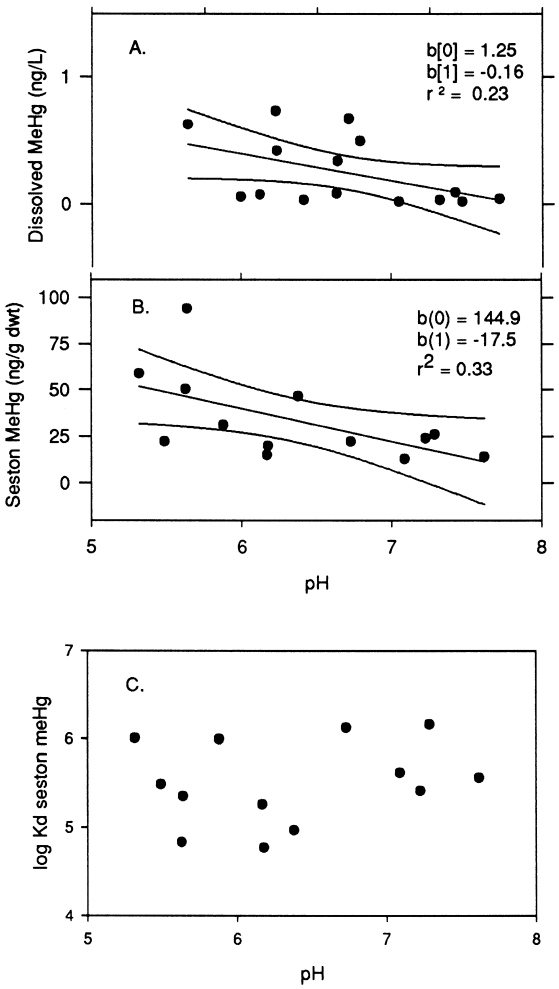

Fig. 4. Dependence of meHg concentration and partition coefficient on pH in the 15 Wisconsin study lakes. (A) Aqueous meHg; (B) seston meHg; and (C) apparent partition coefficient (log K_d). Regression lines and parameters as in Fig. 3.

example, we found that the accumulation of meHg or Hg^{II} by microseston was independent of Cl concentration even though aqueous Cl concentrations varied by a factor of 30 among lakes (Fig. 5). We also observed no correlation between meHg in seston and the ambient $meHgCl^0$ concentration (Fig. 6), which was calculated for each lake from the observed $meHg_D$, Cl, pH and DOC following Hudson et al. (1994). Instead, seston meHg was positively correlated with the calculated aqueous concentration of meHgOH and $meHg^+$ (Fig. 6A,B).

The dependence of seston meHg on either the hydroxide or free ionic meHg species is consistent with the hypothesis that uptake is dominated by active transport into phytoplankton and bacterioplankton. Although meHgOH may be transported passively as a neutral species, its diffusion rate across the cell membrane is only $0.04\times$ the diffusion rate of $meHgCl^0$ (Mason et al., 1996). Further evidence of control by active transport at low pH is provided by the seston–water partition coefficient (K_d). K_d was not correlated with pH for either Hg^{II} or meHg (Fig. 4C). This observation suggests that the negative correlation between sestonic meHg and pH is related to increases in aqueous meHg concentrations at low pH rather than to increases in seston–water partitioning. This conclusion is consistent with earlier findings by Bloom et al. (1991) and Watras et al. (1994) who reported no correlation between pH and seston–water partition coefficients or between pH and perch bioaccumulation factors for meHg in several North American lakes.

3.3. Zooplankton

Mean Hg_T concentrations in zooplankton ranged from 33 to 206 ng/g dry wt. in the 15 study lakes (Table 6). Specific taxa had Hg_T concentrations as high as 484 ng/g dry wt. (e.g. predacious water mites, Table 6). Among crustacean zooplankton, meHg constituted 60–80% of the total Hg on average. These observations are similar to previous findings for zooplankton in remote Canadian lakes (Tremblay et al., 1995; Tsalkiztis, 1995; Wescott and Kalff, 1996), Swedish lakes (Meili, 1991), Finnish lakes (Rask et al., 1994), northern Minnesota lakes (Sorenson et al., 1990) and northern Wisconsin lakes (Watras and Bloom, 1992; Back and Watras, 1995).

Concentrations of meHg and the % meHg were higher in zooplankton than in microseston. However, the average concentration of Hg^{II} was substantially lower in zooplankton than microseston. Thus, within the plankton community we observed biomagnification of meHg but not Hg^{II}. The differential behavior of biotic meHg and Hg^{II} is consistent with previous observations in Little Rock Lake (Watras and Bloom, 1992; Watras et

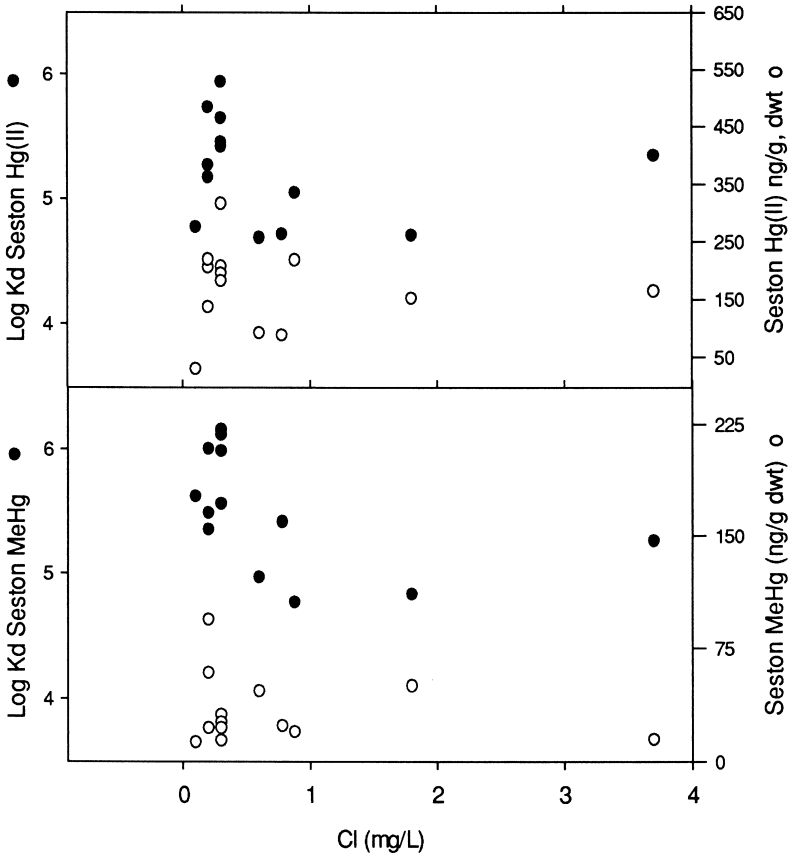

Fig. 5. Aqueous Cl concentration vs. seston–water partition coefficients (log K_d) and sestonic concentrations of Hg^{II} (A) and meHg (B) in the 15 WI study lakes.

al., 1996) as well as observations on other divalent metals in aquatic ecosystems (Suedel et al., 1994).

The meHg concentration in zooplankton was negatively correlated with pH (and pH-related variables) and it was positively correlated with DOC and dissolved meHg (Fig. 7A). The strength of correlation varied with the level of taxonomic resolution applied to the zooplankton community. When all species were lumped together for a given lake (i.e. 'zooplankton I' on Fig. 7A), correlation coefficients were low. For individual zooplankton genera (i.e. *Diaptomus*), correlation coefficients were substantially higher. This result is parallel to numerous observations on fish which clearly show the importance of taxonomic, morphometric, and ontogenic characteristics on mercury bioaccumulation (Spry and Wiener, 1991; Wiener and Spry, 1996).

As observed with sestonic meHg, zooplankton meHg was more strongly dependent on aqueous meHgOH and $meHg^+$ than $meHgCl^0$ regardless of the level of taxonomic resolution (Fig. 7B). For Crustacea, the dependence on aqueous meHgOH was strongly linear and there was no dependence on $meHgCl^0$ (Fig. 8). Crustacean meHg was also strongly correlated with seston meHg (Fig. 9A) and it showed a dependence on pH similar to that observed with seston (cf. Fig. 9B and 5B). These observations are consistent with the trophic transfer and biomagnification of meHg from seston to crustacean zooplankton. Zooplankton may also accumulate some meHg directly from solution

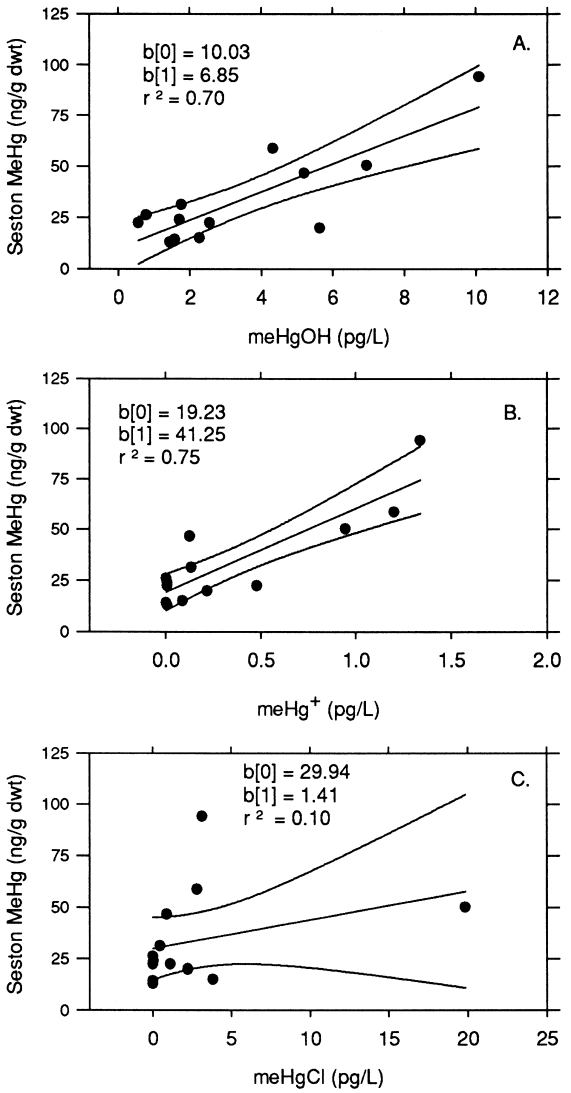

Fig. 6. Dependence of seston meHg concentration on aqueous meHgOH (A), $meHg^{+}$ (B) and $meHgCl^{0}$ (C). Regression parameters as in Fig. 3. Concentration of aqueous meHg species were calculated from known concentrations of $meHg_D$, Cl, DOC and pH in surface waters according to the assumptions of Hudson et al. (1994).

and the intercept on Fig. 9A may approximate direct uptake.

3.4. Fish

Mercury concentrations in 223 yellow perch ranged from 19 to 544 ng/g w/w (Fig. 10). Fish length and fish weight varied widely between samples but a strong relationship between length and weight across all fish suggested similarity in growth between lakes (Fig. 10A). However, consistent allometry among lakes does not guarantee that similar size fish will be collected from each lake. Indeed, there was evidence that bigger fish were collected from low pH lakes. Given the extensive body of literature documenting a positive relationship between fish Hg and body size (Scott and Armstrong, 1972; Abernathy and Cumbie, 1977; MacCrimmon et al., 1983; Wren et al., 1983; Mathers and Johnsen, 1985; Skurdal et al., 1985; Wren and MacCrimmon, 1986; Lathrop et al., 1989; Sorenson et al., 1990; Jackson, 1991; Gutenmann et al., 1992; Glass et al., 1993; Suchanek et al., 1993; Lange et al., 1993), an analysis of covariance was performed to factor-out (or standardize) the effect of body size on fish Hg so that valid inter-lake comparisons could be made. Note that the allometric relationship in Fig. 10 implies that either length or weight could be used to standardize fish Hg concentrations. We chose fish weight since it is logically consistent with Hg concentrations measured on a weight–weight basis.

An analysis of covariance (ANCOVA) was performed using a log-transformation of the following expression:

$$\mathrm{meHg}_{\mathrm{perch},j} = LS_{\mathrm{perch},j} \times W_{\mathrm{perch}}^{A_{\mathrm{perch}}}$$

where $\mathrm{meHg}_{\mathrm{perch},j}$ is the concentration of meHg in yellow perch from lake j, W_{perch} is the weight of the sampled fish, and $LS_{\mathrm{perch},j}$ is a categorical variable that is used to factor out the effects of the particular lake (Wente, 1997). Note the weight coefficient A_{perch} was assumed to be consistent between lakes. Therefore the model assumes that size-related variation in meHg bioconcentration is a characteristic of the yellow perch rather than its environment. This approach differs from fitting individual log–log regressions for each lake — a procedure that would allow the size-related variation in bioaccumulation to vary by lake. The ANCOVA indicated that (log) yellow perch Hg concentrations (and therefore, bioaccumulation factors) varied directly with (log) weight (Fig. 11, $A_{\mathrm{perch}} = 0.27$, $P < 0.0001$). The results support our

Table 6
Concentration of mercury in zooplankton from the Wisconsin study lakes

Taxon	*n*	Hg_T (ng/g dry wt.)	Hg^{II} (ng/g dry wt.)	$meHg_T$ (ng/g dry wt.)	% meHg
All zooplankton	15	83 (33–206)	29 (10–48)	53 (6–161)	57 (11–83)
Crustacea	13	78 (23–179)	24 (10–47)	54 (13–143)	70 (52–83)
Cladocera	10	110 (50–197)	36 (8–79)	73 (35–148)	70 (50–87)

assumption that size-related variation in meHg bioconcentration is a characteristic of the fish rather than its environment. A 30-g perch was selected as the standard fish.

For the standard 30-g perch, Hg concentration was more strongly dependent on pH ($r^2 = 0.72$) than on DOC ($r^2 = 0.33$) (Fig. 12). This result is consistent with our observations on microseston and zooplankton where pH was also the dominant correlate of meHg concentration. The strength of the pH correlation was higher for fish than for microseston or crustacean zooplankton, but similar to that observed with *Diaptomus* (Fig. 7A) — perhaps reflecting again the importance of taxonomic resolution. We did not find evidence that fish age influenced the correlation with pH or DOC. When the mean Hg concentration in 3-year-old perch from each lake was used as the dependent variable (107 fish total), results were similar to those obtained with the standard 30-g perch.

The dependence of biotic meHg on the free ion or hydroxide species observed with seston and zooplankton carried over to the perch (Fig. 13). Since fish are several trophic levels above seston, other factors such as diet influence meHg accumulation. Nonetheless, our data indicate that direct meHg uptake at low trophic levels ripples through the aquatic food web.

3.5. Sediments

The Hg_T content of organic, surficial sediments ranged from 12 to 398 ng/g dry wt. (Table 7),

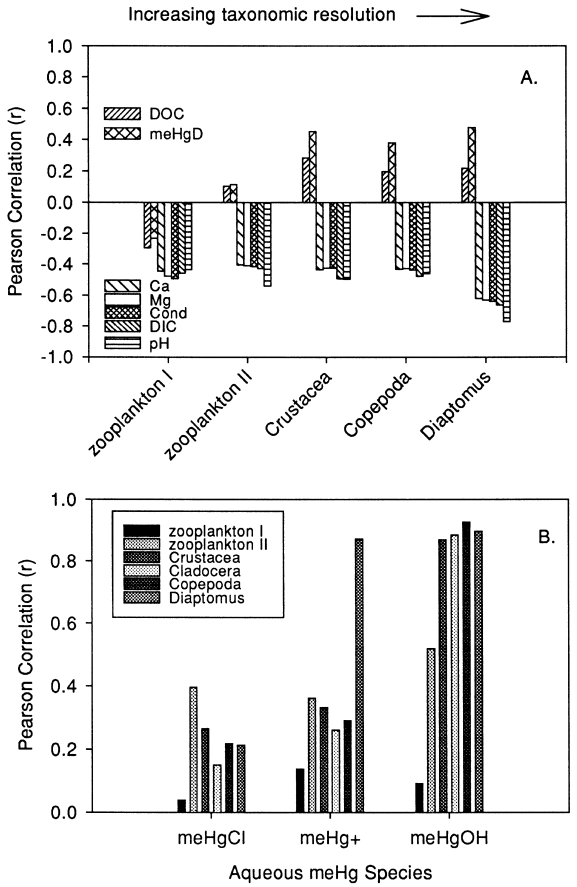

Fig. 7. Correlations between zooplankton meHg and several aqueous constituents in the Wisconsin study lakes. (A) The strength of correlations between zooplankton meHg and either pH-related variables (negative r) or DOC-related variables (positive r) depends on the taxomomic specificity of the zooplankton data. (B) Correlations between zooplankton meHg and the 'available' meHg species in lake water for all taxonomic groupings. Data are mean values for each lake. Zooplankton I are all taxa pooled for a given lake. Zooplankton II are all taxa except water mites (*Hydracarina*). Concentration of aqueous meHg species calculated as in Fig. 6.

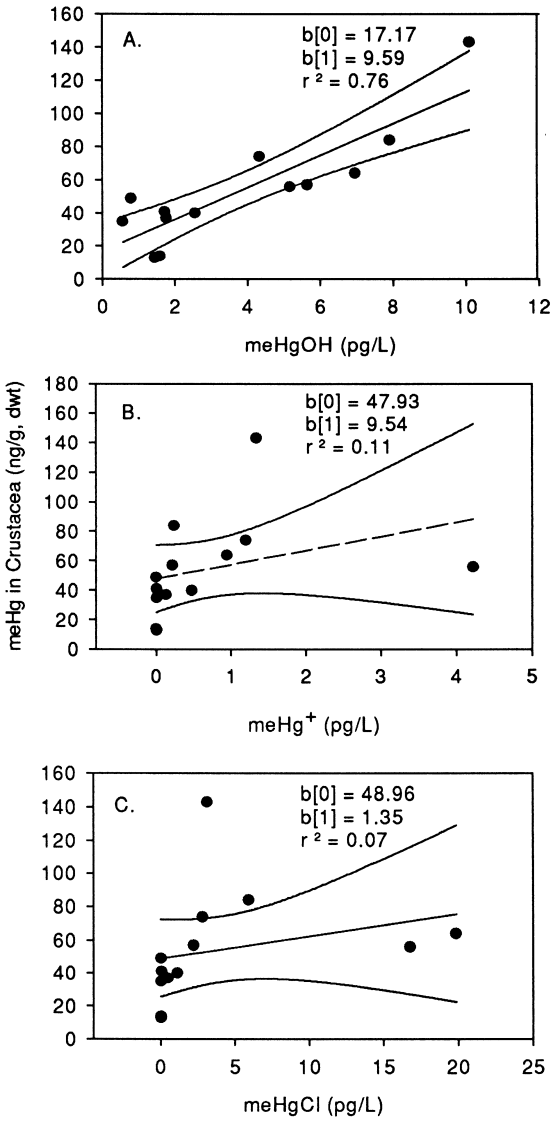

Fig. 8. Dependence of meHg concentration in crustacean zooplankton on the concentration of aqueous meHg species in the Wisconsin study lakes. Zooplankton data are mean values for individual lakes. Concentration of aqueous meHg species calculated as in Fig. 6. Regression parameters as in Fig. 3.

which is within the range reported earlier from a smaller set of northern Wisconsin lakes (Rada et al., 1993). The meHg content of all surficial sediments was low, averaging 2.6 ± 1.8 ng/g dry wt. across lakes. On average meHg constituted 1.5% of the Hg_T in surficial sediments, ranging from 0.1 to 5.4% (Table 7).

Since organic sediments largely comprise material settled from pelagic waters, they contain information about the fate of biotic mercury. The Hg_T content of sediments was similar to that observed in plankton, but meHg concentrations in sediments were much lower than in pelagic organisms. This observation indicates that biotic meHg is lost prior to sediment deposition. Rein-

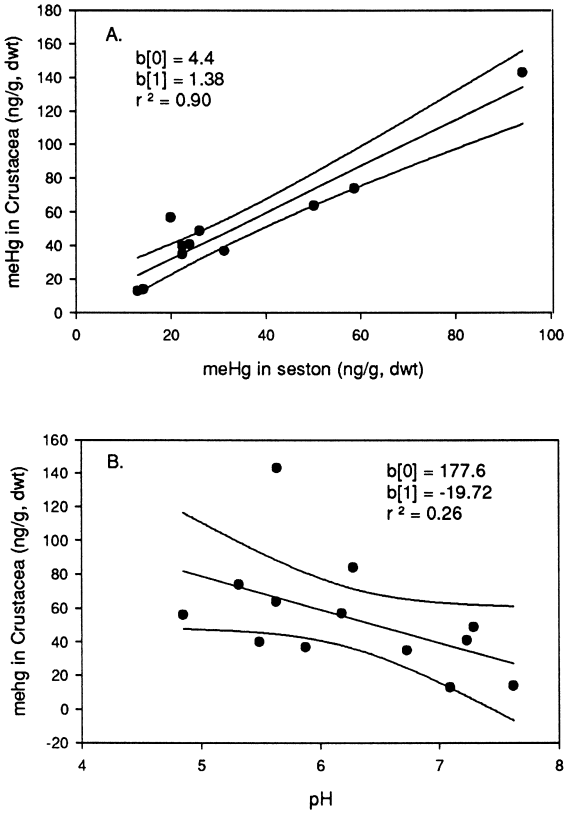

Fig. 9. Relationship between meHg in crustacean zooplankton and meHg in microseston (A) or pH (B) in the Wisconsin study lakes. Regression parameters as in Fig. 3.

felder and Fisher showed that many pelagic trace metals are biologically recycled rather than directly removed to sediments via settling detritus (Reinfelder and Fisher, 1991; Fisher and Reinfelder, 1995). Although recycling extends the residence time of trace elements in surface waters, it cannot defer their fate indefinitely. Biotic meHg may also be recycled in surface waters, but our sediment data indicate that most of it is eventually demethylated.

Sediment Hg_T was positively correlated with four water column variables: aqueous mercury, SPM, DOC and aqueous Fe (Table 8). The dependence of sediment Hg on these variables was not linear, however. Exponential expressions provided the best fit to these data (Fig. 14). A nonlinear regression model with aqueous Hg_T as the independent variable accounted for 70% of the

meHg was not dependent on DOC or SPM in the water column (Fig. 15).

4. Synthesis

The above observations highlight the complex interplay between the concepts of chemical speciation and bioaccumulation in aquatic ecosystems. Chemical speciation includes both the different chemical forms of an element (e.g. Hg^{II}, Hg^{0} and meHg) and different aqueous species (e.g. $meHg^{+}$, meHgCl and organically-complexed meHg), which all differ in their tendency to bioaccumulate. Similarly, bioaccumulation involves two distinct processes — uptake from water into biota at

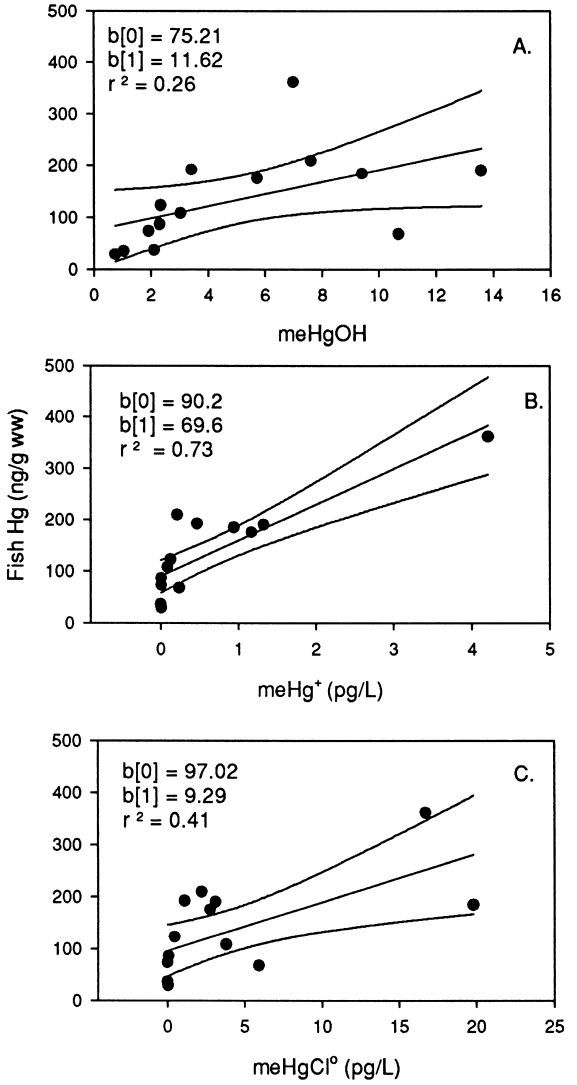

Fig. 13. Dependence of meHg concentration in fish (yellow perch) on the concentration of aqueous meHg species in the Wisconsin study lakes. Fish data are mean values for individual lakes. Concentration of aqueous meHg species calculated as in Fig. 6. Regression parameters as in Fig. 3.

lower trophic levels and transfer between trophic levels — that are influenced by chemical speciation to different degrees. In what follows, we consider these two processes and the influence of speciation on them. Examining the relative bioaccumulation of different forms of Hg between trophic levels illustrates the concept of biomagnification; examining the dependence of meHg

bioaccumulation on solution speciation illustrates the concept of bioconcentration.

4.1. Biomagnification

Biomagnification is defined here as the increasing concentration of a contaminant at successively higher trophic levels of a food web. As observed by Suedel et al. (1994), there is sparse evidence for biomagnification among the metallic elements in aquatic ecosystems. Indeed, most elements become progressively less concentrated at higher trophic levels, perhaps because the increasing ratio of body volume to surface area decreases the relative rate of uptake from the water and because the trophic transfer of most metals is inefficient (see Reinfelder et al., 1998). Although the term biomagnification is not neces-

Table 8
Environmental correlates of mean sediment mercury concentrations in the Wisconsin study lakes

Correlate	Sediment Hg	Sediment meHg
Hg_T, water column	0.75	0.21
SPM	0.71	−0.02
$meHg_T$, water column	0.67	0.38
DOC, water column	0.65	0.13

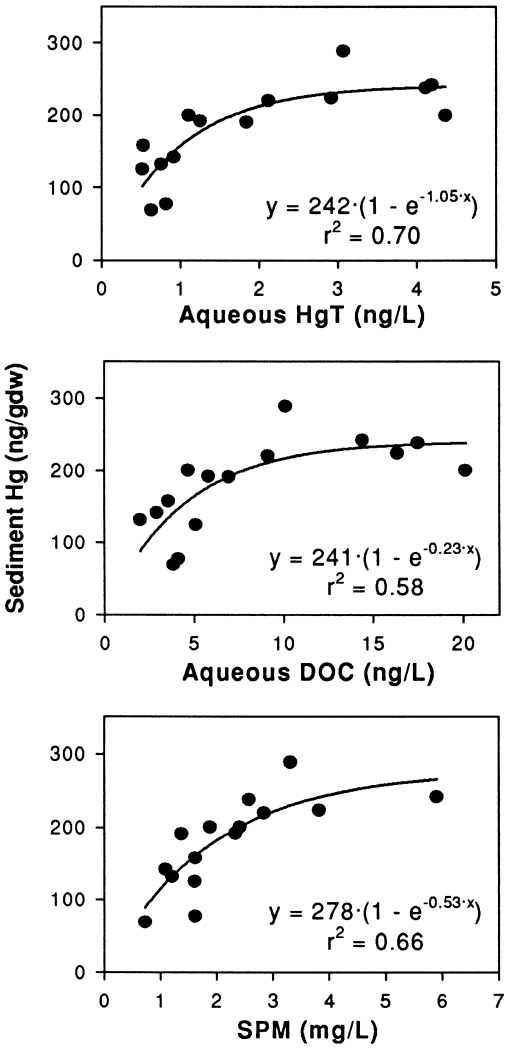

Fig. 14. Relationship between mean sediment Hg_T and mean aqueous Hg, DOC or suspended particulate matter (SPM) in the water column of the 15 WI study lakes.

sarily tied to a specific uptake mechanism, observation of this phenomenon has been interpreted as de facto evidence of trophic transport. Biomagnification results from trophic transport when consumers absorb contaminants from carbon sources (food) and then respire carbon at a rate faster than they depurate the contaminant.

Our data clearly show that meHg increased with increasing trophic level in the 15 Wisconsin study lakes while Hg^{II} did not (Table 9). In fact, Hg^{II} concentrations decreased as trophic level increased, leading to the u-shaped behavior of total Hg in the biota. This finding is consistent with earlier observations on the pelagic biota of Little Rock Lake (Watras and Bloom, 1992) and several Scandinavian lakes (Surma-Aho et al., 1986; Meili, 1991) and with the observations of increasing meHg fraction ($meHg/Hg_T$) between marine algae, mussels, and fish reported by May et al. (1987). It also helps to explain the earlier conclusions of Knauer and Martin (1972) and Williams and Weiss (1973) that the biomagnification of Hg_T does not occur in pelagic marine communities.

Dissolved organic carbon competes with organisms for Hg^{II} and meHg. However, on a unit carbon basis, the biota has a substantially stronger affinity for meHg. Assuming organisms are roughly 50% C (dry wt.), we find that microseston, zooplankton and fish are enriched in meHg by factors of 3, 5 and 20 (respectively) relative to DOC (Table 9). This enrichment corresponds to biomagnification factors ranging from 1.6 to 4 between trophic levels.

The effect of DOC on bioaccumulation and biomagnification is shown across three trophic

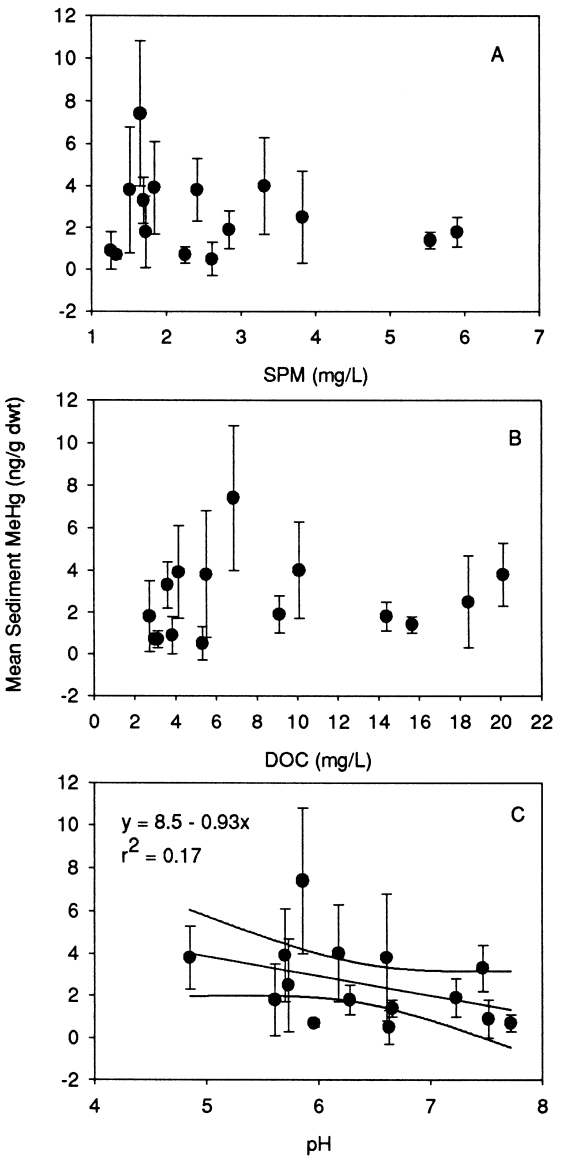

Fig. 15. Relationship between meHg in surficial sediments and SPM, DOC, or pH in surficial waters of the 15 WI study lakes. Data are means ± 1 S.D. for each lake.

levels on Fig. 16. The bioaccumulation factors (BAF) observed in this study lie within the range observed earlier on Little Rock Lake (Watras and Bloom, 1992), but the variability among the 15 lakes is high in part because of the uncorrected effects of variables like DOC (Fig. 16A). Compared across all 15 lakes, the effect of DOC on BAFs is similar for all three trophic levels on Fig. 16B. The regression slopes are statistically indistinguishable and the difference in elevation reflects the degree of biomagnification between trophic levels.

4.2. Bioconcentration

Bioconcentration refers to the tendency of a substance to accumulate in biota relative to water. Typically, bioconcentration is quantified by the ratio of the dissolved concentration of the substance to its concentration in a particular biota b of interest

$$\mathrm{BCF}_{b,j} = \mathrm{meHg}_b / [\mathrm{meHg}_D] \tag{2}$$

where the subscript j refers to the lake or system from which the water and biota were sampled. For metals such as Hg^{II} and meHg, bioconcentration factors vary widely between lakes. Here, we wish to examine how much of this variability between lakes can be accounted for via modeling the equilibrium aqueous speciation of meHg.

Since uptake via different mechanisms can lead to different metal species controlling uptake rates (Hudson, 1998), we must first define a bioconcentration factor with respect to rate-controlling species $\mathrm{meHg_i}$:

$$\mathrm{BCF}^{\mathrm{i}}_{b,j} = \frac{\mathrm{meHg}_{b,j}}{[\mathrm{meHg_i}]_j} = f(\mathrm{chem}_j, \mathrm{biota}_j) \tag{3}$$

where f expresses any remaining dependencies on lake chemical and biological parameters. For organisms that acquire most of their meHg directly from water, this expression implies that $\mathrm{meHg_i}$ controls the uptake rate while f reflects the ratio uptake rate constant:specific growth rate (or $V_{\mathrm{net}}/[\mathrm{meHg_i}] \times u$ in Eq. 1). For organisms that take up meHg primarily from food, the dependence on species $\mathrm{meHg_i}$ would reflect uptake from water into the lower trophic levels while f would contain terms expressing both food web interactions and organism-specific factors (cf. Cabana et al., 1994). In both cases a direct proportionality between concentrations in water and

Table 9
Bioaccumulation of mercury and biomagnification of methylmercury in the lower trophic levels of pelagic food webs

Compartment	Marine ecosystem[a] Hg_T (ng/g dwt)	Freshwater ecosystems[b]				
		Number of lakes	Hg_T (ng/g dry wt.)	Hg^{II} (ng/g dry wt.)	meHg (ng/g dry wt.)	% meHg
DOC[c]		15	193 (84–326)	170 (77–279)	23 (3–61)	11[d] (4–22)
Microseston	410	15	202 (43–343)	170 (30–316)	34 (13–94)	18 (7–34)
Zooplankton	130	15	83 (33–206)	29 (10–48)	53 (6–161)	57 (11–83)
Small fish	720	14	512 (131–924)	27 (7–48)	485 (124–876)	95[e]

Note. Data are mean values of the 15 Wisconsin lakes with range in parentheses.

[e] % meHg in small fish from Grieb et al. (1990), Bloom (1992) and Watras (unpublished).

biota are predicted. (Note that in order to consider concurrent uptake of different species, a hybrid concentration would need to be defined.)

One way to test these models is to check for correlations between the concentrations of meHg in the biota and the aqueous meHg species of interest, as implied by rearranging Eq. (3). In doing so, one must be cautious to retain the direct proportionality between mercury in biota and water. In other words, strong correlations only support the hypothesized controlling species if they have a slope of near unity [log-transform of (4) or an intercept of nearly zero (linear form)]. Taking the log transform of Eq. (3) is a convenient means of forcing the proper relationship and it also has the advantage of being consistent with the typical proportionality between the mean and variance of these samples (log-normal distribution). Once the bioconcentration factors are computed for each hypothesis, we can then examine them to see if they are correlated with water quality or biological parameters in order to explore the nature of the function f. The test criterion is the ability to account for variability in meHg bioconcentration factors observed between lakes at different trophic levels.

As noted above, standard bioconcentration factors are calculated using $meHg_D$ in the denominator of log-transformed Eq. (3). Since no uptake mechanism is intended when one uses this approach, we may regard it as the null hypotheses — i.e. that chemical speciation has no effect on uptake. We may then test alternative hypotheses based on the uptake mechanisms and speciation models proposed for other metals where there is evidence that the different aqueous species are taken up at different rates (e.g. free ion, hydroxide, chloride and organic complexes). The hypotheses under consideration may be summarized as follows:

1. $meHg_D$: all species are equally available. This assumption could apply to an actual mechanism if all meHg complexes are kinetically labile and if uptake is strongly limited by diffusion or occurs via a kinetically controlled transporter.
2. $meHgCl/OH^0$: passive absorption of neutral $meHgCl^0$ and $meHgOH^0$. We use a mixed concentration that is defined according to the ratio of the passive permeability coefficients of these species (Mason et al., 1996):

$$[meHgX^0] \equiv [meHgCl^0] + 0.041 \times [meHgOH^0]$$

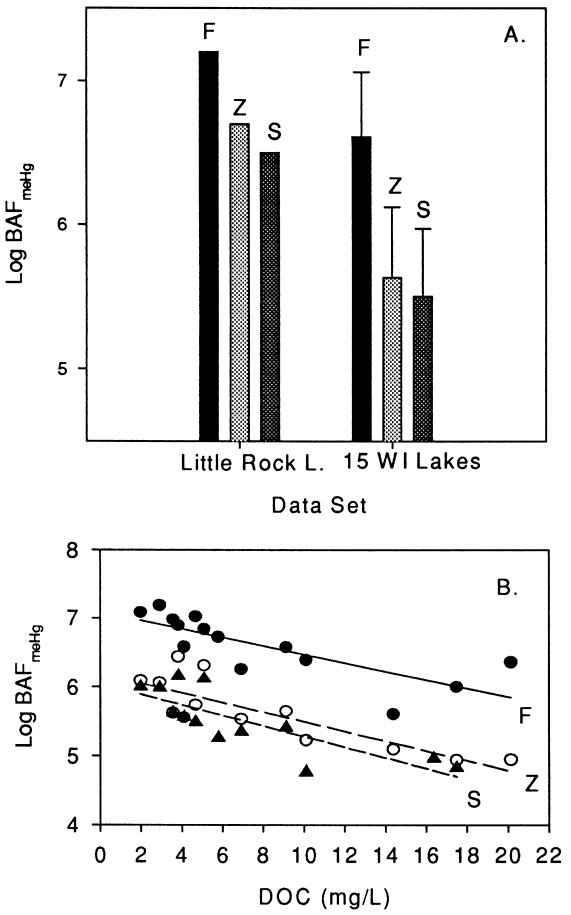

Fig. 16. Comparison of bioaccumulation factors for meHg in fish, zooplankton, and microseston in northern Wisconsin lakes (log BAF_{meHg} = log C_b/log C_w, where C_b is the meHg concentration in biota on a dry weight basis and C_w is $meHg_D$). (A) Comparison between earlier data from Little Rock Lake [modified from Watras and Bloom (1992)] and data from this study; bars show mean value ± S.D. (B) Dependency of log BAF_{meHg} on DOC for microseston (S, filled triangles, short dash), crustacean zooplankton (Z, open circles, long dash), and fish (F, filled circles, solid line). Data are mean values for the 15 study lakes. Regression equations are: fish: $y = 7.09 - 0.06x$, $r^2 = 0.61$; zooplankton: $y = 6.19 - 0.07x$, $r^2 = 0.70$; microseston: $y = 6.04 - 0.08x$, $r^2 = 0.64$.

3. $meHg^+/X_{transporter}$: free ion control of facilitated uptake. MeHg uptake would require two steps:

$$meHg^+ + X_{transporter} \overset{\text{Binding}}{\longleftrightarrow} meHgX^+_{transporter}$$

$$meHgX^+_{transporter} \overset{\text{Internalization}}{\longrightarrow} meHg_{cell} + X_{transporter}$$

4. $meHg^+/HX_{transporter}$: free ion control of facilitated uptake via a protonated transporter site. The binding reaction in this case is:

$$meHg^+ + HX_{transporter} \longleftrightarrow meHgX_{transporter} + H^+$$

which is equivalent to meHgOH uptake:

$$meHgOH + HX_{transporter} \longleftrightarrow meHgX_{transporter} + H_2O.$$

More relationships between speciation and uptake are possible (Hudson et al., 1994; Hudson, 1998), but will not be considered here.

To test these hypotheses, we applied the logarithmic form of equation (3) to the lake-averaged data for: (1) microseston; (2) crustacean zooplankton; and (3) yellow perch using aqueous concentrations of the various meHg species calculated according to the assumptions of Hudson et al. (1994). The reactions considered include:

$$meHg^+ + OH^- \longleftrightarrow meHgOH^0$$

$$meHg^+ + Cl^- \longleftrightarrow meHgCl^0$$

$$meHg^+ + Y^-_{DOM} \longleftrightarrow meHgY_{DOM}$$

$$H^+ + Y^-_{DOM} \longleftrightarrow HY_{DOM}$$

where Y_{DOM} is an approximation for the meHg-binding moieties of aquatic DOM. The mean BCF and variance were computed for each meHg species and the correlations between BCF and pH, DOC and other solutes were determined (Table 10a–c). The main test criterion was the variance of $BCF^i_{b,j}$, which should be lowest for the best model. Correlations between BCF and other analytes indicate which factors might further reduce the variance of BCF.

As shown on Table 10a–c, the lowest variability

Table 10
Correlations between BCF and pH, DOC and other solutes

Species *i*	Log BCF		Correlates					
	Mean	S.D.	pH		log DOC		Other	
			Slope	*r*	Slope	*r*	Solute	Slope/*r*
(a) Seston meHg bioconcentration factors (BCF, l / kg dry wt.: see text)								
$meHg_D$	5.5	0.46	0.14	0.23	−1.5	−0.81	SPM	−2.0/−0.83
							Cl	−0.60/−0.59

$meHgX^{0A}$	7.7	0.78	0.68	0.81	−1.1	−0.46	Mn	−1.2/−0.60
(c) Perch (3-year-old) meHg bioconcentration factors (BCF, l / kg dry wt.: see text)								
$meHg_D$	6.7	0.45	0.09	0.14	−1.4	−0.83	SPM	−1.8/−0.79
							SO_4	1.7/0.74
$meHg^+$	9.8	0.85	0.83	0.86	−0.63	−0.24	Ca	1.9/0.79
							Mg	1.8/0.74
meHgOH	**8.2**	**0.26**	**−0.006**	**−0.02**	**−0.49**	**−0.46**	**SPM**	**−0.88/−0.62**
							Chl *a*	**−0.73/−0.60**
$meHgX^{0A}$	8.7	0.69	0.58	0.66	−1.2	−0.50	Mn	−1.1/−0.66

Note. Data are the mean values and standard deviation (S.D.) calculated using Eq. (3).

in BCFs (reported as standard deviation, S.D.) was consistently associated with either $meHg^+$ or meHgOH species, but not with $meHgX^0$, which is mainly the neutral chloride complex. The meHg species which resulted in the least variable BCFs, also had the lowest correlation with ancillary variables like pH and DOC. This result indicates that normalizing biotic concentrations of meHg to that particular aqueous species of meHg effectively removed the influence of the ancillary variable. In other words, the effect of the ancillary variable was to reduce the bioavailability of the important meHg species in water.

Acknowledgements

This research was supported by funds from the Electric Power Research Institute (Contract Nos. 4TS3432/6424-WO5136-01; CF3297-096-13100; and RP3297-02) and the Wisconsin Department of Natural Resources. We thank Vanessa Visman, John Frank, Jim Thoyre, and Jodi Host for technical assistance in the field and laboratory. Many of the meHg and trace element analyses were performed at Frontier Geosciences, Seattle, WA. This is a contribution from the Trout Lake Station, Center for Limnology, University of Wisconsin–Madison.

EXECUTIVE SUMMARY

About This Document

This document is the basis for a human health Ambient Water Quality Criterion (AWQC) for methylmercury. This AWQC replaces the AWQC for total mercury in published in 1980 and partially updated in 1997. Under Section 304(a) of the Clean Water Act, EPA must periodically revise criteria for water quality to accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects of pollutants on human health.

This document uses new methods and information described in the Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000) (2000 Human Health Methodology) (U.S. EPA, 2000a,b). These new methods include updated approaches to determine toxicity dose-response relationships for both carcinogenic and noncarcinogenic effects, updated information for determining exposure factors, and new procedures to determine bioaccumulation factors.

The Mercury Study Report to Congress (MSRC) (U.S. EPA, 1997), an eight-volume report prepared by the U.S. Environmental Protection Agency (EPA) and submitted to Congress in 1997, serves as a primary information source on methylmercury. However, as the state of the science for methylmercury is continuously and rapidly evolving, the information from the MSRC has been supplemented by inclusion of published information since 1997.

Exposure to Methylmercury

The major pathway for human exposure to methylmercury is consumption of contaminated fish. Dietary methylmercury is almost completely absorbed into the blood and is distributed to all tissues including the brain; it also readily passes through the placenta to the fetus and fetal brain.

Major Health Effects of Methylmercury

Methylmercury is a highly toxic substance with a number of adverse health effects associated with its exposure in humans and animals. Epidemics of mercury poisoning following high-dose exposures to methylmercury in Japan and Iraq demonstrated that neurotoxicity is the health effect of greatest concern. These epidemics led to observation of methylmercury effects on the fetal nervous system. High-dose

human exposure results in mental retardation, cerebral palsy, deafness, blindness, and dysarthria in utero and in sensory and motor impairment in adults. Although developmental neurotoxicity is currently considered the most sensitive health endpoint, data on cardiovascular and immunological effects are beginning to be reported and provide more evidence for toxicity from low-dose methylmercury exposure.

Three large prospective epidemiology studies in the Seychelles Islands, New Zealand, and the Faroe Islands were designed to evaluate childhood development and neurotoxicity in relation to fetal exposures to methylmercury in fish-consuming populations. Prenatal methylmercury exposures in these three populations were within the range of some U.S. population exposures. No adverse effects were reported from the Seychelles Islands study, but children in the Faroe Islands exhibited subtle developmental dose-related deficits at 7 years of age. These effects include abnormalities in memory, attention, and language. In the New Zealand prospective study, children at 4 and 6 years of age exhibited deficiencies in a number of neuropsychological tests.

In addition to the three large epidemiological studies, studies on both adults and children were conducted in the Amazon; Ecuador; French Guiana; Madeira; Mancora, Peru; northern Quebec; and Germany. Effects of methylmercury on the nervous system were reported in all but the Peruvian population.

Other Health Effects of Methylmercury

Methylmercury causes chromosomal effects but does not induce point mutations. The MSRC concluded that because there are data for mammalian germ-cell chromosome aberration and limited data from a heritable mutation study, methylmercury is placed in a group of high concern for potential human germ-cell mutagenicity. There is no two-generation study of reproductive effects, but shorter term studies in rodents, guinea pigs and monkeys have reported observations consistent with reproductive deficits. There are no data to indicate that methylmercury is carcinogenic in humans, and it induces tumors in animals only at highly toxic doses. Application of the proposed revisions to the Guidelines for Cancer Risk Assessment (EPA 1999)leads to a judgment that methylmercury is not likely to be carcinogenic for humans under conditions of exposure generally encountered in the environment.

Quantitative Risk Estimate for Methylmercury

The quantitative health risk assessment for a noncarcinogen relies on a reference dose (RfD). This is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious health effects during a lifetime. To derive an RfD, one first establishes a no adverse effect level (NOAEL) for a particular endpoint. This can be done by inspection of the available data or by using a mathematical modeling procedure to estimate the NOAEL; the latter approach was used for methylmercury. Next the NOAEL is divided by a numerical uncertainty factor to account for areas of variability and uncertainty in the risk estimate.

There has been considerable discussion within the scientific community regarding the level of exposure to methylmercury that is likely to be without an appreciable risk of deleterious health effects during a lifetime. In 1999, the Congress directed EPA to contract with the National Research Council (NRC) of the National Academy of Sciences to evaluate the body of data on the health effects of methylmercury. NRC was to concentrate on new data since the 1997 MSRC, and to provide recommendations regarding issues relevant to the derivation of an appropriate RfD for methylmercury. NRC published their report, *Toxicological Effects of Methylmercury*, in 2000. EPA generally concurred with the NRC findings and recommendations. The NRC document was used as a resource in determining the EPA RfD for methylmercury documented here.

Choice of Study

The adverse effect of methylmercury observed at lowest dose is neurotoxicity, particularly in developing organisms. The brain is considered the most sensitive target organ for which there are data suitable for derivation of an RfD. There is an extensive array of peer-reviewed, well-analyzed data from human studies of low-dose exposure to methylmercury. NRC and EPA considered three epidemiologic longitudinal developmental studies suitable for quantitative risk assessment: the Seychelles Child Development Study (SCDS); the ongoing studies of children in the Faroe Islands; and the study of children in New Zealand. All cohorts consisted of children exposed in utero through maternal consumption of mercury-contaminated fish or marine mammals. In all studies there were biomarkers of maternal exposure (hair), and in the Faroes study cord blood was also used as an additional measure of fetal exposure. The SCDS yielded no evidence of impairment related to methylmercury exposure, but the two other studies have found dose-related adverse effects on a number of

neuropsychological endpoints. EPA chose to base the RfD on data from the Faroes study. The SCDS has no findings of effects associated with methylmercury exposure, and thus is not the best choice for a public health protective risk estimate. While the New Zealand study does show mercury-related effects it relatively small by comparison to the other two. Advantages of the Faroes study include these:

- Large sample size ($n > 900$ for some measures)
- Good statistical power as calculated by conventional means
- Use of two different biomarkers of exposure
- Comprehensive and focused neuropsychological assessment
- Assessment at an age and state of development when effects on complex neuropsychological functions are most likely to be detectable
- Statistically significant observations which remain after adjusting for potential PCB effects
- Extensive scrutiny in the epidemiological literature

The Faroe Islands study was used for derivation of the RfD.

Estimation of the No Adverse Effect Level

A benchmark dose analysis was chosen as the most appropriate method of quantifying the dose-effect relationship. The level chosen was a Benchmark Dose Lower Limit (BMDL); this was the lower 95% limit on a 5% effect level obtained by applying a K power model ($K \geq 1$) to dose-response data based on mercury in cord blood. The BMDL was chosen as the functional equivalent of a no-adverse-effect level for calculation of the RfD.

Choice of Endpoint

Several endpoints are sensitive measures of methylmercury effects in the Faroese children. EPA considered the recommendations of the NRC and EPA's external scientific peer review panel in coming to a decision as to the appropriate endpoint. The NRC recommended the use of a BMDL of 58 ppb mercury in cord blood from the Boston Naming Test (BNT). The external peer panel felt that the BNT scores showed an effect of concomitant PCB exposure in some analyses. They preferred a PCB-adjusted BMDL of 71 ppb mercury in cord blood for the BNT. A difficulty with this choice is that this BMDL is based on scores from only about one-half of the total cohort. The peer panel further suggested using a composite index across several measures in the Faroes data set. EPA prepared a comparison of the

endpoints recommended by NRC and peer reviewers; this also included the BMDLs from the NRC integrative analysis and geometric means of four scores from the Faroes. These BMDLs and corresponding estimates of ingested methylmercury are within a very small range. Rather than choosing a single measure for the RfD critical endpoint, EPA considers that this RfD is based on several scores. These test scores are all indications of neuropsychological processes related to the ability of a child to learn and process information.

Calculation of Ingested Methylmercury Dose

In the risk assessment discussion EPA uses the NRC-recommended BMDL of 58 ppb mercury in cord blood as an example in the dose conversion and RfD calculation. The BMDL in terms of mercury in cord blood was converted to an estimate of ingested methylmercury. This was done by use of a one-compartment model similar to that used in the MSRC. Single-parameter estimates were used rather than a distributional approach. It was assumed that the cord blood methylmercury level was equal to maternal blood level. The ingested dose of methylmercury that corresponds to a cord blood level of 58 ppb is 1.081 μg/kg bw/day.

Uncertainty Factor

Several sources of variability and uncertainty were considered in the application of a composite uncertainty factor of 10. This included a factor of 3 for pharmacokinetic variability and uncertainty; one area of pharmacokinetic uncertainty was introduced with the assumption of equivalent cord blood and maternal blood mercury levels. An additional factor of 3 addressed pharmacokinetic variability and uncertainty. Other areas of concern include inability to quantify possible long-term sequelae for neurotoxic effects, questions as to the possibility of observing adverse impacts (such as cardiovascular effects) below the BMDL, and lack of a two-generation reproductive effects assay.

Methylmercury Reference Dose

The RfD derived in this assessment is 0.1 μg/kg bw/day or $1x10^{-4}$ mg/kg bw/day. The RfD for methylmercury was not calculated to be a developmental RfD only. It is intended to serve as a level of exposure without expectation of adverse effects when that exposure is encountered on a daily basis for a lifetime. In the studies so far published on subtle neuropsychological effects in children, there has been no definitive separation of prenatal and postnatal exposure that would permit dose-response modeling.

That is, there are currently no data that would support the derivation of a child (vs. general population) RfD.

Relative Source Contribution

The assessment of methylmercury exposure from common media sources (e.g., diet, air) and relative source contribution (RSC) estimates follows the 2000 Human Health Methodology. The RSC is used to adjust the RfD to ensure that the water quality criterion is protective, given other anticipated sources of exposure. The exposure assessment characterizes the sources of methylmercury exposure in environmental media, providing estimates of intake from the relevant sources for children, women of childbearing age, and adults in the general population. Based on available data, human exposures to methylmercury from all media sources except freshwater/estuarine and marine fish are negligible, both in comparison with exposures from fish and compared with the RfD. Estimated exposure from ambient water, drinking water, nonfish dietary foods, air, and soil are all, on average, at least several orders of magnitude less than those from freshwater/estuarine fish intakes. Therefore, these exposures were not factored into the RSC. However, ingestion of marine fish is a significant contributor to total methylmercury exposure. For the methylmercury criterion, the RSC is the estimated exposure from marine fish intake. This is subtracted from the RfD when calculating the water quality criterion. One hundred percent of the mercury in marine fish was assumed to be present as methylmercury. The estimated average exposure to methylmercury from marine fish is 2.7 x 10-5 mg/kg-day. This exposure represents almost 30% of the RfD.

Methylmercury Bioaccumulation

Methylmercury is a chemical that bioaccumulates and biomagnifies in aquatic food webs. The fates of mercury and methylmercury in the environment are complex processes affected by numerous biotic and abiotic factors that are subjects of ongoing research. Methylation of mercury is a key step in the entrance of mercury into food chains. The biotransformation of inorganic mercury forms to methylated organic forms in water bodies can occur in the sediment and the water column. Inorganic mercury can be absorbed by aquatic organisms but is generally taken up at a slower rate and with lower efficiency than is methylmercury. Methylmercury continues to accumulate in fish as they age. Predatory organisms at the top of aquatic and terrestrial food webs generally have higher methylmercury concentrations because methylmercury is typically not completely eliminated by organisms and is

transferred up the food chain. Nearly 100% of the mercury that bioaccumulates in upper-trophic-level fish (predator) tissue is methylmercury.

Numerous factors can influence the bioaccumulation of mercury in aquatic biota. These include, but are not limited to, the acidity (pH) of the water, length of the aquatic food chain, temperature, and dissolved organic material. Physical and chemical characteristics of a watershed, such as soil type and erosion or proportion of area that is wetlands, can affect the amount of mercury that is transported from soils to water bodies. Interrelationships among these factors are poorly understood and are likely to be site-specific. No single factor (including pH) has been correlated with extent of mercury bioaccumulation in all cases examined. Two lakes that are similar biologically, physically, and chemically can have different methylmercury concentrations in water, fish, and other aquatic organisms.

The Methylmercury Criterion is a Fish Tissue Residue Criterion

EPA concluded that it is more appropriate at this time to derive a fish tissue (including shellfish) residue water quality criterion for methylmercury rather than a water column-based water quality criterion. This decision considered issues of mercury fate in the environment, the NRC report on the toxicological effects of mercury, and in particular the methylmercury peer review comments. EPA believes a fish tissue residue water quality criterion is appropriate for many reasons. Such a criterion integrates spatial and temporal complexity that occurs in aquatic systems and that affects methylmercury bioaccumulation. A fish tissue residue water quality criterion is more closely tied to the CWA goal of protecting the public health because it is based directly on the dominant human exposure route for methylmercury. The concentration of methylmercury is also generally easier to quantify in fish tissue than in water and is less variable over the time periods in which water quality standards are typically implemented in water quality-based. Thus, the data used in permitting activities can be based on a more consistent and measurable endpoint. A fish tissue residue criterion is also consistent with how fish advisories are issued. Fish advisories for mercury are based on the amount of methylmercury in fish tissue that is considered acceptable, although they are usually issued for a certain fish or shellfish species in terms of a meal size. A fish tissue residue water quality criterion should enhance harmonization between these two approaches for protecting the public health.

The methylmercury water quality criterion is, thus, a concentration in fish tissue. It was calculated using the criterion equation in the 2000 Human Health Methodology rearranged to solve for a protective concentration in fish tissue rather than in water.

$$TRC = \frac{BW \times (RfD - RSC)}{\sum_{i=2}^{4} FI_i}$$

Where:

TRC = Fish tissue residue criterion (mg methylmercury/kg fish) for freshwater and estuarine fish

RfD = Reference dose (based on noncancer human health effects) of 0.0001 mg methylmercury/kg body weight-day

RSC = Relative source contribution (subtracted from the RfD to account for marine fish consumption) estimated to be 2.7×10^{-5} mg methylmercury/kg body weight-day

BW = Human body weight default value of 70 kg (for adults)

FI = Fish intake at trophic level (TL) i (i = 2, 3, 4); total default intake is 0.0175 kg fish/day for general adult population. Trophic level breakouts for the general population are: TL2 = 0.0038 kg fish/day; TL3 = 0.0080 kg fish/day; and TL4 = 0.0057 kg fish/day.

The resulting Tissue Residue Criterion is 0.3 mg methylmercury/kg fish. This is the concentration in fish tissue that should not be exceeded based on a total fish and shellfish consumption-weighted rate of 0.0175 kg fish/day. EPA strongly encourages States and authorized Tribes to develop a water quality criterion for methylmercury using local or regional data rather than the default values if they believe that such a water quality criterion would be more appropriate for their target population.

1.0 INTRODUCTION

1.1 PURPOSE OF THIS DOCUMENT

This document provides guidance to States and Tribes authorized to establish water quality standards under the Clean Water Act (CWA) to protect human health, pursuant to Section 304(a) of the CWA. Under the CWA, States and authorized Tribes are to establish water quality criteria to protect designated uses. While this document constitutes the U.S. Environmental Protection Agency's (EPA's) scientific recommendations regarding concentrations of methylmercury in fish and shellfish that protect human health, this document does not substitute for the CWA or EPA's regulations, nor is it a regulation itself. Thus, it cannot impose legally binding requirements on EPA, States, Tribes, or the regulated community, and may not apply to a particular situation based upon the circumstances. State and Tribal decision makers retain the discretion to adopt approaches on a case-by-case basis that differ from this guidance when appropriate. EPA may change this guidance in the future.

This document establishes a water quality criterion for methylmercury. The U.S. Environmental Protection Agency (EPA) originally published an Ambient Water Quality Criterion (AWQC) for total mercury in 1980. That AWQC was partially updated in 1997 to incorporate a change in the reference dose (RfD). As required under Section 304(a) of the Clean Water Act, EPA must periodically revise criteria for water quality to accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on human health from the presence of pollutants in any body of water. The criterion uses new methods and information described in the *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (2000) (2000 Human Health Methodology) and in the Methodology's accompanying *Federal Register Notice* (U.S. EPA, 2000a,b). These new methods include updated approaches to determine toxicity dose-response relationships for both carcinogenic and noncarcinogenic effects, updated information for determining exposure factors, and new procedures to determine bioaccumulation factors.

Development of a methylmercury criterion involves some unique considerations compared with many of EPA's past efforts in the water quality criteria program. Traditionally, EPA has established recommended 304(a) criteria to protect human health as ambient concentrations in water. For those pollutants that bioaccumulate, such as methylmercury, exposure through the food pathway is estimated by using a bioaccumulation factor (BAF). However, following review of available data and

recommendations made by external peer reviewers (U.S. EPA, 2000c), EPA determined that it is more appropriate to base the methylmercury criterion on a fish tissue residue concentration than on an ambient water concentration. This determination was partly based on the current scientific understanding of the fate of mercury and methylmercury in aquatic ecosystems. Another factor was the limited information on sources of mercury and the conversion to methylmercury (and its bioavailability). Additional considerations were the difficulty in measuring methylmercury in the water column and relating it to concentrations in aquatic organisms. EPA believes that the latest data and science on methylmercury exposure, effects, and environmental fate support the derivation of a fish tissue residue criterion.

1.2 PRIMARY DATA SOURCE

Much of the information in this document has been taken from the *Mercury Study Report to Congress* (MSRC) (U.S. EPA, 1997b-h). This comprehensive, eight-volume study was prepared by EPA and submitted to Congress in 1997 to fulfill the requirements of section 112(n)(1)(B) of the Clean Air Act, as amended in 1990. The MSRC provides an assessment of the magnitude of U.S. mercury emissions by source, the health and environmental implications of those emissions, and the availability and cost of control technologies. As the state of the science for methylmercury continues to evolve, information from the MSRC has been supplemented by data and analyses published since 1997. The health effects information used in the derivation of the reference dose (RfD) for the fish tissue residue concentration is based on the recommendations of the National Academy of Sciences National Research Council report, *Toxicological Effects of Methylmercury* (NRC, 2000). For additional discussion on the NRC recommendations, see Section 4 of this criteria document. The comments of the methylmercury RfD scientific peer review panel also guided the risk assessment.

1.3 CHEMICAL AND PHYSICAL PROPERTIES

The water quality criterion is being derived for methylmercury (CAS No. 22967-92-6). Synonyms for methylmercury include MeHg, methylmercury ion, methylmercury ion (1+), methylmercury (1+), methyl mercury, and methylmercury(I) cation (Prager, 1997). A commonly occurring form of methylmercury is methylmercuric chloride ($CH_3Hg^+Cl^-$), a stable salt form that exists as a white crystal. This compound is often used in laboratory dosing experiments investigating the toxicological properties of methylmercury. Because methylmercury exists as a free ion only in minute quantities (Prager, 1997), the chemical and physical data provided below are for the chloride salt.

The table below presents available chemical and physical data for methylmercuric chloride (ATSDR, 1999; Kaufman, 1969).

Chemical formula	CH_3HgCl
Chemical structure	$CH_3—Hg^+ Cl^-$
Molecular weight	251.10 (g/mol)
Physical state (25°C)	White crystal
Boiling point (at 25 mm Hg)	No data
Melting point	170°C
Density (25°C)	4.06 g/mL
Vapor pressure (25°C)	0.0085 mm Hg
Water solubility (21°C)	<100 mg/L
Log octanol/Water partition coeff.	No data
Odor threshold (air)	No data
Conversion factors (air)	1 ppm = 10.27 mg/m^3; 1 mg/m^3 = 0.0974 ppm

2.0 TOXICOKINETICS

This section presents information on the absorption, distribution, metabolism, and excretion of methylmercury in humans and animals. This information is summarized from Volume V, Chapter 2 of the *Mercury Study Report to Congress* (MSRC) (U.S. EPA, 1997e).

2.1 ABSORPTION

2.1.1 Oral Absorption

Methylmercury is efficiently absorbed from the gastrointestinal tract following ingestion. Approximately 94%-95% of methylmercury in fish ingested by volunteers was absorbed from the gastrointestinal tract (Aberg et al., 1969; Miettinen, 1973). Aberg et al. (1969) found uptake of greater than 95% of radiolabeled methylmercuric nitrate administered in water to human volunteers.

Data from studies on rats, cats, and monkeys support these absorption estimates (ATSDR, 1999). Studies on rats indicate rapid and complete absorption of inhaled methylmercury vapor into the bloodstream (Fang, 1980). Female cynomolgus monkeys administered 0.5 mg mercury per kilogram of methylmercuric chloride by oral gavage experienced complete absorption within 6 hours (Rice, 1989).

2.1.2 Absorption via Other Routes

Limited information is available on absorption via inhalation and dermal routes. There is one reported human dermal exposure when a 48-year-old chemistry professor inadvertently spilled drops (0.4-0.5 mL) of dimethylmercury from her pipette into her latex gloves. Penetration of dimethylmercury through the gloves occurred instantaneously. Mercury hair level was elevated to almost 1,100 ppm, with a half life of 74.6 days. Five months after exposure, the woman experienced severe neurotoxicity and died 9 months later (Blayney et al., 1997; Nierenberg et al., 1998).

Skog and Wahlberg (1964) evaluated the dermal absorption of the methylmercuric cation in guinea pigs. The test material was applied as the dicyandiamide salt. Absorption was estimated by disappearance of the applied compound and by appearance of mercury in kidney, liver, urine, and blood. Approximately 3% to 5% of the applied dose was absorbed during a 5-hour period.

Indirect evidence in animals indicates that inhaled methylmercury vapor is absorbed readily through the lungs. Fang (1980) showed a correlation between tissue mercury levels and both exposure level and exposure duration in rats exposed to radioactively labeled methylmercury vapor. The percent absorbed was not quantified.

2.2 DISTRIBUTION

After absorption from the gastrointestinal tract, methylmercury is readily absorbed into the blood and distributes to all tissues, including the brain and fetus. The fraction of the absorbed dose that is found in the blood has been estimated in three studies. Kershaw et al. (1980) reported an average fraction of 0.059 of the absorbed dose in total blood volume, based on a study of five adult male subjects who ingested methylmercury-contaminated tuna. In a group of nine male and six female volunteers who had received ^{203}Hg-methylmercury in fish, approximately 10% of the total mercury body burden was present in 1 L of blood in the first few days after exposure; this dropped to approximately 5% over the first 100 days (Miettinen et al., 1971). Sherlock et al. (1984) derived an average value of 1.14% for the percentage of absorbed dose in 1 kg of blood from data on subjects who consumed a known amount of methylmercury in fish over a 3-month period. Average daily intake in the study ranged from 43 to 233 µg/day. There was a dose-related effect on percentage of absorbed dose that ranged from 1.03% to 1.26% in 1 L of blood. Each of these values was multiplied by 5 to yield the total amount in the blood compartment, as there are approximately 5 L of blood in an adult human body.

Methylmercury in the blood is found predominantly in the red cells (Kershaw et al., 1980; Thomas et al., 1986). It is distributed throughout the body following absorption from the gastrointestinal tract into the blood (Clarkson, 1972; Hansen, 1988; Hansen et al., 1989; Nielsen and Andersen, 1992; Soria et al., 1992; Suzuki et al., 1984). Although the distribution of methylmercury in the body is generally uniform, at least one animal study indicates that high levels can be found in the kidney. Rice (1989b) administered 0.025 or 0.05 mg mercury/kg-day as methylmercuric chloride in apple juice to cynomolgus monkeys for approximately 2 years. Kidney tissue concentrations of mercury ranged from 10 to 28 ppm in the cortex and 1 to 10 ppm in the medulla when assessed more than 200 days after cessation of treatment. In contrast, mercury concentration was less than 2 ppm in the other tissues evaluated.

Methylmercury easily penetrates the placental barrier in humans and animals (Hansen, 1988; Hansen et al., 1989; Nielsen and Andersen, 1992; Soria et al., 1992; Suzuki et al., 1984). Several studies

have demonstrated mercury in newborn cord blood. The relationship to maternal blood is variable (Grandjean et al., 1999). Information on this relationship is discussed in Section 4.5.4.1.

The distribution of methylmercury in animals may vary by age and sex (Thomas et al., 1982,, 1986, 1988). Female rats exposed to methylmercury had higher peak levels of mercury in the kidney (primarily as methylmercury) than males; inorganic mercury levels did not differ significantly between the sexes (Thomas et al., 1986). Accumulation of mercury was found to be higher in the bodies of neonatal rats (Thomas et al., 1988) than in adult rats (Thomas et al., 1982). Ten days after administration of methylmercury, 94% of the dose was still detected in neonates while approximately 60% was retained in adults (Thomas et al., 1988). The longer retention of mercury in neonates may result from multiple factors, including the high levels of mercury accumulated in the pelt of neonates owing to lack of clearance (Thomas et al., 1988) and the lack of a fully developed biliary transport system in neonates (Ballatori and Clarkson, 1982).

2.3 METABOLISM

The time required for methylmercury metabolism to inorganic mercury may account for the latent or silent period observed in epidemiological studies from methylmercury poisoning incidents in Japan and Iraq. During the latent period (both during and after the cessation of exposure) the patient feels no untoward effects. It is possible that a number of biochemical changes may take place in parallel during this period, and some may not be causatively related to the clinical outcome. Ganther (1978) hypothesized that the carbon-mercury bond in methylmercury undergoes homolytic cleavage to release methyl free radicals. The free radicals are expected to initiate a chain of events involving peroxidation of lipid constituents of the neuronal cells. The onset of symptoms is delayed for the period of time that cellular systems are able to prevent or repair effects of lipid peroxidation. When the cellular defense mechanisms are overwhelmed, rapid and progressive degeneration of the tissue results. In the Iraqi poisoning incident, the latent period before toxic signs were noted varied from a matter of weeks to months. In contrast, the latency observed in the Japanese poisoning incident was as long as a year or more. The difference in duration may in part be due to the presence of selenium in the fish ingested by the Japanese population.

Rat liver microsomes can metabolize methylmercury into inorganic mercury via the NADPH-cytochrome P-450 reductase, also known to control hydroxyl radical production in liver microsomes (Suda and Takahashi). To a lesser degree, an oral dose of methylmercuric chloride may also be

converted into inorganic mercury via the intestinal flora (Nakamura et al, 1977; Rowland et al., 1980). The intestinal wall is poor in absorbing the inorganic mercury, thus almost all of it is excreted. Studies in mice appear to indicate that toxicity from exposure to dimethylmercury results from the biotransformation of dimethylmercury to methylmercury (Ostland, 1969). Following acute exposure to methylmercury, most of the mercury in the brain is in the organic form; however, with chronic exposures, a greater amount is in the inorganic form, suggesting that the rate of demethylation increases with long-term exposure (Aschner and Aschner, 1990). Rice (1989a, 1989) demonstrated that tissue half-life of methylmercury in the brain may be significantly longer than the blood half-life.

In rats, methylmercury in the body is relatively stable and is only slowly demethylated to form mercuric ion (Norseth and Clarkson, 1970). The demethylation appears to occur in tissue macrophages (Suda and Takahashi, 1986), intestinal microflora (Nakamura et al., 1977; Rowland et al., 1980), and fetal liver (Suzuki et al., 1984).

2.4 EXCRETION

In humans, approximately 90% of the absorbed dose of methylmercury is excreted in the feces (U.S. EPA, 1997e). Excretion via the urine is relatively minor but slowly increases with time; at 100 days after dosing, urinary excretion of mercury accounted for 20% of the daily amount excreted. The urinary excretion of mercury may reflect the deposition of demethylated mercury in the kidneys and its subsequent excretion. In humans the major routes of excretion are via the bile and feces.

Feces are also the predominant route of methylmercury elimination in adult animals (Farris et al., 1993; Hollins et al., 1975; Thomas et al., 1987). Biliary excretion of methylmercury and its demethylation in gastrointestinal flora have been reported in rats (Farris et al., 1993). After a single oral dose of methylmercury, the major elimination route was the feces (65% of the administered dose as inorganic mercury and 15% of the administered dose as methylmercury) and the minor route was urine (1% of the administered dose as inorganic mercury and 4% of the administered dose as methylmercury) (Farris et al., 1993). Following administration of methylmercuric nitrate, 33% of the administered dose was excreted in 49 days; 0.18% to 0.27% excretion in the urine in 10 days and 3.3% urinary excretion in 49 days. This continued for up to 71 days postingestion (Miettinen, 1973). Forty to 50 days postingestion, <0.12% of the administered dose of mercury was found per gram of hair. The half-life for methylmercury appeared to be 70-74 days. In humans the whole body half-life of methylmercury was estimated to be between 70 and 80 days (Aberg et al., 1969; Miettinen, 1973; Bernard and Purdue, 1984).

Mercury is excreted into the hair of methylmercury-exposed humans and animals. Incorporation of mercury into hair is irreversible, and hair analysis is thus a useful tool for monitoring exposure to methylmercury. Segmental analysis of hair may be used to provide a historical record of exposure patterns.

Methylmercury is excreted in breast milk (Bakir et al., 1973; Sundberg and Oskarsson, 1992). The ratio of mercury in breast milk to mercury in whole blood was approximately 1:20 in women exposed to methylmercury via contaminated grain in Iraq between 1971 and 1972 (Bakir et al., 1973). Evidence from the Iraqi poisoning incident also showed that lactation decreased blood mercury clearance half-times from 75 days in males and nonlactating females to 42 days in lactating females; the faster clearance due to lactation was confirmed in mice (Greenwood et al., 1978). In mice, of the total mercury in the breast milk, approximately 60% was estimated to be methylmercury. Skerfving (1988) has found that 16% of mercury in human breast milk is methylmercury. Studies in animals indicate that the mercury content of breast milk is proportional to the mercury content of plasma (Sundberg and Oskarsson, 1992; Skerfving, 1988).

In rat and monkey neonates, excretion of methylmercury is severely limited (Lok, 1983; Thomas et al., 1982). In rats dosed prior to 17 days of age, essentially no mercury was excreted (Thomas et al., 1982). By the time of weaning, the rate of excretion had increased to adult levels. The failure of neonates to excrete methylmercury may be associated with the inability of suckling infants to secrete bile (Ballatori and Clarkson, 1982) and the decreased ability of intestinal microflora to demethylate methylmercury during suckling (Rowland et al., 1977).

Currently, five studies report clearance half-lives for methylmercury. Three studies suggest a half-life of approximately 70 to 80 days (Aberg et al., 1969; Bernard and Purdue, 1984; Miettinen, 1973). Smith et al. (1994) reported a half-life of 44 days in a study of seven adult males treated intravenously with methylmercury. In this study, methylmercury and inorganic mercury concentrations in blood and excreta were determined separately based on differential extractability into benzene. The predominant species in the blood was methylmercury; there was no detectable methylmercury in the urine. Al-Shahristani and Shihab (1974) calculated a "biological half-life" of methylmercury in a study of 48 male and female subjects who had ingested seed grain contaminated by organic mercurials. The half-life, determined from distribution of mercury along head hair, ranged from 35 to 189 days with a mean of 72 days.

The relatively long half-life of methylmercury in the body results partly from reabsorption of methylmercury secreted into the bile (hepatobiliary cycling) (Norseth and Clarkson, 1971). In this cycle, methylmercury forms a complex with glutathione in the hepatocyte and the complex is secreted into the bile via a glutathione carrier protein (Clarkson, 1993). The methylmercury-glutathione complex in the bile may be reabsorbed from the gallbladder and intestines into the blood. This cycle is terminated when intestinal microorganisms demethylate methylmercury to form mercuric ion (Rowland et al., 1980). Mercuric mercury is poorly absorbed from the intestines and the fraction that is not reabsorbed is excreted in the feces. As noted above, approximately 90% of the absorbed dose of methylmercury is ultimately excreted in the feces as mercuric mercury.

2.5 BIOLOGICAL MONITORING

Distribution of methylmercury to hair and blood provides a means for biological monitoring of methylmercury exposure. This section provides an overview of the use of hair and blood for assessing exposure and outlines the available methods for quantitation.

2.5.1 Blood

Methylmercury distributes freely throughout the body, and thus blood is a good medium for estimating short-term exposure. Blood levels may not necessarily reflect methylmercury intake over longer periods, as an individual's intake may fluctuate (Sherlock et al., 1982; Sherlock and Quinn, 1988).

The characteristic partitioning of mercury in the blood permits identification of the form of mercury to which an individual has been exposed. Measurements of blood hematocrit and mercury concentrations in both whole blood and plasma can be used to calculate the red blood cell to plasma mercury ratio. In the case of methylmercury, examination of this ratio enables estimation of interference from exposure to high levels of elemental or inorganic mercury (Clarkson et al., 1988).

2.5.2 Hair

Scalp hair is a useful indicator for estimating methylmercury exposure (Phelps et al., 1980). Mercury is incorporated into scalp hair at the hair follicle in proportion to its content in blood. The hair-to-blood ratio in humans has been estimated as approximately 250:1 expressed as μg mercury/g hair to mg mercury/l blood. Uncertainty in measurements, interindividual variation in body burden, differences

in hair growth rates, and variations in fresh and saltwater fish intake have led to estimates ranging from 190:1 to 370:1 and higher (Birke et al., 1972; Skerfving, 1974; Phelps et al., 1980; Turner et al., 1980; Sherlock et al., 1984). Once incorporated into the hair, the mercury is stable, and can give a longitudinal history of blood methylmercury levels (Phelps et al., 1980; WHO, 1990). The identity of the predominate chemical species (inorganic or methylmercury) depends on exposure patterns and the extent of methylmercury demethylation.

Chemical analyses to determine mercury content of hair assay total mercury rather than chemical species of mercury. As a result, the fraction of hair mercury that is methylmercury is an estimate based on knowledge of environmental and occupational exposure patterns (U.S. EPA, 1997f). Analysis of hair mercury levels may be confounded by several factors, including adsorption of mercury vapor onto the hair strands, natural hair color, hair treatment, and growth rate (Francis et al., 1982; Suzuki, 1988).

Analysis of mercury in maternal hair has been utilized to estimate the fetal burden. This approach has been validated by Cernichiari et al. (1995), who collected blood samples and autopsy brains from terminally ill neonates in a population exposed to methylmercury via fish consumption. Maternal blood and hair samples were also obtained. The concentrations of total mercury in six major brain regions of the neonates were highly correlated with the concentration of mercury in a 1-cm segment of maternal hair next to the scalp (correlation coefficients 0.6 to 0.8, $p<0.01$). These correlations were confirmed by a series of comparisons utilizing maternal hair, maternal blood, neonate blood, and neonate brain tissue.

2.5.3 Methods of Analyzing Mercury Concentrations in Biological Samples

The most common methods used to determine mercury levels in biological media include atomic absorption spectrometry, neutron activation analysis, X-ray fluorescence, and gas chromatography. Another method is anodic stripping voltammetry (Liu et al., 1990). Gas chromotography-electron capture is the only method capable of differentiating methylmercury from other species, whereas cold vapor atomic absorption spectrometry will detect mercury at parts per billion in both urine (Magos and Cernik, 1969) and blood samples (Magos and Clarkson, 1972). Mercury content in hair has been measured by cold vapor atomic absorption spectrometry, atomic fluorescence spectrometry, X-ray fluorescence, and neutron activation analysis (Zhuang et al., 1989).

Another method for analyzing biological samples containing methylmercury is with the use of *Pseudomonas putida* strain FB1. The method is considered very reliable and specific for methylmercury

quantification because chemical inference is negligible. The *Pseudomonas putida* bacteria is capable of converting methylmercury to methane gas and elemental mercury (Baldi and Filippelli, 1991), thus allowing the detection of 15 ng of methylmercury in 1 g of biological tissue with a coefficient of variation of 1.9%.

New methods, such as inductively coupled plasma-mass spectrometry (Kalamegham and Ash, 1992) for analyzing mercury in biological samples are being developed, but are considered very costly and unaffordable by many laboratories. For additional detail on other methods, please refer to the Toxicological Profile for Mercury (Update) (ATSDR, 1999) and in the World Health Organization (WHO) report Methylmercury (IPCS, 1990).

2.6 PHARMACOKINETIC MODELS

A number of extrapolations are generally required in risk assessments, including high-dose to low-dose extrapolations, route-to-route extrapolations, cross-species extrapolations, and extrapolations for varying exposure durations. Physiologically based pharmacokinetic (PBPK) modeling can increase the accuracy of these extrapolations if one has data to use in the model parameters. (Clewell and Andersen, 1985, 1989; Clewell, 1995a; Andersen et al., 1995).

For methylmercury, PBPK modeling in the risk assessment process is used to estimate the relationship between the measure of exposure used in epidemiological studies (mercury in hair and blood) and the daily ingested dose used to determine a reference dose. Several human PBPK models have been developed (Luecke et al., 1994, 1997; Smith et al., 1994; Gearhart et al., 1995; Clewell et al., 1999) to address this issue. Two animal models (Farris et al., 1993; Gray, 1995) were also developed to describe the disposition and metabolism of methylmercury and its major metabolite, mercuric mercury, in rats. A brief description of the pharmacokinetic models developed for methylmercury is presented here.

A PBPK model was developed by Farris et al. (1993) to simulate the disposition of methylmercury and its primary metabolite, inorganic or mercuric mercury, in the adult rat. Farris et al. (1993) also conducted metabolism and distribution studies in rats to collect the data needed to understand the processes that influence the pharmacokinetics of both methylmercury and mercuric mercury. This model incorporated time-dependent compartment volume changes, compartment volume-dependent clearance rates, and the recycling of mercury as a result of hair ingestion during grooming. The Farris model served as the foundation for several subsequent models developed for methylmercury.

On the basis of the modeling results reported by Farris et al. (1993), Smith et al. (1994) developed a simple human PBPK model. Smith et al. (1994) assumed that methylmercury behaved as a single pool while the behavior of its metabolite (inorganic mercury) varied in different tissues. Smith et al. (1994) also conducted experimental studies in human volunteers to monitor levels of methylmercury and inorganic mercury in the blood, urine, and feces following a single intravenous injection of a tracer dose of methylmercury. The modeling results indicated that inorganic mercury accumulated in the body and was the predominant form of mercury present at longer times following administration. The biological half-life of methylmercury in the body was estimated to be 44 days, with an estimated 1.6% of the body burden excreted each day.

Gray (1995) developed a PBPK model for methylmercury in the rat that could be used to evaluate the developmental toxicity observed following *in utero* exposure to methylmercury. The model consists of a maternal model with a fetal submodel. This model can be used to obtain fetal and maternal organ methylmercury concentration-time profiles for any maternal dosing regimen, including the dosing patterns used in rat developmental neurobehavioral studies.

Luecke et al. (1994) developed a generic PBPK model for human pregnancy that was applied (Luecke et al., 1997) to both rat and human kinetic data for methylmercury. This model consists of four submodels and incorporates the changes observed in both the mother and the fetus during the time course of pregnancy. Both rat and human data have been simulated using the model following various routes of exposure to methylmercury.

Stern (1997) identified data on the distribution of parameters in the one-compartment model from the published literature. Available data specific to women between the ages of 18 and 40 were used; data between men and women were also used to determine statistical differences, if any. Blood volume and body weight were assumed to be correlated. A similar approach was used by Swartout and Rice (2000). In that analysis, however, some of the parameters are described by different distributional shapes or by distributions from different data sources than those used by Stern (1997).

Swartout and Rice (2000) performed an uncertainty analysis of the estimated ingestion rates used to derive the methylmercury reference dose. The uncertainty arising from the calculation of ingestion dose levels in mg/kg per day corresponding to measured concentrations of mercury in hair is estimated through a Monte Carlo analysis of the EPA dose conversion model. The Monte Carlo model was modified to include a methylmercury elimination concentration that was converted to an equivalent half-

life, and a term was added to account for measurement error of hair-mercury concentrations. The authors assumed correlations between several pairs of parameters: the hair-to-blood ratio and the elimination-rate constant, body weight and blood volume, and the fraction of the absorbed dose in the blood and body weight. Applying the results of this analysis and assuming the input correlations to the benchmark dose of 11 ppm mercury in hair used in the derivation of the methylmercury RfD results in a lower 95% confidence limit of 4.07×10^{-4} mg/kg-day. The dose conversion factor simulation is 8.0×10^{-5} with a 90% confidence interval of 3.7×10^{-5} to 1.6×10^{-4}. The corresponding dose conversion value used in the derivation of the methylmercury reference dose is 9.8×10^{-5}. The 90% confidence interval spans a three fold to five fold range of ingestion doses for any given concentration of mercury in hair. The hair-to-blood mercury concentration ratio contributed to the variance of the output.

Gearhart et al. (1995) developed a multicompartment adult and fetal model to analyze epidemiological data for a methylmercury risk assessment. This model was recently reparameterized by Clewell et al. (1999) for use in a Monte Carlo variability and sensitivity analysis. The model structure, a modification of the model developed by Farris et al. (1993), consists of a maternal model with a fetal submodel. Changes in both maternal and fetal tissues during gestation are described. The model has the capability to estimate maternal hair and blood concentrations following ingestion of methylmercury, as well as the resulting fetal cord blood concentrations. This model was used to address the relationship between mercury in maternal hair and daily ingested dose, which has been identified as a major issue in conducting a risk assessment for methylmercury. The results of Monte Carlo analysis using the model provided an estimate of the variability in ingestion rates associated with a measured hair concentration. The predicted variability (ratio of median to 5th percentile equals 1.5) is comparable to similar analyses performed using a simple compartmental model (U.S. EPA, 1997e; Stern, 1997). The results of a sensitivity analysis of the model suggest that the most important determinants of pharmacokinetic variability for methylmercury are the hair:blood partition, body weight, and hair growth rate.

3.0 TOXICOLOGICAL BASIS FOR CRITERIA

This section of the *Water Quality Criteria for the Protection of Human Health* document for methylmercury relies heavily on information provided in the *Mercury Study Report to Congress* (MSRC) (U.S. EPA, 1997e) for summaries of studies published before 1997. Data published after 1997 are summarized in this chapter. The *Water Quality Criteria for the Protection of Human Health* document for methylmercury is not intended to be an exhaustive survey of the voluminous health effects literature available; rather, it includes detailed information on studies that form the basis for EPA's hazard identification and dose-response assessment. The database on neurodevelopmental effects of methylmercury is quite extensive. Developmental neurotoxicity is currently considered the most sensitive health endpoint. Data on cardiovascular and immunological effects are beginning to be published and may provide a more sensitive endpoint for low-dose methylmercury effects. This chapter will focus on developmental neurotoxic, cardiovascular, and immunological toxic effects of methylmercury exposure. The reader is referred to the MSRC for information on other toxic effects of methylmercury.

3.1 INTRODUCTION

Methylmercury is a highly toxic substance with a number of adverse health effects associated with its exposure in humans and animals. Human exposure following high-dose poisonings in Japan and Iraq resulted in effects that included mental retardation, cerebral palsy, deafness, blindness, and dysarthria in individuals who were exposed *in utero* and sensory and motor impairment in exposed adults. Chronic, low-dose prenatal methylmercury exposure from maternal consumption of fish has been associated with more subtle endpoints of neurotoxicity in children. Results from animal studies also show effects on cognitive, motor, and sensory functions. The following section focuses on studies reporting neurotoxicity as an endpoint for methylmercury exposure.

3.2 NEUROTOXICITY

3.2.1 Human Studies

3.2.1.1 Minamata and Niigata, Japan

Minamata Bay, Japan

The first documented widespread human methylmercury poisoning occurred in Minamata, Japan, between 1953 and 1960. Over time the source of the poisoning was traced to consumption of contaminated fish and seafood from Minamata Bay. An industrial plant was found to have discharged waste containing mercury directly into the waters of the bay. The initial cases of what was later called Minamata disease were two young women with what appeared to be encephalitis. Public awareness of the situation grew after the sudden deaths of cats in the surrounding area. Cats were brought into Minamata in February 1957 to study the possible health impact of environmental exposure to methylmercury. Within 32 to 65 days after arrival, all developed similar symptoms (e.g., excessive salivation, violent rotational movements, inability to walk in a straight line, and collapsing death or voluntarily jumping into the sea to drown) (Harada, 1995). This episode revealed the potential neurotoxic effects on humans exposed to methylmercury.

Adult Minamata Disease

Officially, approximately 2,200 persons have Minamata disease. Many other cases of the disease have either not been reported or were misdiagnosed. Many had eaten contaminated fish and shellfish for quite some time before the symptoms appeared (Iwata et al., 1975). In human patients, the early stage of Minamata disease brought gross disturbance of the central nervous system, which affected approximately 88 people living in the area around Minamata Bay. Of those 88 people, 12 died within 100 days, while the others had permanent disability. Among those with permanent disability, symptoms included appallic symptoms and idiotic disorders, with nervous symptoms resulting from widespread disturbance of brain cortices. In those with advanced illnesses from moderate poisoning, symptoms included tremor, disturbance of sensation, severe generalized ataxia, dysarthria, concentric constriction of the visual fields, and difficultly in hearing (Takeuchi et al., 1975).

The most common clinical signs observed in adults were paresthesia, ataxia, sensory disturbances, tremors, impairment of hearing, and difficulty in walking. Examination of the brains of severely affected patients who died revealed marked atrophy of the brain (55% normal volume and weight), with lesions in the cerebral cortex and cerebellar cortex, and changes in the nerve fibers, cystic cavities, and spongy foci (Harada, 1995). Microscopically, entire regions of the brain were devoid of neurons, granular cells in the cerebellum, Golgi cells, and Purkinje cells. In addition to effects on the brain, methylmercury is known to have direct effects on the visual field. Korogi et al. (1997) presented results from a study on the comparison of magnetic resonance imaging findings of the striate cortex with visual field deficits in patients with Minamata disease. Results from this study indicated that the central 10° and 15° of vision represent 20% and 30% of the surface area of the striate cortex, respectively. The central portion of the visual fields occupied the posterior area as well as a greater proportion of the striate cortex. The visual field deficits in patients with Minamata disease correlated well with the magnetic resonance findings of the striate cortex. In severe cases of Minamata disease, the visual fields are identical with bilateral homonymous hemianopsia, with sparing of central vision (Korogi et al., 1997).

Delayed Onset-Type Minamata Disease

Mercury content in the hair and blood samples of Minamata patients was not analyzed until 1959. This was due in large part to the latency of the disease; the Minamata incident had apparently continued for such a protracted period that symptoms were delayed in appearing. In some cases, symptoms appeared more than 5 years after methylmercury intake ceased. Symptoms of delayed Minamata also were complicated by other diseases or aging. In the case of maternal exposure, symptoms usually did not appear until 5 to 8 years after the birth of the child. At this time, hair samples from mothers ranged from 1.82 to 191 ppm, while that of their offspring (congenital patients) ranged from 5.25 to 110 ppm (Harada, 1995).

Congenital Minamata Disease

Awareness of the developing fetus as a sensitive subpopulation came to light when a number of children were born with congenital cerebral palsy. These patients experienced symptoms such as mental retardation, primitive reflex, cerebellar ataxia, disturbances in physical development and nutrition, dysarthria, deformity of the limbs, hyperkinesia, hypersalivation, paroxysmal symptoms, strabismus, and pyramidal symptoms. Pathological findings of congenital Minamata disease patients include general atrophy and hypoplasia of the brain cortex and abnormality of the cytoarchitecture, remaining matrix

cells, hypoplasia of the corpus callosum, intramedullary preservation of the nerve cells, and dysmyelination of the pyramidal tract. In the cerebellum, hypoplasia of the granular cell layer and other layers as well as degeneration of granular cells were observed (Harada, 1995).

In a small fishing village called Yudo, 7 cases of cerebral palsy and 10 cases of infantile Minamata disease were found in a total of 50 households. Between 1955 and 1958, there were 188 births in the small fishing villages of Yudo, Tsukinowa, and Modo, with a 9.0% incidence of cerebral palsy, while the overall national incidence ranged from 0.2% to 2.3% (Harada, 1995).

Extensive investigations of congenital Minamata disease were undertaken and 20 cases that occurred over a 4-year period were documented. The exact number of congenital Minamata disease patients is not known, as some undiagnosed patients were already deceased. At present, 64 cases have been confirmed as congenital Minamata disease. In all instances congenital cases showed a higher incidence of symptoms than did the cases where exposure occurred as an adult. The congenital patients are unable to perform ordinary functions of living (Harada, 1995).

From 1950 to 1969, a total of 151 umbilical cords were collected from residents of the Minamata area. Included in this pool were 25 patients with congenital Minamata disease. Levels of methylmercury in the umbilical cords ranged from 0.35 ppm in 1952 to 0.96 ppm in 1955. The methylmercury levels in the cords from patients with congenital Minamata disease showed higher values than the cords of patients who had Minamata disease (0.72 ppm), mental retardation (0.74 ppm), other diseases (0.22 ppm), and no symptoms (0.28 ppm) (Harada et al., 1999).

Kinjo et al. (1993)

A case-control study examined the relationship between health complaints of patients with Minamata disease and exposure to methylmercury. A total of 1,144 Minamata disease patients older than 40 years of age were surveyed. A control group was also established; this group included nonexposed people living in neighboring towns, matched by age and sex. A questionnaire was used to obtain information on subjective complaints and activities of daily living (ADL). Results from analysis of the data indicated that Minamata disease patients had significantly higher rates of all complaints than did controls. Subjective complaints of Minamata disease patients, overall, were more prevalent than in controls. The results remained unchanged with age when the subjective complaints were categorized into two groups: those where frequency increased with age and those related to sensory disturbance. The

authors noted that the reason for the high prevalence rate of sensory disturbance among current Minamata disease patients is unclear. The data from the ADL questionnaire, when analyzed, were used to estimate functional capability in the elderly. Results indicate that ADL was significantly lower for Minamata disease patients aged 60 and over in comparison with controls. The authors conclude that ADL disability in Minamata disease patients is accelerated by aging. Overall, the prevalence of deficits was relatively greater in cases compared with controls as a function of increasing age.

Harada et al. (1998)

In 1995, Harada et al. (1998) measured mercury concentration in hair samples from 191 fishermen and family members living in mercury-polluted areas in the Minamata region of Japan. The study participants fished for a living and had previously consumed methylmercury-contaminated fish and shellfish caught in this region. Estimates of fish consumption were not provided. The study population comprised 83 men and 108 women who ranged in age from 32 to 82 years. Data on subjective symptoms and lifestyle factors were collected by questionnaire. In addition, each participant was administered relevant neurological tests (test details not provided) by a group of neurologists. Mercury concentrations in hair were less than 10 ppm in 185 out of 191 subjects. The mean concentrations were 5.0 ± 3.4 ppm and 2.1 ± 1.1 ppm for men and women, respectively. All six subjects with hair concentrations greater than 10 ppm were men. The mean concentration for men in the study was only slightly higher than the mean value of 4.6 ppm for normal nonexposed Japanese men. There appeared to be an upward trend in hair mercury concentration associated with increased frequency of fish consumption. Although the hair mercury concentrations approached what was considered normal (≤10 ppm in hair samples), the study participants exhibited a high incidence of a variety of neurological conditions. More than 85% of subjects reported subjective symptoms including numbness, forgetfulness, pain in the extremities, focal cramps, headache, and motor disturbances. Clinical findings included sensory disturbance, ataxia, speech impediment, hearing impairment, constriction of visual fields, and tremor. "Stocking and glove" sensory disturbance (a hallmark of Minamata disease) occurred in 69% of the participants. A dose-response relationship between clinical symptoms and hair concentration was not evident, indicating that hair level data were of limited use for diagnosis of chronic Minamata disease.

Fukuda et al. (1999)

A study was completed in Kumamoto, Japan, near Minamata City, to evaluate the relationship between the number of neurological complaints from symptoms and methylmercury exposure. A total of

1,304 exposed adults living in a methylmercury-polluted area and 446 nonexposed age-matched adults, living in an area not known to be polluted with methylmercury, participated in an interview and questionnaire survey. The data from 64 participants of the survey were analyzed by comparison of prevalence, factor analysis, and cluster analysis. Results indicated that the exposed population had more neurological complaints in comparison with those not exposed. The factor analysis proposed four factors: arthritic, muscular, sensory, and nonspecific complaints. All four were higher in the exposed population in comparison with the nonexposed. The authors suggest that the increased neurological and nonspecific complaints may be due to past exposure to methylmercury.

Futatsuka et al. (2000)

A case-control study was conducted to estimate the role of various risk factors, including methylmercury exposure, for diseases such as liver disease, renal disease, and diabetes mellitus. The study population included 1,500 subjects over 40 years of age living in the town of Tsunagi since 1984. The town of Tsunagi was methylmercury polluted, with 36.9 diagnosed Minamata disease patients for every 1,000 population. Urine, blood, physical, and ultrasonographic examinations were administered to determine evidence of liver disease, renal disease, and diabetes mellitus. Personal interviews were conducted to collect information on risk factors and specific details on the complaints. Results from this study indicated that prevalence of disease, liver disease, renal disease, and diabetes mellitus was not higher in the methylmercury-polluted area compared with other areas in Japan. However, subjects in the polluted area had more complaints than those in the nonpolluted area. The authors concluded that past exposure to methylmercury may have influenced these results.

Niigata, Japan

From 1963 to 1965, patients with Minamata disease-like symptoms were reported in the basin of the Agano River in Niigata. Methylmercury, a residual product from acetoaldehyde synthesis, was released from a manure factory located 70 km up the river. Untreated wastewater from the factory drained into the Agano River, contaminating the fish and shellfish population. By 1973, 325 patients with Minamata disease were identified. This poisoning was later named "Niigata Minamata disease." Similar to the incident in Minamata, the symptoms progressed even after cessation of exposure. Numbness in the extremities and in the perioral area was the most frequently reported (Iwata et al., 1975). In the Niigata incident, the maternal hair mercury concentration immediately after giving birth to a congenital patient was 293 ppm. The maternal symptoms associated with this level of exposure were

mild, with sensory disturbances and other Minamata disease-related symptoms. The level of mercury exposure required to initiate the onset of Minamata disease was established at 50 ppm maternal mercury hair level. Because of the previous experience in Minamata with methylmercury poisoning, women with hair mercury levels above 50 ppm were advised not to become pregnant. As a consequence, there was only one case of congenital Minamata disease in the Niigata incident (Harada, 1995).

3.2.1.2 Iraq Outbreak

In fall 1971, 90,000 metric tons of methylmercury-treated seed grain were imported through the southern seaport of Basra, Iraq, and distributed freely throughout the countryside. Because the grain was delivered at planting time, residents of the area baked the grain into bread. There are no records on the size of the population who consumed grain treated with methylmercury fungicide. Nor are there reliable estimates of the number of people who ate methylmercury-treated grain and developed signs and symptoms but did not seek medical attention. It was not until late December 1971 that the first case of methylmercury poisoning was recorded. Within 2 months, 6,530 hospital admissions and 459 hospital deaths were recorded from methylmercury ingestion. Included in this exposed population were pregnant women (Bakir et al., 1973). Children exposed *in utero* manifested severe sensory impairments such as blindness and deafness, general paralysis, hyperactive reflexes, cerebral palsy, and impaired mental development (Amin-Zaki et al., 1974).

A study was conducted by Marsh et al. (1987) to investigate the relationship between methylmercury exposure, as measured by maternal hair concentrations during pregnancy, and associated adverse effects in offspring. A total of 81 mother-infant pairs participated; maternal hair mercury levels served as the index for prenatal exposure and were measured by x-ray fluorescent spectrometric analysis to range from 1 to 674 ppm. Clinical evaluations were conducted along with interviews with the mother about labor, delivery, any abnormalities at birth, size of the baby, early childhood development, and age at which infants achieved developmental milestones. These milestones included sitting without support, standing and walking unaided, and speaking two or three meaningful words. Developmental retardation was indicated by the child's inability to walk a few steps unsupported by 18 months of age or to speak two or three meaningful words by 24 months of age. Additional questions included any observations of involuntary movements, seizures, impaired vision or hearing, lack of coordination, and the mother's general impression of the child's physical and mental development. The interview was limited by the mothers' recall of the age of their children; moreover, this culture did not use Western calendars to record family events. The physical examination of the child included observation; head circumference

and body length measurements; cranial nerve signs; speech; limb tone, strength; deep tendon reflexes; plantar responses; coordination; dexterity; primitive reflexes; sensation; posture; and ability to sit, stand, walk, and run. Neurological examinations scored 0 to indicate normal functions and 3 to indicate definite abnormality. Unclear readings were denoted with points for borderline findings, whereas scores of 0-3 reflect no definite abnormality. The highest score in the most severely affected child was 11.

The impact of methylmercury on neurological function of infants exposed *in utero* during the Iraqi poisoning incident is described in a series of reports by Amin-Zaki et al. (1974, 1976, 1979, 1981), Marsh et al. (1980, 1981, 1987), and Seafood Safety (1991). The major symptoms observed in this epidemic closely resembled those recorded in Minamata, Japan. The predominant symptom noted in adults was paresthesia, and it usually occurred after a latent period of 16 to 38 days following initiation of exposure. Additional dose-dependent symptoms observed in the more severely affected individuals included ataxia, blurred vision, and constriction of the visual field leading to blindness in severe cases, slurred speech and hearing difficulties. Fatalities from methylmercury exposure usually resulted from failure of the central nervous system (Bakir et al., 1973). Of the 28 children with the highest exposures, 7 had seizures, whereas none of the 53 children with the lowest exposures experienced seizures. Maternal hair mercury levels for those seven children ranged between 78 and 674 ppm.

Results indicate that boys appeared to be more severely affected than girls. Statistically significant differences were apparent for regressions for boys and girls, where boys had the steeper slope to indicate increased severity in late walking and talking than girls.

Cox et al. (1989) performed an analysis of the Iraqi data to identify the threshold for adverse neurodevelopmental effects if one existed. A variety of statistical models such as logit, hockey-stick, and nonparametric kernel-smoothing methods were used in the attempt. Analyses were limited by the lack of data on the background prevalence of poor outcomes among Iraqi children. The authors estimated a population threshold of approximately 10 ppm for the outcomes investigated. The uncertainty associated with such an estimate, however, is highly dependent upon the assumed background prevalence of poor outcomes (e.g., motor retardation, neurological abnormality) (Cox et al., 1989). In another attempt at reanalyzing the data, Crump et al. (1995) reported that the estimate of the population threshold was highly dependent on the choice of the model and highly sensitive to the definition of abnormality. For example, delayed walking was heavily influenced by four cases of delayed walking among children with corresponding maternal hair mercury levels below 150 ppm. Crump et al. (1995) concluded that the statistical upper limit of the threshold could be as high as 255 ppm. Furthermore, their maximum

likelihood estimate of the threshold using a different parametric model was said by the authors to be virtually zero.

Cox et al. (1995) analyzed the Iraqi data on late walking in children exposed to methylmercury *in utero*. The results indicated that dose-response analyses based on late walking endpoints were unreliable because of four influential observations in the group of responders with hair mercury levels below 150 ppm. Based on visual interpretation of the plot of the data, the four observations are isolated from the remainder of the responders and would be expected to have considerable influence on the threshold estimate. No quantitative sensitivity analysis was performed to further investigate the effect of removing one or more of these data points. The authors point out that if the four data points were to represent background, the threshold for late walking would be greater than 100 ppm. This is, however, considered unlikely given that no responses were observed in the 37 individuals with lower levels of exposure.

3.2.1.3 Peru

A prospective study (Marsh et al., 1995) was conducted in Mancora, Peru, between 1981 and 1984 but not published until 1995. Mancora was selected as the study site based on a number of criteria, but mainly for its dependence on marine fish as a large source of dietary protein. A diet high in seafood was presumed to be associated with methylmercury exposure. Study participants consisted of 369 pregnant women and 194 of their children. Maternal hair samples were collected from the final group of 131 mother-infant pairs to analyze for methylmercury content. The geometric mean hair level was 7.05 ppm, with a range of 0.9 to 28.5 ppm. The peak maternal hair methylmercury levels during pregnancy ranged from 1.2 to 30 ppm, with a geometric mean of 8.3 ppm. Neurological examinations were administered to children. Frequencies were reported for tone decreased; tone increased; limb weakness; reflexes decreased; Babinski's sign, which is an indicator of a pyramidal-tract abnormality; primitive reflexes; and ataxia. This study identified no significant relationship between maternal hair methylmercury levels and measures of infant development or neurological signs. The authors suggested that marine fish may contain elements, such as selenium, that reduce the toxicity of methylmercury, thereby masking any neurological effects associated with methylmercury exposure.

3.2.1.4 Northern Quebec, Canada

A cross-sectional study of 234 Cree Indian children between the ages of 12 and 30 months on July 1, 1978, was conducted by McKeown-Eyssen et al. (1983). These children resided in four northern

Quebec communities known to have the highest levels of methylmercury exposures within Quebec. Maternal hair mercury level was the index to reflect prenatal exposure. Methylmercury levels of the hair were measured in alternate 1-cm segments, beginning with the scalp-end segment. The average maternal hair methylmercury concentration was 6 ppm, with only 6% of the samples exceeding 20 ppm. Physical and neurologic examinations were administered to the children, with the additional measures of special senses, cranial nerve function, sensory function, muscle tone, stretch reflexes, coordination, persistence of Babinski's response, and a summary of signs for the absence or presence of neurologic abnormality. At 4 years of age, four measures of the Denver Developmental Scale (gross and fine motor development, language development, and personal and social skills) were administered to assess the child's development. Associations between exposure and neurological outcome were analyzed by multiple regression analyses adjusted for alcohol and caffeine intake, tobacco use, age of mother, and multiparity.

No significant association between methylmercury exposure and neurological deficits was identified in girls. Abnormality of tendon reflexes was evidenced in 11.4% of the boys and 12.2% of the girls, but was only significantly associated with maternal hair mercury in boys. The prevalence of abnormality of muscle tone or reflexes was found to increase seven times with each increase of 10 ppm of the prenatal exposure index. However, the authors caution the interpretation of the results on boys because the abnormality of muscle tone or reflexes tended to consist of isolated abnormalities of mild severity that are of doubtful clinical importance. In addition, there was no dose-response relationship.

3.2.1.5 Seychelles Islands

The Seychelles Child Development Study (SCDS) was initiated in 1981 to examine the effects of low-dose fetal exposure to methylmercury from maternal consumption of fish. The SCDS was planned and conducted in two separate stages. The preliminary cross-sectional stage of the study sought to provide additional detail and guidance on how to design the main study. The main study, started in 1989, was a double-blind, prospective, longitudinally designed study that followed a cohort of infant-mother pairs from 6 months to 66 months postgestation.

Demographics

The Seychelles Islands is a Westernized archipelago in the middle of the Indian Ocean, more than 1,500 kilometers from the eastern coast of mainland Africa. The Seychellois population is of African and European origin with some minority groups from India and China. English, French, and Creole are

the three official national languages, with Creole being the most popular language at home. A majority (~85%) of the population consume a high amount of marine fish on a daily basis. In general, the Seychellois population is considered quite healthy, with easy access to good health care and education (Marsh et al., 1995).

Cross-Sectional Pilot Study (Myers et al., 1995b,c)

From 1987 to 1988, a cohort of 789 mother-infant pairs was selected after exclusion criteria were exercised. The fetal exposure index used was maternal hair total mercury. The levels ranged from 0.59 to 36.4 ppm, while the median level in this study was 6.6 ppm total mercury. The Denver Developmental Screening Test-Revised (DDST-R) was administered and a medical and neurological examination was performed for each child between 5 and 109 weeks of age. Covariates were selected for statistical analysis because of their potential to bias the assessment of the association between maternal mercury and developmental outcomes. These covariates included gender, birth weight, Apgar score, age at testing, and medical history. Mother's age, use of alcohol and tobacco, and medical history also were used. When DDST-R scores of questionable and abnormal results were grouped, mercury effects were seen and were more pronounced in boys and declined as age of testing increased. In general, males had higher response rates on the DDST-R than females, independent of mercury level. No association, however, was observed between mercury exposure and overall neurological examination results. The authors cautioned the interpretation of the results because the developmental association with fetal mercury exposure disappeared when DDST-R scores of "questionable" were treated in the standard manner as passes.

A subset (217 children) of the children from the pilot study cohort (Myers et al., 1995a) was tested at 66 months of age with the same battery of tests as planned for the main study at similar age. Maternal hair mercury levels during pregnancy ranged from 1.0 to 36.4 ppm, while the median level was 7.1 ppm. Nine endpoints were evaluated in this second evaluation: the McCarthy Scales of Children's Abilities that yield the general cognitive index (GCI), perceptual performance, memory, and motor ability; the Preschool Language Scale that yields total language score and subscores for verbal ability and auditory comprehension; and the letter-word identification and applied problems subscales of the Woodcock-Johnson Tests of Achievement. The association between maternal hair mercury concentration and outcome was assessed by multiple regression analysis. Prenatal mercury exposure correlated with outcomes at 66 months on the McCarthy GCI and perceptual performance subscale and with total language and auditory comprehension scores. After removing outliers and influential points, however,

mercury effects were no longer significant except for the Preschool Language Scale auditory comprehension subscale.

Prospective Longitudinal Main Study

A double-blinded, prospective longitudinal study was initiated with a new cohort of 740 mother-infant pairs that were selected between 1989 and 1990. These participants resided on the island of Mahe, which is one of the largest islands in the archipelago of the Seychelles where 90% of all Seychellois citizens live. Maternal hair mercury level was used as the marker of fetal mercury exposure. The levels ranged from 0.5 ppm to 26.7 ppm, with a median of 5.9 ppm. The cohort was followed from ages 6.5 months to 66 months, with evaluations occurring uniformly at four critical periods (6.5, 19, 29, and 66 months of age) (Myers et al., 1995). Tests of 7-year-old children have also been done, but results are not yet published. Age-appropriate tests were administered at the time points indicated in Table 3-1.

6-Month Evaluation (Myers et al., 1995c)

At 6 months of age, all children were administered a standardized test of visual recognition memory (Fagan Infantest); a standardized screening test to measure personal-social, fine motor adaptive, language, and gross motor development (DDST-R); and a general medical and neurological examination. Covariates of this main study included those evaluated in the pilot study, with the addition of birth order, gestational age of the child, primary caregiver intelligence, maternal and paternal educational levels, history of breastfeeding, language spoken at home, and family income. Medical conditions related to poor neurodevelopmental outcomes were also included as covariates in the statistical analysis. The study results indicate no association at 6 months of age with DDST-R, neurological examination, and Fagan Infantest. However, males had lower scores on both tests than females.

19- and 29-Month Evaluations (Davidson et al., 1995)

At 19 months of age, children were evaluated with the Bayley Scales of Infant Development (BSID), while the primary caregiver was administered the Raven Standard Progressive Matrices. The cohort was evaluated again at 29 months. Infant intelligence was measured by BSID Mental and Psychomotor Scales. To measure adaptive behaviors, a modified version of the BSID Infant Behavior Record was completed at 29 months. Between the ages of 42 and 56 months, children were administered

the Pre-School Caldwell-Bradley Home Observation for Measurement of the Environment (HOME). Hair samples were collected from all children at both 19 and 29 months of age for analysis of total mercury concentration to determine postnatal exposure. The median maternal hair mercury concentration during pregnancy for the 738 mother-infant pairs in the cohort at 19 months was 5.8 ppm. Twenty-two percent of the children at 19 months had child hair mercury levels ≥ 10 ppm (Myers et al., 1997). The same covariates and modeling strategy were used as in the primary analysis. No effects of mercury were detected on the BSID scores at either age. Results of this study indicate that one functional behavior—the examiner's subjective rating of the child's test session activity level—was related to maternal hair mercury levels in the mothers of male children: activity level decreased as maternal hair mercury level increased. Independent of mercury exposure; activity level was rated higher in males. Authors of this study conclude that these two results suggest that prenatal exposure to mercury may lower activity level in males. This result should be interpreted with caution as it is not yet clear whether the lower activity in males is a direct result of increased mercury exposure.

19-Month Evaluation of Walking and Talking (Myers et al., 1997)

The 19-month cohort was selected for evaluations of two developmental milestones. Data for age of first walking (n = 720) and talking (n = 680) were obtained from the primary caregiver of each child. Age at walking was defined as the age when the child was able to walk without support, while age at talking was defined as the age the child first said words other than "mama" and "dada." The mean age for walking was 10.7 months for girls and 10.6 months for boys, while for talking it was 10.5 months for girls and 11.0 months for boys. Multiple regression analysis was used to assess the relationships between each developmental milestone, maternal hair mercury levels, and covariates. Covariates evaluated are the same as those included in the study reported by Davidson et al. (1995) described in the previous paragraph. In this study, there was a marginally significant relationship between prenatal mercury exposure from eating fish and the age at which males started to walk, but this depended on four statistical outliers. No association between prenatal mercury exposure and either the age at which females started to walk or either gender started to talk was found.

Semiparametric Modeling of the 19-Month Data (Axtell et al., 1998)

In addition to the multiple regression analysis used in the prospective longitudinal main study of the SCDS, a semiparametric generalized additive model was used to identify nonlinearities in the relationship between prenatal methylmercury exposure and developmental milestone achievements. The

specific milestones evaluated in the main SCDS cohort at 19 months of age (n = 738 children) were age that children walked and said words. Walking was defined as the number of steps without support and talking was any word except "mama" or "dada." Maternal hair total mercury was used as an index of fetal exposure. No significant nonlinear relationships with mercury were identified in any of the models for age at talking; this implies that the original linear regression models were appropriate for this analysis. A General Additive Model analysis indicated that the relationship between maternal hair mercury level and age at walking may not be linear. Walking appeared at a later age as exposure increased in the range from 0 to 7 ppm. Walking appeared slightly earlier with increasing mercury levels above 7 ppm. However, there was no evidence from any models that higher levels of mercury exposure resulted in further delays in walking. There is no biological or developmental hypothesis to explain the increase in age of walking at lower levels and not at higher levels.

66-Month Evaluation (Davidson et al., 1998)

An evaluation was conducted on 711 mother-child pairs at 66 months of age. At this age, six neurobehavioral tests were administered: McCarthy Scales of Children's Abilities, the Preschool Language Scale, the Woodcock-Johnson Applied Problems and Letter and Word Recognition Tests of Achievement, the Bender Gestalt Test, and the Child Behavior Checklist (CBCL). Maternal hair mercury and child hair mercury were measured. Mercury exposure was assessed by total mercury in segments of maternal hair representing growth during pregnancy. The mean maternal hair total mercury level was 6.8 ppm while the mean child hair total mercury level at age 66 months was 6.5 ppm. The covariates evaluated include all those included in the previous study period, in addition to hearing status of the child and Hollingshead socioeconomic status of the family. Two multiple linear regression analyses were performed for each of the six primary measures. Secondary analyses tested the hypothesis that associations between developmental outcomes and total mercury exposure might be nonlinear. Four of the six measures (all except for Bender Gestalt and Woodcock-Johnson Applied Problems Tests of Achievement) showed better scores in the highest methylmercury groups compared with lower groups for both prenatal and postnatal exposure. For both prenatal and postnatal methylmercury exposure, no adverse developmental effects were reported for toddlers. Postnatal exposure at 66 months, however, was associated with a small but statistically significant increase on several developmental outcomes even though there is no reason to suppose that such effects are associated with exposure to methylmercury. There are studies, however, that indicate the methylmercury levels in the infant were surrogate for the length of breastfeeding, which is reported to have a positive association with developmental outcomes (Grandjean et al. 1992).

New Analysis—CBCL Main Cohort 66 Months (Myers et al., 2000)

No effect of mercury was identified on the Child Behavior Check List (CBCL) at 66 months of age in the main cohort of the Seychelles study as determined by the total T score (Davidson et al., 1998). The CBCL is a report inventory scored by the caregiver that assesses eight domains: withdrawn, somatic complaints, anxious/depressed, social problems, thought problems, attention problems, delinquent behavior, and aggressive behavior. An analysis of these subscales was performed on the 711 children assessed on this test (Myers et al., 2000). No effect of mercury was identified on individual subscales.

New Analysis—Main Cohort 66 Months (Axtell et al., 2000; Palumbo et al., 2000)

The investigators performed additional analyses of the 66-month data to evaluate the possibility of nonlinear relationships associated with mercury exposure (Axtell et al., 2000). Endpoints included the six primary variables analyzed previously: McCarthy GCI, Preschool Language Scale (PLS), Wodcock-Johnson Applied Problems, Woodcock-Johnson Letter/Word Recognition, Bender copying errors, and CBCL total T score. Generalized additive models, which make no assumptions about the relationship between exposure and test score, were used. Maternal hair levels during pregnancy were used as a measure of prenatal exposure and child's hair mercury at 66 months was used for postnatal exposure. Nonlinearities were identified between prenatal exposure and PLS and CBCL, and between postnatal exposure and McCarthy GCI. For the PLS the trend involved a decrement of 0.8 points (poorer performance) from 0-10 ppm and an increase of 1.3 points above 10 ppm. For the CBCL there was an increase (representing a poorer score) between 0 and 15 ppm and a decrease above 10 ppm. The GCI increased (improved) by 1.8 points through 10 ppm mercury in the child's hair and declined by 3.1 above 10 ppm. Although these results are difficult to interpret, they provide limited evidence of an adverse effect of mercury exposure below 10 ppm maternal hair on two measures, and a somewhat greater association of adverse effects with child's hair mercury above 10 ppm on the GCI. As pointed out by the authors, there are fewer data points above 10 ppm (this is especially true for child's hair mercury), and therefore trends above this level are estimated less precisely.

The investigators in the Seychelles study further examined by multiple linear regression the results of the McCarthy GCI administered at 66 months (Palumbo et al., 2000). They analyzed the standard MSCA subscales and also constructed subscales to approximate the domains of cognitive functioning assessed in the Faroe Islands study: attention, executive function, expressive language, receptive language, nonverbal memory, visuospatial ability, visuomotor ability, and gross motor ability. They

found a positive association between child's hair mercury at 66 months and the standard memory subscale, with no other associations identified. As with all previous analyses of these variables, the raw scores were converted to "normative" scores. As pointed out by an OSTP panel (NIEHS 1998, Section 3.5 of the Confounders and Variables Section), the applicability of U.S. norms to this population is unclear, and the use of standardized scores may decrease sensitivity by collapsing different raw scores to one standard score.

Pilot Cohort Analysis at 108 Months (Davidson et al., 2000)

Further evaluation was performed on a portion of the Seychelles pilot cohort at 108 months of age (Davidson et al., 2000). Eighty-seven children were tested on five subtests of the WISC-III (Information, Block Design, Vocabulary, Digit Span, and Coding), California Verbal Learning Test (CVLT), Boston Naming Test (BNT), Beery-Buktenica Development Test of Visual Motor Integration (VMI) (copying geometric figures), Finger Tapping, grooved pegboard, Trailmaking (tracing the correct route through a form with a pencil), and the design memory subtest of the Wide Range Assessment of Memory and Learning (WRAML) (drawing each of four geometric designs from memory). Performance on BNT, VMI, and grooved pegboard showed a positive association (better performance) related to mercury exposure in males, with no effects identified in females. There were trends toward poorer performance related to mercury exposure for grooved pegboard in females ($p = 0.07$) as well as marginal p values on the full model that were not further analyzed (Finger Tapping, digit span). The investigators did not report power calculations, but with such a small number of subjects the power was probably quite low, so these largely negative results need to be interpreted with caution.

Benchmark Analysis (Crump et al., 2000)

A benchmark analysis (Crump et al., 2000) was conducted on data from the SCDS, with the goal of providing an alternative basis for deriving an appropriate human exposure level for methylmercury. The data modeled included responses from the neurological test batteries conducted at 6.5, 19, 29, and 66 months of age. In addition, data for developmental milestones (age first walked and age first talked) were analyzed. Maternal hair mercury concentrations measured in this study ranged from 0.5 to 26.7 ppm and averaged 6.8 ppm.

Most of the measured endpoints in the SCDS were recorded as continuous responses, and the k-power model, the Weibull model, and the logistics models for continuous data were applied. Test scores

below a predetermined value, $P_0 = 0.05$, were considered abnormal. For this analysis, the BMR was defined as 10% (BMR = 0.1). (For a description of modeling terms see Section 4.3).

In cases where responses were recorded as quantal responses (abnormal/normal), the data were modeled using the Weibull dose-response model for quantal data. Quantal responses reported in children in the Seychelles study included deep tendon reflexes, limb tone, overall neurological responses, and psychomotor index. In addition, each continuous response was converted to a quantal response by considering a response abnormal if it was more than 2 standard deviations away (in the adverse direction) from the mean response of the entire cohort, and then analyzed using the Weibull model. In these analyses, the BMD was defined in the same way as in the analyses of the continuous response.

The analyses of continuous response were conducted without covariates. Analyses with P_0 specified were conducted using both an expanded set and a reduced set of covariates for the children: sex, birth weight, birth order, whether or not the child was breastfed, medical history, maternal age, maternal smoking and alcohol use during pregnancy, maternal medical history, language spoken in home, score from home visit, Raven group (caregiver's intelligence quotient), maternal and paternal education level, family income, gestational age, Hollingshead socioeconomic scale, auditory scores, and the child's mercury level. Covariates were not included in the analyses of quantal responses or in the analyses of continuous responses in which x_0 was specified.

Parameter estimates were obtained using the maximum likelihood method, and statistical confidence bounds were computed by the profile likelihood method. The BMDL was defined conventionally as the 95% statistical lower confidence bound on the BMD. Results indicated that the most reliable analyses were represented by 144 calculated lower statistical bounds on the BMD (BMDL, or the lower statistical bound on maternal mercury hair level corresponding to an increase of 0.1 in the probability of an adverse response) derived from the modeling of continuous responses.

The results of BMD modeling are shown in Table 3-2. The average value of the BMDL in these 144 analyses was 25 ppm mercury in maternal hair, with a range of 19 to 30 ppm. With the exception of the linear model, which produced larger BMDLs, the dose-response models applied to continuous end points all produced comparable BMDLs.

Table 3-2. BMDL values (expressed as ppm mercury in maternal hair) for neurological responses and developmental milestones from the Seychelles Child Development Study

3.2.1.6 New Zealand

A study was conducted in the northern New Zealand islands to study the effects of prenatal methylmercury exposure on children exposed *in utero* from maternal fish consumption. Between 1982 and 1983, 11,000 mother-infant pairs were requested to submit hair samples and fill out a detailed diet questionnaire. Of those 11,000 pairs approximately 1,000 of these mothers had consumed fish more than three times per week for the 9 months of pregnancy. Seventy-three had hair mercury levels above 6 ppm, with the highest level being 86 mg/kg. This study was conducted in two stages.

Preliminary Tests at Age 4 (Kjellstrom et al., 1986)

From the 73 mothers with high mercury exposure (> 6 ppm) during pregnancy, a total of 31 matched pairs were selected to participate in a study on the effects of prenatal methylmercury exposure on children exposed *in utero* from maternal consumption of fish. A reference child matched for mother's ethnic group, age, and child's birthplace and birth date was located for each child selected from the high-fish-consumption group. Mercury exposure during gestation was determined from maternal hair analysis. The average hair concentrations for high-exposure mothers and the reference group were 8.8 ppm and 1.9 ppm, respectively. At 4 years of age, the children were tested using the DDST. Standardized vision tests and sensory tests were also performed to measure development of these components of the nervous system. The prevalence for developmental delay in children was 50% for progeny of high-mercury mothers and 17% for progeny of mothers of the control group. These results were statistically significant. Analysis of the DDST results by sector showed that developmental delays were most commonly noted in the fine motor and language sectors, but the differences between the experimental and control groups were not significant. The authors concluded that children born to mothers with mean hair mercury levels above 6 ppm have twice the risk of delayed development, as tested by the DDST, in comparison with the control group.

Psychological Tests at Age 6-7 (Kjellstrom et al., 1989)

In 1985 when the children were 6 to7 years of age, a follow-up study was conducted. In this study, 61 of the 74 high-exposure children were compared with three control groups with lower prenatal mercury exposure. Average maternal hair mercury concentrations in the control groups were 3 to 6 ppm and 0 to 3 ppm, respectively. The high-exposure group, with maternal hair mercury levels ranging from 6 to 86 ppm, was matched with controls for maternal ethnic group, age, smoking habits, residence, and sex

of the child. Each child was tested with a battery of 26 scholastic, psychological, and behavioral tests, which included Test of Language Development (TOLD), the Wechsler Intelligence Scale for Children (WISC), and McCarthy Scale of Children's Abilities as described in Table 3-3. Confounding factors such as language used at home, maternal and paternal occupation, maternal alcohol consumption, and number of children in the household were controlled using linear multiple regression analysis.

An average hair mercury level of 13 to 15 ppm during pregnancy was consistently associated with decreased test performance. Results of the psychological test variables were influenced by ethnic background and social class. After controlling for confounding factors and eliminating outliers, the association between prenatal methylmercury exposure and decreased performance in psychological tests remained unchanged. The children who had the poorest performance in the WISC IQ test at age 6 also had a high prevalence of abnormal or questionable DDST scores at age 4, indicating that the effects evidenced in this follow-up study confirm those found in the preliminary study at age 4. The authors

conclude that effects of methylmercury leading to developmental delays may later lead to deficits in psychological tests.

Benchmark Modeling of the 1985 Data (Crump et al., 1998)

Crump et al. (1998) performed a reanalysis and BMD modeling of the Kjellstrom et al. study results. Crump et al. used actual hair mercury levels as opposed to an indicator variable for mercury level in hair; additional confounding factors, such as parent's education and age at which the child was tested were also controlled for. They also and evaluated all 26 scholastic and psychological tests (illustrated in Table 3-4) administered to the 237 6 to 7-year old children. No significant associations between mercury exposure and children's test scores were identified. This finding, however, was highly influenced by one child whose mother's hair mercury level was 86 ppm, fourfold higher than observed for any other mother. When this outlier was omitted, scores on six tests were found to be significantly associated with maternal hair mercury concentrations: Clay reading test-concepts, Clay reading test-letter test, McCarthy-general cognitive test, McCarthy-perception, TOLD-grammar completion, and TOLD-grammar understanding. BMDs calculated from five tests (TOLD-spoken language quotient, WISC-performance IQ, WISC-full scale IQ, McCarthy perceptual, and McCarthy-motoric) ranged from 32 to 73 ppm and BMDL of 17 to 24 ppm, respectively. When the child with the highest maternal hair mercury was excluded, the BMDs ranged from 13 to 21 ppm with BMDLs spanning 7.4 to 10 ppm (Table 3-4).

Table 3-4. BMD and BMDL values (expressed as maternal hair mercury concentration, ppm) for neurobehavioral endpoints in New Zealand children evaluated at 6 to 7 years of age

Test	All New Zealand children		Child with highest maternal mercury concentration omitted	
	BMD[a]	BMDL[b]	BMD	BMDL

3.2.1.7 Faroe Islands

A large human prospective longitudinal study was conducted in the Faroe Islands to determine if increased methylmercury exposure is related to decreased neurobehavioral function. Before the prospective study, a pilot study was conducted to assess the magnitude of fetal mercury exposure in the Faroes. At 12 months of age, a follow-up evaluation was conducted and then a prospective study was initiated with children born at consecutive deliveries within a 22-month period at nearby hospitals.

Demographics

The Faroes is a group of 18 islands located in the North Atlantic between Scotland and Iceland. The Faroese population is homogenous with respect to cultural and socioeconomic factors. The culture is mainly Scandinavian, with a traditional stable family unit that has easy access to good health care, education, and social systems. Dietary deficiencies are virtually nonexistent, alcohol intake is low, rate of preterm delivery of low-birth-weight infants is also low, and rate of breastfeeding is high for at least 12 months (Budtz-Jorgensen et al., 2000). Seafood constitutes a major part of the average diet in fishing communities in the North Atlantic like the Faroe Islands (Grandjean et al., 1995). The major source of methylmercury exposure is pilot whale, which according to ancient tradition was hunted and distributed within the community (Grandjean et al., 1997). Other components of the Faroese diet include lamb, potatoes, dairy products, and foods imported from other countries (Steurwald et al., 2000).

Pilot Study (Grandjean et al., 1992)

A pilot study was conducted by Grandjean et al. (1992) to assess the magnitude of fetal mercury exposure in the small fishing village of Lorvik, Faroe Islands. Blood samples were collected from a group of 53 women of fertile age, between 20 and 50, identified through a municipal register. Between 1986 and 1987, 1,023 umbilical cord blood samples were also collected at consecutive deliveries at three local hospitals. Women had a median blood mercury level of 12.1 µg/L, with values that ranged from 2.6 to 50.1 µg/L. The median mercury concentration in cord blood for all 250 samples exceeded 40 µg/L, while 20 samples had levels higher than 100 µg/L. Hair samples had mercury content that exceeded 10 ppm, and five samples exceeded 25 ppm. In 34 hair samples the measured mercury levels exceeded 15 ppm. Mercury concentrations tended to be 20% to 65% higher in cord blood than in the venous blood of mothers. Highly increased mercury concentrations in maternal hair and umbilical cord blood were related to maternal consumption of pilot whale.

12-Month Evaluation (Grandjean et al., 1995b)

At 12 months of age, 583 children were selected for further evaluation. These children were followed for 1 year after birth. Three age-appropriate developmental milestones were evaluated: sitting, creeping, and standing. The age at which the child achieved a developmental milestone was not associated with indices of prenatal mercury exposure, either from cord blood (average of 174 μg/L) or maternal hair (approximately 15% of mothers had concentrations above 50 nmol/g). Infants who reached the milestone criteria early had significantly higher mercury concentrations in their hair at 12 months than those who did not. The child's hair mercury concentration was found to be highly correlated to the period of breastfeeding. Breast milk may transfer contaminants such as methylmercury, but it is also known to confer certain advantages such as maternal antibodies. The authors concluded that if methylmercury exposure from human milk had any adverse effect on milestone development in these 12 month-old infants, the effect was compensated for by advantages offered through breastfeeding.

Computer-Assisted Neurobehavioral Tests in 7-Year-Olds (Dahl et al., 1996)

In this study, 917 children were evaluated at 7 years of age. The study focused on computer-assisted neurobehavioral tests and whether or not they could serve as meaningful parameters of neurotoxicity; three Neurobehaviroal Evaluation System (NES) tests were administered with slight modifications. The NES tests were selected to assess motor speed (Finger Tapping [FT]), sustained attention (Continuous Performance Test [CPT]), and motor coordination (Hand-Eye Coordination [HEC] Test). The CPT was modified to use animal silhouettes as a stimuli instead of letters to accommodate those children who had not yet started school and were unfamiliar with the alphabet.

Finger Tapping was relatively easy for most children, but the HEC test was considered too difficult. Of the 914 children who completed the full HEC, 755 had fewer than 25% nonresponses. Decreased visual acuity, strabismus, use of eyeglasses, and contrast sensitivity were markedly associated with decreased performance, especially on the CPT. Boys and older children performed better than girls and younger children, but this was due to increased familiarity with computers and use of a joystick. The authors concluded that maternal hair mercury and cord blood mercury were clearly associated with NES results, especially in the FT and CPT tests.

Main Prospective Longitudinal Study of 7-Year-Olds (Grandjean et al., 1997)

The cohort consisted of 917 children at 7 years of age who survived from the original cohort established in the pilot study. Indices of prenatal exposure included cord blood and maternal hair, and the index for postnatal exposure was children's hair mercury. The geometric mean cord blood mercury concentration was 22.8 μg/L, and the concentration found in children's hair averaged 11.68 ppm. Detailed neurobehavioral and physical examinations and neuropsychological and neurophysiological testings were performed. The neuropsychological tests (Table 3-5) included NES FT Test, NES HEC Test, Tactual Performance Test, NES CPT, Wechsler Intelligence Scale for Children - Revised (WISC-R), WISC-R Similarities, WISC-R Block Designs, Bender Gestalt Test, California Verbal Learning Test-Children [CVLT]), Boston Naming Test (BNT), and Nonverbal Analogue Profile of Mood States. These tests were chosen for their sensitivities in detecting neuropathological abnormalities. The neurophysiological tests were chosen to exclude those with electrical stimulation or long measurement times. These tests include pattern reversal visual-evoked potentials with binocular full-field stimulation, brain stem auditory-evoked potentials (BAEP), and postural sway.

Fewer than 60% of the children completed three of the most difficult tests. The WISC-R Similarities Test, NES HEC Test, and Nonverbal Analoguous Profile of Mood States were found to be too difficult for many of the children to reveal the subtle neurotoxic effects associated with methylmercury. The geometric mean cord blood mercury concentration for the 85 children who failed or refused to take the mood test was 29.5 μg/L, compared with 22.3 μg/L in children who voluntarily completed it. Reciprocal motor coordination and simultaneous finger movement showed no relation to mercury exposure. In the finger opposition test, however, 465 children with geometric mean blood concentrations of 21.8 ug/L mercury performed optimally, whereas those with blood concentrations of 23.9 μg/L had questionable or deficient performances.

Mercury-related abnormalities were not identified in either the neurophysiological or clinical examination. However, in the neuropsychological testing, statistically significant mercury-related dysfunction was observed. This was most pronounced in the areas of language, attention, and memory, and to a lesser extent visuospatial and motor functions. After adjustment of covariates and exclusion of children with maternal hair mercury above 10 ppm, the association remained. This indicates effects of methylmercury at doses lower than that which result in 10 ppm maternal hair mercury. In the neurophysiological test, girls showed significantly shorter latencies of evoked potentials than boys in the electrophysiological tests. For the BAEP latencies, peak I at 40 Hz and 20 Hz was slightly delayed at

increased prenatal mercury exposures and the delays for peaks III and V were statistically significant, but the interpeak latencies showed no associations with mercury. Body sway showed a slight negative association with mercury exposure in all four conditions: eyes open, no foam; eyes closed, no foam; eyes open with foam; and eyes closed with foam.

Four tests were selected for further analysis. Tests were chosen to reflect each of the following brain functions: motor function (Finger Tapping with preferred hand), attention (CPT reaction time), visuospatial performance (error score on the Bender Visual Motor Gestalt Test), language (Boston Naming Test after cues), and memory (long-delay recall on the California Verbal Learning Test). After

adjustment for covariates using the Peters-Belson method, children with scores in the lowest quartile were identified and distributed into quartile groups of mercury exposure (< 15, 15-30, 30-50, and > 50 μg/L). These results indicate that there is a statistically significant trend for the attention, language, and memory test with increasing prenatal mercury exposure (Grandjean et al., 1997).

Pilot whale blubber is also consumed by the Faroese population, and this could result in increased exposure to PCBs, a potential confounding factor. A subset (n = 436) of the cord tissue samples was evaluated for PCBs; inclusion of PCB exposure as a covariate in the regression analysis affected only the regression for the BNT. The authors conclude that results of the expanded data analysis do not suggest that the mercury effect can be explained by concomitant PCB exposure, or that PCB exposure enhances the mercury-associated effects.

Reevaluation of the Evoked Potentials in the Prospective Study (Murata et al., 1999a)

Significant associations with delays in evoked potential latencies and mercury exposure (Murata et al., 1999a) initiated the reanalyses of the data from the prospective longitudinal study. This analysis is limited to only children born during the first half of the cohort generation in 1993. Data from the second year were excluded because of shorter BAEP latencies and delayed latency on the visual-evoked potentials. Three sets of mercury exposure data were utilized in regression analyses: (1) mercury in cord blood (geometric mean of 23.0 μg/L, range of 3.3-351 μg/L), (2) mercury in maternal hair at parturition (geometric mean of 4.49 ppm, range of 0.9-39.1 ppm), and (3) mercury in the child's hair (geometric mean of 3.42 ppm, range of 0.04-26.4 ppm). The mercury concentration in maternal hair was a significant predictor for peak III latency and the I-III interval, where the child's own hair mercury concentration at the time of examination was not associated with these response variables. The cord blood concentration was, however, a significant predictor, supporting the notion that the latency delays are related to increased prenatal methylmercury exposure.

Nested Case-Control Study (Grandjean et al., 1998)

Following the evaluation of 7-year-olds in the prospective longitudinal study, the data were evaluated as a nested case-control study. From the original cohort of 1,022 established in the pilot study, the cases and controls were selected based on maternal hair mercury concentration. The case group of 112 children whose mothers had hair mercury concentrations of 10 to 20 ppm was matched to children with prenatal exposure below 3 ppm (control). Age, sex, time of examination, and maternal Raven score

were matching criteria. The median maternal hair mercury concentrations in the two groups were 1.8ppm for the control group and 12.5 ppm for the cases, a sevenfold difference. The median cord blood mercury concentrations for the control and cases were 11.9 and 59.0 μg/L, respectively. Neuropsychological tests evaluated were these: NES2 FT Test, NES2 HEC Test, NES2 CPT, WISC-R Similarities, WISC Block Designs, Bender Visual Motor Gestalt Test, CVLT, and BNT. The case group performed less satisfactorily than those in the control. On 6 of the 18 test outcomes, the inferior scores achieved by the case group were statistically significant. In particular, the case group showed a deficit on the Finger Tapping condition and the overall hand-eye coordination. Girls and boys scored differently on the Bender Gestalt Test, California Verbal Learning Test, all three Finger Tapping conditions, CPT reaction time, and the average hand-eye coordination score. No differences were reported between girls in the cases versus controls, but boys in the case group scored poorer in the Finger Tapping reaction time than the boys in the control group. The deficit in motor coordination, especially in Finger Tapping with both hands, was highly significant for boys only. The author noted that the findings of this matched case-control study are in accordance with regression analyses performed on all 900 children at the 7-year evaluation; methylmercury effects appear in the several domains of the brain, focusing on motor function, language, and memory.

Benchmark Modeling (Budtz-Jorgesen et al., 2000)

Benchmark modeling of the data from the Faroese children at 7 years of age was reported by Budtz-Jorgesen et al. (2000). The exposure was modeled both as mercury concentration in cord blood and in maternal hair. The number of children that completed neuropsychological tests varied between 837 and 901. One neuropsychological test was selected for evaluation of each of the five domains of brain function:

1. Motor speed (NES FT Test)
2. Attention: NES2 CPT
3. Visuospatial performance: Bender Visual Motor Gestalt Test
4. Language: BNT
5. Short-term memory: CVLT

For tests of motor function, language, and memory, a logarithmic dose-response model tended to show a better fit than a linear dose model using cord blood mercury concentration as the dose parameter. The default p_0 is 5%, which equates to the level (x_0) of abnormal test performance as defined by a probability

of 5% in the unexposed population. The Faroese cohort does not include an unexposed control group; thus the performance level for an unexposed child is obtained by fitting a dose-response curve to all data points, followed by extrapolating to zero exposure. Four different dose-response models were employed: *K* power, linear, square root, and logarithmic.

The results from this analysis indicate that BMDs and BMDLs vary substantially. Of the four models, the logarithmic dose-response model provided the best fit for some of the outcome variables that showed the closest association with the cord blood mercury concentration. The lowest BMDLs averaged approximately 5 μg/L cord blood, which is equivalent to approximately 1 ppm in maternal hair. Most BMDLs for hair mercury concentrations were higher. However, the results for a BMR of 5% are the same order of magnitude as the cord blood results at a BMR of 10%. The authors concluded that the results of the benchmark calculation are highly dependent on the assumed dose-response model. Results of this analysis are discussed further in the Risk Assessment chapter (Chapter 4). (For a description of modeling terms see Section 4.3).

Second Cohort (Steurwald et al., 2000)

During a period from 1994 to 1995, a second cohort of 182 singleton term births was generated from consecutive births at the National Hospital in Thorshavn, Faroe Islands (Steurwald et al., 2000). Maternal hair, serum, breast milk, and umbilical cord blood were analyzed for contaminants, while selenium, thyroid hormones, and fatty acids were measured in cord blood. In addition to methylmercury, PCBs were examined as a possible confounder in test outcome. At 2 weeks of age, infants were administered a neurological examination. Assessment of functional abilities, reflexes and responses, and stability of behavioral status during examination were completed with a score of optimal, questionable, or suboptimal performance. The Neurologic Optimality Score (NOS) was the number of items rated as optimal out of a total of 60. Results from this study indicate that prenatal exposure to methylmercury and PCBs increased from maternal intake of seafood. After adjustment for confounders, a tenfold increase of the cord blood mercury concentration was associated with a decreased NOS of 2.0. This effect corresponds to a decrease in gestational age of about 3 weeks. The authors conclude that prenatal exposure to methylmercury from contaminated seafood was associated with an increased risk of neurodevelopmental deficit. No evidence for a protective or beneficial effect with respect to neurological optimality score (the number of main items rated optimal out of 60) was observed for essential fatty acids or selenium.

3.2.1.8 Germany

Cross-Sectional Study (Altmann et al., 1998)

From a larger comparative environmental screening study, 384 children between the ages of 5 and 8 years were selected to participate in a smaller field experiment to investigate the effects of low-level lead and mercury exposure on the functions of the developing visual system. Blood lead levels and urinary excretion of lead and mercury were used as exposure indices. Neurophysiological and psychophysical measurements were administered to the children. Visual functions were assessed for neurophysiological measurements, while psychophysical measurements were assessed by visual-evoked potentials and contrast sensitivity. Linear regression analyses were used to analyze the possible relationship between exposure to lead and mercury and outcome variables. Adjustments were made for potential confounding factors such as parental education, birth weight, length of lactation, and premature birth.

After adjustment for potential confounding factors, contrast sensitivity values were significantly reduced with increasing urinary mercury levels; four of the ten contrast sensitivity values tested showed a statistically significant decrease with increasing urinary mercury. Very subtle changes in the visual system function were noted at very low levels of urinary mercury. However, no significant associations were found between urinary mercury output and any visually evoked potential outcome variables.

3.2.1.9 Nambija, Ecuador

Cross-Sectional Study on Neurosensory Dysfunction (Counter et al., 2000)

A cross-sectional study was conducted in the remote Andean settlement of Nambija, Ecuador, to investigate whether blood mercury levels are associated with auditory neurosensory dysfunction. Participants in this study included 36 children and 39 adults living in Nambija , an area known to have extensive gold-mining operations where mercury is used in the extraction process. Mercury exposure was measured in whole blood. The mean blood mercury level was 17.5 µg/L. A group of 34 subjects (15 children and 19 adults) from a non-gold-mining area were selected as the control group. Their mean blood mercury level was 3.0 µg/L. A neuro-otological examination was administered; a neurological examination of the cranial nerves was administered using standard procedures and an audiological test was administered to 21 children and 19 adults.

Of those examined, 45% of the group complained of headaches and/or memory loss, three cases involved severe neurological impairment and four cases involved middle ear pathology. A statistically significant relationship was identified between blood mercury level and hearing level in children at 3 kHz in the right ear only. Adults were not affected. BAEP responses showed a significant correlation between blood mercury and the I-III interpeak latency on the left side. The authors conclude that the findings of this study suggest that overall auditory sensory-neural function and neural conduction time at the brain stem level were generally unaffected by elevated blood mercury levels in either children or adults.

3.2.1.10 Amazonian Basin

The conditions in the Amazon—extremely high temperatures and humidity with seasonal fluctuation of water during rainy and dry seasons—are conducive for mercury methylation because of high quantities of suspended organic matter, high temperature, acidity, and redox potential. These elements influence the availability of fish as a food resource. In 1996, Lebel and colleagues published results from a small preliminary study on individuals from the Amazonian basin to determine the relationship between mercury exposure and neurological outcomes and reported the decrease of visual and motor functions with increasing hair mercury levels. In 1998, Lebel and colleagues published another study to determine the neurofunctional and clinical manifestations of nervous system dysfunction in relation to hair mercury levels below 50 ppm. In 1999, Grandjean et al. published results from a study of populations living in four comparable Amazonian riverine communities located upstream of gold-mining fields, while in 2000, Dolbec et al. published results from a cross-sectional study in a village on the Tapajos River.

Lebel et al. (1996)

Lebel et al. (1996) published a study of 29 adult residents living in two villages located on the Tapajos River, a tributary of the Amazon, located approximately 200 kilometers from several gold-mining sites. Total hair mercury concentration ranged from 5.6 to 38.4 ppm; methylmercury constituted between 72.2% and 93.3% of the total mercury measured in hair samples. A quantitative behavioral neurophysiological battery was modified for administration to persons with minimal formal education living in an area without electricity. Women exhibited a decrease in manual dexterity, as measured in the Santa Ana Test (Helsinki version) that was correlated with increased mercury concentration in hair. For both men and women, there was a statistically significant decrease in color discrimination capacity with

increasing hair mercury concentrations. Near visual contrast sensitivity profiles and peripheral visual field profiles were both reduced in the individuals with the highest hair mercury concentrations. The authors note that constriction of the visual field has been observed in other instances of mercury intoxication and that changes in contrast sensitivity have been noted in nonhuman primates exposed to methylmercury (Rice and Gilbert 1982,1990).

Lebel et al. (1998)

A later study was conducted in a Tapajos River village that depends on fish as its main source of protein. A total of 91 adults (45 men and 46 women between the ages of 15 and 81) of the 98 voluntary participants were examined. Four measures of hair mercury concentrations were used: (1) mean total hair mercury, (2) total hair mercury, (3) total hair mercury in the highest value obtained out of all centimeters analyzed, and (4) total hair mercury in the first centimeter and methylmercury in the first centimeter. Several tests were administered to score for neuropsychological dysfunction. Motor strength was determined with a dynameter for grip test; manual dexterity was measured with the Santa Ana Test (Helsinki version); and visual functions, color vision, and contrast sensitivity were assessed with a battery of sensitive neurofunctional tests. Results were analyzed by multiple regression.

There was no difference between genders for all tests except the grip strength test. Women also exhibited decreased grip strength with increasing peak mercury levels. Intermediate and higher frequencies of near visual contrast sensitivity and manual dexterity (measured with the Santa Ana Test) varied with the level of mercury in hair. Gender-nonspecific muscular fatigue was also noted with increasing mercury levels. The authors suggest that there appears to be a dose-effect relationship for certain motor and visual functions. Manual dexterity, alternating hand coordination, and muscular fatigue were associated with hair mercury levels, while near visual contrast sensitivity and restricted visual fields were dose-dependently altered.

Cross-Sectional Study (Grandjean et al., 1999)

A cross-sectional study was conducted in four comparable Amazonian riverine communities located upstream toward gold-mining fields. Fish is consumed as a large part of the population's staple diet. Of the 420 eligible children between the ages of 7 and 12, 351 were examined for neurobehavioral dysfunction. Mercury exposure was measured through children's hair mercury levels because only 37% of the participants had maternal hair mercury samples. Children's hair mercury concentrations had an

overall geometric mean of 11.0 ppm and a median of 12.8 ppm, while mothers had geometric mean hair mercury levels of 11.6 ppm and a median value of 14.0 ppm. Maternal hair mercury concentrations were highly correlated with those of their children. Several neuropsychological tests of motor function, attention, and visuospatial capability were administered. These included Finger Tapping, Santa Ana form board, WISC-III Digit Spans Test, and two subtests of the Stanford-Binet Intelligence Scale (the copying test and memory condition). The relation between mercury exposure and neurobehavioral function was analyzed by multiple regression analyses with adjustment for covariates including, age, sex, health status, maternal education, and maternal marital status.

The Santa Ana form board and Stanford-Binet copying test showed the clearest associations with the hair mercury concentration. The authors note that the effect of mercury was significantly greater in younger children only for the nonpreferred hand condition of the Santa Ana Test. In interpreting these results, the authors caution that there were no data for the level of prenatal exposure experienced in the test children because of the lack of maternal hair samples. Additional sources of uncertainty in this study include nutritional deficiencies that occurred in the past and possible infection of tropical diseases that may have influenced the capabilities of these children at the time of neurological evaluation.

Cross-Sectional Study (Dolbec et al., 2000)

A cross-sectional study was conducted in May of 1996 in a village on the banks of the Tapajos river in the Amazonian Basin, Brazil (Dolbec et al., 2000). This study was conducted on 84 fish-eating adults between the ages of 15 and 79, to evaluate the effect of mercury exposure on motor performance. The mean hair total mercury level was 9 ppm. Pychomotor performance was evaluated using the Santa Ana Test for manual dexterity, the Grooved Pegboard Fine to test fine motor skills and NES Finger Tapping Test for motor speed. Motor strength was measured by dynamometry for grip and pinch strength.

Multivariate analysis of the variance indicated that the hair mercury levels were inversely associated with overall performance on the psychomotor tests, whereas an association was reported with blood mercury. Semipartial regression analyses reported that hair total mercury accounted for 8%-16% of the variance of psychomotor performance. The authors conclude that the findings of this study demonstrated neurobehavioral manifestations of subtle neurotoxic effects on motor functions associated with low-level methylmercury exposure.

3.2.1.11 Madeira

Cross-Sectional Study (Murata et al., 1999b)

A cross-sectional study (Murata et al., 1999) was conducted in the Madeiran community to determine possible—mercury exposure-related effects on evoked potentials in 149 children between the ages of 6.4 and 7.4 years. Children's hair mercury concentrations were used to reflect current exposure levels, while maternal hair levels from mothers who had followed consistent diets since pregnancy represented prenatal mercury exposures 7 years ago. The use of maternal hair concentration as a substitute for exposure during pregnancy is based on the assumption that mercury exposure has changed very little over time. The authors acknowledge, however, that current maternal hair mercury levels provide an imprecise indication of exposure during pregnancy and any recent dietary change would tend to weaken the association with the outcome variables. The 149 children were administered physical and functional neurological examinations, with an emphasis on motor coordination and perceptual motor performance. Tests included these:

- NES2 FT
- NES2 HEC
- NES2 CPT
- WISC-R subtests: Digit Spans forward condition and Block Designs
- Stanford-Binet Bead Memory Test

Evoked potentials were determined with a four-channel electromyograph, while pattern reversal visual-evoked potentials with binocular full-field stimulation were conducted in a darkened room. Associations between these outcomes and exposure to methylmercury were assessed by multiple regression analysis and were adjusted for possible confounding variables: age, sex, maternal and paternal education and employment, maternal alcohol use and smoking during pregnancy, numbers of older and younger siblings, school, and the level of the child's computer acquaintance.

Increased exposure to methylmercury was associated with delays in evoked potential latencies; peak III on the BAEP at 40 Hz, and N145 on the pattern reversal visual-evoked potentials at the 15-minute condition. When the maternal hair mercury concentration exceeded 10 ppm, the increase of the N145 visual-evoked potential latency at 15 minutes was 3.16 milliseconds (ms). The N75-N145 and P100 and N145 interval latencies showed similar regression coefficients for mercury, although

significance was evident only for the 15-minute condition. The authors suggest that this may indicate that there is a mercury-associated delay occurring between P100 and N145. Weak associations were also evidenced between maternal hair mercury levels and deficits on Digit Spans and Bead Memory tests.

3.2.1.12 French Guiana

Case-Control Study (Cordier and Garel, 1999)

High-exposure areas were selected in the Amerind villages in the Upper Maroni, with two other Amerind villages with less mercury contamination to serve as reference groups (Cordier and Garel, 1999. 261 children participated in the study, 69 from the village of Camopi (control), 82 from Awala (control) a total of and 110 in the Upper Maroni (cases). Hair samples were collected from both children and mothers to represent exposure indices. Maternal hair mercury levels ranged from 2.5 to 6.7 ppm. This was used as a surrogate for prenatal exposure. Children had slightly lower hair mercury levels than adults, but this did not vary with age. Neurological examinations were administered to children from 9 months to 6 years of age with special emphasis on neuromotor examination of the upper and lower limbs, axis of the body, deep reflexes, postural reactions, examination of the effects on neuromotor functions, neurosensory examination, and cranial growth. The battery of tests was selected to measure the child's abilities outside of educational or cultural influences; these include the NES FT Test to measure fine motor function, coordination, and speed of execution; and the Stanford-Binet Intelligence Scale, with subtests of immediate memory (bead memory) and ability to assess visuospatial and visuoconstructional function (block-copying). In addition, the McCarthy memory test for digits (backward and forward) and the McCarthy leg coordination test were utilized. Associations were analyzed by linear regression, adjusting for potential confounding factors (alcohol consumption during pregnancy, parity, place of birth of the child, and illnesses during childhood).

Within the case group, there is a significant decrease in the scores with exposure category for the Leg Coordination test and close to significance for the Copying test. When boys and girls were examined separately for the FT test, boys had higher scores than the girls, while a significant decrease is observed in the score on the Block Design test correlated with exposure in girls. Boys also exhibited greater incidence of increased reflexes correlated with maternal hair mercury concentrations. The authors conclude that results of this study suggest a link between exposure to mercury and perturbations of the child's neurological and intellectual development.

3.2.2 Animal Studies

Substantial information on the neurotoxicity of methylmercury has been generated from animal studies that support neurological effects reported in humans. Relatively brief, high-level exposures in rats have been shown to cause characteristic signs of neurotoxicity (flailing and hindlimb crossing when the animal is lifted by the tail), as well as neuronal degeneration in the cerebellum, cerebral cortex, and dorsal root ganglia (Inouye and Murakami, 1975; Leyshon and Morgan, 1991; Magos et al., 1985; Yip and Chang, 1981). As observed in humans, there is a latency period before onset of neurological symptoms. Toxic effects may not be observed or may not show maximal severity until several days after the initiation of dosing. In short-term studies, toxicity may not become evident until after the cessation of dosing. This section summarizes a few selected animal studies on neurotoxicity. For additional detail, please refer to Volume V of the *MSRC* (U.S. EPA, 1997e) and the *Toxicological Effects of Methylmercury* (NRC, 2000).

3.2.2.1 Acute Toxicity

In an acute study, exposure of rats to a single gavage dose of 19.9 mg mercury/kg as methylmercuric chloride resulted in impaired open-field tests such as decreases in standing upright, area traversed, and activity compared with the control group (Post et al., 1973). Animals were lethargic and ataxic initially, but symptoms disappeared within 3 hours.

3.2.2.2 Chronic Toxicity

Longer term, low-level exposures revealed that evidence of neuronal degeneration may be observed before the onset of overt signs of toxicity. Degeneration in the cerebellum was found in rats given 10 mg mercury/kg as methylmercuric chloride once every 3 days for 15 days (Leyshon and Morgan, 1991). Severe degenerative changes in the dorsal root fibers were observed in rats given 1.6 mg mercury/kg-day as methylmercuric chloride for 8 weeks (Yip and Chang, 1981). Munro et al. (1980) observed demyelination of dorsal nerve roots and damage in sciatic nerves with oral exposure to 0.25 mg mercury/kg-day as methylmercuric chloride for up to 26 months. In mice given 1.9 mg mercury/kg-day as methylmercury, cerebellar lesions were observed as early as 8 days after the start of dosing, but changes in motor activity did not develop until after 24 weeks of exposure (MacDonald and Harbison, 1977). Similarly, cats receiving methylmercury in the diet for 11 months displayed degenerative changes

in the cerebellum and cerebral cortex, but uncoordinated movements or weakness were observed only in a small number of animals with histopathological changes (Chang et al., 1974).

A 2-year feeding study of methylmercuric chloride was conducted in B6C3F1 mice (60 mice/sex/group) at doses of 0, 0.4, 2, and 10 ppm (0, 0.03, 0.15, and 0.73 mg mercury/kg-day in males; 0, 0.02, 0.11, and 0.6 mg mercury/kg-day in females) to evaluate chronic toxicity and carcinogenic effects (Mitsumori et al., 1990). Mice were examined clinically during the study, and neurotoxic signs characterized by posterior paralysis were observed in 33 males after 59 weeks and in 3 females after 80 weeks in the 0.6 mg mercury/kg-day group. A marked increase in mortality and a significant decrease in body weight gain were also observed in the high-dose males, beginning at 60 weeks. Postmortem examination revealed toxic encephalopathy consisting of neuronal necrosis of the brain and toxic peripheral sensory neuropathy in both sexes of the high-dose group. An increased incidence of chronic nephropathy was observed in the 0.11- and 0.6-mg mercury/kg-day males.

Groups of Wistar rats (50/sex/group) were administered daily doses of 0.002, 0.02, 0.05, and 0.25 mg mercury/kg-day as methylmercuric chloride for 26 months (Munro et al., 1980). Female rats that received 0.25 mg/kg-day had reduced body weight gains and showed only minimal clinical signs of neurotoxicity. Male rats that received this dose did show overt clinical signs of neurotoxicity, had decreased hemoglobin and hematocrit values and reduced weight gains, and showed increased mortality. Histopathologic examination of rats of both sexes receiving 0.25 mg/kg-day revealed demyelination of dorsal nerve roots and peripheral nerves. Males showed severe kidney damage and females had minimal renal damage. This study identified a NOAEL of 0.05 mg/kg-day and a LOAEL of 0.25 mg/kg-day, based on the observed demyelination effect.

Bornhausen et al. (1980) reported a decrease in operant behavior performance in 4-month-old rats whose dams had received methylmercuric chloride on gestation days 6 to 9. A statistically significant effect was seen in offspring whose dams had received 0.01 and 0.05 mg/kg five times during gestation. The authors postulated that more severe effects of *in utero* exposure would be seen in humans because the biological half-life of mercury in the brain of humans is five times longer than in the rat. In addition, much longer *in utero* exposure to mercury would occur in humans because gestation is much longer.

In a study of prenatal coexposure to metallic mercury vapor and methylmercury and their effects on the developing central nervous system, Fredriksson et al. (1996) reported interactive behavioral effects following exposure of pregnant female Sprague-Dawley rats to methylmercury and metallic mercury

vapor. Between 4 and 5 months, testing of behavioral function, spontaneous motor activity, spatial learning in a circular bath, and instrumental maze learning for food were performed. Exposure to mercury vapor at 1.8 mg/m^3 for 1.5 hours per day on gestation days 14 to 19 was related to hyperactivity and decreased spatial learning. Although exposure to methylmercury at 2 mg/kg per day on gestation days 6 to 9 was not related to adverse behavioral effects, coexposure to methylmercury and mercury vapor potentiated the activity and spatial learning effects observed with mercury vapor alone. The results of this study indicate that mercury vapor causes central nervous system functional disturbances in offspring after both prenatal and postnatal exposure. The authors also suggest that coexposure to methylmercury served to significantly aggravate the changes, whereas methylmercury alone did not cause any significant functional alterations in this study.

Ramussen and Newland (1999) studied the acquisition of Multiple Differential Reinforcement of High-Rate Extinction (MULT DRH-N:T EXT) schedules of reinforcement in female rats exposed to methylmercury during development. Female rats were administered methylmercury (0, 0.5, or 6.4 ppm) in drinking water from 4 weeks premating to postnatal day 16. Postnatal methylmercury concentrations in the brain at birth were 0.49 and 9.8 ppm for two exposure groups. In the MULT DRH-N:T EXT, female offspring were trained to press levers under schedules of reinforcement. Whenever a response occurred within a specific time measured in seconds, a food pellet was given. Two acquisition protocols were examined; one imposed three successive sessions in a 3:1, 5:2, and 9:4 ratio. Values were chosen so that the same rate of response was required by the schedules. The second acquisition protocol required lever repressing as reestablished and the three schedules were continued until the behavior became stable, which required more than 10 sessions. This study was not able to replicate the finding of abnormal response patterns using the DRL paradigm used by Bornhausen (1980).

Cholinergic systems also play an important role in learning and memory. Coccini et al. (2000) investigated the effect of low-level methylmercury exposure on muscarinic cholinergic receptor (mAChR) binding characteristics in adult female Sprague-Dawley rats. The rats (4/dose) were administered methylmercury in the drinking water at nominal concentrations of 0, 2.5, and 10 µg/L for 16 days. Mean daily intake in the methylmercury-exposed groups was 0.45 and 1.8 mg/kg-day, respectively. mAChR binding was assessed using the muscarinic antagonist [^{3}H]quinuclidinyl benzilate (QNB) to label receptors in excised brain tissues (cerebral cortex, hippocampus, and cerebellum). Exposure to methylmercury selectively increased mAChR density in the hippocampus and cerebellum by 20% to 44%. This response was characterized by a 2-week latency period before onset. Receptor affinity was

unaffected, as indicated by values for the dissociation constant. No significant effect on mAChR in cerebral cortex was observed.

Nonhuman Primates—Macaca Fascicularis Monkeys

Monkeys appear to be more sensitive to the neurotoxic effects of methylmercury than are rodents. The primate model is particularly useful for studies of developmental exposures because monkeys, like humans, have relatively prolonged periods of gestation, infancy, and adolescence (Burbacher and Grant, 2000). Long-term studies in primates have shown neurological impairment at doses as low as 0.05 mg mercury/kg-day. Exposure of monkeys to 0.03 mg mercury/kg-day as methylmercury for approximately 4 months caused no detectable changes in motor activity or effects on vision or hearing, but degenerative changes were observed in neurons of the calcarine cortex and sural nerve when these were examined by electron microscopy (Sato and Ikuta, 1975). At higher doses (0.08 mg mercury/kg-day), slight tremor, lack of motor coordination, and blindness were observed in monkeys after 4 months of exposure (Burbacher et al., 1988).

Gunderson et al. (1986) administered daily doses of 0.04–0.06 mg mercury/kg as methylmercuric hydroxide to 11 crab-eating macaques *(Macaca fascicularis)* throughout pregnancy. This dosing protocol resulted in maternal blood levels of 1,080–1,330 µg/L in mothers and 1,410–1,840 µg/L in the offspring. Infants of treated mothers exhibited visual recognition deficits when tested 35 days after birth.

Rice (1989b) dosed five cynomolgus monkeys *(Macaca fascicularis)* with 0.05 mg mercury/kg-day as methylmercuric chloride from birth to 7 years of age. Clinical and neurological examinations were performed during the dosing period and for an additional 6 years. Impairment of spatial visual function was observed after 3 years. In the later stages of the observation period, monkeys dosed with methylmercury were clumsier and slower to react when placed in the exercise cage than were unexposed monkeys. Decreased fine motor performance, touch, and pinprick sensitivity, and impaired high-frequency hearing were observed 6-7 years after cessation of dosing (Rice 1989a; Rice and Gilbert, 1982, 1990).

Rice (1998) did auditory testing of *Macaca fascicularis* monkeys exposed to methylmercury chloride at 10, 25, or 50 ug/kg per day *in utero*, throughout gestation, plus 4 years postnatally at 11 and 19 years of age. Results from this study indicated that at 19 months of age, all five *Macaca fascicularis* monkeys experienced deterioration in auditory function and elevated pure-tone thresholds throughout the

full range of frequencies tested (0.125 to 31.5 kHz) when compared with age-matched controls. The elevation of thresholds was in some cases 50 dB or higher. Because the auditory deficits are experienced approximately 7 to 15 years after cessation of methylmercury exposure, they are considered irreversible and permanent. The author concluded from this study that the high-dose monkeys experience an earlier onset of effect on the auditory function than do low-dose monkeys. The group of monkeys that showed delayed neurotoxicity at 15 years also had visual deficits identified at 3 years, as well as auditory and somatosensory impairment. The high-dose monkeys were also impaired at 11 years, and relatively more impaired than controls at 19 years, thus providing evidence for accelerated aging. These results provide evidence for the accelerated impairment of auditory function during aging as a consequence of developmental methylmercury exposure.

In another study by Rice (1998), monkeys with robust methylmercury-induced deficits in visual, auditory, and somatosensory function were tested on a series of tasks assessing central processing speed. This task is thought to be similar to tests measuring human intelligence. Five *Macaca fascicularis* monkeys were dosed with 50 μg/kg per day methylmercuric chloride from birth until 7 years of age. Blood mercury levels ranged from 0.8 to 1.1 μg/g until cessation of dosing. At 20 years of age, the monkeys and four age-matched and rearing-matched controls were tested on a series of simple and complex reaction-time tasks. In the simple reaction-time test, the monkeys were required to press a button when it changed from off to on (bright red light). The monkeys then performed a sequence of complex reaction-time tasks: two-button pressing, four-button pressing, and several tasks of increasing complexity using four buttons and multiple colors. The results indicated no differences between groups on any aspect of the experiment. The author concluded that the data provide further evidence for the absence of cognitive impairment in monkeys exposed developmentally to methylmercury.

In 1999, Burbacher et al. published a study that assessed visual and auditory functions in adult *Macaca fascicularis* monkeys exposed to methylmercury *in utero*. Maternal doses were 0, 50, 70, or 90 μg/kg per day; this resulted in infant blood mercury levels that ranged from 1.04 to 2.45 ppm. When the monkeys reached 15 years of age, they were tested on spatial visual contrast sensitivity tasks at spatial frequencies of 1, 4, 10, and 20 cycles per degree of visual angle and auditory pure tone detection tasks at frequencies of 125, 500, 1,000, 4,000, 10,000, 25,000, and 31,500 Hz. The results of these tests indicated that *in utero* exposure to methylmercury has long-term effects on visual contrast sensitivity thresholds. Preliminary results from the auditory task suggest that auditory thresholds are not affected by methylmercury exposure. The authors suggest that results from this study point to the postnatal period as a possible critical window for methylmercury induced auditory neurotoxicity.

3.3 CARDIOVASCULAR TOXICITY

3.3.1 Human Studies

3.3.1.1 Cardiovascular Effects From the Faroe Islands (Sorensen et al., 1999)

Sørensen et al. (1999) evaluated the relationship between prenatal exposure to methylmercury and occurrence of cardiovascular effects at 7 years of age in a birth cohort (n = 1,000) of children from the Faroe Islands. Prenatal exposure was assessed by analysis of cord blood and maternal hair collected at parturition. More than 80% of the hair samples exceeded a methylmercury concentration of 2 ppm, which corresponded to a cord blood concentration of approximately 10 μg/L. The cardiovascular endpoints evaluated at 7 years included systolic and diastolic blood pressure, heart rate, and heart rate variability. Weight, height, body mass index, sex, and maternal hypertension were examined as predictors of blood pressure and heart rate in approximately 900 children. Birth weight and placental weight were also examined as predictors of blood pressure. Following adjustment for body weight, diastolic and systolic blood pressure increased by 13.9 mm mercury (95% confidence limits [CL] = 7.4, 20.4) and 14.6 mm mercury (95% CL = 8.3, 20.8), respectively, as cord blood mercury concentrations increased from 1 to 10 μg/L. No further increase was noted at higher concentrations of mercury. Low-birth-weight children were more likely to experience methylmercury-related increase in blood pressure. A gender-specific decrease in heart rate variability was also noted with increasing mercury exposure. This effect was most pronounced in boys, where a 47% reduction in heart rate variability was observed when cord blood mercury concentrations increased from 1 to 10 μg. The authors concluded that the findings suggest that prenatal exposure to methylmercury may influence the development of cardiovascular regulatory mechanisms.

3.3.1.2 Cross-Sectional Study (Salonen et al., 1995)

Salonen et al. (1995) examined the relationship between dietary intake of fish and mercury and risk of acute myocardial infarction (AMI), death from coronary heart disease (CHD), and other cardiovascular diseases (CVD). Participants of this study included 1,833 men in eastern Finland between the ages of 42 and 60 with no clinically diagnosed CHD, claudication, stroke, or cancer. Baseline examinations were administered between March 1984 and December 1989. Fish consumption was assessed at time of blood sampling with an interview-verified 4-day food record. The food recording was repeated approximately 12 months after the baseline examination in a random sample of 50 men in the

cohort. Daily fish intake ranged from 0 to 619.2 g (mean of 46.5 g/day). Mercury in hair and urine was determined by flow injection analysis-cold vapor atomic absorption spectrometry and amalgamation. Hair mercury concentrations ranged from 0 to 15.67 ppm (mean of 1.92 ppm) while dietary mercury intake ranged from 1.1 to 95.3 μg /day (mean of 7.6 μg per day). In 2 to 7 years, 73 of the 1,833 men experienced an AMI; 18 of the 73 patients with AMI died of CHD, while 24 of the 73 died of CVD. Covariates included these: age; examination year; family history of CHD; place of residence (rural vs. urban); diabetes; socioeconomic status; iron intake; number of cigarettes, cigars, and pipefuls of tobacco currently smoked daily; duration of regular smoking in years; alcohol consumption; history of myocardial infarction; angina pectoris and other ischemic heart disease; presence of hypertension; and current antihypertensive medication. The Cox models reported dietary intakes of fish and mercury associated with increased risk of AMI and death from CHD, CVD, and any death. Results from this study indicated that eastern Finnish men with hair mercury levels exceeding 2 ppm had a twofold age- and CHD-adjusted risk of AMI and a 2.9-fold adjusted risk of cardiovascular death compared with those having lower hair mercury content.

3.3.1.3 Nested Case-Control Study (Salonen et al., 1995)

A nested case-control study was also conducted using a subsample of the original study participants. Serum immune complexes containing oxidized LDL were measured in a subsample of 187 control subjects using an ELISA assay with copper-oxidized LDL as the antigen. Pearson correlation coefficients adjusted for age and year of baseline examination were used to determine the association between hair mercury content and dietary intakes of fish and mercury. Partial associations of hair and urinary mercury with titers of immune complexes against oxidized LDL were estimated by SPSS step-up least-squares regression analysis. A multivariate logistic model included the following covariates: cigarette-years, serum ferritin concentration, ischemic exercise ECG, serum apolipoprotein, family history of CHD, maximal oxygen uptake, and serum HDL2 cholesterol. There was a statistically significant association between urinary mercury excretion and the risk of AMI was reported. For each microgram of mercury excreted daily, the risk of AMI increased by 36%. From the immunotoxicity test, both the hair and urinary excretion mercury levels were associated with immune complex titers measured with a rabbit antiserum against oxidized LDL and the γ-globulin fraction of a rabbit antiserum against oxidized LDL. Overall, hair mercury was the strongest predictor of both immune complex titers.

On the basis of these data, the authors concluded that a high intake of mercury from nonfatty freshwater fish, and the consequent excess risk of AMI as well as death from CHD and CVD in eastern Finnish men, may be due to the promotion of lipid peroxidation by mercury.

3.3.2 Animal Studies

Data on cardiovascular effects following oral methylmercury exposure were obtained from two studies in rats. Rats given two daily doses of methylmercuric chloride exhibited decreases in heart rates following two daily doses of methylmercury at 12 mg/kg per day (Arito and Takahashi, 1991). Wistar rats (n = 80) treated by subcutaneous injection with 0.5 mg/kg-day methylmercuric chloride for 1 month had increased systolic blood pressures beginning 42 days after cessation of dosing (Wakita, 1987). This effect persisted for more than a year.

Mitsumori et al. (1983, 1984) fed Sprague-Dawley rats diets containing methylmercuric chloride (males 0, 0.011, 0.05, or 0.28 mg/kg/day; females 0.014, 0.064, or 0.34 mg/kg/day) for up to 130 weeks. Polyarteritis nodosa and calcification of the arterial wall were seen at the highest dose. Histological examination revealed evidence of hemosiderosis and extramedullary hemotopoiesis of the spleen.

In a study on 7-week-old, hypertensive SHR/NCrj rats, Tamashiro et al. (1986) reported an increase in blood pressure resulting from exposure to methylmercury chloride once a day at 2 mg/kg/day for 26 consecutive days. Body weight loss, an early sign of methylmercury intoxication, was more marked in males than females. All male rats died by the 29th day posttreatment. Neurological signs, hindleg crossing, disturbed righting movement and abnormal gait always preceded death. No mortality was reported for the female rats. However, increase in blood pressure was sex-specific, being observed only in females. The authors noted that considerable variation was observed in blood pressure for both the methylmercury-exposed and the control rats; and that these findings suggest strain differences in male-female toxicity of methylmercury chloride.

3.4 IMMUNOTOXICITY

3.4.1 Human Studies

At this time, there are no studies published on the effect of methylmercury on the human immune system. In occupational exposure studies, elemental mercury has been found to affect particular immune

parameters. A study by Queiroz and Dantas (1997) evaluated B-lymphocyte, T-helper, T-suppressor, and T-cell proliferative response to phytohemagglutinin in 33 male workers in a Brazilian mercury production facility. These workers had a mean age of 29 and a mean mercury exposure period of 19 months. All of the workers had urinary mercury concentrations below 50 µg/g of creatinine. Analysis of the T-cell populations found a reverse CD4+ to CD8+ ratio that was characterized by a reduction in the number of CD4 lymphocytes. B-lymphocytes were also significantly reduced. Analysis of serum antibody levels found increased immunoglobulin E levels but did not detect anti-DNA or anti-nucleolar antibodies. No changes were observed in the proliferative response to phytohemagglutinin of lymphocytes from exposed individuals. The authors reported a negative correlation between the length of exposure to mercury and IgE levels, and no correlations between lymphocyte changes and urinary mercury concentrations, time of exposure, or the age of the workers. (Queriroz and Dantas, 1997)

Another occupational exposure study by Moszczynski et al. (1995) examined the lymphocyte subpopulation of T-cells, T-helper cells, T-suppressor cells, and natural killer cells in the peripheral blood of 81 men exposed to metallic mercury vapors and 36 unexposed men. The average workplace exposure to mercury in air was 0.0028 mg/m^3. Urinary mercury concentrations ranged from 0 to 240 µg/L and concentrations in the blood varied from 0 to 30 µg/L. Stimulation of the T-lymphocytes manifested by an increased number of T-cells, T-helper cells, and T-suppressor cells was observed.

3.4.2 Animal Studies

Data on the potential immunotoxic effects of methylmercury are available from several animal studies. Suppression of humoral and cellular immune responses has been observed in animals after oral exposure to methylmercury or methylmercuric chloride. Decreases in the production of antibody-producing cells and/or decreased antibody titer following inoculation with immune-stimulating agents (such as sheep red blood cells) have been observed in mice and rabbits (Blakley et al., 1980; Koller et al., 1977; Ohi et al., 1976). Decreases in natural killer T-cell activity and reduced thymus weight have been observed in female mice after 14 weeks of exposure to methylmercury (Ilback, 1991). Bernaudin et al. (1981) observed IgG deposits along the glomerular capillary wall of Brown Norway rats treated with methylmercury for 2 months and noted that these deposits were suggestive of autoimmune disease. The following sections include summaries of selected studies.

Wild et al. (1997) evaluated immune function in the offspring of Sprague-Dawley rats exposed to methylmercuric chloride (5 or 500 µg/L) or methylmercury sulfide (5 µg/L) via drinking water. There

were three exposed groups and one control group. The control group was fed plain tap water. Rats of both sexes were treated for 8 weeks prior to mating and treatment of female rats continued throughout pregnancy and nursing. The total duration of indirect exposure of the offspring to methylmercury was 42 days. Immunological function was assessed in six offspring per treatment group at 6 and 12 weeks of age (3 and 9 weeks after termination of methylmercury exposure at weaning, respectively). At 6 weeks, total body weights, splenic weights, and thymic weights were increased in the methylmercury chloride-exposed rats, whereas the rats exposed to methylmercury sulfide experienced only an increase in thymic weight at 6 weeks. At 12 weeks, natural killer cell activity was markedly depressed (56%) for rats exposed to methylmercury chloride in comparison with controls. Methylmercury sulfide appeared to have different effects on the immune system than did methylmercury chloride. For example, the sulfide form affected only thymic weight and had no significant effect on NK or splenocyte cell activity or splenocyte LPR. Whether this result reflects differential distribution of the sulfide form or affinity for different targets in the immune system is unknown. The authors concluded that methylmercury chloride seems to have an effect on splenocytes and natural killer cell activity.

Inorganic mercury has been observed to induce a variety of immune effects in mice. However, until recently there has been limited investigation of the ability of methylmercury to induce similar immune responses. Hultman and Hansson-Georgiadis (1999) investigated the ability of subcutaneously injected methylmercury to induce systemic autoimmunity in five genetically susceptible and resistant strains of mice. Female SJN/L, A.SW, B10.S (H-2^s), BALB/C, DBA/2 (H-2^d), A.TL, and B10.TL (H-2^u) mice were administered subcutaneous injections of 1 mg/kg methylmercury every third day for 4 weeks. This treatment protocol resulted in an average daily dose of approximately 350 µg mercury/kg-day. The immune response to methylmercury differed qualitatively and quantitatively from the response to inorganic mercury. Treatment with methylmercury induced at most a small increase in serum Ig concentrations after 4 weeks of treatment. The observed increases during the treatment period were generally marginal when compared with increases induced by mercuric chloride. Treatment with methylmercury induced development of antinucleolar antibodies (ANoA) targeting the nucleolar protein fibrillarin in the susceptible SJL, A.SW, and B10.S strains. Susceptibility to development of ANoA was linked to the mouse major histocompatibility complex H-2. However, background genes determined the strength of the response in susceptible strains. Serum IgE concentration and ANoA titer increased 2 to 3 weeks after cessation of treatment with methylmercury. In H-2^s mice, methylmercury induced a weaker general (polyclonal) and specific (ANoA) response when compared to mercuric chloride. Unlike mercuric chloride-treated mice, animals administered methylmercury did not develop systemic or renal immune system deposits.

3.5 REPRODUCTIVE TOXICITY

3.5.1 Human Studies

There are no studies of reproductive deficits in humans exposed to low-dose methylmercury.

3.5.2 Animal Studies

There are no two-generation reproductive assays for methylmercury.

3.6 GENOTOXICITY

3.6.1 Human Studies

Data from several studies in humans suggest that ingesting methylmercury may cause chromosomal aberrations and sister chromatid exchanges (SCE) (Skerfving et al., 1970; Wulf et al., 1986; Franchi et al., 1994).

A study of nine Swedish subjects who consumed mercury-contaminated fish and four controls showed a statistically significant rank correlation between blood mercury and percentage of lymphocytes with chromosome breaks (Skerfving et al., 1970). An extension of this study (Skerfving et al. 1974) included 23 exposed (5 females and 18 males) and 16 controls (3 females and 13 males). The authors reported significant correlations between blood mercury level and frequency of chromatid changes and "unstable" chromosome aberrations; there was no correlation with "stable" chromosome aberrations.

The Wulf et al. (1986) study was of 92 Greenlander Eskimos. Subjects were divided into three groups based on intake of seal meat (six times per week; two to five times per week, once a week, or no consumption of seal meat). Higher frequency of SCE in lymphocytes was correlated with blood mercury concentration; an increase of 10 μg mercury per liter of blood was associated with an increase of 0.3 SCE/cell. Positive correlations were also found for smoking, diet, living district, and cadmium exposure.

Franchi et al. (1994) evaluated formation of micronuclei in peripheral blood lymphocytes of Mediterranean fishers, a group with presumed high exposure to methylmercury. Fifty-one subjects were

interviewed on age, number of seafood-based meals/week, and habits such as smoking and alcohol consumption. Total blood mercury was measured; the range was 10.08-304.11 ng/g with a mean of 88.97 ± 54.09 ng/g. There was a statistically significant correlation between blood mercury concentration and micronucleus frequency and between age and micronucleus frequency (U.S. EPA, 1997e)

3.6.2 Animal Studies

In a study with cats (Charbonneau et al. 1976), methylmercury did not induce dose-related unscheduled DNA synthesis in lymphocytes or chromosomal aberrations in bone marrow cells after oral exposure for up to 39 months (Miller et al., 1979). Statistically significant decreases in unscheduled DNA synthesis and increases in chromosomal aberrations were observed, but there was no dose-response.

Strain-specific differences exist with respect to the ability of methylmercury to produce dominant lethal effects in mice (Suter, 1975). When (SEC × $C57B_1$)F_1 males were injected with 10 mg/kg methylmercury hydroxide, there was a slight reduction in the total number of implantations and a decrease in the number of viable embryos. This was not observed when (101 × C3H)F_1 males were exposed in a similar fashion. When female (10 × C3H)F_1 mice were treated with methylmercuric hydroxide, no increase in the incidence of dead implants was observed (unlike the case for mercuric chloride). Changes in chromosome number, but no increase in chromosome aberrations, were observed in oocytes of Syrian hamsters treated with one interperitoneal injection of 10 mg/kg methylmercuric chloride (Mailhes, 1983). Methylmercury was administered subcutaneously to golden hamsters at doses of 6.4 mg or 12.8 mg mercury/kg/body weight. Polyploidy and chromosomal aberrations were increased in bone marrow cells, but there was no effect on metaphase II oocytes. There was an inhibitory effect on ovulation, which the authors noted was not as severe as that induced by mercuric chloride in the same study (Watanabe et al., 1982). Nondysjunction and sex-linked recessive lethal mutations were seen in *Drosophila melanogaster* treated with methylmercury in the diet (Ramel, 1972).

As reviewed in WHO (1990), methylmercury is not a point mutagen but is capable of causing chromosome damage in a variety of systems. In vitro studies have generally shown clastogenic activity but only weak mutagenic activity. Methylmercuric chloride and dimethylmercury were both shown to induce chromosome aberrations and aneuploidy in primary cultures in human lymphocytes; methylmercuric chloride was the more potent clastogen at equally toxic doses (Betti et al., 1992). Both methylmercury and mercuric chloride induce a dose-dependent increase in SCE in primary human

lymphocytes and muntjac fibroblasts; methylmercury was about five times more effective in this regard (Verschaeve et al., 1984; Morimoto et al., 1982).

Methylmercury has been shown to inhibit nucleolus organizing activity in human lymphocytes (Verschaeve et al., 1983). Methylmercury can induce histone perturbation and has been reported to interfere with gene expression in cultures of glioma cells (WHO, 1990). Impaired growth and development was noted in cultured mouse embryonic tissue treated in vitro with methylmercuric chloride, but there was no increase in SCE (Matsumoto and Spindle, 1982). Costa et al. (1991) showed that methylmercuric chloride caused DNA strand breaks in both V79 and rat glioblastoma cells treated in vitro. Methylmercuric chloride produced more strand breaks than did mercuric chloride.

Evidence of DNA damage has been observed in the *Bacillus subtilis* rec-assay (Kanematsu et al., 1980). These authors reported negative results for methylmercury in spot tests for mutagenicity in the following bacterial strains: *E. coli* B/r WP2 and WP2; and *Salmonella typhimurium* strains TA1535, TA1537, TA1538, TA98, and TA100. Jenssen and Ramel (1980) indicated in a review article that methylmercury acetate was negative in both micronucleus assays and mutagenicity tests in Salmonella; the article referred to Heddle and Bruce (1977) and provided no experimental details. Weak mutagenic responses for methylmercuric chloride and methoxyethyl mercury chloride were observed in Chinese hamster V79 cells at doses near the cytotoxic threshold (Fiskesjo, 1979), and methylmercury produced a slight increase in the frequency of chromosomal nondysjunction in *Saccharomyces cerevisiae* (Nakai and Machida, 1973). Methylmercury, however, caused neither gene mutations nor recombination in *S. cerevisiae* (Nakai and Machida, 1973). Methylmercury retarded DNA synthesis and produced single-strand breaks in DNA in L5178Y cells (Nakazawa et al., 1975).

3.7 CARCINOGENICITY

3.7.1 Human Studies

At this time, no human studies have reported an association between methylmercury exposure and overall cancer rates. Three studies were identified that examined the relationship between methylmercury exposure and cancer. No persuasive evidence of increased carcinogenicity attributable to methylmercury exposure was observed in any of the studies. Interpretation of these studies, however, was limited by poor study design and incomplete descriptions of methodology and/or results.

3.7.2 Animal Studies

The results from three dietary studies in two strains of mice indicate that methylmercury is carcinogenic. Interpretation of two of the positive studies was complicated by observation of tumors only at doses that exceeded the Maximum Tolerated Dose (MTD). Therefore, only one positive animal study is appropriate for consideration. A fourth dietary study in mice, three dietary studies in rats, and a dietary study in cats failed to show carcinogenicity of methylmercury. Interpretation of four nonpositive studies was limited because of deficiencies in study design or failure to achieve an MTD.

Methylmercuric chloride was administered in the diet at levels of 0, 0.4, 2, or 10 ppm (0, 0.03, 0.14, and 0.69 mg Hg/kg-day in males and 0, 0.03, 0.13, and 0.60 mg Hg/kg-day in females) to B6C3F1 mice (60/sex/group) for 104 weeks (Mitsumori et al., 1990). In high-dose males, a marked increase in mortality was observed after 60 weeks (data were presented graphically; statistical analyses not performed). Survival at study termination was approximately 50%, 60%, 60%, and 20% in control, low-, mid-, and high-dose males, respectively, and 58%, 68%, 60%, and 60% in control, low-, mid-, and high-dose females, respectively. The cause of the high mortality was not reported. At study termination, the mean body weight in high-dose males was approximately 67% of controls and in high-dose females was approximately 90% of controls (data presented graphically; statistical analyses not performed). Focal hyperplasia of the renal tubules was significantly ($p<0.01$) increased in high-dose males (14/60; the incidence was 0/60 in all other groups). The incidence of renal epithelial carcinomas (classified as solid or cystic papillary type) was significantly ($p<0.01$) increased in high-dose males (13/60; the incidence was 0/60 in all other groups). The incidence of renal adenomas (classified as solid or tubular type) was also significantly ($p<0.05$) increased in high-dose males; the incidence was 0/60, 0/60, 1/60, and 5/60 in control, low-, mid-, and high-dose males, respectively, and 0/60, 0/60, 0/60, and 1/60 in control, low-, mid-, and high-dose females, respectively. No metastases were seen in the animals. The incidences of a variety of nonneoplastic lesions were increased in the high-dose rats including these: sensory neuropathy, neuronal necrosis in the cerebrum, neuronal degeneration in the cerebellum, and chronic nephropathy of the kidney. Males exhibited tubular atrophy of the testis (1/60, 5/60, 2/60, and 54/60 in control, low-, mid-, and high-dose, respectively) and ulceration of the glandular stomach (1/60, 1/60, 0/60, and 7/60 in control, low-, mid-, and high-dose males, respectively). An MTD was achieved in middose males and high-dose females. High mortality in high-dose males indicated that the MTD was exceeded in this group.

Mitsumori et al. (1981) administered 0, 15, or 30 ppm of methylmercuric chloride (99.3% pure) in the diet (0, 1.6 and 3.1 mg Hg/kg-day) to ICR mice (60/sex/group) for 78 weeks. Interim sacrifices of up to 6/sex/group were conducted at weeks 26 and 52. Kidneys were microscopically examined from all animals that died or became moribund after week 53 or were killed at study termination. Lungs from mice with renal masses and renal lymph nodes showing gross abnormalities were also examined. Survival was decreased in a dose-related manner; at week 78 survival was 24/60, 6/60, and 0/60 in control, low-, and high-dose males, respectively, and 33/60, 18/60, and 0/60, in control, low-, and high-dose females, respectively (statistical analyses not performed). The majority of high-dose mice (51/60 males and 59/60 females) died by week 26 of the study. Examination of the kidneys of mice that died or were sacrificed after 53 weeks showed a significant ($p<0.001$) increase in renal tumors in low-dose males (13/16 versus 1/37 in controls). The incidence of renal epithelial adenocarcinomas in control and low-dose males was 0/37 and 11/16, respectively ($p<0.001$). The incidence of renal epithelial adenomas in control and low-dose males was 1/37 and 5/16, respectively ($p<0.01$). No renal tumors were observed in females in any group. No metastases to the lung or renal lymph nodes were observed. Evidence of neurotoxicity and renal pathology was observed in the treated mice at both dose levels. The high mortality in both groups of treated males and in high-dose females indicated that the MTD was exceeded in these groups.

A followup study to the Mitsumori et al. (1981) study was reported by Hirano et al. (1986). Methylmercuric chloride was administered in the diet to ICR mice (60/sex/group) at levels of 0, 0.4, 2, or 10 ppm (0, 0.03, 0.15, and 0.73 mg Hg/kg-day in males and 0, 0.02, 0.11, and 0.6 mg Hg/kg-day in females) for 104 weeks. Interim sacrifices (6/sex/group) were conducted at 26, 52, and 78 weeks. Complete histopathological examinations were performed on all animals found dead, killed *in extremis*, or killed by design. Mortality, group mean body weights and food consumption were comparable to controls. The first renal tumor was observed at 58 weeks in a high-dose male, and the incidence of renal epithelial tumors (adenomas or adenocarcinomas) was significantly increased in high-dose males (1/32, 0/25, 0/29, and 13/26 in the control, low-, mid-, and high-dose groups, respectively). Ten of the 13 tumors in high-dose males were adenocarcinomas. These tumors were described as solid type or cystic papillary types of adenocarcinomas. No invading proliferation into the surrounding tissues was seen. The incidence of renal epithelial adenomas was not significantly increased in males, and no renal adenomas or adenocarcinomas were observed in any females. Focal hyperplasia of the tubular epithelium was reported to be increased in high-dose males (13/59; other incidences not reported). Increases in nonneoplastic lesions in high-dose animals provided evidence that an MTD was exceeded. Nonneoplastic lesions reported as increased in treated males included the following: epithelial

degeneration of the renal proximal tubules; cystic kidney; urinary cast and pelvic dilatation; and decreased spermatogenesis. Epithelial degeneration of the renal proximal tubules and degeneration or fibrosis of the sciatic nerve were reported in high-dose females.

No increase in tumor incidence was observed in a study using white Swiss mice (Schroeder and Mitchener 1975). Groups of mice (54/sex/group) were exposed from weaning until death to methylmercuric acetate in the drinking water at two doses. The low-dose group received 1 ppm methylmercuric acetate (0.19 mg Hg/kg-day). The high-dose group received 5 ppm methylmercuric acetate (0.95 mg Hg/kg-day) for the first 70 days and then 1 ppm, thereafter, due to high mortality (21/54 males and 23/54 females died prior to the dose reduction). Survival among the remaining mice was not significantly different from controls. Significant ($p<0.001$) reductions in body weight were reported in high-dose males (9–15% lower than controls) and high-dose females (15–22% lower than controls) between 2 and 6 months of age. Mice were weighed, dissected, gross tumors were detected, and some sections were made of heart, lung, liver, kidney, and spleen for microscopic examination. No increase in tumor incidence was observed. This study is limited because complete histological examinations were not performed, and pathology data other than tumor incidence were not reported.

Mitsumori et al. (1983, 1984) conducted a study in Sprague-Dawley rats. They administered diets containing 0, 0.4, 2, or 10 ppm of methylmercuric chloride (0, 0.011, 0.05, and 0.28 mg Hg/kg-day in males; 0, 0.014, 0.064, and 0.34 mg Hg/kg-day in females) to Sprague-Dawley rats (56 animals/sex/group) for up to 130 weeks. Interim sacrifices of 10/group (either sex) were conducted at weeks 13 and 26 and of 6/group (either sex) at weeks 52 and 78. Mortality was increased in high-dose males and females. At week 104, survival was approximately 55%, 45%, 75%, and 10% in control, low-, mid-, and high-dose males, respectively, and 70%, 75%, 75%, and 30% in control, low-, mid-, and high-dose females, respectively (data presented graphically). Body weight gain was decreased in high-dose animals (approximately 20–30%; data presented graphically). No increase in tumor incidence was observed in either males or females. Noncarcinogenic lesions that were significantly increased ($p< 0.05$) in high-dose rats included the following: degeneration in peripheral nerves and the spinal cord (both sexes); degeneration of the proximal tubular epithelium of the kidney (both sexes); severe chronic nephropathy (females); parathyroid hyperplasia (both sexes); polyarteritis nodosa and calcification of the abdominal arterial wall (females); bone fibrosis (females); bile duct hyperplasia (males); and hemosiderosis and extramedullary hematopoiesis in the spleen (males). In addition, mid-dose males exhibited significantly increased degeneration of the kidney proximal tubular epithelium and hyperplasia

of the parathyroid. An MTD was achieved in mid-dose males and in high-dose females; the MTD was exceeded in high-dose males.

No increase in tumor incidence or decrease in tumor latency was observed in another study using rats (strain not specified) (Verschuuren et al., 1976). Groups of 25 female and 25 male rats were administered methylmercuric chloride at dietary levels of 0, 0.1, 0.5, and 2.5 ppm (0, 0.004, 0.02, and 0.1 mg Hg/kg-day) for 2 years. No significant effects were observed on growth or food intake except for a 6% decrease (statistically significant) in body weight gain at 60 weeks in high-dose females. Survival was 72%, 68%, 48%, and 48% in control, low-, mid- and high-dose males, respectively; and 76%, 60%, 64%, and 56% in control, low-, mid- and high-dose females, respectively (statistical significance not reported). Increases in relative kidney weights were observed in both males and females at the highest dose. No effects on the nature or incidence of pathological lesions were observed, and tumors were reported to have been observed with comparable incidence and latency among all of the groups. This study was limited by the small sample size and failure to achieve an MTD.

No tumor data were reported in a study using Wistar rats (Munro, 1980). Groups of 50 Wistar rats/sex/dose were fed diets containing methylmercury; doses of 2, 10, 50, and 250 micrograms Hg/kg-day were fed for 26 months. High-dose female rats exhibited reduced body weight gains and showed minimal clinical signs of neurotoxicity; however, high-dose male rats showed overt clinical signs of neurotoxicity, decreased hemoglobin and hematocrit values, reduced weight gains and significantly increased mortality. Histopathologic examination of the high-dose rats of both sexes revealed demyelination of dorsal nerve roots and peripheral nerves. Males showed severe dose-related kidney damage, and females had minimal renal damage.

No increase in tumor incidence was observed in a multiple generation reproduction study using Sprague-Dawley rats (Newberne et al., 1972). Groups of rats (30/sex) were given semisynthetic diets supplemented with either casein or a fish protein concentrate to yield dietary levels of 0.2 ppm methylmercury (0.008 mg Hg/kg-day). Another group of controls received untreated rat chow. Rats that received diets containing methylmercury during the 2-year study had body weights and hematology comparable to controls. Detailed histopathologic analyses revealed no lesions of the brain, liver, or kidney that were attributable to the methylmercury exposure. Mortality data were not presented. Interpretation of these data is limited by the somewhat small group sizes and failure to achieve an MTD.

No increase in tumor incidence was observed in a study using random-bred domestic cats (Charbonneau et al., 1976). Groups of cats (4–5/sex/group) were given doses of 0.0084, 0.020, 0.046, 0.074 or 0.176 mg Hg/kg-day either as methylmercury-contaminated seafood or as methylmercuric chloride in the diet for up to 2 years. Controls were estimated to have received 0.003 mg Hg/kg-day. Food consumption and body weight were not affected by treatment with methylmercury. Due to advanced signs of neurotoxicity (loss of balance, ataxia, impaired gait, impaired reflexes, weakness, impaired sensory function, mood change and tremor), cats at the highest dose tested were sacrificed after approximately 16 weeks, and cats at the next highest dose were sacrificed after approximately 54–57 weeks. Cats at the next highest dose generally exhibited mild neurological impairment (altered hopping reaction and hypalgesia). One cat at this dose was sacrificed after 38 weeks because of neurotoxicity, and one cat died of acute renal failure after 68 weeks. Cats at the two highest doses had pathological changes in the brain and spinal cord, but no histopathological changes were noted in other tissues examined. Interpretation of the results of this study is limited because of the small group sizes, early sacrifice of cats at the two highest dose levels and no available data regarding pathological changes in cats at the three lowest dose levels. This study was also limited by its short duration when compared to the lifespan of a cat.

Blakley (1984) administered methylmercuric chloride to female Swiss mice (number/group not specified) in drinking water at concentrations of 0, 0.2, 0.5 or 2.0 mg/L for 15 weeks. This corresponded to approximately 0, 0.03, 0.07 and 0.27 mg Hg/kg-day. At the end of week 3, a single dose of 1.5 mg/kg of urethane was administered intraperitoneally to 16–20 mice/group. No effects on weight gain or food consumption were observed. Lung tumor incidence in mice not administered urethane (number/group not specified) was less than 1 tumor/mouse in all groups. Statistically significant trends for increases in the number and size of lung adenomas/mouse with increasing methylmercury dose were observed; the tumor number/mouse was 21.5, 19.4, 19.4, and 33.1 in control, low-, mid- and high-dose mice, respectively, and the tumor size/mouse was 0.70, 0.73, 0.76 and 0.76 mm in control, low-, mid- and high-dose mice, respectively. The study authors suggest that the increase in tumor number and size may have been related to immunosuppressive activity of methylmercury. It should be noted that this is considered a short-term assay and that only pulmonary adenomas were evaluated.

4.0 RISK ASSESSMENT FOR METHYLMERCURY

4.1 BACKGROUND

Methylmercury is highly toxic to mammalian species and causes a variety of adverse effects. It is a developmental toxicant in humans and animals. It causes chromosomal effects but does not induce point mutations. The *Mercury Study Report to Congress* (MSRC) (U.S. EPA, 1997) concluded that because there are data for mammalian germ-cell chromosome aberration and limited data from a heritable mutation study, methylmercury is placed in a group of high concern for potential human germ-cell mutagenicity. There is no two-generation study of reproductive effects, but shorter term studies in rodents, guinea pigs, and monkeys have reported observations consistent with reproductive deficits. There are no data to indicate that methylmercury is carcinogenic in humans, and it induces tumors in animals only at highly toxic doses. Application of the revised Guidelines for Cancer Risk Assessment leads to a judgment that methylmercury is not likely to be carcinogenic for humans under conditions of exposure generally encountered in the environment.

The quantitative health risk assessment for a noncarcinogen is the reference dose (RfD). This is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious health effects during a lifetime.

EPA has published two RfDs for methylmercury that represented the Agency consensus at that time. The original RfD of 0.3 μg/kg/day was determined in 1985. The current RfD of 0.1 μg/kg/day was established as the Agency consensus estimate in 1995. While EPA was developing the MSRC (U.S. EPA, 1997), it became apparent that considerable new data on the health effects of methylmercury in humans were emerging. Among these data sources were large studies of seafood-consuming populations in the Seychelles and Faroe Islands. Smaller scale studies were being reported on effects in populations around the U.S. Great Lakes and in the Amazon basin. Publications also included novel statistical approaches and applications of physiologically based pharmacokinetic (PBPK) models.

In 1997 the MSRC was undergoing final review; at that time many of the new data had either not been published in the peer-reviewed press or not been subjected to rigorous review. EPA decided that it was premature to make a change in the 1995 methylmercury RfD for the MSRC. This decision was in accordance with the advice of the Science Advisory Board (SAB). Since 1997 the field of

methylmercury toxicology and assessment has expanded dramatically. This criteria document presents a revised RfD that considers data from the human studies published in the 1990s, recent evaluations of health and pharmacokinetic data, and recent statistical and modeling approaches to assessing those data.

The following sections include brief descriptions of the previously published EPA RfDs as well as descriptions of some of the evaluation processes that took place at the end of the 1990s.

For this document the following definitions apply. These reflect usage in the National Research Council publication *Toxicological Effects of Methylmercury* (NRC, 2000) (see Section 1.5).

NOAEL No-observed-adverse-effect level. An exposure level at which there are no statistically or biologically significant increases in the frequency or severity of adverse effects in a comparison between an exposed population and a control group. Effects may be seen at this level of exposure, but they are not considered to be adverse. For risk assessment the NOAEL is generally the highest level at which no adverse effects are seen.

LOAEL Lowest-observed-adverse-effect level. The lowest exposure level at which there are statistically or biologically significant increases in frequency or severity of adverse effects in a comparison between an exposed population and a control group.

BMD Benchmark dose. In common parlance this term refers to a quantitative assessment for noncancer health effects that uses a curve-fitting procedure to determine a level functionally equivalent to a NOAEL. In this chapter, BMD will be used to mean an estimated dose that corresponds to a specified risk above the background risk.

BMDL Benchmark dose lower limit, a statistical lower limit on a calculated BMD. In this document that will be the 95% lower confidence limit. The BMDL will be used as the starting point for the calculation of the methylmercury RfD.

4.1.1 Other RfDs Published by EPA

Two RfDs based on human studies have been published as consensus values for EPA. In addition, the MSRC (EPA, 1997) describes an RfD that could be estimated from animal data.

4.1.1.1 1985 RfD

A hazard identification and dose-response assessment was proposed for methylmercury in 1980 (U.S. EPA, 1980). This assessment was reviewed and consensus was achieved by the EPA RfD/RfC (reference concentration) Work Group on December 2, 1985. This RfD was published on EPA's Integrated Risk Information System (IRIS) in 1986. The critical effects were multiple central nervous system (CNS) effects, including ataxia and paresthesia in populations of humans exposed to methylmercury through consumption of contaminated grain (summarized by Clarkson et al., 1976; Nordberg and Strangert, 1976; and WHO, 1976).

The RfD for methylmercury was determined to be 3×10^{-4} mg/kg-day (0.3 µg/kg/day), based on a LOAEL of 0.003 mg/kg-day (corresponding to 200 µg/L blood concentration) and an uncertainty factor of 10 to adjust the LOAEL to what is expected to be a NOAEL. An additional uncertainty factor (UF) of 10 for sensitive individuals for chronic exposure was not deemed necessary, as the adverse effects were seen in what was regarded as a sensitive group of individuals: adults who consumed methylmercury-contaminated grain.

The RfD/RfC Work Group ascribed medium confidence to the choice of study, the database, and the RfD. The blood levels associated with the LOAEL were well supported by more recent data, but neither the chosen studies nor supporting database described a NOAEL. Medium confidence generally indicates that new data may change the assessment of the RfD.

4.1.1.2 1995 RfD

After publication of the RfD of 0.3 µg/kg/day, questions were raised as to its validity; some of these questions were in formal submissions requesting a change on the IRIS entry. In particular it was asked whether the RfD based on effects in exposed adults was protective against developmental effects. Subsequent to the RfD publication, the effects in Iraqi children of *in utero* exposure to methylmercury were reported by Marsh et al. (1987). The RfD/RfC Work Group discussed the methylmercury RfD in 1992 and again in 1994. Consensus on a revised RfD was reached in January 1995. Detailed description of the RfD derivation can be found in Volume V of the MSRC (U.S. EPA, 1997e).

Marsh et al. (1987) was chosen as the most appropriate study for determination of an RfD protective of a putative sensitive subpopulation, namely infants born to mothers exposed to

methylmercury during gestation. The data collected by Marsh et al. (1987) summarize clinical neurologic signs of 81 mother-and-child pairs. Maternal hair mercury concentrations were collected as the exposure metric. Concentrations ranging from 1 to 674 ppm mercury were determined from X-ray fluorescent spectrometric analysis of selected regions of maternal scalp. These were correlated with clinical signs observed in the affected members of the mother-child pairs. The hair concentration at a hypothetical NOAEL for developmental effects was determined by application of a BMD approach (see subsequent section for discussion of methods and data used). The analysis used the combined incidence of all neurological effects in children exposed *in utero* as reported in the Marsh et al. (1987) study. A Weibull model for extra risk was used to determine the BMD; in current terminology, this was a BMDL (95% lower confidence limit) on the dose corresponding to a 10% risk level. This level was calculated to be 11 ppm mercury in maternal hair (11 mg/kg hair). A description of BMD determination, choice of model, and issues on grouping of data is on pages 6-25 to 6-31 of Volume V of the MSRC.

The BMD of 11 ppm maternal hair mercury was converted to an exposure level of 44 μg mercury/L blood using a 250:1 ratio as described in the MSRC (U.S. EPA, 1997e, pp. 6-22 to 6-23):

$$11 \text{ mg/kg hair} / 250 = 44 \text{ μg/L blood}$$

To obtain a daily dietary intake value of methylmercury corresponding to a specific blood concentration, factors of absorption rate, elimination rate constant, total blood volume, and percentage of total mercury present in circulating blood were taken into account. Calculation was by the following equation, based on the assumptions that steady-state conditions exist and that first-order kinetics for mercury are being followed:

$$d\ \mu g/day = \frac{C \times b \times V}{A \times f}$$

where:

d = daily dietary intake (expressed as μg of methylmercury)
c = concentration in blood (expressed as 44 μg/L)
b = elimination constant (expressed as 0.014 $days^{-1}$)
V = volume of blood in the body (expressed as 5 L)

A = absorption factor (expressed as a unitless decimal fraction of 0.95)

f = fraction of daily intake taken up by blood (unitless, 0.05)

Solving for d gives the daily dietary intake of mercury that results in a blood mercury concentration of 44 µg/L. To convert this to daily ingested dose (µg/kg-day), a body weight of 60 kg was assumed and included in the equation denominator:

$$d = \frac{c \times b \times V}{A \times f \times bw}$$

$$d = \frac{44\ \mu g/L \times 0.014\ days^{-1} \times 5\ L}{0.95 \times 0.05 \times 60\ kg}$$

$$d = 1.1\ \mu g/kg\text{-}day$$

The dose d (1.1 µg/kg-day) is the total daily quantity of methylmercury that is ingested by a 60-kg individual to maintain a blood concentration of 44 µg/L or a hair concentration of 11 ppm. The rationales for use of the hair:blood ratio and specific values for equation parameters can be found on pages 6-21 to 6-25 of Volume V of the MSRC.

A composite uncertainty factor of 10 was used. This uncertainty factor was applied for variability in the human population, in particular the wide variation in biological half-life of methylmercury and the variation that occurs in the hair-to-blood ratio for mercury. In addition, the factor accounts for lack of a two-generation reproductive study and lack of data for possible chronic manifestations of adult effects (e.g., paresthesia observed during gestation). The default value of 1 was used for the modifying factor.

The RfD was calculated using the following equation:

$$RfD = \frac{BMD}{UF \times MF}$$

$$= \frac{1.1\ \mu g/kg\text{-}day}{10}$$

$$= 1 \times 10^{-4}\ mg/kg\text{-}day$$

or 0.1 µg/kg/day.

Confidence in the supporting database and in the RfD were considered medium by the RfD/RfC Work Group. The MSRC (U.S. EPA, 1997e) says the following:

> The principal study (Marsh et al. 1987) is a detailed report of human exposures with quantitation of methylmercury by analysis of specimens from affected mother-child pairs. A strength of this study is that the quantitative data are from the affected population and quantitation is based upon biological specimens obtained from affected individuals. A threshold was not easily defined; extended application of modeling techniques was needed to define the lower end of the dose-response curve. This may indicate high variability of response to methylmercury in the human mother-child pairs or misclassification in assigning pairs to the cohort.

Further discussion of areas of uncertainty and variability are on pages 6-31 to 6-51 of Volume V of the MSRC (U.S. EPA, 1997e). A quantitative analysis of uncertainty in an RfD based on the Iraqi data is found in Appendix D of Volume V, and additional discussions of areas of uncertainty are in Volume VII, Risk Characterization, of the MSRC (U.S. EPA, 1997g).

4.1.1.3 Reference Values Derived From Animal Data

There are issues inherent to epidemiological studies, including the possibility of coexposure to other potential toxicants, that are not of concern in controlled experimental animal studies. It is therefore informative to compare RfDs that may be derived from animal studies to those derived from the epidemiological literature. RfDs derived from monkey studies are particularly relevant, as the neurotoxic effects produced by developmental methylmercury exposure in monkeys are similar to those identified in humans (Burbacher et al., 1990a; Gilbert and Grant-Webster, 1995). The studies at the University of Washington were of a relatively large cohort of macaque monkeys whose mothers were exposed throughout pregnancy to 50 µg/kg/day of methylmercury. The studies revealed deficits on cognitive tests during infancy, which may represent retarded development (Burbacher et al., 1986; Gunderson et al., 1986, 1988). These methylmercury-exposed monkeys also displayed aberrant play and social behavior (Burbacher et al., 1990b). Studies at the Canadian Health Protection Branch in the same species of monkey, dosed with 50 µg/kg/day from birth to 7 years of age, revealed visual, auditory, and somatosensory deficits, including evidence of delayed neurotoxicity identified in middle age (Rice and Gilbert, 1995, 1992, 1982; Rice, 1989a). Research in a cohort of monkeys dosed beginning *in utero* and continuing until 4 years of age revealed similar sensory system impairment (Rice, 1998; Rice and Gilbert, 1995, 1990). Three individuals dosed at 10 or 25 µg/kg/day all exhibited impaired function in at least

one sensory system in addition to evidence of delayed neurotoxicity (Rice, 1998). In none of these studies was a NOAEL identified.

Calculation of an RfD from these data according to the method typically used by the EPA would include application of a number of UFs, including dividing the LOAEL by a factor of 10 (because no NOAEL was identified), division by 10 again for extrapolation from animal to human data, and division by another factor of 10 in consideration of individual variation in sensitivity. Monkeys and humans have approximately the same brain:blood mercury ratio following chronic exposure (Burbacher et al., 1990a), although the ratio in humans may be slightly higher than in monkeys (Rice, 1989b). However, the half-life of mercury in the blood of monkeys is about 15 days (Rice, 1989c), whereas clearance times for humans averaged 45-70 days in several studies, with some individuals having even longer clearance times (see Section 4.2.3). The shorter clearance time in monkeys would result in an UF of at least 5 based on pharmacokinetic considerations alone; therefore an overall factor of 10 appears appropriate for interspecies extrapolation. This calculation would yield an RfD of 0.05 µg/kg/day from the *in utero* and postnatal exposure studies, and an RfD as low as 0.01 µg/kg/day based on combined *in utero* and postnatal exposure (Rice, 1996). Gilbert and Grant-Webster (1995) suggested an RfD of 0.025 µg/kg/day based on the same data.

4.1.2 Risk Assessments Done by Other Groups

Quantitative estimates of hazards of oral exposure to methylmercury have been considered by the Food and Drug Administration (FDA), Agency for Toxic Substances and Disease Registry (ATSDR), and other countries (WHO/IPCS), among others.

4.1.2.1 Food and Drug Administration

In 1969, in response to the poisonings in Minamata Bay and Niigata, Japan, the U.S. FDA proposed an administrative guideline of 0.5 ppm for mercury in fish and shellfish moving in interstate commerce. This limit was converted to an action level in 1974 (Federal Register *39*, 42738, December 6, 1974) and increased to 1.0 ppm in 1979 (Federal Register *44*, 3990, January 19, 1979) in recognition that exposure to mercury was less than originally considered. In 1984, the 1.0 ppm action level was converted from a mercury standard to one based on methylmercury (Federal Register *49*; November 19, 1984).

The action level takes into consideration the tolerable daily intake (TDI) for methylmercury as well as information on seafood consumption and associated exposure to methylmercury. The TDI is the amount of methylmercury that can be consumed daily over a long period of time with a reasonable certainty of no harm. FDA established a TDI based on a weekly tolerance of 0.3 mg of total mercury per person, of which no more than 0.2 mg should be present as methylmercury. These amounts are equivalent to 5 and 3.3 μg, respectively, per kilogram of body weight. Using the values of methylmercury, this tolerable level would correspond to approximately 230 μg/week for a 70-kg person, or 33 μg/person/day (0.47 μg/kg bw/day). The TDI was calculated from data developed in part by Swedish studies of Japanese individuals poisoned in the Niigata episode, which resulted from the consumption of contaminated fish and shellfish and the consideration of other studies of fish-eating populations.

Based on observations from the later poisoning event in Iraq, FDA has acknowledged that the fetus may be more sensitive than adults to the effects of mercury (Federal Register *44*, 3990, January 19, 1979; U.S. FDA Consumer, September 1994). In recognition of these concerns, FDA has provided advice to pregnant women and women of childbearing age to limit their consumption of fish known to have high levels of mercury (U.S. FDA Consumer, 1994). FDA believes, however, that given existing patterns of fish consumption, few women (less than 1%) eating such high-mercury fish will experience slight reductions in the margin of safety. However, because of the uncertainties associated with the Iraqi study, FDA has chosen not to use the Iraqi study as a basis for revising its action level. Instead, FDA has chosen to wait for findings of prospective studies of fish-eating populations in the Seychelles Islands.

4.1.2.2 World Health Organization

The International Programme on Chemical Safety (IPCS) of the World Health Organization published a criteria document on mercury (WHO, 1990). In that document, it was stated that "a daily intake of 3 to 7 μg Hg/kg body weight would cause adverse effects of the nervous system, manifested as an approximately 5% increase in the incidence of paraesthesias." The IPCS expert group also concluded that developmental effects in offspring (motor retardation or signs of CNS toxicity) could be detected as increases over background incidence at maternal hair levels of 10-20 ppm mercury. These levels of concern were based on evaluation of data including the human poisoning incident in Iraq.

4.1.2.3 ATSDR

In 1993, ATSDR first published a Minimal Risk Level (MRL) for methylmercury. An MRL is derived in a manner similar to the RfD; it is defined as an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. In 1999 ATSDR published a revised methylmercury MRL using the Seychelles Islands study (SCDS) (Davidson et al., 1998) as the starting point (ATSDR, 1999). In this study (described in detail in Section 3.2.2.5 and summarized in Section 4.2.13), the investigators examined the correlation between subtle neurological effects and low-dose chronic exposure to methylmercury. No correlation between maternal hair mercury concentrations and neurological effects was seen in the SCDS 66-month-old children. ATSDR determined a minimal risk level of 0.3 μg/kg per day, based on a dose of 1.3 μg/kg per day, which reflects the average concentration of the upper quintile of the exposed population but does not necessarily correspond to a NOAEL. ATSDR used a UF of 1.5 to account for pharmacokinetic variability within the human population; they made their choice based on the analyses of Clewell et al. (1998). An additional factor of 1.5 was applied to account for any other individual variability (e.g., pharmacodynamics) as well as a modifying factor of 1.5 to account for the possibility that domain-specific tests used in the Faroe Islands study might have allowed detection of subtle neurological effects that were not evaluated in the Seychelles cohort. Although the conventional risk assessment approach is to multiply UFs, ATSDR summed these factors to develop an overall safety factor of 4.5.

4.1.3 SAB Review of the Mercury Study Report to Congress

The Science Advisory Board (SAB) is a public advisory group providing extramural scientific information and advice to the Administrator and other officials of the EPA. The SAB is structured to provide balanced, expert assessment of scientific matters relating to problems facing the Agency. The SAB reviewed a draft of the eight-volume MSRC (U.S. EPA, 1997a-h) in the context of a public meeting held February 13 and 14, 1997. A panel of 33 scientists reviewed the entire MSRC. A subgroup focused on the health effects data, and in particular EPA's use of those data to derive the methylmercury RfD of 0.1 μg/kg/day, based on effects observed in Iraqi children exposed *in utero*.

The SAB report was published in October 1997 (EPA-SAB-EC-98-001). It made the following statement:

> In general, from the standpoint of looking at human health effects and the uncertainties, the draft report [MSRC] is a very good document and an important step forward in terms of bringing the relevant information together into one place for the first time. The current RfD, based on the Iraqi and New Zealand data, should be retained at least until the on-going Faeroe and Seychelles Islands studies have progressed much further and been subjected to the same scrutiny as has the Iraqi data.

The SAB report continued:

> Investigators conducting two new major prospective longitudinal studies—one in the Seychelles Islands, the other in the Faeroe Islands—have recently begun to publish findings in the literature and are expected to continue releasing their findings during the next 2-3 years. These studies have advantages over those cited in the previous paragraph in that they have much larger sample sizes, a larger number of developmental endpoints, potentially more sensitive developmental endpoints, and control a more extensive set of potential confounding influences. On the other hand, the studies have some limitations in terms of low exposures (to PCBs in the Faeroes) and ethnically homogenous societies. Since only a small portion of these new data sets have been published to date and because questions have been raised about the sensitivity and appropriateness of the several statistical procedures used in the analyses, the Subcommittee concluded that it would be premature to include any data from these studies in this report until they are subjected to appropriate peer review. **Because these data are so much more comprehensive and relevant to contemporary regulatory issues than the data heretofore available, once there has been adequate opportunity for peer review and debate within the scientific community, the RfD may need to be reassessed in terms of the most sensitive endpoints from these new studies.** [Emphasis theirs]

4.1.4 Interagency Consensus Process

Among the many reviews of the MSRC was one by scientists and policy-makers from interested Federal agencies, sponsored by the Committee on Environment and Natural Resources (CENR), Office of Science and Technology (OSTP). This review highlighted many divergent points of view as to the appropriate basis for quantitative assessment of the low-dose effects of methylmercury exposure. It was decided that an interagency process with external involvement would be undertaken to review new methylmercury data and evaluate new and existing data. EPA committed to participate in this process and, at its conclusion, to assess its 1995 RfD for methylmercury to determine if a change was warranted. Subsequently a workshop was organized by an interagency committee at the request of OSTP. The organizing committee was chaired by the National Institute of Environmental Health Sciences (NIEHS) and included representatives from several agencies:

Department of Health and Human Services (DHHS)
Office of the Assistant Secretary for Planning and Evaluation
Centers for Disease Control and Prevention (CDC)
Agency for Toxic Substances Disease Registry (ATSDR)
Food and Drug Administration (FDA)
Environmental Protection Agency (EPA)

National Oceanic and Atmospheric Administration (NOAA)

Office of Science and Technology Policy (OSTP)

Office of Management and Budget (OMB)

The Methylmercury Workshop was a response to the suggestion that the emerging Seychellois and Faroese data undergo a level of scrutiny beyond journal peer review if they were to be used in policy setting.

The Workshop on the Scientific Issues Relevant to Assessment of Health Effects from Exposure to Methylmercury was held in Raleigh, North Carolina, November 18–20, 1998. The purpose of the workshop was to discuss and evaluate the major epidemiologic studies associating methylmercury exposure with an array of developmental measures in children. The workshop did not attempt to derive a risk assessment, but it was assumed by participants that the workshop evaluation would facilitate agreement on risk assessment issues. The major studies considered were those that have examined populations in Iraq, the Seychelles, the Faroe Islands, and the Amazon, along with the most relevant animal studies. Study authors made detailed presentations to respond to a series of questions on study exposures, potential confounders, measurements of effect, and other related topics. Five expert panels discussed the presentations and published data; panels covered the following areas: exposure, neurobehavioral endpoints, confounders and variables, design and statistics, and experimental (animal and *in vitro*) data. The results of their deliberations were published in the Spring of 1999 (NIEHS, 1999). Conclusions of the report were reviewed by workshop panelists and by Federal scientists who had attended the workshop. The conclusions are quoted below.

1. Methylmercury is a developmental neurotoxin, but effects at low doses encountered by eating fish are difficult to evaluate.

2. All the studies reviewed were considered of high scientific quality, and the panel recognized that each of the investigations had overcome significant obstacles to produce important scientific information. The panel also stated that continued funding of the studies in the Seychelles, Faroes, and Amazon is necessary for the full potential of those studies to be realized. This is particularly the case for the Faroes and Seychelles studies, which have assessed and are currently assessing the potential developmental neurotoxic effects of methylmercury in fish-eating populations. The developmental studies would benefit by evaluation of common endpoints using similar analytical methods. It is important to note that the Amazon study did not assess developmental endpoints but assessed effects in adults.

3. Results from the Faroes and Seychelles studies are credible and provide valuable insights into the potential health effects of methylmercury.

4. Some differences are clearly present in results from the Faroes, Seychelles, and Amazon, but the panel was not able to clearly identify the sources of these differences. Among possible sources are the different effects of episodic versus continuous exposure, ethnic differences in methylmercury responses, lack of common

endpoints in the Faroes and Seychelles studies, and several other confounders or modifying factors such as those found in diet and lifestyle, as well as in chemicals present in seafood, which is the source of methylmercury to these populations. The other chemical constituents of seafood that may be explanatory include those that may be beneficial to fetal neurodevelopment (i.e., omega-3 fatty acids) and those that may be harmful to fetal neurodevelopment (e.g., PCBs).

5. These studies have provided valuable new information on the potential health effects of methylmercury, but significant uncertainties remain because of issues related to exposure, neurobehavioral endpoints, confounders and statistics, and design.

The interagency organizing committee agreed unanimously that the deliberations of the panels and the workshop report will be a key factor in subsequent public health policy actions taken by each of the participating agencies.

4.1.5 National Academy of Sciences Review

Congress directed EPA, through the House Appropriations Report for FY99, to contract with the National Research Council (NRC, a body of the National Academy of Sciences) to evaluate the body of data on the health effects of methylmercury, with particular emphasis on new data since the publication of the MSRC. NRC was asked to provide recommendations regarding issues relevant to the derivation of an appropriate RfD for methylmercury.

The NRC empaneled a group of scientific experts who held public meetings at which there were presentations from methylmercury researchers, government agencies, trade organizations, public interest groups, and concerned citizens. The panel evaluated the scientific basis for risk assessments done by EPA and other groups as well as new data and findings available since publication of the MSRC. The committee was not charged with developing an RfD as an alternative to the EPA assessment, but rather provided scientific guidance that would inform such an assessment. The NRC report, *Toxicological Effects of Methylmercury*, was released to the public on July 11, 2000 (NRC, 2000). Conclusions of that report are summarized below.

The report concludes that methylmercury is a highly toxic substance; a number of adverse health effects associated with methylmercury exposure have been identified in humans and in animal studies. Most extensive are the data for neurotoxicity, particularly in developing organisms. The nervous system is considered by the NRC committee to be the most sensitive target organ for which there are data suitable for derivation of an RfD. The committee also concludes on the basis of data from humans and from animal studies that exposure to methylmercury can have adverse effects on the developing and adult cardiovascular system. They note that some research demonstrated adverse cardiovascular effects at or

below levels associated with effects on the developing nervous system. The NRC also cites evidence of low-dose methylmercury effects on the immune and reproductive systems.

The NRC report presents some conclusions on the public health implications of methylmercury exposure; one conclusion is quoted below:

> The committee's margin-of-exposure analysis based on estimates of MeHg exposure in the U.S. population indicates that the risk of adverse effects from current MeHg exposure in the majority of the population is low. However, individuals with high MeHg exposure from frequent fish consumption might have little or no margin of safety (i.e., exposures of high-end consumers are close to those with observable adverse effects). The population at highest risk is the children of women who consumed large amounts of fish and seafood during pregnancy. The committee concludes that the risk to that population is likely to be sufficient to result in an increase in the number of children who have to struggle to keep up in school and who might require remedial classes or special education. (NRC, 2000 p. 9)

The NRC report gives an evaluation of the 1995 EPA RfD. Their conclusion is as follows:

> On the basis of its evaluation, the committee's consensus is that the value of EPA's current RfD for MeHg, 0.1 μg/kg/day, is a scientifically justifiable level for the protection of public health. However, the committee recommends that the Iraqi study no longer be used as the scientific basis of the RfD (NRC, 2000 p. 11).

The NRC report made several recommendations on the appropriate basis for a revised RfD. The Committee thoroughly reviewed three epidemiological longitudinal developmental studies: the Seychelles Islands, the Faroe Islands, and New Zealand. The Seychelles study yielded scant evidence of impairment related to *in utero* methylmercury exposure through 5.5 years of age, whereas the other two studies found dose-related effects on a number of neuropsychological endpoints. The Faroe Islands study is the larger of the latter two studies and has been extensively peer-reviewed. NRC recommended use of data from the Faroe Islands study for derivation of the RfD (NRC, 2000 p. 11).

NRC recommended BMD analysis as the most appropriate method of quantifying the dose-effect relationship. They recommend the lower limit on a 5% effect level obtained by applying a K-power model ($K \geq 1$) to dose-response data based on Hg in cord blood. NRC noted that for the Faroe Islands data the results of the K-power model under this constraint are equivalent to a linear model (NRC, 2000, pp. 11-12).

NRC recommended use of the Boston Naming Test (BNT) as the critical endpoint. This endpoint yields the second-lowest BMDL but was judged by the Committee to be more reliable than the endpoint

that yields the lowest BMDL. The BMDL for the BNT from the Faroe Islands study is 58 ppb Hg in cord blood.

NRC described alternative dose conversion processes using a one-compartment model similar to that used in the MSRC.

In their discussion of uncertainty factors, NRC reviewed several sources of variability and uncertainty and recommended that an uncertainty factor of at least 10 be used. NRC recommended a factor of 2 to 3 for biological variability in dose estimation. They also recommended an additional factor to account for data gaps relating to possible long-term neurological effects not evident in childhood, as well as possible effects on the immune and cardiovascular systems (NRC, 2000, p. 327).

4.1.6 External Peer Review of Draft RfD

A draft EPA RfD document was submitted for external scientific peer review in late October 2000; the reviewers are listed at the front of this document. At the same time the draft RfD document was circulated for comment to other Federal Agencies through CENR and OSTP. A public scientific review meeting was held November 15, 2000; the final peer review report was delivered to EPA on December 7, 2000, and is available in the docket. The external peer reviewers supported the use of the Faroes data, derivation of a BMD as described by NRC, and application of a tenfold uncertainty factor to the BMDL. They agreed with EPA's use of a one-compartment model for dose conversion as well as with most of the parameter estimates; they commented correlation among some of the parameters. The peer reviewers disagreed with NRC's recommendation to set the RfD on the BNT results from the full Faroese cohort. They felt that the BNT scores showed an effect of concomitant PCB exposure in some analyses. They preferred a PCB-adjusted BMDL of 71 ppb mercury in cord blood for the BNT. They also offered suggested alternatives to use of the BNT test reslts. The peer reviewers validated a final RfD of 0.1 µg/kg bw /day.

4.1.7 Revised RfD

The development of this RfD considered the NRC recommendations and followed them for the most part. Most recommendations of the peer-review panel were incorporated as well. The following sections provide rationales for choices made by EPA in determining the basis for the RfD.

4.2 CHOICE OF CRITICAL STUDY AND ENDPOINT

NRC concluded, and EPA agrees, that the data from human studies showing developmental neurotoxicity are the most appropriate basis for the RfD. NRC concluded that human studies on methylmercury carcinogenicity are inconclusive and that the renal tumors observed in mice were found only when animals were exposed at or above the maximally tolerated dose (MTD). In the MSRC, EPA noted that if one applied the principles of the revisions to the Risk Assessment Guidelines for Carcinogenicity, the following conclusions would be reached:

> Methylmercury is not likely to be a human carcinogen under conditions of exposure generally encountered in the environment. Data in humans were inadequate; interpretation is limited by inappropriate study design and incomplete descriptions of methodology. Dietary exposure in two strains of mice resulted in increased renal adenomas and adenocarcinomas. Tumors were observed only in dose groups experiencing profound nephrotoxicity. Studies in rats exposed to an MTD showed no increased tumor incidence. Several studies show that methylmercury can cause chromosomal damage in somatic cells. While evidence is good for chromosomal effects, it does not appear that methylmercury is a point mutagen. The mode of action in renal tumor induction is likely to be related to reparative changes in the tissues. Human exposure is likely to be from consumption of contaminated foods, especially fish. It is expected that exposure, even in groups consuming large amounts of fish from contaminated sources, will be to levels far below those likely to cause the tissue damage associated with tumor formation in animals (U.S. EPA, 1997).

NRC concluded that human data, as well as results of animal tests, indicate the cardiovascular system is a sensitive target for methylmercury effects. This is particularly true for developing organisms. Their report also cites animal and *in vitro* data linking methylmercury exposure to immunotoxic and reproductive effects (summarized in NRC, 2000, pp. 190-191). It is clear, however, that at the current time the human data set on developmental neurotoxicity is the most extensive, best reviewed, and most thoroughly evaluated. The RfD will thus rely on those data. It is expected that an RfD based on developmental neurotoxicity will be protective against adverse effects likely to occur at higher levels of mercury exposure. Following NRC's recommendation, EPA's choice of critical study was limited to those developmental studies of populations experiencing long-term, low-dose exposure. Only those studies are summarized in subsequent sections of this document.

4.2.1 Summary of Available Data

This section gives brief summaries of studies on the developing central nervous system that were described by NRC. This section follows the format used by the NRC report; studies are grouped into subsections by endpoint and chronologically within subsection. Section 4.2.1.1 describes the evidence for effects of methylmercury on neurological status; Section 4.2.1.2 describes the effects on attainment of

developmental milestones during infancy; Section 4.2.1.3 describes other effects during infancy and early childhood; Section 4.2.1.4 presents evidence for cognitive deficits during childhood (school age); and Section 4.2.1.5 describes sensory and other effects of methylmercury.

For more detailed study descriptions refer to Section 3 of this document or to the MSRC.

4.2.1.1 Status on Neurological Examination

Cree Population—McKeown-Eyssen et al. (1983)

McKeown-Eyssen et al. (1983) studied a population of 234 12- to 30-month-old Cree Indian children for whom prenatal methylmercury exposure was estimated on the basis of maternal hair samples. The subjects lived in four communities in northern Quebec. Hair samples were collected on 28% of the mothers during pregnancy; prenatal exposure for the rest of the cohort was estimated from hair segments assumed to date from the time the study child was *in utero*. No child was judged to have any abnormal physical findings. Overall, 3.5% (4) of the boys and 4.1% (5) of the girls were considered to have abnormal neurological findings. The most frequent abnormality (observed in 11.4% [13] of the boys and 12.2% [14] of the girls) involved tendon reflexes. Abnormalities of muscle tone or reflexes in boys were the only neurological finding for which there was a statistically significant association with prenatal methylmercury exposure, either before or after adjustment for confounding. The risk of an abnormality of tone or reflexes increased seven times with each 10 ppm increase in maternal hair mercury. When exposure was categorized, the prevalence of tone or reflex abnormality did not increase in a clear dose-response manner across categories. In girls, incoordination was negatively associated with prenatal methylmercury exposure. The authors noted that these mild, isolated neurological findings were different from those described in previous reports of neurological abnormalities after prenatal exposure to higher levels of methylmercury.

Mancora, Peru—Marsh et al. (1995)

Neurological examination was done on 194 children in Mancora, Peru. Although the study was conducted in the early 1980s, it was not published until 1995 (Marsh et al., 1995). Fish consumption was the primary route of methylmercury exposure and maternal hair was used as the index of exposure (geometric mean 7.05 ppm; range 0.9 to 28.5 ppm). Comparison of peak and mean hair-mercury concentration suggested that the women's exposure was at steady state because of stability in their fish-

consumption patterns. Maternal hair samples and data on child neurological status were available for 131 children. Several elements of the study design are not described: the size of the eligible population from which the 131 children were sampled, the specific elements of the neurological assessment conducted, and the ages at which the children were examined. Frequencies were reported for the following endpoints: tone decreased, tone increased, limb weakness, reflexes decreased, reflexes increased, Babinski's sign, primitive reflexes, and ataxia. No endpoint was significantly associated with either mean or peak maternal hair mercury.

SCDS Pilot Study—Myers et al. (1995b)

In the cross-sectional or pilot study of the SCDS (Myers et al., 1995), 789 infants and children between the ages of 5 and 109 weeks were evaluated by a pediatric neurologist. Mean maternal hair mercury in the cohort was 6.1 ppm (range 0.6 to 36.4 ppm). The endpoints assessed were mental status, attention, social interactions, vocalizations, behavior, coordination, postures and movements, cranial nerves, muscle strength and tone, primitive and deep tendon reflexes, plantar responses, and age-appropriate abilities such as rolling, sitting, pulling to stand, walking, and running. The statistical analyses focused on three endpoints chosen on the basis of their apparent sensitivity to prenatal methylmercury exposure in the Iraq and Cree studies: overall neurological examination, increased muscle tone, and deep tendon reflexes in the extremities. There was no association between maternal hair mercury and questionable and abnormal results. The frequency of those results ranged from 16.5% in the group with hair mercury at 0 to 3 ppm to 11.7% in the group with Hair mercury at more than 12 ppm. The frequencies of abnormalities of limb tone or deep tendon reflexes were about 8%; there was no dose-dependent variation in frequency of either endpoint.

SCDS Main Study—Myers et al. (1995c)

The main cohort of the SCDS consisted of 779 mother-infant pairs, representing approximately 50% of all live births during the period of recruitment. The final sample size was 740. When the infants were 6.5 months old, a pediatric neurologist administered essentially the same neurological examination that had been used in the pilot phase; testing was blinded as to child's exposure. A total of 3.4% (25) of the children had overall neurological scores considered abnormal or questionable; this frequency was too low to permit statistical analysis of the overall neurological examination. The frequency of abnormalities was 2% for both limb tone and abnormal deep tendon reflexes. Questionable limb tone was identified in approximately 20% of the children, and questionable deep tendon reflexes in approximately 15%.

Although such findings were not considered pathological, they were combined with abnormal findings for statistical analyses. The frequency of abnormal and questionable findings for limb tone or deep tendon reflexes was not significantly associated with maternal hair mercury concentrations.

Faroes Population—Dahl et al. (1996)

A functional neurological exam was part of a general physical examination administered to a cohort of 7-year-old children from the Faroe Islands. Of 1,386 infants eligible at recruitment, cord-blood and maternal hair samples were obtained from 1,022 singleton births (75%), and 917 children were examined (66%) (Grandjean et al., 1992). The mean cord-blood concentration was 22.9 μg/L; the mean maternal hair mercury concentration was 4.3 ppm. The examination focused on motor coordination and perceptual-motor performance (Dahl et al., 1996). Results were scored as automatic, questionable, or poor. There was no association between cord-blood mercury and the number of tests on which a child's performance was considered automatic or performed optimally. On the tests of reciprocal motor coordination, simultaneous finger movement, and finger opposition, fewer than 60% of the children achieved a score of automatic for optimal performance. On the finger opposition test, children with questionable and poor performance (425 children) had a significantly higher mean cord-blood mercury concentration than children with automatic performance (465 children) (23.9 versus 21.8 μg/L, $p = 0.04$) (Grandjean et al., 1997).

Faroes Population—Steurwald et al. (2000)

A cohort of 182 singleton, full-term infants born in the Faroe Islands between 1994 and 1995 was recruited. The cohort represented 64% of all births in the study area. Data were collected on maternal hair mercury, cord whole-blood mercury, and cord serum mercury. A total of 15 maternal hair measurements exceeded 10 ppm. Measurements were also taken of 18 pesticides or metabolites and 28 polychlorinated biphenyl (PCB) congeners in maternal serum. At 2 weeks of age infants were given a neurological examination designed to assess functional abilities, reflexes and responses, and stability of behavioral status during examination. Responses were categorized as optimal, questionable, or suboptimal. The neurological optimality score (NOS) was the number of items rated as optimal out of a total of 60. Two subscores were generated (muscle tone and reflexes) and a variety of thyroid-function indices were also assessed. Maternal hair mercury concentrations were not significantly associated with NOS score, but there was a significant inverse relationship between NOS scores and cord whole-blood mercury. The mean mercury concentration was 20.4 μg/L (range 1.9 to 102 μg/L). Based on NOS score,

a tenfold increase in cord-blood mercury was associated with the equivalent of a 3-week reduction in gestational age. Adjustments for total PCBs and fatty acid concentrations had no effect on results, and selenium was not an effect modifier. Muscle-tone and reflexes subscores were not significantly associated with any exposure biomarker.

Cordier and Garel (1999)

Cordier and Garel (1999) studied a cohort of Amerind children from a gold-mining area in French Guiana. Median maternal hair concentration was 6.6 ppm with a range of 2.9 to 17.8 ppm; 35% of maternal hair mercury levels were greater than 10 ppm. Neurological examination included the following: neuromotor examination of the upper an lower limbs, body axis, deep reflexes, and postural reactions; neuromotor functions; neurosensory examination; and cranial growth. The authors report that for children greater than 2 years of age, increased reflexes were found with greater incidence as a function of maternal hair mercury; the effect was greater in boys than in girls. When 10 children were retested 9 months later by a different examiner, only 3 were found to have the increased reflex response. The authors commented that this poor reproducibility makes the reflex response difficult to interpret.

Conclusions

There is some evidence that neurological status in children is associated with low-dose *in utero* exposure: (1) an increased incidence (not dose dependent) of tone or reflex anomalies in boys associated with increased maternal hair mercury (McKeown-Eyssen et al., 1983); (2) an inverse association between newborn neurological optimality score and cord-blood mercury in Faroese children (Steurwald et al., 2000); (3) a statistically significant increase in the mean cord-blood mercury of 7-year-old Faroese children who performed less than optimally on a finger opposition test, compared with Faroese children with normal performance (Grandjean et al., 1997); (4) the association of increased reflexes with increasing maternal hair mercury in a group of children aged 9 months to 6 years in French Guiana (Cordier and Garel, 1999). NRC notes that a particular limitation of the use of neurological status is the categorical nature of the response; in other words, the subject has either an abnormal response or a normal response. This may have been a factor in the evaluation of results from the SCDS. The number of abnormal responses in this population was very low; thus there was reduced statistical power for hypothesis testing.

4.2.1.2 Age at Achievement of Developmental Milestones

SCDS—Myers et al. (1997) and Axtell et al. (1998)

The association between achievement of developmental milestones and prenatal methylmercury exposure was evaluated in the main cohort of the SCDS (Myers et al., 1997). Data were available for 738 of the 779 children enrolled. The mean average age for walking was 10.7 months for girls and 10.6 months for boys; for talking it was 10.5 months for girls and 11.0 months for boys. The mean age at which a child was considered to talk was not significantly associated with maternal hair mercury in any of the regression models used. In regressions stratified by child sex, a positive association was found between age at walking and maternal hair mercury in boys only. The interaction between mercury and sex was not statistically significant in the analyses of the complete cohort. The authors considered the magnitude of the delay in boys' walking to be clinically insignificant; a 10-ppm increase in maternal hair mercury was associated with approximately a 2-week delay. This association in boys was not significant when four statistical outliers were excluded from the analysis. Authors concluded that hockey-stick models provided no evidence of a threshold for developmental delay, as the fitted curves were essentially flat.

Axtell et al. (1998) reanalyzed the milestone data, applying semiparametric generalized additive models that are less restrictive than the approaches used by Myers et al. (1997). Their major finding was that the association between age at walking and maternal hair mercury in boys was nonlinear. In their modeled estimates, walking was delayed as maternal hair concentrations increased from 0 to 7 ppm but was observed at a slightly earlier age as mercury concentration increased beyond 7 ppm. The size of the effect associated with the increase from 0 to 7 ppm was very small, corresponding to a delay of less than 1 day in the achievement of walking. Because of the contradictory nature of the dose-response relationships above and below 7 ppm, the authors expressed a doubt that the association found below 7 ppm reflected a causal effect of mercury exposure on age at walking.

Mancora, Peru—Marsh et al. (1995)

Data on developmental milestones were collected in the Peruvian study conducted by Marsh et al. (1995). The study was conducted prospectively, and data were apparently collected in an ongoing manner over the course of a mother's visits to a postnatal clinic. Regression analyses, including analyses stratified by child sex, did not reveal any significant associations between maternal hair mercury

concentrations and the ages at which children sat, stood, walked, or talked. The rates of developmental retardation, especially in speech (13 of 131), were substantial. Children's birthweight, height, and head circumference were unrelated to maternal hair mercury concentrations.

Faroes Population—Grandjean et al. (1995)

Ages at achievement of motor development milestones were investigated in a 21-month birth cohort (1,022 infants born in 1986-1987) of children in the Faroe Islands. Complete data were available for 583 children. Three motor-development milestones commonly achieved between 5 and 12 months of age were selected for analysis: "sits without support," "creeps," and "gets up into standing position with support." There was no significant association between age at achievement and either cord-blood or maternal hair mercury for any of the three milestones. For all three, however, the authors reported a significant inverse association between age at achievement and the child's hair mercury concentration at 12 months. Children's hair mercury was interpreted as an index of postnatal exposure to methylmercury. Breastfeeding was associated with both increased hair mercury concentrations and more rapid achievement of milestones. Therefore, the authors concluded that the inverse association reflected residual confounding by duration of breastfeeding.

Conclusions

The recent human studies provide little evidence of an association between maternal hair mercury below 30 ppm and delayed developmental milestones. The NRC report noted that in the SCDS, mean age of walking was higher in the part of the population born to mothers with higher hair mercury. The association was for male children only and it was not dose related. In the Faroese population, there was a negative association for maternal hair mercury and three developmental milestones. The study authors attributed this to higher mercury exposure in the breastfed population and the salutary effect of breast milk on development. The NRC report commented on the reported developmental delays in the Iraqi population, which has been the subject of much discussion as to the degree of uncertainty in the estimates (see also MSRC Volumes V and VII). NRC cites analyses by Cox et al. (1995) and Crump et al. (1995), which indicate that the earlier estimates of the Iraqi threshold for late walking were too low. The threshold for late walking appears highly dependent on assumptions on background incidence, the definition of delayed walking, and the effect of a small number of influential data points.

4.2.1.3 Infant and Preschool Development

Cree population—McKeown-Eyssen et al. (1983)

In the study of a Cree population, the Denver Developmental Screening Test (DDST) was administered to the 12- to 30-month-old children in the cohort (n = 234). Scores were reported as the percentage of items passed on each subscale as well as on the entire test. The authors did not provide estimates of significance of association between test scores and maternal hair mercury concentrations; they concluded that there was no significant association indicative of an adverse effect of methylmercury before or after adjustment for confounding variables.

New Zealand population—Kjellstrom et al. (1986)

Kjellstrom et al. (1986) studied a cohort of New Zealand children for whom prenatal methylmercury exposure was estimated on the basis of maternal hair samples as well as dietary questionnaires collected during the period when the study child was *in utero*. Exposure information was collected on nearly 11,000 women; the study focused on 935 women who reported eating fish more than three times per week during pregnancy. Seventy-three women had hair mercury concentrations greater than 6 ppm. The 74 children of those women were designated as the high-mercury group. Efforts were made to match each child in the high-mercury group with a reference child on the basis of maternal ethnicity, hospital of birth, maternal age, and child age. In the followup evaluations at 4 years of age, a total of 38 exposed and 36 reference children were tested; this data set included 30 completely matched pairs. Fifty-two percent of the children in the high-mercury group had an abnormal or questionable DDST score compared with 17% of the children in the control group ($p < 0.05$). That result corresponds to an odds ratio of 5.3. Results were similar when pairs that were poorly matched on ethnicity were excluded.

SCDS pilot study—Myers et al. (1995b)

In the SCDS cross-sectional study, a revised version (DDST-R) of the DDST was administered to 789 children between the ages of 1 and 25 months. No association was found between maternal hair mercury concentration during pregnancy (mean 6.6 ppm) and DDST-R results when normal and questionable examinations were combined. The prevalence of abnormal findings was so low (three children <1%) that the statistical analysis was not meaningful. When abnormal and questionable results

were grouped (in 65 children, 8%), high maternal hair mercury concentrations were significantly associated with poor outcomes ($p = 0.04$, one-tailed test). That result was largely attributable to the higher frequency of abnormal and questionable results among children in the highest maternal hair mercury category (greater than 12 ppm), by contrast to the frequency of approximately 7% among children in each of the other four groups (0-3, 3-6, 6-9, and 9-12 ppm).

SCDS main study—Myers et al. (1995c)

In the main SCDS study, the DDST-R was administered to a cohort of 740 children at age 6.5 months. The frequency of examinations considered to be abnormal or questionable was very low, precluding meaningful statistical analysis of the DDST-R data. The researchers also administered the Fagan Test of Infant Intelligence, an assessment of visual-recognition memory or novelty preference. Results were not related to maternal hair mercury concentrations.

SCDS main cohort at 19 and 29 months—Davidson et al. (1995)

The Bayley Scales of Infant Development (BSID) were administered to children in the SCDS cohort at ages 19 and 29 months. In addition, at 29 months, six items of the Infant Behavior Record, a rating scale, were completed by the examiner. There are two primary scores on the BSID: the mental development index (MDI) and psychomotor development index (PDI). At both ages, MDI scores were similar to the expected mean for U.S. children. At both ages, however, the Seychellois children performed markedly better on PDI than the expected mean for U.S. children. There was no association between MDI scores at 19 or 29 months with maternal hair mercury concentration during pregnancy. Similar results were obtained in a secondary analysis that included only children with the lowest or highest maternal hair mercury concentrations. Assessments of perceptual skills at 19 months were not associated with mercury exposure. Scores on that test at 29 months could not be evaluated because of a pronounced ceiling effect; that is, there were so many high scores on the test that no difference would be detectable. Likelihood of a PDI score below the median was not significantly associated with maternal hair mercury concentration in the full logistic regression model, but was associated with this exposure index in a model that included limited covariates.

Conclusions

There is some indication of low-dose mercury effects in very young children, but there are difficulties in the measurement of such effects. The DDST was administered to four study populations. When abnormal and questionable results were combined, there was a significant association with increasing maternal hair mercury in the New Zealand cohort and in the SCDS cross-sectional study (but not the main study). The NRC report comments on the bases for the different findings: age at examination, different rates of abnormal and questionable scores, and the possibility that test items or criteria for judging scores differed among studies. NRC offered the general conclusion that screening tests such as the DDST are not useful in neurobehavioral toxicology studies; such tests are insufficiently sensitive to variations in the range of normal performance (NRC 2000, p. 200).

The NRC panel noted that the BSID is currently considered to be the best available instrument for infant assessment and is useful for measurement of prenatal exposures to neurotoxicants (NRC 2000, p. 200). In the SCDS main study there was no significant association between young children's scores on the BSID and maternal hair mercury. At 19 and 29 months, the Seychellois children scored higher than the means for U.S. children on the PDI portion of the scales.

4.2.1.4 Childhood Development

New Zealand population—Kjellstrom et al. (1989)

Children in the New Zealand cohort were followed up at 6 years of age. Children were given a battery of 26 psychological tests, tests of scholastic aptitude, and behavioral tests. The following domains were assessed: general intelligence, language development, fine and gross motor coordination, academic attainment, and social adjustment. Maternal hair mercury concentration was associated with poorer scores on full-scale IQ tests (Wechsler Intelligence Scale for Children, Revised [WISC-R]), language development (Test of Language Development, spoken language quotient), and visual-spatial and gross-motor skills (McCarthy Scales of Children's Abilities). Multiple regression analyses were done on these endpoints: Test of Language Development, spoken language quotient (TOLD-SL); WISC-R, performance IQ; WISC-R full-scale IQ; McCarthy Scales, perceptual performance; and McCarthy Scales, motor scales. Covariates in the regressions were these: maternal ethnic group, maternal age, maternal smoking and alcohol use during pregnancy, length of maternal residence in New Zealand, social class, primary language, siblings, sex, birthweight, fetal maturity, Apgar score, and duration of

breastfeeding. Observations were weighted in the regression to deal with outliers. In the analyses there were statistically significant associations between maternal hair mercury and poorer scores on the following measures: full-scale IQ; language development (spoken language quotient), visual-spatial skills (perceptual-performance scale), and gross motor skills (motor scale). The poorer mean scores of the children in the high-mercury group were largely attributable to children of mothers with mercury concentrations above 10 ppm. In this group, mean average hair mercury was 13 to 15 ppm and mean peak was 25 ppm. Maternal hair mercury concentrations accounted for relatively small amounts of variance in the outcome measures and generally accounted for less than covariates such as social class and ethnic group.

In the original analyses of five test scores (Kjellstrom et al., 1986), hair mercury was used in regression analyses as a binary variable; that is, either >6 ppm or between 3 and 6 ppm. Analyses found an association between high prenatal mercury exposure and decreased test performance. Later regression analyses by Crump et al. (1998), which used maternal hair mercury level as a continuous variable, did not find significant associations between mercury and children's test scores. However, this finding was highly influenced by a single child whose mother's mercury hair level (86 ppm) was more than four times that of any other. When this child was excluded, there were significant associations between hair mercury and TOLD-SL and MC-PP scores. When regression analyses were done on scores from all 26 scholastic and psychological tests, and the data on the influential point were omitted, scores on six tests were significantly associated with mothers' hair mercury: Clay Reading Test-concepts, Clay Reading Test-letter test, McCarthy Scales-general cognitive index, McCarthy Scales-perceptual-performance scale, Test of Language Development-grammar completion, and Test of Language Development-grammar understanding.

SCDS pilot study— Myers et al. (1995a), Davidson et al. (2000), Davidson et al. (1998), Myers et al. (2000).

A portion of the pilot cohort of 789 children were given developmental assessments; these were children who were 66 months old within a 1-year testing window (Myers et al., 1995a). Of the 247 eligible children, 217 were administered a test battery consisting of the McCarthy Scales of Children's Abilities, the Preschool Language Scale, and two subtests of the Woodcock-Johnson Tests of Achievement (letter-word identification and applied problems). The median maternal hair mercury concentration in that subsample of the pilot cohort was 7.1 ppm. Maternal hair mercury was associated with significantly lower general cognitive index (GCI) scores on the McCarthy scales. Scores declined

approximately five points between the lowest and highest exposure categories. Similar associations were found on the perceptual-performance scale of the McCarthy scales and on the auditory comprehension scale of the Preschool Language Scale. Scores declined approximately 2.5 points across the range of maternal hair mercury concentrations. When outliers and influential points were removed from the regressions the statistical significance of the associations was lost for all except auditory comprehension (Preschool Language Scale Auditory Comprehension subscale). In the pilot phase of the SCDS, information was not collected on several key variables that frequently confound the association between neurotoxicant exposures and child development. Those variables are socioeconomic status, caregiver intelligence, and quality of the home environment.

Further evaluation was performed on a portion of the Seychelles pilot cohort at 108 months of age (Davidson et al., 2000). Eighty-seven children were tested on five subtests of the WISC-III (Information, Block Design, Vocabulary, Digit Span, and Coding), CVLT, BNT, Beery-Buktenica Development Test of Visual Motor Integration (VMI) (copying geometric figures), finger tapping, grooved pegboard, Trailmaking (tracing the correct route through a form with a pencil), and the design memory subtest of the Wide Range Assessment of Memory and Learning (WRAML) (drawing each of four geometric designs from memory). Performance on BNT, VMI, and grooved pegboard showed a positive association related to mercury exposure in males, whereas there were trends toward poorer performance related to mercury exposure for grooved pegboard in females ($p = 0.07$). Given the small number of subjects, the power of the study was probably quite low; these largely negative results should be interpreted with caution.

No effect of mercury was identified on the Child Behavior Check List (CBCL) at 66 months of age in the main cohort of Seychelles study as determined by the total T score (Davidson et al., 1998). The CBCL is a report inventory scored by the caregiver that assesses eight domains: withdrawn, somatic complaints, anxious/depressed, social problems, thought problems, attention problems, delinquent behavior, and aggressive behavior. An analysis of these subscales was performed on the 711 children assessed on this test (Myers et al., 2000). No effect of mercury was identified on individual subscales.

SCDS Main Study—Davidson et al. (1998), Axtell et al. (2000), Palumbo et al. (2000)

As part of the main SCDS, 711 children 66 months of age (from the original cohort of 779) were evaluated with a battery of standardized neurodevelopmental tests. At this evaluation, mercury was measured in a 1-cm segment of the child's hair as an indicator of postnatal exposure. The following were assessed: general cognitive ability (McCarthy Scales of Children's Abilities), expressive and receptive

language (Preschool Language Scale, PLS), reading achievement (letter-word recognition subtest of the Woodcock-Johnson Tests of Achievement), arithmetic (applied problems subtest of the Woodcock-Johnson Tests of Achievement), visual-spatial ability (Bender Gestalt Test), and social and adaptive behavior (CBCL). The scores of the six primary endpoints indicated no adverse effect of either prenatal or postnatal mercury exposure. The only significant associations were consistent with enhanced performance among children with increased exposure to methylmercury. Increased pre- and postnatal mercury concentrations were significantly associated with better scores on the total score of the Preschool Language Scale. For the applied problem test, increased postnatal mercury concentrations were associated with better scores. Among boys, increased postnatal mercury concentrations were associated with fewer errors on the Bender Gestalt Test.

The investigators published additional analyses of the 66-month data evaluating the possibility of non-linear relationships associated with mercury exposure (Axtell et al., 2000). Endpoints included the six primary variables analyzed previously: McCarthy GCI, PLS, Woodcock-Johnson (WJ) applied problems, WJ letter/word recognition, Bender copying errors, and CBCL total T score. Generalized additive models, which make no assumptions about the relationship between exposure and test score, were used. Nonlinearities were identified between prenatal exposure and PLS and CBCL, and between postnatal exposure and McCarthy GCI. For the PLS the trend involved a decrement of 0.8 points (poorer performance) from 0 to 10 ppm and an increase of 1.3 points above 10 ppm. For the CBCL there was an increase (representing a poorer score) between 0 and 15 ppm and a decrease above 10 ppm. The GCI increased (improved) by 1.8 points through 10 ppm in the child's hair and declined by 3.1 above 10 ppm. Although these results are difficult to interpret, they provide limited evidence of an adverse effect of mercury exposure below 10 ppm maternal hair on two measures, and are associated with child's hair mercury concentration above 10 ppm on the GCI. As pointed out by the authors, there are fewer data points above 10 ppm (this is especially true for child's hair mercury), and therefore trends above this level are estimated less precisely.

The SCDS investigators used multiple linear regression to assess the results of the McCarthy GCI administered at 66 months (Palumbo et al., 2000). They analyzed the standard MSCA subscales and also constructed specific subscales to approximate the domains of cognitive functioning assessed in the Faroe Islands study: attention, executive function, expressive language, receptive language, nonverbal memory, visuospatial, and gross motor visuomotor development. They found a positive association between the child's hair mercury at 66 months and the standard memory subscale, with no other associations identified. As with all the previous analyses of these variables, the raw scores were converted to "normative" scores. As pointed out by the OSTP panel (NIEHS, 1999, Section 3.5 of the Confounders

and Variables Section), the applicability of U.S. norms to this population is unclear, and the use of standardized scores may decrease sensitivity by collapsing different raw scores to one standard score.

Faroes Population—Grandjean et al. (1997)

Testing was done at approximately 7 years of age on 917 of the surviving members of a 1986-1987 birth cohort of 1,022 singleton births. Maternal hair was sampled at parturition (geometric mean 4.3 ppm); children's hair mercury was measured at 12 months (geometric mean = 1.1 ppm) and 7 years of age (geometric mean = 3.0 ppm). Mercury was also measured in cord blood. The neuropsychological tests were these: computer-administered tests from the Neurobehavioral Evaluation System (NES) (finger tapping, hand-eye coordination, and continuous performance test); Tactual Performance Test; three subtests of the WISC-R (digit span, similarities, and block design); Bender Gestalt Test; CVLT; the BNT; and Nonverbal Analogue Profile of Mood States. Not all children could complete the entire battery; this was associated with increased mercury exposure for some tests such as the finger opposition test and mood test.

In multiple-regression analyses, increased cord-blood mercury concentration was significantly associated with worse scores on finger tapping, continuous performance test (CPT) (in the first year of data collection), WISC-R digit span, BNT, and CVLT. The investigators estimated that a tenfold increase in cord mercury concentration was associated with delays of 4 to 7 months in those neuropsychological domains. The maternal hair mercury concentration showed regression coefficients that were generally lower than those obtained with cord-blood mercury as the exposure indicator. For the finger tapping test, maternal hair mercury was a better predictor of effect, especially for the both-hands condition. The child's hair mercury measured at 12 months was a significant predictor for finger tapping with both hands and CPT reaction time; by contrast, hair mercury at the time of examination was significantly associated with continuous performance test reaction time, block designs, and Bender Visual Motor Gestalt errors.

When the Peters-Belson method for covariate adjustment was used, two additional endpoints (WISC-R block design, Bender Gestalt Test errors) were found to be associated with mercury exposure. Associations remained significant when the part of the cohort with maternal hair mercury concentrations greater than 10 ppm was excluded from the analyses. A term for the interaction between mercury and sex was not statistically significant, indicating that the effects were similar among boys and girls. In general, children's test scores were more strongly associated with cord-blood mercury concentration than

with either maternal hair mercury concentration or mercury concentrations in samples of children's hair collected at 1 and 7 years of age.

Grandjean et al. (1998) also analyzed the Faroese data in a case-control fashion. Two groups were assembled: a case group of 112 children with maternal hair concentrations of 10 to 20 ppm at parturition, and a control group of 272 children with maternal hair mercury concentrations less than 3 ppm. Controls were matched to cases on age, sex, year of examination, and caregiver intelligence. The median maternal hair mercury concentrations in the two groups were 1.8 and 12.5 μg/g, constituting a sevenfold difference. Median cord-blood mercury concentrations also differed substantially (59.0 μg/L in the case group versus 11.9 μg/L in the control group). On 6 of the 18 endpoints, the case group scored significantly lower than did the control group. The results of those analyses differ in certain respects from those of the main analyses. First, the set of endpoints on which the cases and controls differed is similar but not identical to the set of endpoints that was significantly associated with cord blood mercury concentration found in the main analyses. In the case-control analyses, a term for the interaction between mercury and sex was statistically significant for several scores: the Bender Gestalt Test error score, short-term reproduction on the CVLT, all three finger tapping conditions, CPT reaction time, and average hand-eye coordination score. For all scores, adverse mercury effects were noted for boys but not girls.

Amazon Valley—Grandjean et al. (1999)

A study cohort was assembled numbering 351 children ages 7 to 12. The population, which was drawn from four riverine communities in Amazonian Brazil, had increased exposures to methylmercury because of their consumption of fish contaminated by upstream gold-mining activities. When data on all four villages were combined, children's hair mercury concentrations were significantly associated with their scores on finger tapping, Santa Ana dexterity test, WISC-III digit span, Stanford-Binet copying and recall, and Stanford-Binet bead memory. Adjustment for community generally reduced the magnitude of the associations, sometimes dramatically. It was noted that hair mercury concentrations and village residence were so highly confounded, however, that adjustment for village might be inappropriate.

French Guiana population—Cordier and Garel (1999)

Cordier and Garel (1999) studied a cohort from a gold-mining area in French Guiana. Median maternal hair concentration was 6.6 ppm with a range of 2.9 to 17.8 ppm. Children ages 5 to 12 years old (n = 206) were administered a battery of neuropsychological tests: finger tapping, three subtests from the Stanford-Binet (block design, copying designs, bead memory), and two subtests from the McCarthy

scales (numerical memory, leg coordination). After adjustment for potential cofounders, increased maternal hair mercury concentrations were significantly associated with copying-design score; the effect was greater in boys. The data were reanalyzed to include only those observations from the region with highest mercury exposures (Upper Maroni). When observations were separated by gender, there was an association in boys between mercury exposure and poorer leg coordination, and with poorer block-design scores in girls.

Conclusions

There is ample evidence of low-dose *in utero* mercury effects on neuropsychological indices in school-age children. In the New Zealand population, maternal hair mercury was associated with poorer scores on several measures: full-scale IQ, language development (spoken language quotient), visual-spatial skills (perceptual-performance scale), and gross motor skills (motor scale). The poorer mean scores in the high-mercury group were largely attributable to the children of mothers with hair mercury above 10 ppm. One analysis by Crump et al. (1998) used maternal hair mercury as a continuous, rather than binary, variable; in this analysis there was no significant association with hair mercury. These analyses were heavily influenced by a single data point (a child with purported high developmental exposure who showed no abnormal scores). If data for this child are excluded, and parental education and age at testing are included as covariates, there are significant associates between mercury exposure and six scores.

In the SCDS pilot (cross-sectional) study, increasing maternal hair mercury was associated with the GCI and the perceptual performance scale of the McCarthy scales. Exclusion from analyses of several influential points reduced the significance of the mercury effect. As it was intended as a feasibility study, the pilot SCDS did not collect information on socioeconomic status, caregiver intelligence, or quality of home environment. In the SCDS main study there was no observation of any adverse effect of prenatal or postnatal mercury exposure. The NRC report commented on the regression model for the GCI score:

> The R^2 (square of the multiple correlation coefficient) value (0.10) of the reduced regression model for the GCI score in the main SCDS study was identical to that in the pilot study. That also appeared to be true for scores on the Preschool Language Scale.... That finding is puzzling because the pilot-study models...did not include several key covariates...and because the regression coefficients for socioeconomic status and caregiver intelligence were statistically significant for total scores of the GCI and Preschool Language Scale in the main study cohort. Those differences suggest that maternal hair Hg concentration is very highly confounded with

those key covariates in the Seychelles population, or they suggest that the associations between child neurodevelopment and the covariates differ substantially in the pilot and main study cohorts, or both (NRC 2000, pp. 203, 205).

In the Faroes population, mercury exposure measured in cord blood was associated with deficits on several measures: finger tapping, preferred hand; CPT (first year of data collection, two scores); mean reaction time, WISC-R digit span; BNT (with and without cues); and CVLT (short-term and long-term reproduction). The mercury effect was similar in males and females. Most test scores were more strongly associated with cord-blood mercury than with maternal hair mercury. In the case-control analysis, the case group scored significantly lower than the control group on 6 of 18 endpoints.

In two smaller populations there were observed effects of mercury exposure. Combining results from four communities in the Amazon basin showed a significant association of children's hair mercury with deficits on four measures. In a French Guiana cohort (n = 206), it was shown that maternal hair mercury was associated with one measure (a Stanford-Binet subtest), particularly in boys.

4.2.1.5 Sensory, Neurophysiological, and Other Endpoints in Children

Faroes population—Grandjean et al. (1997)

In the Faroe Islands cohort, the evaluation of 7-year-old children included assessments of visual acuity, near-contrast sensitivity, otoscopy and tympanometry, and some neurophysiological tests. Visual acuity, contrast sensitivity, auditory thresholds, and visual-evoked potentials were not significantly associated with prenatal methylmercury exposures. For brainstem auditory-evoked potential, peaks I, III, and V were slightly delayed at increased cord-blood mercury concentrations at both 20 and 40 Hz; interpeak latencies were not associated with mercury at either frequency.

Madeira population—Murata et al. (1999b)

Many of the same neurophysiological tests that had been done in the Faroe Islands study were administered to 6- to 7-year-old children living in Madeira. This was a cross-sectional study of 149 subjects. For brainstem auditory-evoked potential, maternal hair mercury was significantly associated with I-III and I-V interpeak latencies at both 20 and 40 Hz, as well as with total latencies for peaks III and V at both frequencies. Those results are similar to the findings in the children tested in the first year of the Faroes cohort. For visual-evoked potentials on a pattern-reversal task, maternal hair mercury

concentration was significantly associated with one of the three latencies, as well as with the N75-N145 and P100-N145 latencies.

Ecuador—Counter et al. (1998)

Auditory function in children and adults was investigated by Counter et al. (1998). The study sample consisted of 75 individuals (36 children and 39 adults) from a gold-mining region in Ecuador and 34 individuals (15 children and 19 adults) from nonmining areas as a control. Blood mercury concentrations were significantly higher in individuals (both adults and children) from the gold-mining area than in individuals from the control region (mean level of 17.5 μg/L versus 3.0 μg/L). Neurological examinations were carried out on all individuals. In children, blood mercury was significantly associated with hearing threshold at 3 kHz in the right ear only. No association was found for adults. A borderline association was found between blood mercury concentration and I-III interpeak transmission time on the left side in both children and adults. The authors concluded that overall auditory sensory-neural function and neural conduction time at the brainstem level were generally unaffected by elevated blood mercury levels in either children or adults.

Conclusions

There is increasing evidence of adverse endpoints other than cognitive development in mercury-exposed children. In the Faroes cohort, there were delays in some auditory-evoked potential peaks as a function of cord-blood mercury. Similar findings were reported for a smaller population from a fishing village in Madeira. A population of children in a gold-mining region of Ecuador showed an association between blood mercury and hearing threshold in the right ear at 3 kHz.

4.2.2 Choice of Study

Of the three large human developmental studies, two reported associations between low-dose *in utero* exposure to methylmercury and performance on standardized neurobehavioral tests. The Faroes investigators reported effects in the domains of attention, fine-motor function, confrontational naming, visual-spatial abilities, and verbal memory. Although similar results were reported for the New Zealand population (and in the Seychelles pilot study), there were no observations of adverse effects attributable to methylmercury in the main SCDS.

This section discusses issues relevant to the choice of critical study for calculation of a reference dose from among these three studies.

4.2.2.1 Critique of New Zealand Study

The study by Kjellstrom et al. (1986) included 57 fully matched groups of four 6-year-old children each as well as four incomplete sets, for a total of 237. As was the case for the Faroes study, these authors reported deficits in measures associated with methylmercury exposure. NRC noted (NRC, 2000 p. 251) that the New Zealand population's sources of methylmercury exposure and the study endpoints were similar to those examined in the Seychelles. While EPA was developing its RfD for the MSRC, the New Zealand data were available as a report that had not been subjected to standard peer-review procedures. In 1998, Crump and associates published a reanalysis of the New Zealand data that was peer reviewed. This paper reported associations of prenatal methylmercury exposure with several endpoints (when one extreme outlier was excluded), including four endpoints that were not found to be related to methylmercury in the Seychelles study. The New Zealand study has been criticized for errors in matching exposed children to controls and for testing exposed children and controls at different ages (Myers et al., 1998). Those errors occurred in the 4-year followup but were corrected in the 6-year followup. NRC notes (NRC, 2000, p. 209) that there is no reason to expect differential measurement error across the studies. An error of that type is likely to be nondifferential (i.e., unbiased), and it would reduce the likelihood of detecting associations between methylmercury exposure and neurobehavioral test scores.

The Kjellstrom et al. (1986) study collected data on several potential confounding factors and used a broad battery of standardized measures that were administered by trained examiners. It is likely that the exposure was relatively low-dose and not episodic, reflecting well-established food consumption patterns. The section below discussed controls for possible confounders in the SCDS and Faroes studies. An important variable is the concomitant exposure to organochlorine compounds such as PCBs and pesticides that could have neurotoxic effects. There is essentially no information on the extent of such exposures in the New Zealand study population, either in the original report or in follow-up analyses (e.g. Crump, 1998).

4.2.2.2 Control for Possible Confounding

Both the Faroes study and the SCDS evaluated most of the variables that have been linked to childhood cognitive development. Table 6-2 of the NRC report lists these and notes which study

controlled for the particular variable. Although neither study controlled for all potential confounders, it was felt by the authors of the NRC report that the influences of those variables on cognitive outcome are probably too weak to account for any major inconsistencies between the two studies. The Confounders and Variables Panel of expert workshops sponsored by OSTP had earlier concluded that neither the SCDS nor the Faroese study was critically flawed and that these studies were suitable for determination of the upper limit of a methylmercury NOAEL (NIEHS, 1999).

Place of Faroese residence—town versus country

At the 1998 OSTP workshop, the Faroes investigators noted that the maternal Ravens scores and the child verbal-test scores were generally higher among families residing in one of the three towns in the Faroes compared with those living in the countryside (NIEHS, 1999). This was thought to be due to social-class differences. It was suggested that because more fish and, in particular, whale meat was consumed by rural residents, the associations of mercury exposure with child verbal-test scores could in fact reflect those social-class differences. However, analyses presented at the workshop showed that these associations remained significant even after controlling for a dichotomous town-country control variable (Table 6-3 in the NRC report). NRC felt it would not be appropriate to control for town residence in all analyses. They made the following statement:

> Because fish and whale consumption constitute a large proportion of the rural diet, the disappearance of associations after controlling for residence could be due to the fact that residing in a rural area leads to increased Hg exposure which, in turn, causes an adverse outcome. It would not necessarily indicate that the lower social class associated with rural residence is the true cause of the Hg-associated deficit. The disappearance of an association between Hg and neurobehavioral effects under those circumstances would be very difficult to interpret, because the interpretation would depend upon what condition is considered the reason for the association between living in a rural area and poor outcome (i.e., lower social class or greater Hg exposure) (NRC, 2000, p. 261).

Another source of town versus country difference could be the distance traveled to the testing site, with resulting fatigue in the children from the countryside. However, analyses showed that the regression coefficients for prenatal mercury exposure remain significant even after controlling for child's residence.

Test administration

The neuropsychological test examiner was routinely controlled for in the Faroe Islands study (see NIEHS, 1999, Section 3.5), but not the SCDS. It was suggested at the OSTP workshop that if an examiner who is less adept at eliciting optimal performance from the subjects tested a large proportion of less-exposed children, the results could be affected (NIEHS, 1999). NRC noted:

> If those children performed more poorly than they otherwise would have on the test, an association between Hg concentration and test scores might be obscured by failure to control for the examiner. That result could also occur if an adept tester tested a large proportion of the more heavily exposed children, leading them to achieve higher scores than they would have if tested by other examiners (NRC, 2000 p. 263).

Age at testing

The SCDS controlled for age at testing by converting the raw test scores to age-corrected standard scores with conversion tables based on U.S. norms (NIEHS, 1999). The Faroes investigators analyzed the raw scores by adjusting statistically for the child's age (measured in days since birth). NRC found the latter approach to be preferable (NRC, 2000, p. 263). They noted, first, that the applicability of U.S. norms to these study populations is uncertain. In this context it should be noted that the Seychellois scores on the BSID were higher than U.S. averages at both 19 and 29 months. Second, NRC felt that the use of age-corrected standard scores could reduce the sensitivity of the test, because several adjacent raw scores are treated as equivalent in converting to standard scores. Last, they noted that age-corrected standard scores use 3-month intervals, which introduces a degree of arbitrariness in assigning a child to a particular group. The NRC report found the approach of controlling statistically for age by multiple regression to be appropriate, because the effect of age is likely to be linear across the relatively short age period (3 months in both studies); that is, over short time periods, development is most likely to take place at a constant rate.

Some members of the scientific community have noted the possibility that the most important difference in the design of the two studies is the age of the child at assessment; 7-year-olds were tested in the Faroes as opposed to children 5.5 years of age in the SCDS. Developmental assessments are likely to be less sensitive in detecting subtle neurotoxic effects when they are administered during a period of rapid developmental change. Individual differences in the rate of neurocognitive maturation may mask subtle differences in function attributable to toxic exposures. NRC (2000, pp. 257-258) also noted that

infant assessments in the SCDS (namely the 19 and 29 month Bayley Scale examinations) were not given at optimal age points for detecting effects, particularly in this developmentally robust population.

Selection bias from exclusion of individuals with severe impairments

The OSTP workshop Confounders and Variables Panel (NIEHS, 1999) identified what they considered a serious potential issue with the SCDS. They noted that recruitment was limited to children with no severe debilitating conditions. This panel felt that such a restriction could lead to underestimation of effect when the shape of the dose-response curve is not known.

PCB exposure in the Faroese population

PCB exposure through maternal consumption of whale blubber was discussed at length at the OSTP workshop and in the report of the Confounders and Variables Panel (NIEHS, 1999). Using the data from the part of the cohort for which cord PCB was measured, Grandjean et al. (1997) performed a series of analyses to ascertain if the PCB and mercury effects could be separated. Of the eight outcomes for which there was a significant association with cord-blood mercury, four were also associated ($p<0.1$) with log transformed PCB levels in cord tissue before adjustment for mercury. These four endpoints were also significantly related to mercury cord-blood concentrations. These were CPT reaction time, BNT with and without cues, and CVLT long-term reproduction (Table 4-1). When PCBs were included in the regression analysis, only the CPT reaction time remained significantly associated with mercury. CVLT and BNT with no cues were not significantly associated with either agent, whereas BNT with cues was about equally associated with both ($p \leq 0.10$). It is important to recognize that such an analysis removes the shared variance related to both mercury and PCBs, thereby reducing the p value associated with either agent.

The Faroes investigators considered CPT reaction time to be a test of attention, BNT to assess language, and CVLT to assess memory (Grandjean et al., 1997). Deficits in overall cognitive functioning and verbal comprehension have been found to be associated with *in utero* PCB exposure in a study of 4.5-year-old children in the Netherlands (Patandin et al., 1999a), whereas deficits on a vigilance task similar to the CPT were associated with cord PCB levels (commission errors) as well as the child's concurrent PCB exposure (reaction time) (Patandin et al., 1999b). In the Patandin et al. study, PCB and dioxin exposure was through diet unrelated to fish consumption. Another study reported effects of exposure to children through their mothers' consumption of contaminated Lake Michigan fish. Deficits in attention, language processing (reading comprehension), and memory related to prenatal PCB

Table 4-1. Regression coefficients (betas) for effects of logarithmic transformations of mercury before and after adjustment for PCB concentrations on Faroese neuropsychological tests: results from 7-year-old children from the first year of testing.

	Before Adjustment		After Adjustment for PCB			
				p-Values		
Neuropsychological Test	Beta	p-Value	Beta	Mercury	PCB	Both
Continuous Performance Test

exposure were identified in 11-year-old children (Jacobson and Jacobson, 1996). Other contaminants undoubtedly present in the fish, including methylmercury, were not assessed in this study; the potential contribution of methylmercury exposure to the observed effects could not be evaluated.

It is informative to compare PCB levels in other studies reporting adverse effects associated with PCBs with PCB levels in the Faroese women. No breast milk or blood PCB levels from the mothers or infants in the Faroe Islands cohort have been published. However, a recent study compared levels of PCB congener 153 in human blood in pregnant women from the Faroe Islands consuming 0-1 blubber meals/month ("low") or 2-3 blubber meals/month ("high") with other populations (Fängström et al., 2000). "Low" Faroese exposure was comparable to blood PCB levels in an unspecified number of pregnant women in the Netherlands, whereas "high" Faroese blood PCB levels were comparable to those in an identified highly exposed population in the Quebec Arctic. The Faroese samples in the Fängström et al. (2000) analysis were collected in 1994-1995, and the cohort for the Faroe study of developmental neurotoxicity was recruited in 1986-1987. It is unclear when the Dutch samples in the Fängström et al. (2000) study were collected; the cohort in the Dutch developmental study was recruited in 1990-1992. Blood levels cannot be directly compared between the Dutch study and the Fängström et al. (2000) data because one was on lipid-adjusted serum and the other on non-lipid-adjusted plasma. Similarly, breast

milk levels cannot be directly compared (Grandjean et al., 1995; Steurwald et al., 2000; Lanting et al., 1998). In general, human body burdens of PCBs have decreased by about 50% over the past decade, so it is possible that blood levels in the Dutch study were higher than those reported in the Fängström *et al.* (2000) paper. It is also quite probable that PCB levels in the Faroe Islands were higher in the mid-1980s than the mid-1990s, suggesting that the "low" Faroe exposure is comparable to levels in the Dutch study. It is important to reiterate that whereas there may have been effects of PCBs in addition to those of methylmercury, statistical analyses indicated that the effects were independent in this population (Budtz-Jørgensen et al., 1999).

The Confounders and Variables Panel at the OSTP meeting (NIEHS, 1998) concluded that both PCB and mercury had adverse effects on the CVLT score and on the BNT scores with and without cues. They felt that it was not possible to determine the relative contribution of each. NRC concluded that there was no empirical evidence or theoretical mechanism to support the opinion that *in utero* Faroese exposure to PCBs exacerbated the reported methylmercury effect. They note that statistical tests for interaction between PCB and mercury show no interaction. NRC reached a similar conclusion to the Confounders and Variables Panel; a likely explanation is that both PCB and mercury adversely affect some test outcomes, but their relative contributions cannot be determined given their co-occurrence in the Faroes population. NRC states it is unlikely that a difference in PCB exposure between the two populations explains the lack of developmental neurotoxic effects in the Seychelles (NRC, 2000, pp. 220 and 223).

In a second set of analyses, Budtz-Jørgensen et al. (1999) found that the effect of prenatal PCB exposure was reduced when the data were sorted into tertiles by cord PCB concentrations. Regressions assessing mercury exposure and the five principal test outcomes were then run separately for each of the three groups. The regression coefficients for a mercury effect in the lowest PCB tertile were no weaker than those for the higher two PCB groups. This lends additional credence to a conclusion that the associations between mercury and test outcomes are not attributable to confounding by prenatal PCB exposure. Calculations of benchmark doses and lower limits (BMDLs) were done using the whole cohort, after a PCB correction and for the portion of the cohort with the lowest PCBs (NRC 2000 , Table 7-4, reproduced here as Table 4-2). In this table results are reported separately for methylmercury measured in hair and cord blood and are calculated using the K-power model described in Section 4.3.4. NRC commented on the results for the low-PCB-exposed subset for the two endpoints that were related to PCB exposure, the BNT and the CVLT. They noted that the BMDs for these outcomes did not differ from the BMDs for the total sample by any more than the BMDs for the two endpoints that were not related to PCB exposure. NRC opined that the variability seen in Table 4-2 is no more than that expected

by chance; the BMDs and BMDLs for both the PCB-adjusted and the low-PCB subset analyses are within the intervals defined by the BMDs and corresponding BMDLs derived for the full cohort. The difference between the BMDs based on the full cohort and the low PCB subset is less than one standard error of the low PCB subset (NRC, 2000, p. 288). These analyses support a conclusion that there are measurable effects of methylmercury exposure in the Faroese children that are not attributable to PCB toxicity.

PCB body burdens in the Seychellois are very low by comparison to North American and European populations. In 28 serum samples obtained from Seychelles study children, there were no detectable concentrations of any PCB congeners. In the Faroes study, prenatal PCB exposure was measured in 436 stored umbilical cord tissue samples. It was noted at the OSTP workshop that cord tissue PCB concentration has never been validated in relation to blood or milk concentration; because cord tissue is lean and PCBs are lipophilic, the panel felt that it may not be the most reliable indication of total PCB body burden (NIEHS, 1999). The cord samples were analyzed for a small subset of PCB congeners that were used to represent the biologically significant PCB exposure. In an earlier publication (Grandjean, et al., 1995) it was shown that these congeners predominate in samples from the Faroes cohort; comprise these three congeners comprise approximately 50% of the PCBs in breast milk lipid. These same three congeners, along with one other, were used to quantify PCB body burdens in milk and plasma in a study of children in the Netherlands (Lanting et al., 1998). The approach taken in the Faroes for quantifying PCB exposure (adding three key congeners together and multiplying by 2) appears to be a reasonable approach for estimating total PCB exposure and is not expected to introduce a bias into the analysis.

4.2.2.3 Population Differences in Susceptibility

Populations may be more or less susceptible to effects of a toxicant as a consequence of predisposing factors, such as nutritional status, exposure to other agents (see Section 4.2.2.1), or genetic susceptibility.

The SCDS cohort is predominantly African in descent; the Faroes cohort is Caucasian. The latter population has been somewhat isolated and thought to be descended from a small number of "founders." This homogeneity in the Faroes could increase or decrease genetic susceptibility to effects of toxic insult. NRC noted that methylmercury neurodevelopmental effects were observed in a genetically heterogeneous and racially diverse sample studied in New Zealand, a population that was predominantly non-Caucasian.

Table 4-2. BMD (BMDL) Estimates from the Faroe Islands Study with and without adjustment for PCBs and in the subset of Low PCB-exposed children (reproduced from NRC 2000)

		Full Cohort	Adjusted for PCBs	Low PCB subset
Exposure	**Endpoint**	**BMD (BMDL)[a]**	**BMD (BMDL)**	**BMD (BMDL)**
Hair	Finger tapping	20 (12)	17 (9)	7 (4)
	CPT Reaction Time	18 (10)	27 (11)	13 (5)
	Boston Naming Test	15 (10)	24 (10)	21 (6)
	CVLT: Delayed Recall	27 (14)	39 (12)	32 (7)
Cord Blood	Finger tapping	140 (79)	149 (66)	41 (24)
	CPT Reaction Time	72 (46)	83 (49)	53 (28)
	Boston Naming Test	85 (58)	184 (71)	127 (40)
	CVLT: Delayed Recall	246 (103)	224 (78)	393 (52)

[a]BMDs are calculated under the assumption that 5% of the responses will be abnormal in unexposed subjects ($P_0 = 0.05$), assuming a 5% excess risk (BMR = 0.05).

Source: E. Budtz-Jørgensen, Copenhagen University, N. Keiding, Copenhagen University, and P. Grandjean, University of Southern Denmark, unpublished material, April 28, 2000.

Data on birthweight and gestation length in the Faroes and Seychelles show no indication of energy or macronutrient (protein and carbohydrate) deficiency. It is possible that members of either population could be deficient in micronutrients. It has been suggested that certain nutrients found in fish eaten by the Seychelles residents (e.g., omega-3 fatty acids and selenium) could attenuate adverse effects of methylmercury exposure. It should be noted that both the Faroese and New Zealand populations would be considered "high fish consumers" by comparison to U.S. norms, and both populations were observed to have measurable effects of mercury exposure. It is unlikely that general health status of the Faroese and Seychellois was a factor in enhancement or attenuation of mercury effects. Both populations receive excellent health care.

The point was made in Section 4.2.2.2 that recruitment in the SCDS was limited to children with no severe debilitating conditions. In the opinion of some scientists this may contribute to making the Faroes sample more representative of the population at risk in the United States in that it includes infants with some degree of initial perinatal risk.

It has been noted in several scientific forums that the cohort in the main Seychelles study appears to have been robust for psychomotor development at early ages. The SCDS authors report a number of abnormal scores on the Denver Developmental Screening Test that are considered to be exceptionally low by U.S. norms. The population also was observed to have an unusually high mean PDI score and a very low rate of referral for mental retardation. The means and standard deviations of the cognitive measures administered at later ages were similar to U.S. norms. It is not clear what, if any, effect this

developmental robustness has on susceptibility to adverse effects of prenatal Hg exposure. Statistical power to find an adverse effect is discussed in Section 4.2.2.8.

4.2.2.4 Assessment of Prenatal Mercury Exposure

In the Faroes study, mercury in cord blood and maternal hair was measured; in the Seychelles, maternal hair mercury was the biomarker of exposure. The maternal hair samples obtained in the Faroes and Seychelles studies did not necessarily reflect the same period of pregnancy. The Seychelles samples were 9-cm lengths of hair reflecting average mercury exposure during pregnancy. The Faroes study analyzed mercury from hair samples of variable length, some 3 cm (reflecting late second and third trimester) and some 9 cm (presumably reflecting the entire pregnancy).

In the analyses of the Faroese data, cord-blood mercury concentration was significantly associated with a slightly larger number of endpoints than was maternal hair mercury. Given the estimated half-life of methylmercury and what is known of PBPK, it could be assumed that cord-blood mercury reflects the latter part of gestation. Hair mercury could reflect the entire pregnancy or could be segmentally analyzed to provide snapshots of various times in gestation. Some of the effects reported in the Faroese cohort could be related to toxic responses in the latter stages of prenatal development. However, hair mercury concentrations in the Faroe Islands study were only a slightly weaker predictor of methylmercury effects than was cord blood. NRC concluded that it would be reasonable to expect that, if children were affected in the main Seychelles study, some indication of an association between child development and maternal hair mercury concentration would have been observed (NRC, 2000, p. 252). It noted that the findings of developmental effects reported in New Zealand were based solely on maternal hair sample data averaged across the entire period of pregnancy. The difference in the observation of effects between the Faroes study and the SCDS is thus not an artifact of biomarkers of exposure.

4.2.2.5 Level of Exposure

In their analyses the SCDS authors used maternal hair mercury as the biomarker of exposure; the Faroes investigators used both cord blood and maternal hair mercury. A comparison of maternal hair mercury levels indicates that exposure in the two studies was in the same range. For the main SCDS, the median hair mercury was 5.9 ppm with a range of 0.5 ppm to 26.7 for the whole cohort. In the Faroes birth cohort (n = 1,020), the median hair mercury was 4.5 ppm with a range of 2.7 to 42.6 ppm (Grandjean et al., 1992) . That the Seychelles Islands study may entail a lower exposure level than the Faroe Islands study could be concluded from two lines of evidence: the hair:blood ratio from the

Seychelles Islands and laboratory studies suggesting that dietary factors can influence tissue levels of methylmercury.

The ratio of hair mercury to blood mercury in the Seychelles study was estimated to be 416, a value that is higher than ratios reported elsewhere, which span 190 to 367 (Stern, 1997). The hair: cord blood ratio for the Faroes cohort was 191 (Grandjean et al., 1992). The value commonly used in dose conversion models is 250 (Stern, 1997; U.S. EPA, 1997e). If the value of 416 is used in estimating maternal or fetal blood mercury then estimates of the dose experienced by the Seychellois fetuses would be lower, by almost twofold, than assumed.

The hair: blood ratio of 416 is plausible for the Seychellois population considering their high fish diet and suggestions in the literature that diet can influence tissue levels of mercury. Average fish consumption in that population is 12 fish meals/week, which is likely to result in comparatively high levels of n-3 fatty acids and selenium. Such a diet may alter the kinetics of mercury by lowering blood or organ levels of mercury associated with a certain level of intake.

4.2.2.6 Episodic Versus Continuous Exposure

Exposure to methylmercury in the Seychelles is through daily consumption of fish. Although the Faroese eat fish more frequently than does the average consumer in the United States (about three meals a week), a significant source of methylmercury exposure in this population is from eating pilot whale meat. Pilot whale meals are relatively infrequent (less than once per month on the average) (Grandjean et al., 1992) with additional intermittent snacks of dried whale (Grandjean et al., 1998). The whale meat mercury concentration varies with the pod. An analysis of 466 whales showed an average concentration of 1.9 ppm, with a range of 0.59 to 3.30 ppm (Faroese Food Agency data quoted in NIEHS, 1999). There is no evidence to indicate that methylmercury bioavailability from the muscle of pilot whale is any different from that of fish tissue.

In the New Zealand study, there was the assumption of regular consumption of a relatively high-mercury fish (shark) in fish and chips, the major fast food of the area; the actual frequency and pattern of exposure are unavailable.

The degree to which differences in exposure pattern among studies account for differences in outcome is uncertain. It has been suggested that the mercury body burden in the Faroe Islands study was the consequence of a "spike" exposure pattern, in contrast to a more continuous exposure pattern in the

Seychelles study, which nonetheless resulted in a similar body burden. The Faroese investigators did segmental analyses of a small number of long hair strands from cohort mothers. Their results indicated a few instances of hair mercury peaks that implied temporal variation or spiking. They noted, however, that the peak level was only about twice the lowest hair mercury concentration (Budtz-Jørgensen et al., 1999).

The pattern of exposure can be a critical determinant of *in utero* toxicity. For example, the NRC report cites data in animals that showed that maternal ingestion of a given dose of alcohol over a short time caused greater neuronal impairment (Bonthius and West, 1990) and behavioral impairment (Goodlett et al., 1987) than that caused by gradual ingestion of the same total dose over several days. The frequency of exposure has a significant influence on the variation in blood levels, even under steady-state conditions, and is dependent on blood half-life (Rice et al., 1989).

It is probable that both episodic and continuous patterns of exposure are present in the population of the United States. Individuals in some ethnic groups engage in a subsistence-type fishing pattern, consuming fish as their major protein source. Most sport fishers, however, consume fish on an intermittent basis. It is not uncommon for piscivorous fish in inland waters to have mercury levels exceeding 1 to 2 ppm (U.S. EPA, 1997), so that the body burden of mercury in this group of fish consumers would presumably be the result of episodic exposure to food sources with levels of mercury similar to those in the Faroe Islands (see also Section 5.4.4 of this document). It may be that the consumption pattern of the Faroe Islands population better represents the pattern of exposure in the majority of the U.S. population exposed to elevated levels of methylmercury than does the consumption pattern of the population of the Seychelles Islands.

4.2.2.7 Endpoints Assessed

As described in Section 4.2.1, there have been inconsistent indications of adverse effect in newborns or preschool children of mothers experiencing low-dose, long-term exposure to methylmercury. The lack of consistent positive findings using standard newborn neurological tests has been considered unsurprising. Neurological examination of the newborn and young infant presents testing challenges that are difficult to meet in large-scale studies. The state of the newborn determines to a significant degree the quality and intensity of response to stimulation during an examination. "The state of an infant is usually dependent upon factors that are often outside the examiner's control, such as hunger, hydration, illness, and the temporal location of an infant in its sleep-wake cycle. The recognition that state is a key variable in newborn behavior can be found in the fact that neonatal behavioral and

neurologic assessments usually indicate what state the newborn should be in before a given item series is administered..." (K. Deitrich, in U.S. EPA, 2000f).

It has been observed that most of the deficits associated with low-level prenatal exposure to developmental toxicants would not be revealed in a pediatric neurological examination and that gross neurological findings are unlikely in such studies. It has also been shown in studies not related to methylmercury that minor neonatal neurological deviations from the norm are not predictive of later neurobehavioral morbidity (U.S. EPA, 2000f).

Screening tests such as the Denver Developmental Screening Test have been used with highly variable results in methylmercury studies. Section 4.2.1 reports the differences in results among the New Zealand, SCDS pilot, and SCDS main cohorts. Recent research suggests that screening tests are not as sensitive as once believed and are no longer recommended for use in studies of low-level environmental chemical exposures to the fetus or infant (U.S. EPA, 2000f).

In the opinion of most developmental scientists, the Faroes and Seychelles studies used very different neurobehavioral test batteries. The tests selected for use in the SCDS are considered apical or omnibus tests (e.g., the McCarthy Scales of Children's Abilities); these provide global scores that integrate performance over many separate neuropsychological domains. The investigators studying the Faroes population were working from a hypothesis that mercury would have multifocal domain-specific neuropsychological effects. The OSTP Neurobehavioral Endpoints Panel was similarly disposed. They noted that it is plausible that prenatal exposure to methylmercury may not affect IQ, but rather domain-specific areas such as memory deficits, motor delays, or effects on so called "executive functions" – the complex domains that involve planning and cognitive flexibility (NIEHS, 1999). The Faroese test battery consisted of highly focused tests selected from those commonly used in clinical neuropsychology (e.g., CVLT and BNT) and did not include an apical test of global function. They observed effects in areas of language, memory, motor skills, visual-spatial abilities, and attention.

Many of the subscales of the McCarthy Scales might be expected to provide measures comparable to some tests administered to the Faroese children. However, there was no evidence from the McCarthy subtests of domain-specific effects in the Seychelles. These included verbal, perceptual-performance, quantitative memory, and motor scores. One conclusion is that if there were actually domain-specific effects occurring in the 5-year-old Seychellois, they should have been observed in the analyses of the McCarthy Scales results. The NRC panel came to a different conclusion: "Although the Faroe Islands and SCDS test batteries include tests of language and memory, it is not appropriate to view the endpoints

used in the studies to assess each domain to be equivalent either in terms of the specific skills assessed or the test sensitivity." (NRC, 2000, pp. 256-257).

One test was administered to both populations: the Bender-Gestalt Test. The investigators used different scoring systems; the SCDS used the Koppitz system whereas the Faroes used the Gottingen system. The NRC report noted that in a paper by Trillingsgaard et al. (1985) scores derived using the more detailed Gottingen system were significantly associated with low-dose lead exposure, whereas scores on the Koppitz system were not. Thus the Gottingen system used in the Faroe Islands might be more sensitive.

A second important difference in the assessment batteries used in the Faroes study and SCDS is the age of the child at assessment; 7-year-olds were tested in the Faroe Islands in contrast to children 5.5 years of age in the SCDS. Assessments in the New Zealand cohort were done at 4 and 6 years of age. It is generally thought that developmental assessments are likely to be less able to detect subtle neurotoxic effects when they are administered during a period of rapid developmental change. The period covering ages 60 to 72 months (when the SCDS and New Zealand cohorts were evaluated) is such a time; individual differences in the rate of cognitive maturation are likely to eclipse subtle differences in function attributable to a teratogenic exposure (Jacobson and Jacobson, 1991). The NRC panel also felt that in the SCDS, assessments of infants (particularly the 19- and 29-month BSID) were not given at optimal age points. Their report makes the following statement:

> Studies of prenatal exposure to alcohol and other substances that have administered the Bayley scales at multiple ages have repeatedly failed to detect effects at 18 months, probably because it too is a period of rapid cognitive maturation, involving the emergence of spoken language. Twenty-nine months is likely to be an insensitive testing point for the Bayley scales because it is at the end of the age range for which the version of this test used in the Seychelles was standardized, leading to a substantial risk of a "ceiling effect" (i.e., too many children receiving the highest possible scores on numerous items) (NRC, 2000 pp. 257-258).

The overall conclusion of NRC, however, was that discrepancies between the Faroe Islands and the main Seychelles studies are probably not due to differences in the assessments. They point out that the New Zealand study observed associations between methylmercury exposure and scores on the McCarthy Scales of Children's Abilities (the primary outcome measure used in the SCDS) at about the same age of assessment as in the Seychelles study (NRC, 2000, p. 258).

4.2.2.8 Power of Studies

NRC commented on the power to detect subtle effects in the admittedly large human studies (NRC, 2000, pp. 266-267). They noted that it is possible that the differences in response between the Faroes study and the SCDS could be due to between-sample variability in the expression of neurotoxicity at low doses. NRC remarked that even large samples can have insufficient power to detect adverse effects if a relatively small number of subjects are exposed in the upper ranges of the exposure distributions, where those effects will presumably be found.

NRC said that the magnitude of the associations found in the methylmercury studies resembles that reported for other environmental contaminants, such as low-dose lead and PCBs. If the magnitude of an association is not large, it is not likely that it would be detected in every cohort studied. NRC noted by comparison that it is well established in the scientific community that a blood lead concentration in excess of 10 μg/dL places a child at increased risk of poor developmental outcomes. However, not all lead studies have found an association between exposure at this level and decreased performance, and substantial variability exists in the magnitudes of the reported effects (Bellinger, 1995). NRC noted for the SCDS, "the evidence consistent with such effects found in the pilot phase, coupled with the suggestion of unusual developmental robustness in the main study, suggest that the failure to detect apparent adverse effects in the main study could be due to the substantial sample-to-sample variation expected when trying to identify weak associations in an inherently 'noisy' system of complex, multi-determined neurobehavioral endpoints" (NRC, 2000, p. 267).

In another comment on power, NRC says that power analyses based on total sample size can be misleading if adverse effects occur primarily among the most heavily exposed individuals, who typically constitute a small proportion of the sample. They note that of 700 children in the SCDS, only about 35 were exposed at levels concordant with maternal hair mercury of 15 ppm or higher. Because multiple-regression analysis examines associations that are averaged across the entire distribution of exposure, associations that hold only for the most highly exposed children can be difficult to detect. "Thus, if adverse effects of prenatal MeHg exposure occur primarily in the upper range, the power to detect them will be limited, and it would not be surprising if associations found in one Seychelles cohort (the pilot study) were not detected in the next cohort (the main study)" (NRC, 2000, p. 267).

In this context it should be noted that Grandjean et al. (1997) published an analysis of their neuropsychological test data on 7-year-old children, wherein they excluded all scores from children born to mothers with 10 ppm or higher hair mercury. This decreased the number of observations by 15%. In

the multiple-regression analyses, regression coefficients and p values were very similar to those obtained when data on the full cohort were used. This indicates that in this study population, adverse effects of mercury were detectable at exposures below 10 ppm maternal hair mercury.

4.2.2.9 Selection of Study

There is a large database on potential neurodevelopmental effects of methylmercury. In particular, three large, well-designed, prospective longitudinal studies have been peer reviewed and intensively analyzed. Some results from these studies of large populations are in apparent conflict. The previous sections reviewed some of the factors that have been suggested to account for the finding of adverse outcomes associated with *in utero* mercury exposure in the Faroes and New Zealand and the lack of this association in the SCDS. None of these factors represents a critical flaw in study design or execution. None of the factors adequately explains the differences in the study outcomes.

The NRC (NRC, 2000, p. 221) suggests that the finding of a low-dose methylmercury effect in a culturally and genetically heterogenous population in New Zealand study decreases the importance of population sensitivity issues in comparing the Seychelles and Faroes studies. The New Zealand study had a higher baseline rate of abnormal and questionable DDST scores in the test (8%-17% in controls) than did the Seychelles study (8% in the complete pilot cohort, 1.9% of the complete main cohort). This observation is consistent with the suggestion that the lack of effects in the Seychelles population is related to its relatively higher level of neurological performance at critical early life stages. Another possibility is that the manner in which the tests were given in the Seychelles led to better test performance, resulting in a less sensitive measure (i.e., an easier test for children to pass). The SCDS may also have had reduced power because of the small number of maternal-child pairs with methylmercury over 15 ppm. A comparison of the numbers in the relatively high-exposure range is instructive. If one uses 10 ppm maternal hair mercury as the high-exposure cutoff, there are about 150 Faroes subjects, at least 100 Seychelles subjects, and only 16 New Zealand subjects in this category (see Fig. 5-6, p. 166, NRC report).

One strength of the New Zealand study is that an effect was shown in an ethnically heterogeneous sample; another advantage was that the study used developmental endpoints with predictive validity. However, EPA acknowledges and shares the NRC reservations about using the New Zealand study as the basis for the methylmercury RfD. The New Zealand study is relatively small, with 237 subjects, by comparison with the population of up to 900 for the Faroes tests. Moreover, the New Zealand data have

not had the exhaustive scientific scrutiny that have been applied to the SCDS and Faroes study. The advantages of the Faroes study include these:

- large sample size;
- good statistical power as calculated by conventional means;
- the use of two different biomarkers of exposure;
- comprehensive and focused neuropsychological assessment;
- assessment at an age and state of development when effects on complex neuropsychological functions are most likely to be detectable;
- statistically significant observations that remain after adjusting for potential PCB effects; and
- extensive scrutiny in the epidemiological literature.

The Faroes data have also undergone extensive reanalyses in response to questions raised by panelists in the NIEHS (1999) workshop and by NRC (2000). The SCDS shares many strengths of the Faroes study. However, EPA agrees with NRC that a positive study, one that shows statistically significant associations between prenatal mercury exposure and adverse outcomes, is the strongest public health basis for an RfD (NRC, 2000, p. 6). Moreover, although one can model the nonpositive results of the SCDS, the resulting estimates of no effect level are difficult to interpret.

The study selected by EPA as the basis of the methylmercury RfD is the report of developmental neurotoxicity in 7-year-old children in the Faroes. The next section discusses issues in choice of endpoint for the RfD calculation. Many of the arguments in study selection pertain to choice of endpoint as well.

4.2.3 Choice of Critical Effect (endpoint)

EPA considered recommendations of NRC and the external peer reviewers in making the choice of a critical effect or endpoint from the Faroese data on neuropsychological effects in children. Rather than choosing a single measure for the RfD critical endpoint, EPA considers that this RfD is based on several Faroese test scores. These test scores are all indications of neuropsychological processes that are involved with the ability of a child to learn and process information. The issues and decision points in coming to this choice are described in the following sections.

4.2.3.1 Endpoints Suitable for RfD Derivation

Several studies have reported significant associations between increased numbers of combined abnormal and questionable scores on standardized neurological examinations. NRC opined that the functional importance of these effects is uncertain. There is little evidence that relatively low-dose, long-term exposure has any significant effect on language or motor-skill developmental milestones. There is some evidence of an association between *in utero* mercury exposure and deficits on the DDST. The NRC put forth the opinion that this screening test is not as useful as others in developmental neurotoxicological testing.

As is shown in Table 4-3, the tests used in the Seychelles and New Zealand studies in general were apical tests, assessing broad functional categories. These tests are widely used clinically and have been validated and normed for the U.S. population (but not the populations in which they were used). In contrast, the tests used in the Faroe Islands study were chosen to assess specific behavioral domains. The global clinical instruments such as the McCarthy, WISC-R, and CBCL have manuals that describe the tests and domains assessed, as well as the predictive validity of scores on these instruments to "real-world" behavior such as school performance. For the tasks used in Faroe Islands, finger tapping is a commonly used assessment of motor speed (Letz, 1990), and the Bender is a standardized test of childhood development. The other three endpoints also have demonstrated clinical relevance and predictive value As outlined in the table, most of these endpoints are predictive of ability in various academic skills, and therefore school performance. These tests, whether designed to be relatively global or domain-specific, were adversely affected by methylmercury exposure in the Faroe Islands and New Zealand, but not the Seychelles Islands, studies. In addition, motor performance was adversely affected in both New Zealand and the Faroe Islands. The only study that assessed social and adaptive behavior was the SCDS. BMD analysis performed by the NRC committee identified adverse effects on the CBCL at maternal hair levels comparable to those at which effects were observed in the Faroe Islands study (NRC, 2000, Table 7-5, p. 291). As concluded by the NRC (NRC, 2000, p. 325), the deficits observed in the New Zealand and Faroe Islands study can be considered predictive of problems in cognitive and academic performance associated with methylmercury exposure.

NRC presented BMDs and BMDLs for several endpoints in the positive Faroes and New Zealand studies as well as for the nonpositive Seychelles study (the next section discusses choices of model and choices made in BMDL calculation). Reproduced below is Table 7-2 from the NRC report (here as Table 4-4), which compares BMDs from the three studies in terms of maternal hair mercury. Included in this table are the New Zealand BMDs calculated after exclusion of the data from the highest exposed

individual. NRC suggested that this hair mercury concentration of 86 ppm is not plausible. The text reads:

> a hair Hg concentration of 86 ppm is more than 4 times the next highest hair Hg concentration in the study. If the one-compartment pharmacokinetic model and EPA's standard default input assumption are used, it can be estimated that a 60-kg woman would have to eat an average of 0.5 pounds (227 g) of fish containing 2.2 ppm of Hg to reach a hair Hg concentration of 86 ppm. Consistent exposure at such a dose seems unlikely when the mean Hg concentration in fish from fish-and-chips shops, a principal source of exposure in New Zealand (Kjellström et al., 1986), is 0.72 ppm (Mitchell et al., 1982). On the basis of those considerations, the committee concluded that analyzing the New Zealand data without the data from that individual is appropriate. (NRC, 2000, p. 282).

The range of BMDL values is relatively small (4 to 25 ppm maternal hair mercury). Inspection of this table shows that all the BMDs (and corresponding BMDLs) from the New Zealand study are lower than those from the other positive study in the Faroes. Often the most sensitive adverse endpoint is selected as the critical effect for calculation of a RfD. The most common surrogate for "most sensitive" is the lowest BMDL or bounded NOAEL (that is, NOAEL from a study wherein an effect was observed). The lowest BMDL is 4 ppm maternal hair mercury for the McCarthy Perceptual Performance Test calculated by Crump et al. (1998, 2000) on the New Zealand data (Kjellstrom et al., 1986). NRC had reservations about using the Kjellstrom (1986) data as the basis for the methylmercury RfD, with which EPA agreed (see Section 4.2.2.9). In this instance the choice is not of the lowest BMDL, but will be made from among the measures in the Faroese data.

Grandjean and colleagues reported significant associations between either maternal hair mercury or cord-blood mercury and decrements in several neuropsychological measures in 7-year-old Faroese children:

- Finger tapping—preferred hand ($p = 0.05$)
- Continuous Performance Test—first year of data collection
  - – false negatives—($p = 0.02$)
  - – mean reaction time—($p = 0.001$)
- WISC-R Digit Span ($p = 0.05$)
- Boston Naming Test
  - – no cues ($p = 0.0003$)
  - – with cues ($p = 0.0001$)

Table 4-3. Tests modeled by NRC, functions assessed, and potential societal relevance

Study	Test	Domain/Function Assessed	Societal Relevance
Seychelles	Bender Copying Errors	Visuospatial	Math performance
	McCarthy GCI	Full-scale IQ	School performance, intelligence
	WJ Applied Problems	Ability to solve problems	Academic skills
	CBCL	Social and adaptive behavior	Antisocial behavior, need for therapeutic services
	Preschool Language Scale	Broad-based language	Learning, intelligence, school performance
	WJ letter/word recognition	Word recognition	Reading ability, school performance
Faroes	Finger tapping	Motor performance	Motor speed/neuropathy
	CPT Reaction Time	Vigilance, attention, information processing speed	Intelligence, school behavior and performance
	Bender Copying Errors	Visuospatial	Math performance
	Boston Naming Test	Expressive vocabulary	Reading, school performance
	CVLT: Delayed Recall	Memory	Learning ability, school performance
New Zealand	TOLD Language Development	Broad-based language	Literacy skills, learning, school performance
	WISC-R: PIQ	Performance IQ, e.g. visuospatial, sustained attention, sequential memory	Learning, school performance
	WISC-R: FSIQ	Full-scale IQ, e.g. PIQ + verbal processing, expressive vocabulary	Learning, school performance
	McCarthy Perceptual Performance	Performance IQ, e.g. visuospatial, audition, memory	Learning, school performance
	McCarthy Motor Test	Gross and fine motor skills	Motor system integration

- California Verbal Learning Test
  - – short-term reproduction ($p = 0.02$)
  - – long-term reproduction ($p = 0.05$)

When an alternative approach to adjusting for covariates was used (Peters-Belson method) was used, two more measures showed significant associations:

- WISC-R Block Design ($p = 0.05$)
- Bender Gestalt Test errors ($p = 0.05$)

More endpoints were significantly associated with cord-blood mercury than with maternal hair mercury. Table 7-3 from the NRC report is reproduced below as Table 4-5; this presents calculations, in terms of cord-blood mercury concentrations, of BMDs and BMDLs for five Faroese endpoints.

4.2.3.2 Comparison of Endpoints

Boston Naming Test (BNT)

The BNT was the endpoint of choice of the NRC panel (NRC, 2000, p. 327). This test assesses word retrieval and formulation abilities in children, adults, and brain-injured patients. In the test, 60 line drawings are shown to the subject one at a time, and the subject is asked to name each of them. Familiarity (frequency of occurrence of the target names) decreases as the test progresses. Responses of the patient are scored for latency and correctness. When the subject misses an item, two kinds of cues may be given. A "stimulus cue" is a short phrase that gives additional information about the target item (e.g., something to eat). A "phonetic cue" is the first sound of the target word. Scores are summarized according to the number of spontaneously given correct responses, the number of correct responses following stimulus cues, and the number of correct responses following phonetic cues. The number of stimulus cues and the number of phonetic cues given by the examiner also is recorded. The peer-review panel noted that there is not much normative data on the BNT but that it is often used by child clinical neuropsychologists because of its documented validity in various child studies (EPA, 2000e). The BNT

Table 4-5. Benchmark dose calculations (ppb methylmercury in cord blood) from the Faroe Islands Study for various endpoints

Endpoint	BMD[a]	BMDL
Finger Tapping	140	79
CPT Reaction Time	72	46
Bender Copying Errors	242	104
Boston Naming Test	85	58
CVLT: Delayed Recall	246	103

[a]BMDs are calculated from the K-power model under the assumption that 5% of the responses will be abnormal in unexposed subjects ($P_0 = 0.05$), assuming a 5% excess risk (BMR = 0.05).

has been useful as a measure of confrontation naming and word retrieval skills and can be used to differentiate between children with and without language-based learning disabilities; moreover, it is a predictor of related cognitive and academic skills, especially reading achievement (Yeates, 1994, as quoted in U.S. EPA 2000e).

Continuous Performance Test (CPT)

The endpoint from the Faroe Islands study that yielded the lowest BMDL in the NRC analysis was the CPT reaction time. This test was modified from the Neurobehavioral Evaluation System (NES) version, which is a standardized battery used mainly in occupational settings in adults. In the Faroe Islands study, the child was required to respond as quickly as possible when a silhouette of a cat appeared on a computer screen, but not when the silhouettes of other animals (number not specified) appeared (Grandjean et al., 1997). Dependent variables included number of missed responses (omission errors) and average reaction time for the last 3 minutes of a 4-minute task. False positives (errors of commission) apparently were not analyzed. Reaction time in a task that includes decision making (respond to cat, don't respond to others) is a measure of the speed of information processing. The investigators found an increase in reaction time correlated with cord blood using all data; this correlation was still seen when only data were used from children whose mothers had hair concentrations below 10 ppm (low-level exposure). In addition, there was an association between cord blood mercury levels and an increase in omission errors in the full group and low-level exposure group. This finding indicates poorer attention to the task as a function of methylmercury exposure.

Speed of information processing as measured by reaction time is highly correlated with IQ in humans (Jensen and Munro, 1979; Matthews and Dorn, 1989; Vernon, 1983; Vernon et al., 1985; Western and Long, 1996). It has been argued that speed of information processing is a measure of *g*, the highest order common factor in all tests of cognitive ability (Jensen, 1993b). Reaction time in complex reaction time tasks is consistently observed to be correlated with psychometric *g* in studies in several cultural groups (Buckhalt and Jensen, 1989; Ja-Song and Lynn, 1992; Lynn et al., 1991; Lynn and Wilson, 1990; Shigehisa and Lynn, 1991). Generally, the association between *g* and decision reaction time increases with increasing task complexity (Beh et al., 1994; Jensen, 1987). It is estimated that the correlation between reaction time and *g*-loaded psychometric tasks is 0.3-0.5, whereas the correlation based on several reaction time and psychometric tasks approaches 0.7 (Jensen, 1993a; Vernon, 1989), which is similar to the correlation among different IQ tests (Jensen, 1993). Reaction time tasks also discriminate between brain-injured and other individuals (Western and Long, 1996) and identify children with attention deficits (Zahn et al., 1991).

The NRC chose not to rely on CPT reaction time as the critical endpoint because results were from only half the cohort. The Faroe investigators reported that effects on CPT reaction time were significant for the first year of testing but not the second, with combined effects for the 2 years significant at p = 0.01. The authors stated that "[b]ecause supervision was stringent only during the first year, these data were chosen for development of the final regression model" (Grandjean et al., 1997, pp. 422-423). The NRC felt that measures from the full cohort would be more reliable than those based on half the cohort; their report did not state any concerns regarding elimination of the second year data per se (NRC, 2000, p.286).

Advantages of the choice of the CPT reaction time as the critical endpoint would be that there was no evidence of an effect of PCBs on this measure, and the correlation of complex reaction time with measures of intelligence such as IQ. The disadvantage is that the analysis is based on half the cohort. However, this limitation also holds true for the BNT corrected for PCB exposure. Therefore, there is little or no reason to choose one over the other in this regard.

California Verbal Learning Test for Children (CVLT)

The California Verbal Learning Test for Children is a word-list-learning task that measures acquisition of information following repeated exposure to verbal stimuli. Of principal interest are the variables of learning, delayed recall, and perseveration. The test has good test-retest reliability as well as internal consistency. The theoretical foundations of the CVLT are based upon several decades of cognitive science research in brain/behavior relationships. The test discriminates clinical groups such as those with hyperactivity/attention deficit disorders, children with learning disabilities, and children suffering prenatal insults such as fetal alcohol syndrome.

4.2.3.3 Consideration of Potential PCB effect

EPA agrees with NRC that analyses of the Faroese test results show that there are real mercury-related adverse effects that cannot be attributed to concomitant PCB exposure. This was noted in Section 4.2.2.2. The external peer review panel for the methylmercury RfD agreed with that conclusion. However, they disagreed with the NRC choice of the BNT results from the full cohort because of the potential effect of PCB exposure. They thought that the BNT results were the most sensitive to PCB influence of any evaluated in the Faroe Islands. The peer review panel pointed to the analyses presented by NRC (reproduced in this document as Table 4-6) as presenting an opportunity to consider the use of benchmark estimates corrected for any potential PCB influence. The Faroes investigators calculated a

PCB-adjusted BMD and BMDL for the BNT using cord blood as the exposure biomarker; these were considerably greater than the BMD/BMDL for either the full cohort without PCB adjustment or that from the low-PCB tertile. Similar increases after adjusting for PCBs were not seen for finger tapping, CPT reaction time, or CVLT delayed recall tests, when cord blood was the exposure metric. NRC noted that the PCB measurements were done on cords from only about one-half of the Faroese cohort (about 450 children) and that the use of data from only the low-PCB tertile further reduces *n* to about 150 children. NRC reported that the reduced sample sizes in these analyses increased the variability in the results. They saw no clear pattern as to how the PCB-adjusted analyses differed from the original results. The NRC concentrated its focus on the low-PCB subset BMDs and BMDLs. They compared results from two tests with no PCB effect (CPT and finger tapping) with those with potential for PCB influence (BNT and CVLT). They reported that the BMDs for the low-PCB subset for the BNT and CVLT did not differ from the BMDs for the whole cohort any more than did the BMDs for the two tests with no influence of PCBs. The NRC authors felt that the variability seen in Table 4-6 is no more than that which would be expected by chance alone (NRC, 2000, p. 288).

Table 4-6. BMD (BMDL) Estimates from the Faroe Islands Study With and Without Adjustment for PCBs and in the Subset of Low PCB-Exposed Children (calculated using the K-power model)

		Full Cohort	Adjusted for PCBs	Low-PCB subset
Exposure	Endpoint	BMD (BMDL)[a]	BMD (BMDL)	BMD (BMDL)
Hair	Finger tapping	20 (12)	17 (9)	7 (4)
	CPT Reaction Time	18 (10)	27 (11)	13 (5)
	Boston Naming Test	15 (10)	24 (10)	21 (6)
	CVLT: Delayed Recall	27 (14)	39 (12)	32 (7)
Cord				
Blood	Finger tapping	140 (79)	149 (66)	41 (24)
	CPT Reaction Time	72 (46)	83 (49)	53 (28)
	Boston Naming Test	85 (58)	184 (71)	127 (40)
	CVLT: Delayed Recall	246 (103)	224 (78)	393 (52)

[a]BMDs are calculated under the assumption that 5% of the responses will be abnormal in unexposed subjects (P_0 = 0.05), assuming a 5% excess risk (BMR = 0.05).

Source: E. Budtz-Jørgensen, Copenhagen University, N. Keiding, Copenhagen University, and P. Grandjean, University of Southern Denmark, unpublished material, April 28, 2000, in Table 7-4, p. 289, NRC 2000.

4.2.3.4 Supporting Studies

A second Faroese cohort was recruited from children born between 1994 and 1995. In the study reported by Steurwald et al. (2000), decreases in neurologic optimality score (NOS) were associated with increasing cord blood mercury. This association remained statistically significant after adjustment for confounders (including cord and maternal serum PCB levels). Inspection of data plotted in the paper indicate that a decrease in NOS was observed in the two highest quartiles; that is, at cord blood mercury levels greater than 20 ppb. This indicates a dose-dependent effect at levels as low as (or lower than) those for which neuropsychological deficits were reported in the main study of 7-year-old children (Grandjean et al, 1997). The size of this study is rather small (N = 182) and involves subtle changes at a very early developmental period, the clinical implications of which are less clear than the changes found in the main study of 7-year-olds.

NRC conducted an analysis that combined results from the SCDS, New Zealand, and Faroes studies (NRC, 2000, pp. 290-294). Their approach was to use a hierarchical random-effects model that followed a method proposed by Dominici et al. (in press). To inform their analyses, NRC plotted BMDs and BMDLs (as ppm mercury in maternal hair) for measures from all three studies. For outcomes in the SCDS for which there were no BMDs, the analysis used an arbitrary value of 150. They concluded from the plot (Figure 7-3, NRC, 2000, p. 285) that study-to-study variability was large relative to outcome-to-outcome variability. NRC felt that use of a hierarchical model would allow one to borrow strength from the different studies to achieve greater precision in BMD and BMDL estimates. The NRC results are seen in their Table 7-5 (NRC, 2000, p. 291). They present what they refer to as smoothed results, which reflect reduced random variability. For the Faroes data, the BMDL estimates are not much changed from the original values; the unsmoothed range of BMDLs is 10 to 15 ppm mercury in maternal hair, while the smoothed results range from 12 to 15 ppm. The NRC notes that all smoothed BMDLs are closer to their BMDs; they also concluded that the hierarchical modeling reduced much variability among outcomes but not among studies.

NRC estimated a central tendency measure, equivalent to a BMD, across all three studies and all endpoints. They also determined a lower limit based on a theoretical distribution of BMDs, which is the logical equivalent of a BMDL. These values as well as other estimates derived from the Faroes and New Zealand studies are in Table 4-7.

Table 4-7. Central tendency estimates, ppm mercury in maternal hair[a]

Approach	Original values		Smoothed values	
	BMD	(BMDL)	BMD	(BMDL)
Most sensitive endpoint from New Zealand	8	(4)	12	(7)
Median endpoint from New Zealand	12	(6)	13	(8)
Mean of endpoints from New Zealand	12	(6)	13	(8)
Most sensitive endpoint from Faroes	15	(10)	17	(12)
Median endpoint from Faroes	20	(12)	20	(13)
Mean of endpoints from Faroes	22	(12)	21	(13)
Mean of all endpoints		(14)		(15)
Integrative analysis			21[b]	(8[c])

[a] Source: Table 7-6, NRC 2000, p. 294.

[b] Logically equivalent to a BMD.

[c] Logically equivalent to a BMDL.

The external review panel for the methylmercury RfD suggested that a reasonable alternative to using a single test result as the basis for the RfD would be to develop a composite index from several test outcomes. Their recommendation was to evaluate mercury-associated endpoints for any potential PCB effect. The next step would be to use either PCB-adjusted results or only those results with no PCB effect in some compositing approach to provide a multiendpoint BMDL. The most appropriate compositing approach would be one with a weighting scheme to account for different sample sizes for the individual tests.

A second way to proceed would be to use factor analysis to create a composite factor that accounts for the majority of the variance among the individual test results. The resulting estimate would serve as the basis for RfD calculation. The peer review panel that suggested this approach noted that it is novel and would require substantial effort to reanalyze the data (U.S. EPA, 2000f).

EPA has decided that the two suggestions have a great deal of merit. We will pursue some of these analyses for the extant Faroes and New Zealand data and for the SCDS data on 7-year-old children as they become available. We felt, however, that the integrative analysis reported by NRC serves as substantial support for the choice of an endpoint from the Faroese test data. We felt that at this time the use of NRC's integrated BMD /BMDL or one derived form the suggested alternatives as the sole basis for an RfD would introduce an unacceptable degree of model uncertainty into the RfD.

4.2.3.5 Choice of Endpoint

The lowest of the BMDLs from the Faroese tests is 46 μg/L mercury in cord blood for the CPT reaction time scores. NRC recommended a different choice. They remarked that in a neuropsychological test battery, the reliability of the individual endpoints can be highly variable, so the most sensitive endpoint may not be the most appropriate choice. The Faroes investigators reported difficulties in administering the CPT. The data from the second half of the cohort were discarded for the analysis of this endpoint; thus the *n* was about half that for the other tests. The NRC panel suggested that a more appropriate choice would be to select the second most sensitive endpoint, the BNT BMDL of 58 ppb mercury in cord blood (NRC, 2000, p. 300). Interestingly, the BNT had the lowest BMDL in the analyses based on maternal hair mercury.

The external peer reviewers of the methylmercury RfD disagreed with the NRC choice. The felt that the use of a single neuropsychological endpoint to form the basis for making a risk assessment is problematic. They felt that the use of the BNT data from the whole Faroese cohort was not warranted, as the BMDL thus derived could reflect an effect of PCB exposure. The peer reviewers preferred the BNT BMDL adjusted for PCB exposure of 71 ppb mercury in cord blood. In their report they noted that the adverse effect of methylmercury reflected in the BNT scores is not isolated, but rather occurs at levels not far removed from effects on other neuropsychological tests, providing some assurance of its credibility. A difficulty with the use of the PCB-adjusted BMDL is that this BMDL is based on scores from only about one-half of the total cohort. As noted in Section 4.2.3.3, NRC felt it was more appropriate to use the BMDL from analyses with the larger *n*.

The peer review panel described three other options for RfD derivation. One option would be to use the BMDL from the CVLT. The panel noted the clinical relevance and predictive value of this test as the well as likelihood that there is no influence of PCB exposure on this measure. The major drawback to this choice is that the BMDL from this test for the full cohort is the highest (103 ppb mercury in cord blood or 14 ppm mercury in maternal hair) of those listed in Table 4-6. One could easily argue that the RfD based on this measure is not public health protective. In the light of analyses that indicate that mercury correlations with test measures remain when the highest exposure subset is eliminated (10 ppm or more mercury in maternal hair), this would seem a poor choice.

A third option would be to develop a composite index across several measures in the Faroes study. The peer reviewers suggested that the BMDLs from the statistically significant tests could be developed, evaluated for effects of PCBs, and composited in some way, such as a geometric mean. The compositing

method should consider a weighting scheme to deal with varying sample sizes for the different tests. NRC essentially did a composite measure with the integrative analysis; for all endpoints in all three large studies, the BMDL is 8 ppm mercury maternal hair, or 32 ppb cord blood mercury (Table 4-7). Geometric means for the Faroese measures are in Table 4-8 below. These were calculated separately for the whole cohort, PCB-adjusted BMDLs, and lowest PCB subset. EPA will pursue the suggestion of a weighted composite index at a future time.

A final longer term option of the peer review panel was to devise a within-study integrative multivariate approach using factor analysis for analytical derivation of a composite factor that combines results across tests with overlapping functional domains. The panel acknowledged that this would require some statistical methodology development.

EPA prepared a comparison of the NRC and peer-reviewer-recommended approaches, which also includes the BMDLs from the NRC integrative analysis and geometric means of four scores from the Faroes. Table 4-8 presents BMDLs in terms of cord blood mercury. These are converted (using a one-compartment model as in Section 4.4.2) to an ingested dose of methylmercury that would result in the cord blood level. The last column of Table 4-8 shows the corresponding RfD from application of a UF of 10 (see Section 4.5.6). The calculated RfD values converge at the same point: 0.1 μg/kg/day. Among all the endpoints listed, there are few deviations from 0.1 μg/kg/day: 0.2 μg/kg/day for the CVLT entire cohort and 0.05 μg/kg/day for CPT and Finger Tapping, lowest PCB subset. For comparative purposes several measures from the New Zealand data analyses were also included in Table 4-8; the median BMDL from the New Zealand study would give an RfD of 0.05 μg/kg/day. If one were to use the NRC integrative analysis BMDL equivalent value, the resulting RfD would be 0.05 μg/kg/day.

Rather than choosing a single measure for the RfD critical endpoint, EPA considers that this RfD is based on several scores from the Faroes measures. These test scores are all indications of neuropsychological processes involved with a child's ability of a child to learn and process information. The BMDLs for these scores are all within a relatively close range. In subsequent sections, one endpoint is carried through the dose conversion and application of the UF to calculation of the RfD; namely, the NRC-recommended BMDL of 58 ppb mercury in cord blood from the BNT.

Table 4-8. Comparison of BMDLs–endpoint from Faroes, New Zealand and NRC Integrative Analysis[a]

Test[b]	BMDL ppb mercury cord blood	Ingested dose µg/kg bw /day[c]	RfD µg/kg bw /day[d]
BNT Faroes			
Whole cohort	58	1.081	0.1
PCB adjusted	71	1.323	0.1
Lowest PCB	40	0.745	0.1
CPT Faroes			
Whole cohort	46	0.857	0.1
PCB adjusted	49	0.913	0.1
Lowest PCB	28	0.522	0.05
CVLT Faroes			
Whole cohort	103	1.920	0.2
PCB adjusted	78	1.454	0.1
Lowest PCB	52	0.969	0.1
Finger Tap Faroes			
Whole cohort	79	1.472	0.1
PCB adjusted	66	1.230	0.1
Lowest PCB	24	0.447	0.05
Geometric mean			
Whole cohort	68	1.268	0.1
PCB adjusted	65	1.212	0.1
Lowest PCB	34	0.634	0.1
Median values			
Faroes	48	0.895	0.1
New Zealand	24	0.447	0.05
Smoothed values			
BNT Faroes	48	0.895	0.1
CPT Faroes	48	0.895	0.1
CVLT Faroes	60	1.118	0.1
Finger Tap Faroes	52	0.969	0.1
MCCPP New	28	0.522	0.05
MCMT New	32	0.596	0.1
Integrative			
All endpoints	32	0.596	0.1

[a]BMDLs from NRC (2000), Tables 7-4, 7-5, 7-6. Hair mercury was converted to blood mercury using a 250:1 ratio and an assumption of equivalent maternal and cord levels.
[b]Abbreviations: BNT, Boston Naming Test; CPT, Continuous Performance Test; CVLT, California Verbal Learning Test; MCCPP, McCarthy Perceived Performance; MCMT, McCarthy Motor Test.
[c]Calculated using a one-compartment model as in Section 4.4.2.4.
[d]Calculated using an UF of 10 as in Section 4.5.6.

4.3 CHOICE OF DOSE-RESPONSE APPROACH

4.3.1 Benchmark Versus NOAEL

In recent years, EPA has been moving to use of BMDs versus experimental NOAELs as the departure point for calculation of RfDs. The Agency is preparing guidance for application of this methodology. Guidance has been published in the Technical Support Document on Risk Assessment, Human Health Methodology for Ambient Water Quality Criteria (U.S. EPA, 2000g).

NRC also made comments on the applicability or preference for BMDs over NOAELs (NRC, 2000, pp. 272-273). They cite comments by several risk assessment scientists on statistical drawbacks to NOAELs. The NOAEL, for example, must correspond to one of the experimental doses; it can vary considerably across different experiments. In calculating an RfD, there is no statistical or other treatment of the data to adjust for the choice of dose groups by different experimenters. NRC notes that the identification of a no-effect dose group is based on statistical comparisons between exposed and controls; thus, larger studies have higher power to detect small changes and tend to produce lower NOAELs. Furthermore, because NOAELs are identified as a consequence of pairwise comparisons, there is no widely accepted procedure for calculating a NOAEL in settings where exposure is measured on a relatively continuous scale.

In its guidance documents EPA lists some other advantages of BMD over the LOAEL/NOAEL approach. The traditional method does not incorporate information on the shape of the dose-response curve, but rather uses only a single point (NOAEL or LOAEL). This point depends on the number of doses and spacing of those doses in the experiment. The possible LOAEL/NOAELs are limited to the discrete values of the experimental doses, whereas the "real" value of the NOAEL could be any value between the experimental NOAEL and the LOAEL.

The determination of a NOAEL is dependent on the background incidence of the effect in controls. Statistically significant differences between treatment groups and controls are more difficult to detect if background incidence is relatively high, even if biologically significant effects are noted.

The peer reviewers of the methylmercury RfD provided comment on the appropriateness of the BMD methodology for the methylmercury human data:

> Derivation of LOAELs and NOAELs from the data would require disaggregation of the data based upon artificial cutpoints (e.g., quartiles) to determine which range of exposure appears to be different from the baseline group. While this approach provides a useful profile of effect with dose (e.g. Fig. 1 of the 1997 Faroes paper), it uses a grouping of the data that makes specifying the threshold less exact than with the more statistically robust and inclusive benchmark dose approach. The LOAEL/NOAEL approach also does not factor variability into the estimation of the threshold dose in the health protective way that the BMDL concept accomplishes. In the LOAEL/NOAEL approach, the more variable the data the higher the LOAELs and NOAELs tend to become because it is more difficult to define a statistical difference from the control group. In contrast, greater variability will tend to drive down the estimate of the BMDL since it is the lower 95% confidence limit estimate on the BMD. (G. Ginzberg in U.S. EPA, 2000f)

NRC recommended and EPA concurred with the use of a BMD approach to calculate the methylmercury RfD.

4.3.2 Choice of Exposure Metric

NRC discussed at length in its Chapter 4 the suitability of both hair and blood mercury as biomarkers of exposure. The measurement of mercury exposure in the study population serves two purposes when applied to risk assessment. The biomarker serves as the surrogate for the methylmercury dose to the target tissue, in this case fetal brain. As such, the biomarker is one of the coordinates of inputs to the dose-response models. From this perspective, the ideal biomarker is one that is closest pharmacokinetically to the target. Of the measurements available, cord blood represents a compartment closer to fetal brain than does hair, which is an excretion compartment.

The other use of biomarker in this risk assessment is as a surrogate for ingested dose, the unit in which an RfD is expressed. The ideal biomarker for this stage is closest pharmacokinetically or has the best correlation with ingested dose. Maternal hair or blood may be more suitable from this point of view.
