Substantial research at Onondaga Lake, the South River, and EFPC has yielded valuable information for understanding and managing Hg-contaminated sites. Identification and control of ongoing releases of Hg was a first step at all 3 sites and is ongoing at South River and EFPC. The primacy of this step is consistent with USEPA (2005) guidance on contaminated sediment remediation. At Onondaga Lake, MeHg concentrations in stratified bottom water resulted from redox conditions suitable for MeHg production in bottom sediment and release into the hypolimnion. When the oxidative potential in overlying water was increased by nitrate addition, MeHg concentrations declined substantially, thereby reducing the exposure to fish at fall turnover. At the South River, ongoing releases from bank erosion were identified as a primary cause for elevated fish tissue concentrations, and remedial measures to control erosion are underway. At EFPC, fish tissue concentrations remain elevated despite reductions in total Hg concentrations.

TARGETED PARAMETERS FOR SITE ASSESSMENT

The first step in managing Hg-contaminated sites is to identify and eliminate, to the extent practicable, ongoing sources of Hg to the system. Then efforts can be focused on understanding the nature, extent, and potential for net Hg methylation and bioaccumulation (Figure 3). Many of the geochemical controls on Hg methylation (and ultimately on bioaccumulation) have confounding effects on the overall process (Table 1) and would require extensive evaluation to decipher their roles at a particular site. Such a detailed analysis is unnecessary for a general understanding of Hg methylation at most sites.

The following parameters were identified as both straightforward to measure and valuable to interpreting the potential

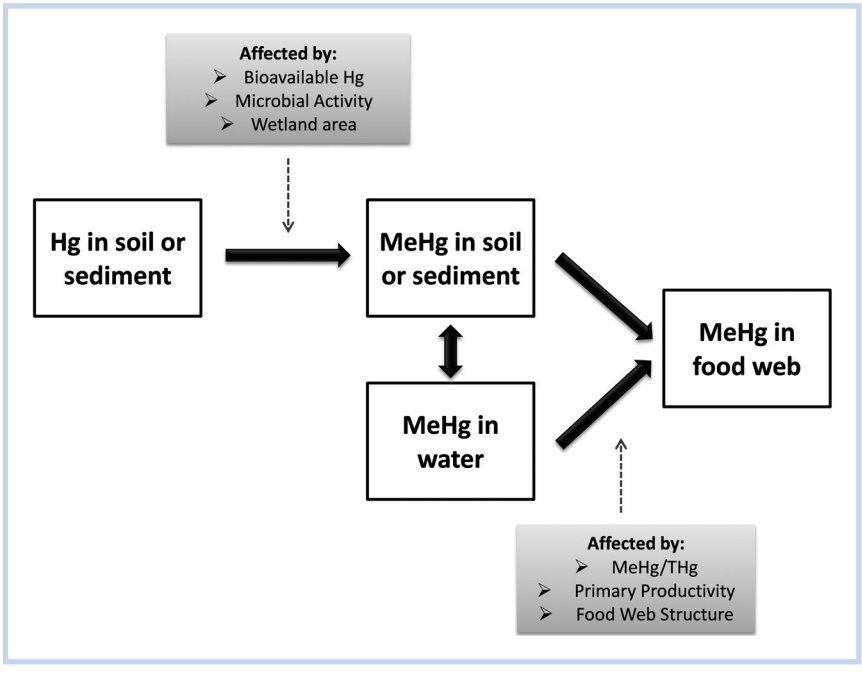

Figure 3. Targets for Hg site assessment. THg = total mercury; MeHg = methylmercury.

Table 1. Effect of geochemical and physical parameters on factors affecting Hg methylation

Geochemical or physical parameter	Bioavailable Hg	Microbial activity	Wetland area	Notes
S	+/–	+	NA	Bioavailability can both increase and decrease based on chemical species formed. The presence of increased sulfate can stimulate activity of sulfate-reducing bacteria, which cause methylation.
Organic C	+/–	+	NA	Organic C can decrease availability through the binding of Hg or increase availability through increased mobility in bound forms. Microbial activity may be enhanced due to the presence of increased electron donors.
Fe	–	+/–	NA	Fe can reduce and bind Hg, making it less bioavailable. It can increase microbial activity through alleviation of toxicity but may shift microbial activity away from methylating populations.
Se	–	–	NA	Se decreases bioavailability of Hg through formation of insoluble selenites.
pH	+/–	+/–	NA	Bioavailability is reduced at high pH, and a pH between 4.5 and 9 is optimum for microbial activity.
Temperature	NA	+/–	+/–	Bacteria have optimal temperatures for growth.
Oxygen availability	+	–	NA	Reduced compounds of Hg tend to be unavailable. Hg methylation occurs under reducing conditions.
Wetting and drying	+	+	+/–	Wetting and drying cycles can increase the release of Hg from particles and provide sulfate to stimulate SRB activity.

SRB = sulfate-reducing bacteria.

for Hg methylation and bioaccumulation: site characteristics, sediment Hg and MeHg concentrations, operationally defined available Hg, and microbial activity, where practical. The measurement of DOC, TOC, and total suspended solids (TSS) also may be helpful and are suggested for measurement due to their relatively low cost. At any site, expenditures for site characterization should be appropriate for the size of the site. For small sites with substantial Hg concentrations, the most expensive remedial action (e.g., removal of contaminated material) may cost less than gathering the data needed to develop a detailed scientific basis for less extensive remedial measures. However, the cost of removal at a large site may be prohibitive, and thorough site evaluation may provide a basis for more effective and efficient remediation and monitoring.

Site characteristics

Site characterization typical of remedial investigations often will provide important information for developing site-specific hypotheses about Hg transport, methylation, bioaccumulation, and risk. First, all point and nonpoint sources to the site must be considered, including background concentrations, especially in urban areas. Remedial investigations at numerous sites have taken much longer than first expected because of difficulties in locating significant sources. For example, the South River site required many years of intensive investigation to understand that erosion of contaminated floodplain soils was a continuing source of new Hg that was methylated in the riverbed. Sites that historically used elemental Hg can be particularly difficult to interpret, because in the presence of O_2, the surfaces of elemental Hg beads in sediments and soils and in building sewers and sumps form an oxide coating (Miller et al. 2015) that is much more soluble than elemental Hg, thus creating a persistent Hg source.

Characterization should include a general understanding of hydrology, redox conditions, and sediment transport. Each of these characteristics has the potential to influence how Hg behaves. For example, hydrological factors, including wetting and drying, affect Hg transport (Liang et al. 2014) and methylation. Another key physical characteristic controlling Hg methylation is the amount of standing water relative to active streams (Krabbenhoft et al. 1999; Yee et al. 2008). Although active streams are typically aerated, standing water is often associated with accumulated sediment and organic debris conducive to microbial activity, anaerobic conditions, and Hg methylation. Standing water could include larger contiguous bodies such as impounded wetlands as well as small-scale riparian zones. Typically, an understanding of redox conditions in sediment will also shed light on the potential for Hg methylation. Because sulfate reduction (and thus MeHg production) occurs under anoxic conditions where sulfate is available, peak MeHg concentrations tend to be at the interface of oxic and anoxic conditions where sulfide produced during sulfate reduction is re-oxidized to sulfate and available again for sulfate reduction. This zone is usually within the top few centimeters of a sediment profile but may be deeper if there is substantial bioturbation, resuspension, or other processes that aerate the sediment column. With respect to sediment transport, erosion of bank or sediment may be a source of ongoing Hg releases to a water body, fine sediment is usually indicative of a depositional environment (and is often correlated with THg and MeHg concentrations), and undisturbed sediment layers such as in cores from the deeper zone of Onondaga Lake may demonstrate natural recovery (i.e., burial of contaminated sediment by cleaner material).

Mercury and methylmercury concentrations

Mercury and MeHg concentrations in biota, sediment, and water provide important information on Hg behavior, methylation, and bio-accumulation. Measurement of Hg concentrations in biota is a direct method for assessing

bioaccumulation potential at a site. For relevance in risk assessment, sampling would include recreationally important fish species for human health risk assessment and important prey species for ecological risk assessment. Although THg in sediment does not necessarily predict the potential for human and ecological exposure, an understanding of the range and distribution of Hg within a site is a fundamental starting point to focus further analyses. Additionally, Hg and MeHg concentrations in water can be important indicators of potential transport and bioaccumulation. Water MeHg concentrations have been correlated to fish concentrations on a site-specific basis in reservoirs (CWB 2013) and, in some systems (i.e., those where accumulation is based on exposure to water via plankton), can be used as an indicator of potential food web exposure.

The ratio of MeHg to THg in sediment has been widely reported to be a strong predictor of net methylation and thus potential Hg bioaccumulation, but the ratio is not constant, and MeHg concentrations tend to plateau at higher THg concentrations. Cossa et al. (2014) recently proposed a Michaelis-Menten–type relationship between THg and MeHg in sediments, which would account for this plateau. Michaelis-Menten is a standard depiction of an enzymatic (i.e., biological) reaction involving a single substrate (in this case, THg) that reaches saturation, meaning that further increases in substrate concentration do not result in an increase in reaction rate (in this case, rate of Hg methylation). The shape of the curve is described using the height of the plateau (Vm) and the substrate concentration at which half of the plateau height is reached (Km). Cossa et al. (2014) focused on a variety of sediment types (marine, freshwater, deep, and surface), plotted MeHg versus THg, and fit a curve to the Michaelis-Menten–type equation. River sediments (the only freshwater sediments in the study and approximately 10% of the total sediments) had low correlations ($R^2 = 0.38$) between MeHg and THg, compared to other categories.

For comparison, published surface sediment data from the 3 previously discussed case studies (Oak Ridge, South River, and Onondaga Lake) were plotted using the approach described by Cossa et al. (2014), and the results (Figure 4) show wide variability in predicted MeHg plateau concentrations but consistent trends within each single site. For example, the 2 samples circled on the plot have very similar THg concentrations and are both river surface sediment samples (South River and EFPC), yet their MeHg concentrations differ by more than an order of magnitude, showing the importance of site-specific characteristics. As noted previously, the South River exhibits higher than expected rates of Hg methylation. This is apparent from Figure 4, where both South River samples plot well outside the typical values found by Cossa et al. (2014) (and, in fact, above the MeHg concentration asymptote defined for their equations). One hypothesis for this variation is the presence of an unusual fraction of highly available Hg continually replenished through bank erosion along the South River. Similarly, Onondaga Lake MeHg concentrations plateau above approximately 1 μg/g THg, well below the plateau described in Cossa's data.

The Onondaga Lake and Oak Ridge EFPC MeHg concentration trends are an order of magnitude lower than the 2 South River samples with similar THg concentrations. Sequestration of Hg as HgS(s) and consequent low bioavailability of inorganic Hg(II) to methylating bacteria may explain the lower MeHg concentrations at these sites compared to South River. Methylmercury concentrations at Onondaga Lake and EFPC, based on the data in Figure 4, would never be expected to reach MeHg concentrations similar to those found in South River, regardless of THg input. Because of differing site characteristics, remediation at these sites may require different THg endpoints in order to reach similar MeHg concentrations.

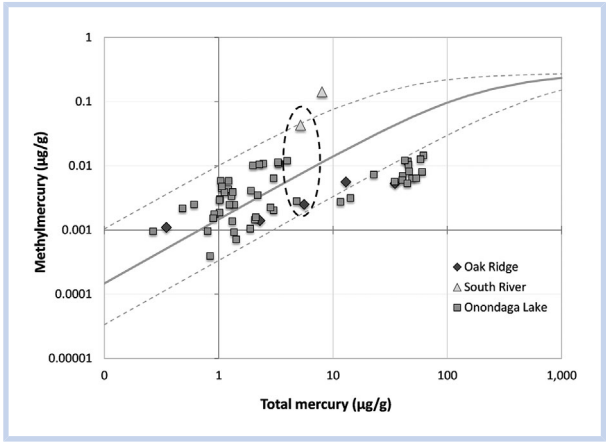

Figure 4. Data from selected sites plotted for comparison with the Michaelis-Menten relationship proposed by Cossa et al. (2014). The dashed circle shows 2 samples with comparable total Hg concentrations but methylmercury values that differ by more than an order of magnitude. The solid and dashed lines represent the curves for $K_m = 188$ (overall fit) and $K_m = 26.5, 825$ (lower and upper 95% confidence interval) determined by Cossa et al. (2014).

We recommend that a new site investigation begin with an initial survey of THg and MeHg concentrations in surface sediment. The results can then be plotted as shown in Figure 4, with or without the Michaelis-Menten half-saturation values as reference (Cossa et al. 2014). This type of plot clearly indicates those samples with the highest methylation efficiency and the THg concentration above which MeHg concentrations plateau.

Available mercury

Although THg concentration is relevant for any investigation of Hg-contaminated soils and sediments, the fraction available for methylation and, ultimately, for accumulation in the food web is of particular importance. As discussed in the previous sections, the geochemistry of the surrounding soil, sediment, or water controls the chemical speciation of inorganic Hg and, therefore, its bioavailability. Because the interactions among Hg, organic matter, and various inorganic constituents are complex, several operationally defined methods have been developed to quantify the Hg fraction that is available for methylation. Identification of the particular chemical species is less important than understanding the overall "available" Hg concentration. In all methods discussed here, the relative amounts in each fractional category are reported in the context of the THg concentration.

Dissolved Hg. In contrast to methods that focus on Hg speciation within the sediment itself, measurement of dissolved Hg in interstitial porewater may serve as a better indicator of the readily bioavailable and mobile fractions of Hg (Zhang and Davison 1995; Hsu-Kim et al. 2013). Besides traditional methods that directly measure chemical concentrations in extracted porewater, technologies such as passive

samplers are being developed to measure dissolved Hg and MeHg. For example, passive sampling with diffusive gradient in thin films (DGTs) has been tested for measurement of bioavailable Hg in river water (Fernández-Gómez et al. 2011) and to measure labile porewater concentrations of MeHg and estimate net methylation rates in sediment (Clarisse et al. 2011). Interpretation of DGT data is challenging because the estimated concentrations of Hg or MeHg are controlled by diffusive rate assumptions and, in the case of Hg, can be strongly influenced by the presence of organic matter. In conjunction with measurements of THg and MeHg in the solid phase, dissolved concentrations can be used to calculate partition coefficients (K_Ds) that indicate the solubility of THg and MeHg. High K_Ds indicate that inorganic Hg is likely bound to the solid phase and less available for methylation.

Chemical extraction techniques to identify the bioavailable fraction of Hg(II) that is reactive with stannous chloride (Marvin-DiPasquale et al. 2006) and with sodium tetraethylborate (Liang et al. 2013) have been developed to quantify bioavailable Hg. More recently, Ticknor et al. (2015) developed a thiol-based sediment extraction technique that uses glutathione to identify bioavailable Hg, mimicking the mechanism involved in Hg binding to methylating bacteria. Results of thiol-based extractions correlated with MeHg production in microcosm methylation experiments using multiple forms of Hg (Ticknor et al. 2015).

Sequential extraction. Two methods, EPA 3200 (USEPA 2014) and the 5-step Selective Sequential Extraction Procedure (Bloom et al. 2003), use a series of sequentially stronger extractants to separate more and less soluble fractions of Hg in a soil or sediment sample. The fractions are then analyzed for THg. The EPA method divides Hg into 4 operationally defined fractions:

1) extractable organic Hg,
2) extractable inorganic Hg,
3) semimobile Hg, and
4) nonmobile Hg.

In general, the extractable inorganic Hg fraction, which includes species such as Hg chloride and Hg nitrate, is considered to be the pool of Hg available for methylation.

Bloom et al. (2003) separated the sample into 5 fractions:

1) F1—water soluble,
2) F2—weak acid soluble,
3) F3—organo-complexed,
4) F4—strong complexed, and
5) F5—mineral-bound.

Tests of the extracts suggest that inorganic Hg extracted in the F4 and F5 fractions is negatively correlated to the fraction of MeHg in sediments (Bloom et al. 2003). Determination of a large Portion of THg in the strongly complexed or mineral-bound fractions can explain why some sites, such as those impacted by Hg mining, have low MeHg (i.e., low availability of Hg for methylation) despite high THg concentrations.

X-ray absorption fine structure spectroscopy. Another approach for identifying the major Hg species in sediment or soil is XAFS. The XAFS spectra can directly reveal the oxidation states and molecular-scale coordination chemistry of Hg (Newville 2001). From this information, one can identify specific chemical forms and abundances of various Hg species. Minor Hg species may not be detected using XAFS, though they might be an important reactive phase. When samples are not subjected to chemical treatments prior to data acquisition, XAFS can provide insightful and direct information on in-situ speciation. The XAFS analysis can complement other operationally defined techniques such as sequential extraction (Kim et al. 2003). However, XAFS measurements require specialized equipment, training, and a synchrotron radiation facility. They are unlikely to be useful as a first-line site assessment method but may be critical for more detailed investigations in which sequestration of Hg in insoluble phases needs to be understood and documented.

DOC, TSS, and TOC

Although DOC concentration in water is not an absolute predictor of Hg methylation or MeHg concentrations (Cossa et al. 2014), it is a straightforward and relatively inexpensive laboratory measurement that may provide important site-specific indicators of methylation potential. As discussed in the context of Oak Ridge, a site-specific correlation between DOC and Hg may provide information about sites of potential elevated Hg methylation. For this reason, it is recommended that DOC in water be measured as part of Hg site assessment. Similarly, TSS in water is routinely analyzed and is essential for interpreting water data for MeHg and especially for THg due to the generally high binding constant for inorganic Hg to particles. Elevated THg concentrations in water are usually correlated with elevated TSS concentrations. Finally, TOC in sediment is a standard site-characterization parameter and often can help to explain patterns of sediment THg and MeHg concentrations. Total Hg and, to a lesser extent, MeHg bind to organic C, and their concentrations are often correlated with TOC.

Microbial activity

Another major factor in understanding the potential for Hg methylation in the environment is the metabolic activity of microorganisms. One proxy for microbial activity is the measurement of redox potential (Eh). This measurement is related to the microbial metabolism present in a specific environment and can range from oxic and nonreducing (O_2 as the terminal electron acceptor, little Hg methylation) to suboxic and mildly reducing (some sulfate reduction occurring, high likelihood of Hg methylation) to anoxic and strongly reducing (sulfate reduction may occur, but sulfide may prevent Hg from being available for methylation). Although there are more sophisticated methods to accurately quantify redox status (e.g., voltammetry), redox potential can be measured inexpensively with a sensor in the field. These results often are considered qualitative, not quantitative, but the general trends from oxic to anoxic can be helpful in predicting locations of potential Hg methylation.

Methodology to directly measure microbial methylation activity in the field is currently unavailable. One laboratory approach to understanding rates of Hg methylation involves adding stable-isotope-enriched Hg or MeHg to sediment samples. The accumulation of the spiked isotope in the

transformation product (e.g., MeHg formed from the added THg) can be measured to determine rates of methylation or demethylation. Results of such incubations may be helpful in determining potential relative methylation or demethylation rates but are unlikely to be truly representative of in-situ rates, which are spatially and temporally variable. Additionally, these are costly and labor-intensive measurements and are generally reserved for academic research.

Other research methods include enumeration of SRB and identification of Hg-methylating bacteria through genetic markers. Sulfate-reducing bacteria, the most widespread Hg methylators, can be enumerated by several commercially available standard methods, including serial dilutions or plate counts, but presence does not necessarily correlate with activity, and not all SRBs methylate Hg. Screening with *hgcAB* genes (Podar et al. 2015) holds promise for describing the distribution and abundance of Hg-methylating genes in the environment, but the applicability to routine site assessment is far off. This is an area of active research and may be an increasingly useful tool for understanding the Hg methylation potential of an environment.

RECOMMENDATIONS

As summarized in the present review, there have been significant advances in deciphering the individual geochemical factors that contribute to the methylation and, ultimately, the bioaccumulation of Hg. While there is no single definitive measurement or equation to quantitatively predict MeHg concentrations, site managers can consider the parameters described in this review in a logical order for designing investigations into the nature and extent of Hg contamination. Understanding site characteristics and the nature of the Hg sources, both point and nonpoint, is the obvious starting point. The form of Hg contamination, whether Hg(II), Hg(0), HgSs, or more unusual forms such as fulminate [$Hg(CNO)_2$], has a strong influence on its availability to be methylated in sediment or soil and can often be deduced from the site history.

The nature of sediment or soil is also a key consideration to guide evaluation of the extent of contamination. Fine-grained substrates typically are more favorable for Hg methylation than are coarse-grained substrates because they tend to contain less oxygen, which is a favorable environment for methylating bacteria. Methylation and methylmercury concentrations tend to be very low in oxic sediments and soils. This generalization, however, can be strongly influenced by other processes, such as the wetting and drying observed in California reservoirs or the continual supply of Hg-contaminated floodplain soil to the South River. Much can be learned by simply plotting THg and MeHg sediment concentrations. Comparing the MeHg and THg results to data from other sites and to the framework developed by Cossa et al. (2014) can provide additional insight on the availability of THg for methylation, including the Hg concentration above which MeHg concentration tends to plateau. If needed, measurements of microbial activity and Hg speciation can help explain anomalous results.

Evaluating potential remediation at Hg-contaminated sites should not rely on THg measurements alone. Ultimately, project managers will need to understand the potential risk to human health and the environment (USEPA 2005), which will entail evaluating exposure pathways and the concentrations of Hg in food sources (e.g., fish). Assessment of THg, MeHg, and a few supporting parameters in sediment provides important information on the site-specific availability of Hg for methylation and of MeHg for bioaccumulation. This site-specific information, along with a broader understanding of biogeochemical controls on MeHg, will help to support identification of cleanup goals and potential remedial actions for Hg-contaminated sites.

Acknowledgment—The authors wish to thank Ariette Schierz (Exponent), Dimitri Vlassopoulos (Anchor QEA), and 2 anonymous reviewers for their review of the manuscript and their helpful comments. We also wish to acknowledge DuPont for their financial support.

Effects of Dryout and Inflow Water Quality on Mercury Methylation in a Constructed Wetland

Shulu Feng · Zhijiu Ai · Shimei Zheng · Binhe Gu · Yuncong Li

Received: 30 August 2013 / Accepted: 4 March 2014 / Published online: 25 March 2014

Abstract The sulfate input and the occurrence of dryout and rewetting may promote the production of toxic methylmercury (MeHg) in a constructed wetland, Stormwater Treatment Area 2 (STA-2) in South Florida. Therefore, the aim of this study was to investigate the influences of inflow water quality, especially inflow sulfate, and the dryout and rewetting cycle on the mercury (Hg) methylation in three independent cells of STA-2 from 2000 to 2007. Because the majority of the total Hg (THg) bioaccumulated in fish is in MeHg form, THg concentration in mosquitofish was used to present the MeHg production in STA-2. Mosquitofish THg in Cells 1 and 2 (with median values of 0.101 and 0.02 mg/kg, respectively) were significantly higher than in Cell 3 and inflow (both with a median value of 0.01 mg/kg). The difference in mosquitofish THg among the three cells was likely a result of the drying and rewetting cycles occurred in Cells 1 and 2, which promoted the Hg methylation. Inflow sulfate, inorganic Hg, and chloride exhibited a significant correlation with mosquitofish THg in cells, suggesting that these inflow variables played important roles on the Hg methylation. The results indicate that inflow sulfate may likely stimulate sulfate-reducing bacteria and subsequently lead to produce MeHg in the three cells. Our findings in this study indicate that preventing the occurrence of dryout in wetland will help to decline the Hg methylation, and sulfate input is a key factor to influence the Hg methylation in wetland.

1 Introduction

Due to its characteristics, such as low melting and boiling points, mercury (Hg) is a globally spread pollutant and released from both natural and anthropogenic sources (Hylander and Meili 2003). As a result of centuries of anthropogenic activities, such as mining and fossil fuel burning, the global atmospheric Hg deposition rate is approximately three times greater than in preindustrial times, leading to increased concentrations in freshwater systems and biota even in remote areas that are free from direct anthropogenic impacts (Ullrich et al. 2001). Hg contamination generally only becomes a

global environmental concern when the methylation of inorganic Hg (IHg) to methylmercury (MeHg) occurs. As a potent neurotoxin, MeHg is the most toxic form of Hg in the environment. Owing to its lipophilic and protein-binding properties, MeHg is also the only Hg compound that is readily bioaccumulated and biomagnified in the food web, which may also pose a threat to humans and other fish-eating animals (Ullrich et al. 2001; Hylander and Meili 2003).

In situ production of MeHg via microbial methylation is the primary source of MeHg to the most aquatic systems (Gilmour and Henry 1991; Gilmour et al. 1992). As far as we know, sulfate-reducing bacteria (SRB) are widely accepted as the primarily methylators of Hg methylation (Compeau and Bartha 1985; Gilmour et al. 1992; Ullrich et al. 2001). SRB thrive in oxygen-free and carbon-rich environments, degrade organic matter, and reduce sulfate to sulfide in both freshwater and estuarine sediments (Ullrich et al. 2001). The formation of MeHg produced in the environments depends on factors that control SRB population growth or metabolic function (Winfrey and Rudd 1990; Gilmour and Henry 1991; Ullrich et al. 2001) and on the bioavailability of Hg for SRB (Ullrich et al. 2001). The significant ecological factors include dissolved organic carbon (DOC) (Ullrich et al. 2001; Aiken et al. 2003), SO_4^{2-}/S^{2-} (Benoit et al. 1999, 2001; Ullrich et al. 2001), pH (Winfrey and Rudd 1990; Regnell 1994; Ullrich et al. 2001), and temperature (Bodaly et al. 1993; Ullrich et al. 2001), which put effect on the microbial growth. The bioavailability of Hg for SRB is likely influenced by complex ligands in environments, such as chlorides (Barkay et al. 1998; Ullrich et al. 2001), sulfides (Benoit et al. 1999, 2001; Ullrich et al. 2001), and organic compounds (Barkay et al. 1997; Ullrich et al. 2001; Aiken et al. 2003), which determine the ability of Hg to cross the microbial cell membranes. Wetlands particularly possess many environmental factors that promote Hg methylation and are recognized as "hot spots" for MeHg production (Gilmour et al. 1992; St. Louis et al. 1994; Branfireun et al. 1999). Besides, the dryout and rewetting cycle in wetland has been found to enhance Hg methylation and microbial sulfate reduction, thereby causing increased Hg methylation in the wetlands (Dmytriw et al. 1995; Gilmour et al. 2004b). Furthermore, Ackerman and Eagles-Smith (2010) reported that agricultural wetlands are potential hot spots for MeHg contamination due to their periodic flooding schedules.

Sulfate at 60 to100 times that of background levels (≤1 mg/L) is delivered to the Everglades in the runoff from Everglades Agricultural Area (EAA) (Orem 2004). Stormwater Treatment Areas (STAs), which are a system of large treatment wetlands, shallow and freshwater marshes, are constructed primarily to remove total phosphorus (TP) from the EAA runoffs before it is discharged to the Everglades Protection Area (Chimney et al. 2000). About 70 % of TP loads was removed through STAs (Orem et al. 2011), but little has been done to reduce sulfate contamination of the ecosystem (i.e., only about 11 % sulfate reduction) (Orem 2004; Orem et al. 2011). Except for the sulfate input, the cycle of dryout and rewetting occurred during the operation in some of STAs, for example, the drought occurred in the early operation period of Stormwater Treatment Area 2 (STA-2). The objective of this work was to investigate the Hg issue in STAs; STA-2 taken as the example for this study. The work included two parts: (1) the effect of dryout and rewetting on the production of MeHg in STA-2; and (2) the relationship between inflow water quality variables and the MeHg production in STA-2, especially the impact of inflow sulfate load on the Hg methylation. This study can obtain the insight into the factors influencing on the Hg methylation and help to better manage and resolve the MeHg issue in the constructed wetlands.

2 Materials and Methods

2.1 Study Area

STA-2 is located in Western Palm Beach County, Florida, immediately west of Water Conservation Area 2 (WCA-2) (Fig. 1), and is divided into four parallel north-south treatment cells with a total surface area of approximately 8,000 ac before 2012 (Cell 4 is constructed in 2007 with about 2,000 ac). Water from flow structures Station 6 (S-6) and Gate 328 (G-328) enter the supply canal and are conveyed southward to the inflow canal, which extends across the northern perimeter of the STA-2. A series of inflow culverts convey water from the inflow canal to the respective treatment cells. Water then flows southward through the treatment cells and eventually discharges into the discharge canal via culverts or gated spillways. The outflow pump station Gate 335 (G-335) conveys water to WCA-2.

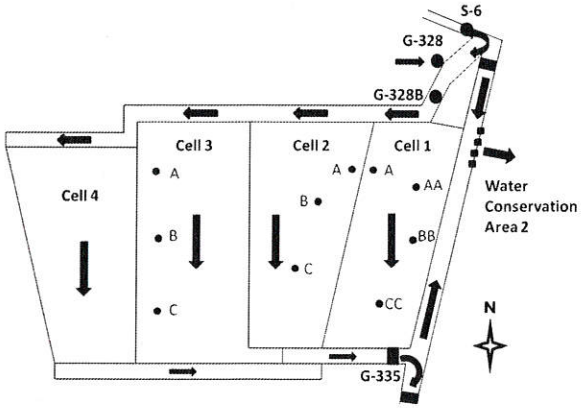

Fig. 1 Schematic diagram of structures and flows at Stormwater Treatment Area 2 (STA-2) before 2012, not to scale. S-6 and G-328 are the inflow structures, G-328B is a sample location in the supply canal, and G-335 is the outflow station

2.2 Data Collection and Analytical Methods

As a condition of its operating permits, the South Florida Water Management District (District) is required to monitor Hg in surface water quality at various locations throughout the Everglades Protection Area. The unfiltered water samples of inflow S-6, G-328, and G-328B (located in the supply canal) were collected biweekly for water quality analysis, including total Hg (THg) and MeHg analyses. The inflow fish was semi-annual sampled in the supply canal. The fish sample in every cell was collected monthly if the fish was available. The fish sampling points for the three cells were showed in Fig. 1; four sampling points (A, AA, BB, and CC, respectively) in Cell 1 and three sampling points (A, B, and C, respectively) both in Cells 2 and 3.

Since only Cells 1, 2, and 3 in STA-2 operated during the study period (from 2000 to 2007), Cell 4 was not included in this study. The following inflow water variables, including sulfate, pH, DOC, temperature, chloride, and IHg (THg minus MeHg), were selected to discuss the influence of inflow water quality on the Hg methylation in the constructed wetland, and the inflow sulfate was the focus of the water quality variables in the present study (Table 1).

It is found that greater than 95 % of THg in fish tissue is in the MeHg form (Celo et al. 2006; Grieb et al. 1990). Furthermore, the analysis of fish tissue for THg, which is a more straightforward and less costly procedure than the analysis for MeHg, can be interpreted as being equivalent to the analysis of MeHg (Fink et al. 2005). Therefore, the fish THg in cells was to represent the in situ MeHg production in the constructed wetland in the present study. The three species of fish, mosquitofish (*Gambusia holbrooki*), sunfish (*Lepomis spp.*), and largemouth bass (*Micropterus salmoides*), were sampled for determining THg bioaccumulation in fish. Among the three species of fish, the mosquitofish is at the low trophic level, which is the prey fish for sunfish and largemouth bass; hence, the THg biomagnifications in sunfish and largemouth bass are greater than in mosquitofish, making the THg data in sunfish and largemouth bass more complicated than in mosquitofish. Moreover, widespread occurrence in the Everglades, relatively small home range, rapid population turnover, and short life span (average life span only 4 to 5 months) make mosquitofish adjust to new condition more rapidly than the populations of sunfish and bass that are longer-lived (Fink et al. 2005; Rumbold and Fink 2006). These characteristics make the mosquitofish a potentially excellent representative indicator of short-term, localized changes in MeHg through time (Fink et al. 2005; Rumbold and Fink 2006). Therefore, in the present study, mosquitofish THg was treated as the MeHg bioindicator. At each sampling site, between 75 and 250 mosquitofish were collected; the individual fish was stored on ice, refrigerated for not more than 48 h, and then composited and homogenized using a Polytron® apparatus. Thereafter, the homogenate was frozen prior to shipment on blue ice or double-bagged wet ice to the Florida Department of Environmental Protection (FDEP) mercury clean laboratory.

All data of the inflow water quality variables and THg in mosquitofish tissue used for this work were obtained from the District's DBHYDRO database (www.sfwmd.gov/dbhydro). Data were generated by the District and the FDEP, both of which are certified by the Florida Department of Health under the National Environmental Laboratory Accreditation Program. For analytes other than THg and MeHg, surface water analyses were conducted by the District's analytical chemistry laboratory on field-preserved samples using standard methods. THg determination in surface water was carried out using US Environmental Protection Agency (USEPA) Method 1631 (Mercury in water by oxidation, purge and trap, and cold vapor atomic fluorescence spectrometry) or a modification of Method 1631. Moreover, THg determination in fish tissue followed either the USEPA Method 245.6

Table 1 Characteristics of multiple inflow water quality variables (sulfate, IHg, chloride, DOC, pH, and temperature) from 2000 to 2007

Inflow water quality parameters	Range	Median	Mean	SD	95 % confidence interval
Sulfate (mg/L)	39.31–110.10	58.16	59.93	14.04	56.66–63.21
IHg (ng/L)	0.21–2.95	0.91	1.06	0.55	0.94–1.19
Chloride (mg/L)	87.62–342	202	197.17	52.66	184.89–209.46

IHg inorganic mercury, *DOC* dissolved organic carbon

(Determination of mercury in tissues by cold vapor atomic absorption spectrometry) or, if at low level, a modification of Method 1631. MeHg analysis in surface water used modified USEPA Draft Method 1630 (Methylmercury in water and tissues by distillation, extraction, aqueous phase ethylation, purge and trap, isothermal GC separation, and cold vapor atomic fluorescence spectrometry).

Quality assurance (QA) measures were incorporated during the sample collection and laboratory analysis to evaluate the quality of the data. All of the above methods use performance-based standards employing the appropriate levels of QA/quality control (QC) required by the National Environmental Laboratory Accreditation Conference, the specific reference method, and the Protocol. Laboratory QC samples included method blanks, lab-fortified blanks, matrix spikes, standard reference materials, and laboratory duplicates. Field QC samples included trip blanks, field blanks, equipment blanks, both of pre-cleaned equipment at the start of sampling and field-cleaned equipment at the end of sampling, container and processing equipment blanks, and field duplicates (Rumbold and Fink 2006).

2.3 Statistical Analysis

All statistical analyses were conducted using PASW® Statistics 18.0 (SPSS Inc., Chicago, USA). Before correlation analysis, the data of inflow water quality and mosquitofish THg concentration were log-transformed to ensure normal distribution. The correlated relationship between individual inflow water quality variable (sulfate, pH, temperature, DOC, chloride, and IHg, respectively) and mosquitofish THg in the individual cell of STA-2 was evaluated using Pearson moment correlation analysis.

3 Results and Discussion

3.1 The Effect of Dryout on the Hg Methylation in STA-2

During the monitoring period at STA-2 from 2000 to 2007, mosquitofish THg concentration in inflow varied from 0.027 to 0.003 mg/kg with a medium value of 0.01 mg/kg, while mosquitofish THg concentration ranged from 0.321 to 0.0078 mg/kg with a medium value of 0.101 mg/kg in Cell 1, varied from 0.103 to 0.003 mg/kg with a medium value of 0.02 mg/kg in Cell 2, and ranged from 0.0335 to 0.0042 mg/kg with a medium value of 0.01 mg/kg in Cell 3. Overall, during the monitoring period, there was no difference in mosquitofish THg concentration between Cell 3 and inflow (ANOVA, $p>0.05$). Nevertheless, THg concentrations of mosquitofish in Cells 1 and 2 from 2000 to 2007 were significantly greater than in inflow and Cell 3 (ANOVA, $p<0.001$ for both Cell 1 and Cell 2 compared with inflow and Cell 3). The discriminations of THg levels in mosquitofish among the three cells and inflow were pronounced (Fig. 2), the greatest in Cell 1, median in Cell 2, and the lowest in Cell 3 and inflow.

The differences in mosquitofish THg between the three cells and inflow are likely attributed to the severe drought during 2000 and 2001, which occurred in both Cells 1 and 2. Cell 1 went periods of dryout in the fall of 2000 and 2001, and Cell 2 went period dry in the summer of 2001 (Fink et al. 2005). During the severe drought of 2000 through 2001 in Cells 1 and 2, supplemental water deliveries were made to Cell 3 to prevent dryout. The process of drying and rewetting has been found to provide fuel for Hg methylation and microbial sulfate reduction, thereby causing increased Hg methylation in the wetland (Dmytriw et al. 1995; Gilmour et al. 2004b). As soil dryout leads to organic matter, iron(II), and sulfide in the surficial soil oxidized to labile organic

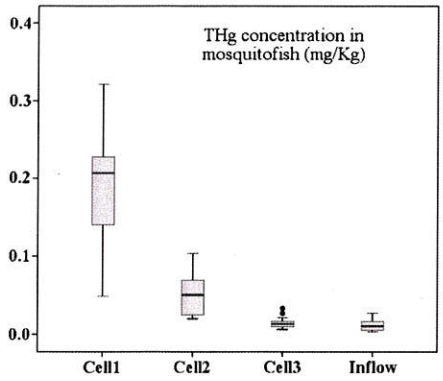

Fig. 2 Box plots for the concentrations of mosquitofish THg in the inflow and Cells 1, 2, and 3 at STA-2 from 2000 to 2007. *THg* total mercury

matter, iron(III), and sulfate, respectively (Dmytriw et al. 1995; Gilmour et al. 2004b), the rewetting of soils after dryout is accompanied by a flush release of sulfate, iron, and labile organic matter (Gilmour et al. 2004b). Following the flush release of sulfate, nutrients, and anoxic conditions, the metabolic activity of SRB is likely to be stimulated and additionally produce MeHg. Thus, the dryout and rewetting cycle made the Hg methylation in Cells 1 and 2 significantly greater than in Cell 3 and inflow, since no dryout occurred in Cell 3 and inflow.

From Fig. 3, it is seen that no clear trend existed in mosquitofish THg concentration in inflow; however, the levels of mosquitofish THg concentrations in all the three cells were decreasing until the beginning of 2004, and kept stabilized from 2004 to 2007. The trends of mosquitofish THg for the three cells indicate that the Hg methylation in all the three cells of STA-2 mainly occurred from 2000 to 2003. Similarly, the mosquitofish THg concentrations in all the three cells along with the concentrations of inflow sulfate (Fig. 4) and IHg (Fig. 5) again clearly demonstrated that the Hg methylation in all the three cells mainly occurred before 2004. Since, the buildup of sulfide (the reduction product of sulfate) and/or depletion of labile organic matter may likely end the pulse of MeHg production that follows the rewetting. The buildup of sulfide in sediment porewater appears to inhibit the Hg methylation through forming insoluble HgS, which decreases the Hg availability to SRB (Gilmour et al. 1992; Benoit et al. 1999; Orem et al. 2011). The labile organic matter provides carbon source for the metabolic activity of SRB (Gilmour et al. 1992; Ullrich et al. 2001). It comes to the conclusion that the conditions in all three cells from 2004 to 2007 were no longer fit for the Hg methylation.

3.2 The Influence of Inflow Water Quality Variables on the Hg Methylation

Since the conditions in all the three cells from 2004 to 2007 were no longer fit for the Hg methylation, accordingly, the correlated relationships between inflow water quality variables and mosquitofish THg in all the three cells were assessed until the beginning of 2004 (Table 2).

Inflow sulfate loading was negatively, significantly correlated with mosquitofish THg in all the three cells (Fig. 6), which accounted for 42, 58.5, and 50.5 % of the variations in mosquitofish THg concentrations in Cells 1, 2, and 3, respectively (Table 2). Among the inflow water quality variables, sulfate loading to STA-2 was of the most concern. The significant correlations between inflow sulfate load and the levels of mosquitofish THg in all the three cells indicate that sulfate input to STA-2 likely stimulated the activity of SRB and played a crucial role in the Hg methylation in all the three cells of the STA-2. The dual effect of sulfur on the Hg methylation, that is, the stimulation effect of sulfate and the inhibition effect of sulfide, produces the so-called "Goldilocks effect", where the levels of sulfate and sulfide are just right for the Hg methylation and the MeHg producing rate is maximum (Orem 2007). This conceptual model for the role of sulfur in the MeHg production has been verified for the Everglades by field, laboratory, and mesocosm experiments (Orem 2007). In the Everglades, Orem (2004) reported that the areas of the highest MeHg production occur where sulfate contamination is moderate (2–10 mg/L), and sulfide levels are low enough to avoid the inhibition of the MeHg formation. Gilmour and Henry (1991) proposed an optimal sulfate concentration range of 19 to 48 mg/L (optimum concentration was ~29 mg/L) for the Hg methylation by SRB in sediments, above which the methylation is inhibited and below which sulfate becomes limiting for the Hg methylation and sulfate-reduction processes. Gilmour et al. (1992) found that the MeHg production increases with sulfate concentrations up to 10 mg/L and declines when porewater sulfide exceeds 0.6 mg/L. Weber (1993) demonstrated that the Hg methylation completely stops at a sulfate concentration exceeding about 480 mg/L. King et al. (1999) observed active MeHg formation in the presence of 2.88 g/L sulfate and millimolar concentrations of dissolved sulfide. In the

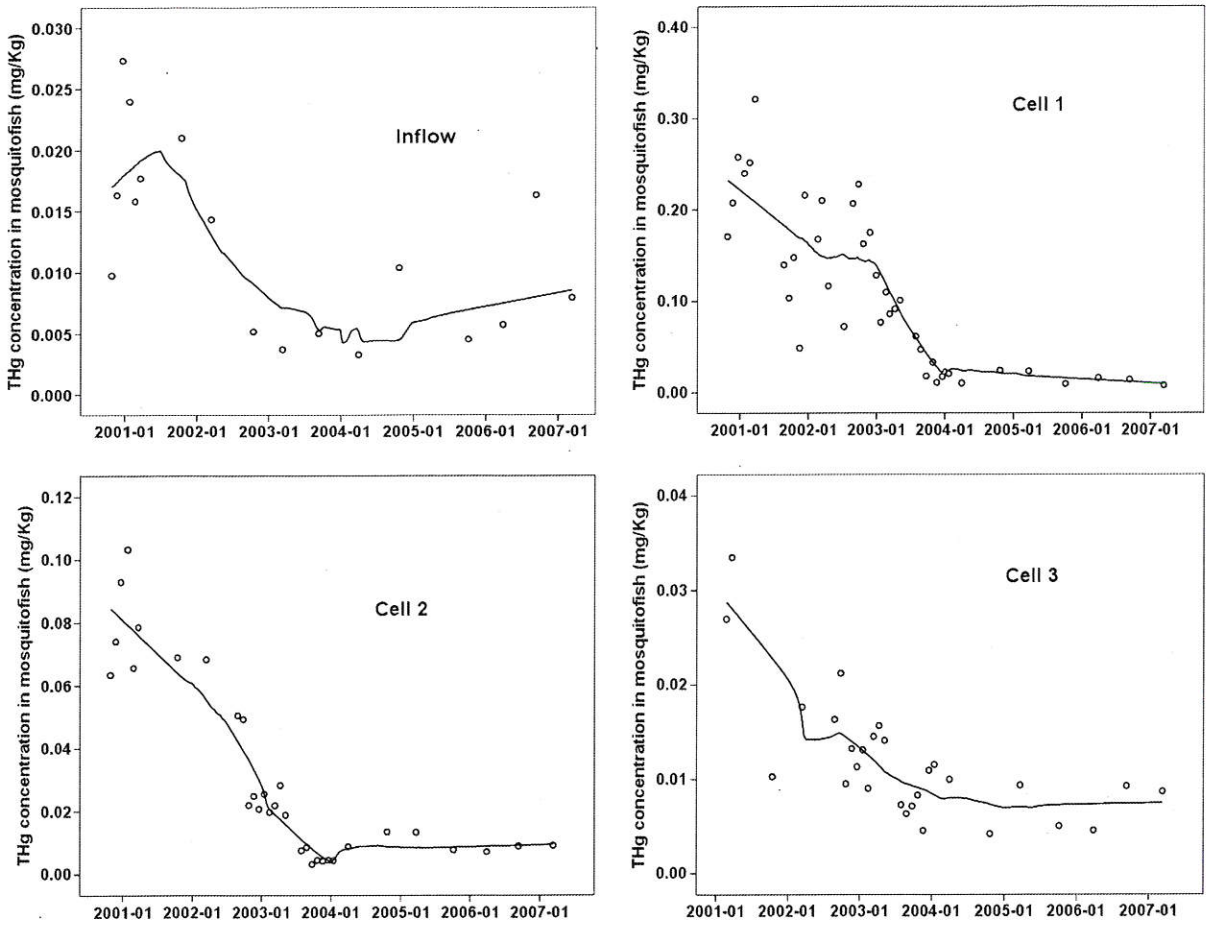

Fig. 3 Trends of the concentrations of mosquitofish THg in the inflow and Cells 1, 2, and 3 at STA-2. *Solid lines* were fitted by locally weighted regression (LOESS) in PASW Statistics 18.0. *THg* total mercury

present study, the negatively correlated relationships between inflow sulfate and mosquitofish THg in all the three cells indicate that the sulfate concentration in inflow was much greater than the optimal concentration for the MeHg production in all three cells of STA-2. Similarly, Selvendiran et al. (2008) also found a significantly negative correlation between MeHg and sulfate concentration (6.33±0.9 mg/L) during the growing season in a forested wetland, along with an increase in MeHg concentration concomitant with the decrease in sulfate concentration in wetland stream waters.

Plenty of studies have recognized that sulfate loading is an important factor in causing the increased Hg methylation in the Everglades (Orem 2004; Gilmour et al. 2007b; Corrales et al. 2011; Orem et al. 2011). Sulfur used in the agricultural application and sulfur released by the oxidation of organic EAA soils (including legacy agricultural applications and natural sulfur) are the primary sources of sulfate enrichment in the EAA canals (Orem 2004; Corrales et al. 2011; Orem et al. 2011). In general, sulfate concentration decreases from north to south in the Everglades ecosystem (Orem 2004; Orem et al. 2011). The dual effect of sulfur on the MeHg production and the north-to-south gradient in sulfate concentrations in the Everglades provide geographic context to the MeHg distributions (Orem et al. 2011). Unenriched areas of the ecosystem with sulfate concentration less than 1 mg/L exhibit low levels of MeHg due to sulfate limitation on the Hg methylation (Orem et al. 2011). In sulfate-enriched areas (concentrations more than 20 mg/L), buildup of sulfide inhibits the MeHg production (Orem et al. 2011). Areas with intermediate concentrations of sulfate (1–20 mg/L) have sulfate and sulfide levels that promote the maximum MeHg production (Gilmour et al. 2007a), where the porewater sulfide concentrations are moderate (5–150 μg/L)

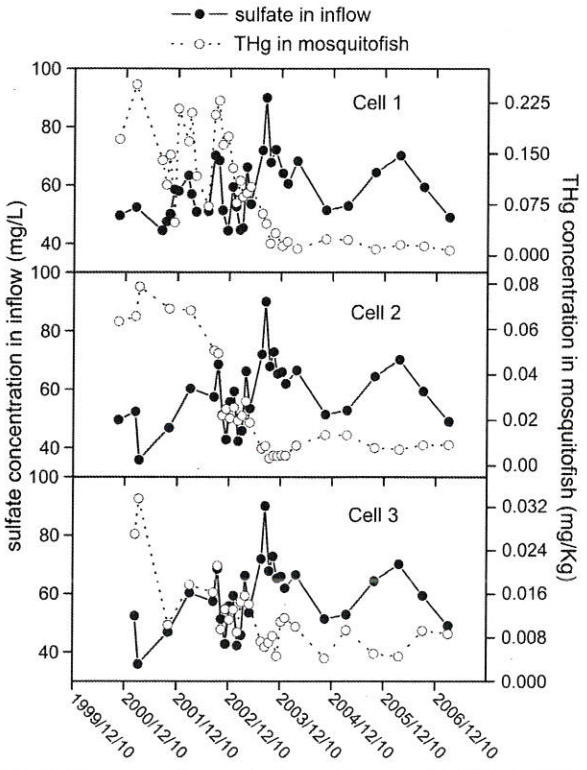

Fig. 4 The temporal concentrations of mosquitofish THg in Cells 1, 2, and 3 along with sulfate concentration in the inflow at STA-2 from 2000 to 2007. *THg* total mercury

(Gilmour et al. 1998; Orem et al. 2011). Several researchers have proposed the sulfate level in surface water to reduce the formation of MeHg in the ecosystem as much as possible. Corrales et al. (2011) recommended 1 mg/L as a sulfate threshold to control the MeHg formation in the Everglades and emphasized that above this level, particularly above 2 mg/L, the ecological risk to the ecosystem increases because at intermediate levels of sulfate, the Hg methylation is optimized. Jeremiason et al. (2006) also demonstrated that sulfate concentrations below 1 mg/L would not favor the Hg methylation process, eventually helping to depress the MeHg levels within the ecosystem as well. Likewise, Orem (2007) stated that a desirable goal for sulfate concentration in the Everglades would be approaching the background level (≤1 mg/L).

Inflow IHg was positively, significantly correlated with the mosquitofish THg in Cells 1 and 2, but not in Cell 3 (Fig. 7), and explained 48 and 51.3 % of the mosquitofish THg variations in Cells 1 and 2, respectively (Table 2). Fink (2002) reported that MeHg is likely to be synthesized primarily from the new IHg being supplied by runoff and wet and dry atmospheric deposition, not from soil release, even following a dryout event. Gilmour et al. (2004a) found that the

increase in MeHg in surface sediments and in fish shows a linear response to the Hg addition and suggested that the newly deposited Hg is much more available for methylation and bioaccumulation than is existing Hg in surface soils. In this study, the good correlations between inflow IHg and mosquitofish THg in Cells 1 and 2 are consistent with the findings of Fink (2002) and Gilmour et al. (2004a), indicating that the newly supplied IHg from inflow for STA-2 was the Hg source for the methylation. No significant correlation between inflow IHg and mosquitofish THg in Cell 3 demonstrates that together, too high sulfate concentration in inflow and no dryout occurrence made the capability of Hg methylation limited in Cell 3, which caused that the Hg methylation in Cell 3 likely could not respond well to the change in inflow IHg loading.

Inflow chloride was positively, significantly correlated with the mosquitofish THg in Cells 1 and 2, but not in Cell 3, and accounted for 44.2 and 51.1 % of the mosquitofish THg variations in Cells 1 and 2, respectively (Table 2). The influence of chloride on the Hg methylation is likely contributable to the competition of chloride for binding Hg, forming chloride-mercury complexes, which endow negatively charged forms (e.g., $HgCl_3^-$, $HgCl_4^{2-}$). Comparatively, the neutral form ($HgCl_2$) is more bioavailable for microbes than negatively charged forms, because its uptake by microbes is likely a passive diffusion process (Barkay et al. 1997; Ullrich et al. 2001). Barkay et al. (1997) reported that when chloride concentrations were above 1 mM, a decreased bioavailability of Hg(II) to the bioindicator was attributed to an increased proportion of negatively charged chlorine-mercury complexes. Hence, the inversely correlated relationships between inflow chloride and the mosquitofish THg in Cells 1 and 2 indicate that the concentration of chloride in inflow favored the formation of negatively charged chlorine-mercury complexes. No significant correlation between inflow chloride and mosquitofish THg in Cell 3 again suggests that the limited capability of Hg methylation in Cell 3 likely could not respond well to the change in inflow chloride loading.

No correlation was found between inflow pH and mosquitofish THg in Cells 1 and 2, but inflow pH

positively, significantly affected the mosquitofish THg in Cell 3, and accounted for 47.8 % of the variations in mosquitofish THg concentration in Cell 3 (Table 2). Generally, the Hg methylation in acidic environment is prone to be enhanced in comparison with alkaline surrounding, and elevated Hg levels in fish are commonly found in acidified lakes (Gilmour and Henry 1991; Ullrich et al. 2001). It is uncertain whether the stimulation of methylation in lake water is a direct effect of low pH on the methylation process, or whether it is related to other factors that are influenced by pH, such as the loss of volatile Hg species from water surfaces, or changes in Hg solubility and partitioning (Ullrich et al. 2001). The positive effect of inflow pH on the mosquitofish THg in Cell 3 was unexpected to occur, which maybe attributable to the unclear effect of pH on Hg methylation. In the present study, the inflow water condition was slightly alkaline, the pH value in inflow was chiefly within the scope of 7 and 8; therefore, insignificant correlation between inflow pH and the mosquitofish THg in Cells 1 and 2 may indicate that the range of inflow pH was possibly too narrow either to influence the availability of Hg to the methylating microorganisms or to impose any effect on the microbial community.

Both inflow DOC and temperature showed insignificant correlation on the mosquitofish THg in all the three cells (Table 2). The effect of DOC on the Hg methylation is complicated. DOC can both decrease and enhance the bioavailability of Hg for microbes (Gorski 2004). The Hg bioavailability can be reduced by DOC, enhancing photochemical reduction of Hg(II) to Hg^0 (Ravichandran 2004), and can be enhanced by the mixed complexes that contain both DOC and reduced sulfur groups (DOC-Hg-SH) (Hsu-Kim et al. 2005; Miller et al. 2007). DOC also can act as energy source for microbial activity to stimulate the Hg methylation (Ullrich et al. 2001). In the areas of Florida Everglades, DOC concentration is quite high in the Everglades marshes due to the high natural production of organic carbon in the peat soils and wetlands (Liu et al. 2008; Aiken et al. 2011), and DOC has been found to be strongly correlated to THg and MeHg in this region (Liu et al. 2008). However, in the present study, inflow DOC displayed no effect on the Hg methylation in all the three cells of STA-2, suggesting that the effect of inflow DOC on the Hg methylation in STA-2 was likely hard to explain because of DOC bearing the complicated property on the Hg methylation. Moderately high temperatures have been found a stimulating effect on the Hg methylation, which is most likely for the sake of the enhanced microbial activity by the increase in temperature (Bodaly et al. 1993; Ullrich et al. 2001), but in this study, no correlated relationship between inflow temperature and mosquitofish THg was observed in Pearson correlation analysis. Inflow temperature mainly ranged from 20 to 30 °C, kept relatively high and almost stable, so the narrow seasonal change in water temperature may be difficult to impact on the microbial activity noticeably.

The results indicate that inflow sulfate, IHg, and chloride were critical inflow water quality parameters influencing MeHg production in STA-2. Some studies also have evidenced the correlation between MeHg production and surface water quality. MeHg production in a temperate lake is found to be related to the Hg(II), sulfate, and DOC input to the lake (Watras and Morrison 2008).

4 Conclusion

Results from this study indicate that the drying and rewetting cycles in Cells 1 and 2 promoted the Hg methylation in STA-2, leading to the MeHg production greater than in Cell 3 and inflow, where no drying occurred. Pearson correlation results demonstrate that inflow sulfate, IHg, and chloride showed significantly correlated relationships with mosquitofish THg in cells, suggesting that these inflow variables played important roles on the Hg methylation in the cells of STA-2. The significant correlations between inflow sulfate and mosquitofish THg in all the three cells suggest that SRB were likely stimulated by the sulfate input to STA-2 and subsequently produced MeHg. And what is more, the negative impacts of inflow sulfate on the Hg methylation in all the three cells indicate that inflow sulfate concentration was much greater than the optimal concentration for the Hg methylation. Our findings in this study indicate that preventing the occurrence of dryout from wetlands will help to abate the Hg methylation, and sulfate input to wetlands is a key factor to affect the Hg methylation.

Can mercury in fish be reduced by water level management? Evaluating the effects of water level fluctuation on mercury accumulation in yellow perch (*Perca flavescens*)

Abstract Mercury (Hg) contamination of fisheries is a major concern for resource managers of many temperate lakes. Anthropogenic Hg contamination is largely derived from atmospheric deposition within a lake's watershed, but its incorporation into the food web is facilitated by bacterial activity in sediments. Temporal variation in Hg content of fish (young-of-year yellow perch) in the regulated lakes of the Rainy–Namakan complex (on the border of the United States and Canada) has been linked to water level (WL) fluctuations, presumably through variation in sediment inundation. As a result, Hg contamination of fish has been linked to international regulations of WL fluctuation. Here we assess the relationship between WL fluctuations and fish Hg content using a 10-year dataset covering six lakes. Within-year WL rise did not appear in strongly supported models of fish Hg, but year-to-year variation in maximum water levels (ΔmaxWL) was positively associated with fish Hg content. This WL effect varied in magnitude among lakes: In Crane Lake, a 1 m increase in ΔmaxWL from the previous year was associated with a 108 ng increase in fish Hg content (per gram wet weight), while the same WL change in Kabetogama was associated with only a 5 ng increase in fish Hg content. In half the lakes sampled here, effect sizes could not be distinguished from zero. Given the persistent and wide-ranging extent of Hg contamination and the large number of regulated waterways, future research is needed to identify the conditions in which WL fluctuations influence fish Hg content.

Introduction

Anthropogenic methylmercury (MeHg) contamination of recreational and commercial fisheries is an on-going concern in many temperate lakes of eastern North America due to impacts on both human and wildlife health (Wiener et al. 2003; Driscoll et al. 2007, 2013). The source of this MeHg is primarily derived from atmospheric deposition of material volatilized by anthropogenic activities (e.g., coal burning power plants; Driscoll et al. 2007). Mercury (Hg) is incorporated into aquatic food webs after inorganic Hg delivered via atmospheric deposition to a watershed or directly to a lake is converted into MeHg by bacteria (Benoit et al. 2003), and so relationships between simple atmospheric deposition of Hg and Hg accumulation in fish are often complex (Munthe et al. 2007; Harris et al. 2007). Much of this methylation is done by sulfate-reducing bacteria (SRB; Benoit et al. 2003), and thus among-system variation in the supply of Hg to SRB and the spatial distribution of favorable habitats for SRB may lead to spatial variation in the availability of MeHg to food webs (Wiener et al. 2006).

Favorable conditions for SRB include anoxic, carbon-rich sediments (Benoit et al. 2003) such as those commonly occurring in wetlands (Bodaly et al. 1984; Kelly et al. 1997), or in areas that have been recently inundated (Gilmour et al.

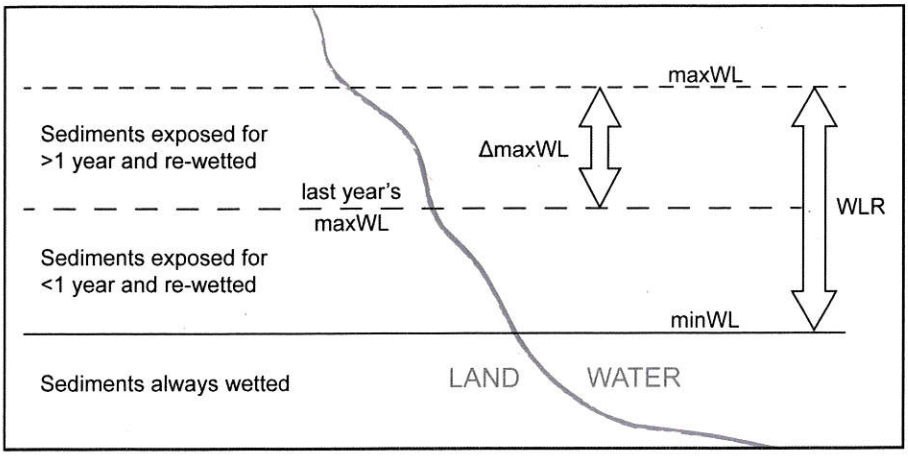

Fig. 1 Conceptual figure of hypothetical sediment classes created by WL fluctuations. Production of MeHg by SRB is hypothesized to be greatest (per unit area) in sediments that have been exposed for more than 1 year, because those sediments have accumulated relatively large quantities of sulfate and organic matter. *maxWL* maximum water level elevation, *minWL* minimum water level, *WLR* water level rise, *ΔmaxWL* change in maximum water level from last year to this year

2004). Studies have generally shown that a combination of water quality parameters associated with the supply of nutrients to SRB (e.g., sulfate concentrations) and the abundance of wetlands (which provide anoxic, carbon-rich sediments) explains much of the considerable spatial variation in fish Hg levels (Wiener et al. 2006). Many areas otherwise considered pristine (i.e., aquatic habitats draining relatively undisturbed watersheds) have high levels of Hg in their food webs because abundant wetlands provide ideal conditions for methylation (Driscoll et al. 2007).

Sorensen et al. (2005) highlighted a link between water level (WL) fluctuations and the MeHg concentrations in young-of-year (YOY) yellow perch (*Perca flavescens*) in Voyageurs National Park (VNP) and surrounding lakes, an area considered relatively pristine. Previous work has established the effect of reservoir establishment (i.e., permanent inundation) on MeHg fluxes into the food web (Bodaly et al. 1984; Kelly et al. 1997), but Sorensen et al. (2005) suggested sediments that have been exposed for months or years and are then re-wetted are a significant source of Hg inputs to the food web (Snodgrass et al. 2000; Selch et al. 2007). The drying and re-wetting of these sediments is controlled by variation in WLs, and Sorensen et al. (2005) found WL fluctuation to have a linear, positive relationship with temporal change in fish Hg content (which is mostly in the form of MeHg; Sandheinrich and Wiener 2011). Indeed, other predictors that are often found to be related to spatial variation in fish Hg were not good predictors of temporal variation in fish Hg after WL fluctuations were taken into account (e.g., total organic carbon content, pH, and Secchi depth). This finding is particularly relevant because WLs in many lakes and reservoirs can be manipulated, and thus might offer a potential management tool for reducing Hg contamination in fish.

Annual WL fluctuations create three sediment classes: sediments that are permanently inundated, sediments that are dried and re-wetted on an annual basis and sediments that are dry for more than 1 year before re-wetting (Fig. 1). These sediment classes likely differ in their production of MeHg due to differences in the delivery and accumulation of sulfur and organic carbon that affect SRB (Driscoll et al. 2013). Exposed sediments receive atmospheric deposition of sulfate and accumulate organic carbon (e.g., via plant growth; Sorensen et al. 2005), both necessary for SRB activity. Sediments exposed for longer time periods (>1 year) may be particularly important, as they not only accumulate more sulfate, but also accumulate organic carbon throughout the growing season. Based on this conceptual understanding, we predicted that either the within-year water level rise (WLR) or the change in maximum water level (ΔmaxWL) from 1 year to the next were likely to be correlated to annual MeHg production and thus annual variation in YOY yellow perch Hg content.

As is the case with many other north temperate lakes, Hg accumulation in fish is a major management issue for the U.S. National Park Service in lakes at VNP (Kallemeyn et al. 2003). WLs in Rainy Lake and the Namakan Reservoir complex (Namakan, Kabetogama, Sand Point, Crane, and Little Vermilion lakes) are actively managed via dams at the outlet of the Namakan Reservoir complex and Rainy Lake (Fig. 2) for hydroelectric power generation (at the outlet of Rainy Lake) and other recognized uses (Kallemeyn et al. 2003). WL management in this system is directed by the International Joint Commission (IJC), a regulatory body comprised of representatives from the United States and Canada.

For the purpose of hydroelectric power generation, WLs in the Namakan complex and Rainy Lake are manipulated

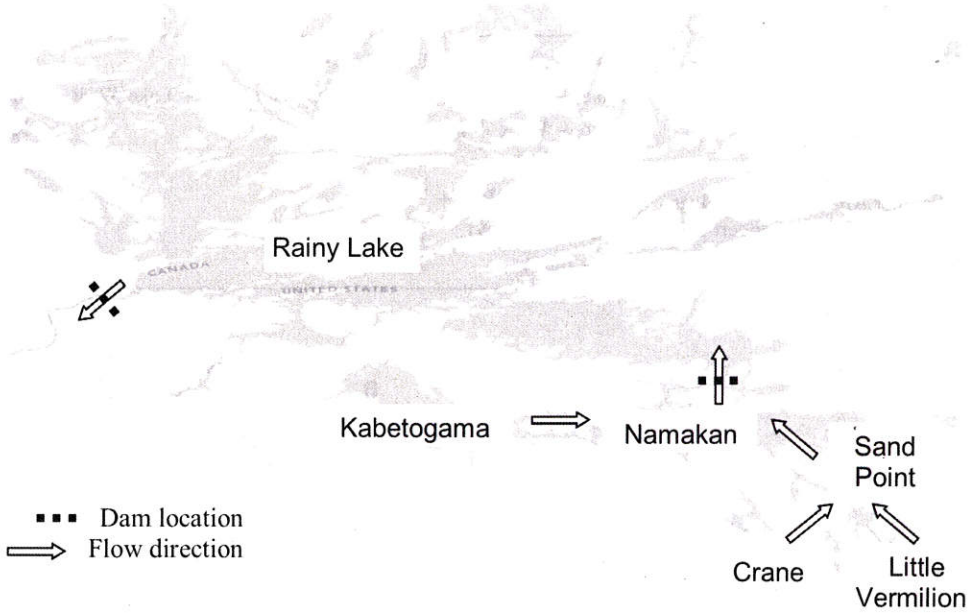

Fig. 2 Hydrologic connections and impoundments in the Rainy Lake–Namakan Reservoir complex on the border between the United States and Canada

so that WL fluctuations in Rainy Lake are reduced. This requires overwinter drawdowns of the Namakan Reservoir and a refilling of the reservoir system to capacity over the spring and summer. The IJC establishes 'rule curves' that prescribe a season-specific range of water elevation values. Dam operators then attempt to keep the water elevation within that range of values, although floods and droughts occasionally limit their success. In 2000, the IJC modified the 'rule curves' governing the range of WLs in these lakes, with the primary change being increased WLs in early spring in the Namakan Reservoir. This increase in minimum WLs also has the effect of reducing the annual WL rise, as ΔmaxWL were not significantly altered. Similar management practices occur in regulated water bodies throughout the developed world for a variety of purposes (e.g., power generation, agriculture, navigation, and waterfowl production).

The primary purpose of this study was to estimate the effects of annual WL variation on fish Hg content in regulated lakes. If the effects of WL fluctuations are evident, then the IJC's rule curves have the potential to influence Hg contamination of aquatic food webs in this reservoir system. The study by Sorensen et al. (2005) is the only analysis to document a strong relationship between annual WL fluctuations and fish Hg content. However, the Sorensen et al. (2005) study was limited to just 3 years in most lakes. Our study builds on the work of Sorensen et al. (2005) by including additional years (for a total of 10 years) on six of those lakes to evaluate whether annual WL fluctuations are related to fish Hg content.

Methods

Sample collection and analysis

Six lakes from the Rainy–Namakan complex, a subset of the lakes sampled by Sorensen et al. (2005), were sampled between 2004 and 2010 (Table 1). Fish were collected between mid-September and mid-October each year. Methods for sampling, aging and determining Hg in YOY yellow perch were the same as those reported in Sorensen et al. (2005) except that fish (between 5 and 20 per lake per year) were collected from only one site per lake. Sorensen et al. (2005) concluded that different sites within the same lake varied in the magnitude of fish Hg content, but the direction and magnitude of year-to-year variation was very similar among sites within a single lake. We incorporated the 2001–2003 data from Sorensen for the six sites we sampled for this study (site locations in S1).

Briefly, fish were collected with 15.2 or 30.5 m bag seines with 6.4 mm mesh (bar). Size thresholds for identifying YOY yellow perch were developed previously (see Appendix F1 from Sorensen et al. 2005) and those lake-specific thresholds were applied in the current dataset as well (see S1 for size thresholds).

WL metrics calculated here were similar to those used in Sorensen et al. (2005). Within-year minimum WL and maximum WL were used to calculate WLR. In addition, change in maximum WL from the previous year was calculated (ΔmaxWL). All WL data were obtained from the Lake of the Woods Water Control Board. WLs in the Rainy–Namakan lake complex follow a seasonal pattern,

Table 1 Results of model selection procedure relating WL parameters and Hg content in yellow perch

Model	−2 log likelihood	AIC[a]	ΔAIC[a]
Lake + ΔmaxWL + Lake[a]ΔmaxWL	5,908.5	5,948.5	0
Lake + ΔmaxWL + WLR + Lake[a]ΔmaxWL + Lake[a]WLR	5,904.5	5,956.5	8
Lake + WLR + Lake[a]WLR	5,920.8	5,960.8	12.3
Lake + WLR	5,938.3	5,968.3	19.8
Lake + ΔmaxWL + WLR	5,936.7	5,968.7	20.2
Lake + ΔmaxWL	5,938.7	5,968.7	20.2
Lake (*null*)	5,945.8	5,973.8	25.7

[a] Smaller AIC and ΔAIC values denote greater data support for the model in question relative to the other models

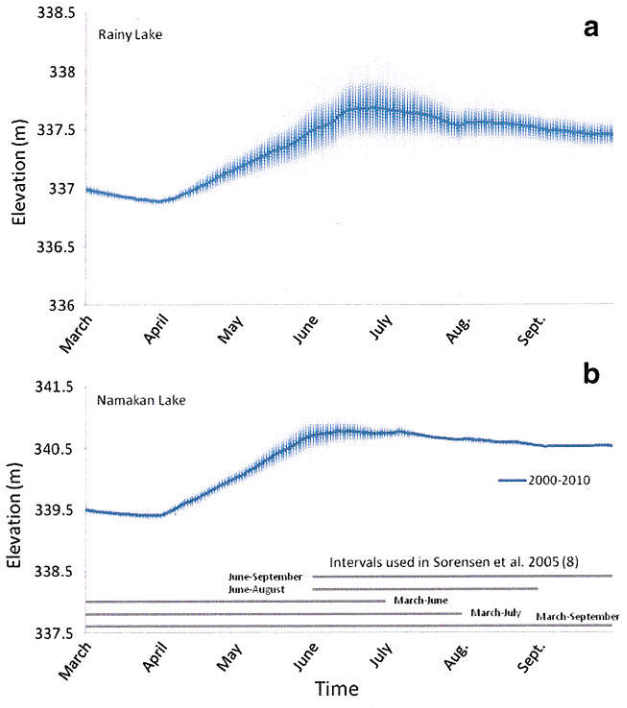

Fig. 3 Daily mean WLs (±SD) from 2000 to 2010 in **a** Rainy Lake and **b** Namakan Lake. At the bottom of **b** are visual depictions of the different intervals used in Sorensen et al. (2005) to evaluate the effect of WL fluctuations

with early-spring minimums and early to mid-summer maximums from 2000 to 2010 (Fig. 3). Sorensen et al. (2005) considered WL fluctuations over several within-year time intervals (Fig. 3). Here, we used WLR over the entire year (January–December), which turns out to be equivalent to WLR in the March–July interval used most often by Sorensen et al. (2005).

Fish Hg analysis

Methods for measuring whole-fish Hg content were identical to those used in Sorensen et al. (2005). Briefly, fish wet weight (WW) and total length are measured, then fish are dried for 24 h at 70 °C and weighed again to estimate moisture content. Length measurements were made using a ruler with 1 mm demarcations (estimates were to the nearest 0.5 mm). Weights were measured using a balance accurate to 0.1 mg. Dried fish were then shredded and ground with mortar and pestle and stored (frozen) until analysis could be completed. Total Hg was measured using USEPA method 245.6 (EPA 1991), as MeHg is generally >90 % of total Hg in fish (Sandheinrich and Wiener 2011). The detection limit for this method was ~3 ng g^{-1} WW^{-1}. Spike recovery was approximately 99 ± 4 % (SD; based on 25 spikes from 2004 to 2010 sampling efforts). Two reference standards were used: NRC Dorm2 (14 runs; recovery ranged between 98 and 105 %) and Mussel NIST 2976 (14 runs; recovery ranged between 96 and 114 %). Other details are described in Sorensen et al. (2005) for samples taken from 2001 to 2003 and reports from the analytical laboratory are available upon request.

Secchi depth, pH and chlorophyll

Secchi depth was collected at each site using methods described in Sorensen et al. (2005). Because field data sheets for 2005 have (apparently) been lost, those Secchi data were treated as missing. No pH was recorded at the time of fish sampling for years 2004–2010, so surface-water pH from mid-lake limnological sampling from 2001 to 2010 was used (US National Park Service, unpublished data). Chlorophyll concentration was also measured at a subset of these mid-lake sites as well. Chlorophyll concentrations were averaged across all sampling dates to give an index of the summer-long average. Mid-lake limnological sampling occurred monthly or bi-weekly (depending on the lake) during the growing season.

Atmospheric deposition of Hg and sulfate

Hg and sulfate deposition were measured by the National Atmospheric Deposition Program. For Hg, annual data from the Fernberg monitoring location (MN18) were obtained from their website (NADP 2012a). For sulfate, annual data from the Sullivan Bay monitoring location (MN32) were collected from their website (NADP 2012b).

Temperature data

Water temperature data are only available from mid-lake locations in these lakes and not available each year in each lake. Vertical water temperatures were taken either monthly or bi-weekly (depending on the lake). Each vertical water temperature profile was averaged, and then all of the measurements taken from May to October were averaged for an estimate of summer-long average water temperature (US National Park Service, unpublished data; water temperature profiles include in S1).

Statistical analysis

YOY yellow perch mean Hg concentration was modeled as a function of lake, year and WL using measurements of individual fish with linear mixed models. In the base model, lake effects were treated as fixed while year and lake × year effects were treated as random (variation at the observation scale occurred by lake). This was compared with models that elaborated the base model by inclusion of WLR, ΔmaxWL and their interactions with lake. We considered the base model to be an appropriate null model for comparisons to models that included WL associations. Data support for the selected models was evaluated using Aikaike's information criterion (AIC; Burnham and Anderson 1998). Smaller AIC values indicate relatively greater data support for given models; the difference between a particular model and the best model is used to rank the models (ΔAIC). Small ΔAIC values (≤2) denote strong support (relative to other models) by the data while ΔAIC values greater than ten indicate essentially no such support (Burnham and Anderson 1998). Models were fitted using maximum likelihood, and SAS's linear mixed modeling procedure (Proc Mixed; SAS 2011).

Associations between ancillary data (water quality, water temperature, Chl *a*, and atmospheric deposition) and YOY perch Hg content were not evaluated in this model selection framework due to the poor data-to-variable ratio and numerous gaps in the ancillary data. Instead a graphical approach was used that allows qualitative evaluation of the effects of ancillary data. Simply put, residuals from the base (null) model and the best model (as selected by AIC) were plotted against ancillary variables.

We estimated associations between fish length and total Hg content using Pearson's correlation statistic (both within individual lakes and among all lakes). The correlation statistic and other descriptive statistics were calculated using R (the "cor()" function). Other descriptive statistics (means, etc.) were also calculated using R. For the purpose of display, annual means were calculated for each lake-year combination: these were strongly correlated to the median (Pearson's $r = 0.997$).

Results

The Hg content of YOY perch collected during the study period varied considerably both among lakes and years (Fig. 4; S1). This variation was most strongly related to a model that included a lake-specific ΔmaxWL association with fish Hg content (Table 1; S1). Other models were only weakly supported (ΔAIC ≥ 8; Table 1). In the best model, the slope of the association between ΔmaxWL and fish Hg content varies by lake (Fig. 5; S1). Although that slope was always positive, the magnitude of the slope varied among lakes and 95 % confidence intervals overlapped zero in half the lakes sampled (Kabetogama, Little Vermilion, and Rainy; Fig. 5). In Sand Point, for example, the linear relationship between ΔmaxWL and fish Hg content had a slope of ~100 (Fig. 5f). This means that in Sand Point an increase in ΔmaxWL of 0.5 m from the previous year was associated with an increase of ~50 ng Hg g^{-1} WW^{-1} (a 50 % increase over the mean Hg content for this lake). The same increase in ΔmaxWL in Kabetogama (where the slope was ~5, Fig. 5b) would have lead to an increase of just ~2.5 ng Hg g^{-1} WW^{-1} (a 6 % increase over the mean Hg content for this lake). Overall, estimates of the magnitude (slope) of the association between ΔmaxWL and fish Hg content were greater than zero in Crane, Namakan and Sand Point lakes (Fig. 5).

YOY yellow perch growth did not appear to be strongly correlated with fish Hg content in our dataset (Pearson's $r < 0.4$ between fish length and fish Hg content) and graphical analysis suggested pH, Secchi depth, chlorophyll concentration, and summer-long average water temperature were not strongly related to model residuals. Visual inspections comparing atmospheric deposition of Hg and sulfate to residuals of the best model or the base model do not suggest these parameters are likely to explain a large portion of the annual variation in fish Hg content (see S2–S13).

Discussion

These results make a subtle but important contribution to our understanding of the relationship between WL fluctuations and fish Hg content. Although the strongest model did include WL fluctuations as a predictor variable, that model also found that WL associations with Hg were limited to a subset of the sampled lakes. Earlier analysis was not able to compare the magnitude of WL associations among lakes (Sorensen et al. 2005), but the current analysis shows that WL associations occur in only a subset of lakes.

Variation in YOY perch Hg content was associated with the year-to-year change in maximum WL, presumably because of variation in the re-wetting of sediments exposed by low WLs. Variation among lakes in WL effects could be

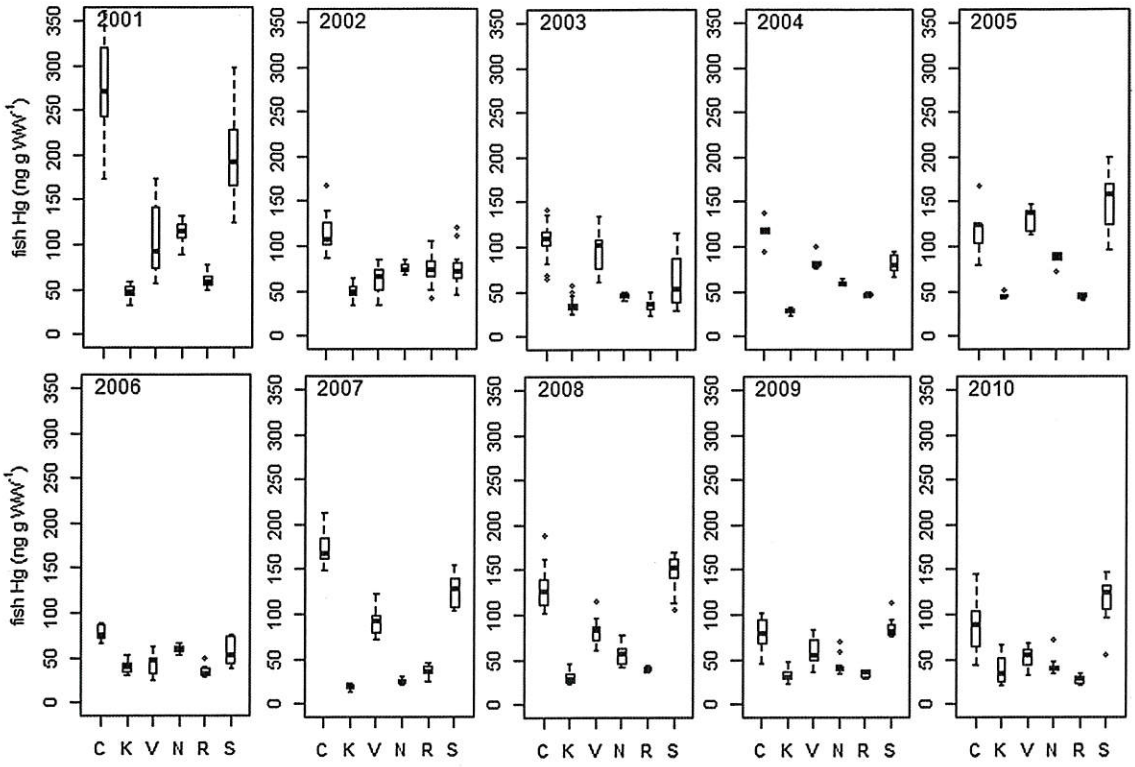

Fig. 4 *Box and whisker plots* showing median Hg content of YOY perch in lakes of the Rainy–Namakan complex from 2001 to 2010. *Boxes* encompass the first and third quartile. The *lines* (*whiskers*) show the largest or smallest observation that falls within 1.5 times the box size. Observations that fall outside the lines are shown individually. *C* Crane, *K* Kabetogama, *V* Little Vermilion, *N* Namakan, *R* Rainy, *S* Sand Point

caused by differences in shoreline characteristics of these lakes. The relationship between WL and the areal extent of exposed sediments is probably not linear in many locations. Locations or lakes with shallow nearshore bathymetries would seem more likely to be strongly influenced by WL fluctuations simply because more sediments are exposed per unit of WL decline. Detailed bathymetry of areas with <1.5 m of depth (areas most likely to be affected) are lacking for the lakes sampled here, but variation in littoral area (defined as area with <4.6 m) of these lakes does not correspond directly to variation in WL effects on fish Hg content. For example, Sand Point and Kabetogama have a similar proportion of littoral areas (Table 2) and very different associations between fish Hg content and WL fluctuations (Fig. 5). Whether "littoral" areas and the area of exposed sediments are directly correlated is unknown. Future efforts to evaluate the effects of WL in these lakes should focus on determining the areal extent of sediments exposed or inundated by WL fluctuations and characterization of those sediments.

Many other lake characteristics influence fish Hg content. The two lakes with large WL effects (Sand Point and Crane) are also the lakes with the highest mean fish Hg content (and highest among-year variability), so perhaps other conditions for high fish Hg content are necessary to detect significant WL effects. Watershed characteristics (Wiener et al. 2006), sediment characteristics (Verta et al. 1986; Bodaly et al. 2004; Gilmour et al. 2004), productivity and fish growth (Essington and Houser 2003) are all known to influence fish Hg content and vary among the lakes sampled here. Watershed and sediment characteristics probably do not change rapidly enough to drive the interannual variation under investigation here (and these data are rarely available on a yearly timescale). Fish growth and productivity certainly do vary among the lakes. For example, Kabetogama is two to three times as productive as the other large lakes in VNP (Kallemeyn et al. 2003). However, we did not observe obvious connections between Hg content and fish length in this study, and model residuals were not well correlated to a surrogate for productivity (Chl *a*). Still, these factors might influence the degree to which MeHg production in sediments contribute to MeHg in the food web, and therefore the magnitude of the WL effect on fish Hg content. Identifying the factors that control the magnitude of WL effects on fish Hg content should be the focus of future research in this area.

Each lake in this study was characterized by a single site (per results in Sorensen et al. 2005). Given our results (i.e., among-lake variation in WL effects), it may be worthwhile

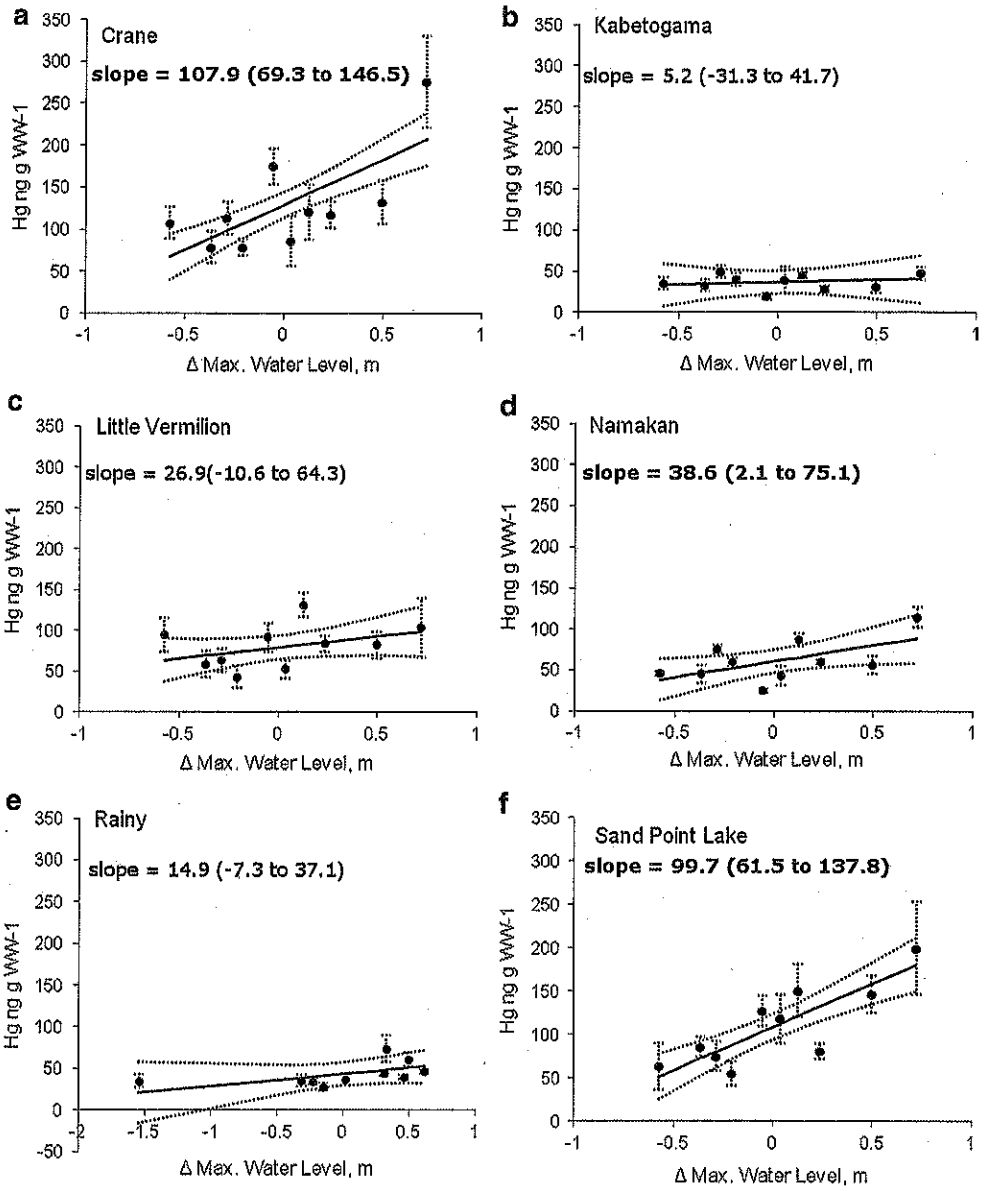

Fig. 5 Annual average Hg content of YOY perch (Hg ng g^{-1} WW^{-1}) as a function of change in ΔmaxWL in lakes of the Namakan–Rainy complex. Data includes samples from 2001 to 2010. *Error bars* denote standard deviation. *Lines* are derived from the best model relating Hg content in YOY perch to ΔmaxWL (see Table 2) with 95% confidence intervals. The slope of the relationship between ΔmaxWL and annual average Hg content of YOY perch (Hg ng g^{-1} WW^{-1}) is included on each figure with 95 % confidence interval. Intervals that do not overlap zero are highlighted in *bold*. Note altered axis scales for Rainy (e)

Table 2 Physical properties of lakes sampled for this study

Lake	Surface area[a] (ac)	Littoral area[a,b] (ac)	Maximum depth[a] (m)	Littoral:total area[a]	Average chlorophyll concentration (μg L^{-1})
Crane	2,920	618	24	0.21	3.21
Kabetogama	24,034	7,440	24	0.31	7.36
Little Vermilion	1,288	231	16	0.18	3.10
Namakan	24,066	5,026	46	0.21	2.10
Rainy	230,301	18,949	49	0.08	2.20
Sand Point	8,526	2,847	56	0.33	3.18

Average chlorophyll concentration was calculated from mid-lake limnological samples collected by the National Parks Service

to examine more carefully whether site-specific (as opposed to lake-wide) characteristics influence WL associations with fish Hg content. If spatial controls over variation in the associations between fish Hg content and WL were understood, then estimates of fish Hg content under different WL management strategies could be made both in the Rainy–Namakan complex and in other regulated systems.

Conclusion

WL management for the purpose of reducing Hg accumulation in YOY perch and by proxy the rest of the aquatic food web is an attractive concept (Mailman et al. 2006). Certainly, the flooding of reservoirs leads to increased Hg in fish and other aquatic biota, apparently due to large quantities of terrestrial Hg being rapidly incorporated into the aquatic food web (Bodaly et al. 2004; Driscoll et al. 2007). Reducing the overall area of flooded terrestrial soils has thus been considered a viable strategy to reduce fish Hg contamination (Mailman et al. 2006). Mechanistically this seems similar to the drying and re-wetting of shallow sediments (Snodgrass et al. 2000; Evers et al. 2007). However, large differences in the effects of flooding on fish Hg content exist even during the initial flooding of reservoirs (when effects would be strongest) due to differences in organic matter content and morphology (Bodaly et al. 2004; Evers et al. 2007). Drying shallow sediments for a few months or a few years does appear associated with fish Hg content in some systems (Verta et al. 1986; Snodgrass et al. 2000; three lakes in this study), but appears unimportant in others (three lakes studied here). The current data are insufficient to identify the conditions necessary for annual WL fluctuations to influence fish Hg content, and thus it is not yet possible to quantitatively estimate how much different WL management regimes might influence overall Hg contamination.

Acknowledgments Thanks to John Sorensen for comments on an earlier version of this manuscript and to Mark Brigham for assistance obtaining Hg and sulfate deposition data. Several anonymous reviewers provided constructive comments that improved the manuscript. Thanks to Robert Kratt for assistance with Fig. 1. Supporting Information

ABSTRACT: Mercury pollution is widespread globally, and strategies for managing mercury contamination in aquatic environments are necessary. We tested whether coagulation with metal-based salts could remove mercury from wetland surface waters and decrease mercury bioaccumulation in fish. In a complete randomized block design, we constructed nine experimental wetlands in California's Sacramento−San Joaquin Delta, stocked them with mosquitofish (*Gambusia affinis*), and then continuously applied agricultural drainage water that was either untreated (control), or treated with polyaluminum chloride or ferric sulfate coagulants. Total mercury and methylmercury concentrations in surface waters were decreased by 62% and 63% in polyaluminum chloride treated wetlands and 50% and 76% in ferric sulfate treated wetlands compared to control wetlands. Specifically, following coagulation, mercury was transferred from the filtered fraction of water into the particulate fraction of water which then settled within the wetland. Mosquitofish mercury concentrations were decreased by 35% in ferric sulfate treated wetlands compared to control wetlands. There was no reduction in mosquitofish mercury concentrations within the polyaluminum chloride treated wetlands, which may have been caused by production of bioavailable methylmercury within those wetlands. Coagulation may be an effective management strategy for reducing mercury contamination within wetlands, but further studies should explore potential effects on wetland ecosystems.

INTRODUCTION

Mercury contamination of aquatic ecosystems is globally extensive due to natural and anthropogenic mercury emissions and transport through the atmosphere.[1] At more localized scales, hydrologic transport of mercury from point sources, such as historic mining activity, can periodically redistribute mercury throughout a watershed and increase levels of local mercury contamination.[2] After deposition, inorganic mercury can be methylated by microbial activity into methylmercury, the form of mercury that biomagnifies through aquatic food chains and poses a health risk to wildlife and humans.[3] Aquatic environments, especially wetlands, often have biogeochemical conditions that are conducive to methylmercury production.[4−6] Thus, aquatic environments worldwide are an important nexus between inorganic mercury pollution and exposure to wildlife and humans.[1]

Regulatory policies to decrease mercury pollution and subsequent exposure to biota are ongoing at both local and global scales.[7] Although removing sources of mercury pollution would be beneficial, there would still be reservoirs of mercury in the environment that would result in secondary mercury emissions,[1] and legacy point sources that could persist for thousands of years.[2] Thus, strategies for managing local mercury contamination in susceptible aquatic environments are necessary, but there are few wetland-scale management techniques that are known to lower mercury contamination.

Several management strategies that might decrease mercury contamination include manipulating wetland habitat type and hydrology,[8,9] or treating surface waters with chemical amendments, absorbents, and coagulants.[10−13] In particular, it was recently shown that 97% of dissolved inorganic mercury and 80% of dissolved methylmercury could be removed from surface waters by applying metal-based salts to coagulate dissolved

organic matter.[11] The coagulants interact with dissolved organic matter and suspended particles by charge neutralization, adsorption, and sweep flocculation mechanisms, transferring the dissolved organic matter, and the mercury associated with it, into colloidal and particulate forms, which subsequently can be removed from solution by settling or filtration.[14,15] Coagulation also increases particle sizes resulting in higher settling velocities.[16] Although coagulants are widely used in water treatment applications to remove impurities,[15] they have rarely been examined for use in reducing mercury contamination. The results from the laboratory study by Henneberry et al.[11] were promising, but it remains unclear whether this mercury removal efficiency could be achieved in the field when scaled up to wetlands used as natural retention systems for the flocculants produced following coagulation. Hybrid coagulation wetland treatment systems have been used to enhance removal of other water quality constituents and shown greater efficiency than using wetland systems alone.[16]

We applied coagulants in the field, under environmentally relevant mercury contamination levels, and at a wetland-scale in a hybrid coagulation wetland treatment system. Specifically, we tested whether metal-based coagulants that were applied to agricultural drainage water, and then passed through a wetland to retain particles, could remove inorganic mercury and methylmercury from wetland surface waters and decrease mercury bioaccumulation in wetland fish. In a complete randomized block design with three replicates, we constructed nine experimental wetlands and continuously applied agricultural water that had been either untreated (control), or treated with polyaluminum chloride or ferric sulfate coagulants. At the inlets and outlets of each wetland, we measured total and methylmercury concentrations in both the particulate and filtered fractions of water. Additionally, we introduced western mosquitofish (*Gambusia affinis*) into each experimental wetland and, after 4 months of exposure, we captured mosquitofish near the inlet, center, and outlet of each wetland and assessed their mercury bioaccumulation. We also compared mercury concentrations in mosquitofish within the experimental wetlands to several reference sites which were under typical agricultural operations, including fields growing white rice (*Oryza sativa*) and both irrigation source and drainage water canals.

EXPERIMENTAL SECTION

Experimental Wetland Design and Treatments. We constructed nine experimental wetlands in 2008 at Twitchell Island within the California Sacramento−San Joaquin Delta. The wetlands revegetated naturally and were dominated by cattail (*Typha* spp.). Each wetland cell was approximately 40 m long (from inlet to outlet), 15 m wide, and 0.4 m deep. Water residence time averaged 3 days (range: 2−7 days). We applied three dosing treatments in a complete randomized block design, with three replicates per treatment (see map in Figure S1 of the Supporting Information). Three experimental wetland cells received water that was treated with polyaluminum chloride coagulant (Kemira Water Solutions Inc., Finland), three wetland cells received water treated with ferric sulfate coagulant (Kemira Water Solutions Inc., Finland), and three wetland cells received untreated water and were used as controls. Locations of treatments were randomized within each of three blocks that were spatially clustered from north to south to account for any spatial trends in soil biogeochemistry or hydrology (see Figure S1 of the Supporting Information). Table S1 of the Supporting Information provides ancillary water quality data by treatment.

Coagulants were injected into pipes that imported water from an irrigation canal, which acted as a common water source (see Figure S1 of the Supporting Information). The coagulation treatments were adjusted to achieve between 60% and 80% removal of dissolved organic carbon from the source water based upon the prior results of Henneberry et al.[11] The coagulant dosing rates were monitored continuously and adjusted as needed in response to any changes in source water quality (polyaluminum chloride dose ranged from 5 to 14 mg/L as aluminum and ferric sulfate dose ranged from 13 to 26 mg/L as iron). As such, the small, nonsignificant differences observed in mercury removal between coagulant treatments at the inlets (see the Results section) were likely due to small differences in coagulant dosing rates, rather than a treatment effect. Coagulation treatments were applied continuously starting on July 5, 2012, with the exception of a 3 week period in October 2012 when the coagulation system was off-line due to equipment failures. All treatments were fully operational for at least five continuous months before any mercury sampling occurred starting in March 2013.

Fish Stocking and Fish Collection. Before introducing mosquitofish, we sampled the experimental wetland cells for naturally occurring mosquitofish and confirmed that wild western mosquitofish (*Gambusia affinis*) were present within each cell. Mosquitofish abundance was relatively low, likely because the source water was pumped through a series of screened pipes and mixers and only larval fish could have entered these newly constructed wetlands. We therefore bolstered the fish population by adding western mosquitofish into each of the 9 experimental wetland cells on March 22, 2013, after the coagulation treatments were operational for 260 days. Approximately 2000 mosquitofish were obtained from the Sacramento−Yolo Mosquito and Vector Control District's aquaculture facility (Elk Grove, California, USA) and a few hundred mosquitofish were introduced into each of the 9 wetland cells.

Nearly 4 months later from July 2−19, 2013 (102−119 days after introduction of fish; 362−379 days after experimental wetland treatments became operational), we captured wild mosquitofish from each of the 9 wetland cells using dip nets and seines. We collected 10−16 mosquitofish at each of 3 subsites (inlet, center, and outlet) within each of the 9 wetland cells. Additionally, we collected wild mosquitofish at several reference sites: the experimental wetlands' source water canal, the experimental wetlands' outlet drainage canal, the main drainage canal for all of Twitchell Island, and at the inlets, centers, and outlets of 3 reference rice fields (see Figure S1 of the Supporting Information). We stored collected fish on ice in the field and in a refrigerator overnight until they could be processed in the lab the next day. During processing, we washed each fish in deionized water and then measured its wet weight (±0.001 g) and standard length (±1 mm). Each mosquitofish was individually bagged, labeled, and frozen at −20 °C until mercury determination.

Water Sample Collection and Processing. We collected water samples monthly at the inlet and outlet pipes of each of the 9 wetland cells from March through June when mosquitofish were exposed to the experimental wetland treatments. Water sampling dates were March 26, April 23, May 20, and June 25, 2013. We collected water samples in 2 L PETG Nalgene bottles using clean techniques and immediately stored them on wet ice for transport to the laboratory where they were processed within 24 h of collection. In the laboratory, we homogenized the water sample (by shaking the 2 L bottle vigorously) and immediately poured it into a clean, Teflon vacuum filtration apparatus loaded

DOI: 10.1021/acs.est.5b00655
Environ. Sci. Technol. 2015, 49, 6304−6311

with a 0.3 μm precombusted glass-fiber filter (Advantec MFS model GF-7547 mm; Advantec MFS, Dublin, California, USA). The volume of sample passed through each filter (at least two filters per sample) was recorded to the nearest mL. After filtration, we preserved the filtered water sample with ultraclean HCl (0.5% of sample volume) and stored it in the dark at room temperature until mercury determination within six months. For each water sample, we placed the two filters that were laden with sample particulates into Teflon Petri dishes and immediately froze them at −20 °C until mercury determination.

Total Mercury Determination in Fish. Methylmercury (MeHg) concentrations are highly correlated with total mercury (THg) concentrations in mosquitofish, with 94% of the THg composed of MeHg.[17] We therefore used THg concentrations as an index of MeHg concentrations. We determined THg concentrations in mosquitofish on a whole-body basis. THg concentrations were determined at the U.S. Geological Survey, Dixon Field Station Environmental Mercury Laboratory (Dixon, California) on a Milestone DMA-80 direct mercury analyzer (Milestone, Monroe, Connecticut, USA) or a Nippon MA-3000 direct mercury analyzer (Nippon Instruments North America, College Station, Texas, USA) following Environmental Protection Agency Method 7473,[18] using an integrated sequence of drying, thermal decomposition, catalytic conversion, and then amalgamation, followed by atomic absorption spectroscopy. Prior to THg analysis, each fish was dried at 50 °C for approximately 48 h until completely dried, and then homogenized to a fine powder with a porcelain mortar and pestle. See the Supporting Information for quality assurance measures.

Total and Methylmercury Determination in Water. We determined THg and MeHg concentrations in the filtered and particulate fractions of each water sample at the U.S. Geological Survey, Mercury Research Laboratory in Middleton, Wisconsin. THg concentrations in filtered water were determined according to U.S. Environmental Protection Agency Method 1631.[19] MeHg concentrations in filtered water were determined using standard distillation and ethylation procedures[20] followed by cold-vapor atomic fluorescence spectrometry. Particulate water samples were analyzed for THg and MeHg concentrations using the procedures described above; however, they required a preanalysis extraction step. Filters for THg were digested in Aqua Regia prior to analysis,[21] whereas filters for MeHg were extracted with methylene chloride prior to Hg determination.[22] We summed the Hg concentrations determined separately for the filtered and particulate water samples to calculate the Hg concentration of the whole water sample. See the Supporting Information for quality assurance measures.

Statistical Analysis of Fish. We compared THg concentrations in mosquitofish using linear mixed-effect models in three main analyses. First, we tested whether THg concentrations in mosquitofish differed among experimental wetland treatments. In this test, $\log_e$-transformed THg concentrations in mosquitofish was the dependent variable and block (1, 2, or 3), treatment (control, polyaluminum chloride, or ferric sulfate), and subsite (inlet, center, or outlet) were fixed factors, standard fish length was a covariate, and individual wetland cell was a random effect. Individual wetland cell was nested within treatment.

Second, we tested whether THg concentrations in mosquitofish differed between the experimental wetland treatments and the canal source and outlet waters. In this test, $\log_e$-transformed THg concentrations in mosquitofish was the dependent variable and habitat type (canal source, control wetlands, polyaluminum chloride treated wetlands, ferric sulfate treated wetlands, canal outlet, or Twitchell Island canal outlet) was a fixed factor, standard fish length was a covariate, and site (within each habitat type) was a random effect.

Third, we tested whether THg concentrations in mosquitofish differed between the three experimental control wetlands and the three reference rice fields. In this test, $\log_e$-transformed THg concentrations in mosquitofish was the dependent variable and habitat (experimental control wetland or rice field) and subsite (inlet, center, or outlet) were fixed factors, standard fish length was a covariate, habitat × subsite was an interaction term, and individual wetland cell was a random effect. We included the habitat × subsite interaction in this analysis because the distance (and water residence times) between the subsites were substantially greater in the rice fields than in the wetlands, and thus the differences between inlet, center, and outlet could be more substantial within rice fields as we have found elsewhere.[17]

We used the Satterthwaite method to estimate the degrees of freedom. We used Student's *t*-tests ($\alpha < 0.05$) to compare differences among groups within factors and interactions that were significant. Unless otherwise noted, we report model-based, least-squares mean ± standard error (SE) Hg concentrations based on back-transformed least-squares means ± SEs. SEs were approximated using the delta method.[23] Mean percent moisture in mosquitofish was 73.8% ($n = 508$), which can be used to convert reported dry weight (dw) concentrations into wet weight (ww) concentrations.

Statistical Analysis of Water. Similar to the fish analyses, we compared Hg concentrations in water using linear mixed-effect models. We used nine separate tests to examine whether Hg concentrations in water differed among experimental wetland treatments. The nine tests had the same model structure and differed only in the dependent variable that was tested. The dependent variables included the filtered (f) and particulate (p) forms of THg and MeHg (i.e., fTHg, pTHg, fMeHg, and pMeHg), the sum of the filtered and particulate forms of THg and MeHg (i.e., THg and MeHg), and the proportion of THg in the MeHg form for each of the filtered (fMeHg/fTHg), particulate (pMeHg/pTHg), and sum of the filtered and particulate forms (MeHg/THg). We $\log_e$-transformed Hg concentrations in water, except for the proportions which were normally distributed. Block (1, 2, or 3), treatment (control, polyaluminum chloride, or ferric sulfate), subsite (inflow or outflow), and month (March, April, May, or June) were fixed factors, treatment × subsite was an interaction term, and individual wetland cell was a random effect. Individual wetland cell was nested within treatment.

Similar to the fish analyses, we used the Satterthwaite method to estimate the degrees of freedom and Student's *t*-tests to compare differences among groups within factors and interactions that were significant in each of the nine water models and considered results statistically significant when $\alpha < 0.05$. We report least-squares mean ± SE THg and MeHg concentrations based on back-transformed least-squares means ± SEs when natural log transformations were employed. In these cases, SEs were approximated using the delta method.[23]

RESULTS

Mercury in Fish. We analyzed 508 wild mosquitofish for THg concentrations, of which 361 fish were collected within the 9 experimental wetland cells. THg concentrations in mosquitofish differed among experimental wetland treatments ($F_{2,4.02} = 9.05$, $p = 0.03$), while statistically accounting for the potential effects of block ($F_{2,4.03} = 2.83$, $p = 0.17$), subsite ($F_{2,349.30} = 0.46$, p

DOI: 10.1021/acs.est.5b00655
Environ. Sci. Technol. 2015, 49, 6304−6311

= 0.63), and fish length ($F_{1,352.40}$ = 26.97, p < 0.0001). THg concentrations in mosquitofish were significantly lower in the ferric sulfate treated wetlands (n = 128 fish; 0.13 ± 0.01 μg/g dw) than in either of the polyaluminum chloride treated wetlands (n = 118 fish; 0.21 ± 0.02 μg/g dw) or control wetlands (n = 115 fish; 0.20 ± 0.02 μg/g dw), but the polyaluminum chloride treated wetlands and control wetlands did not differ (Figure 1).

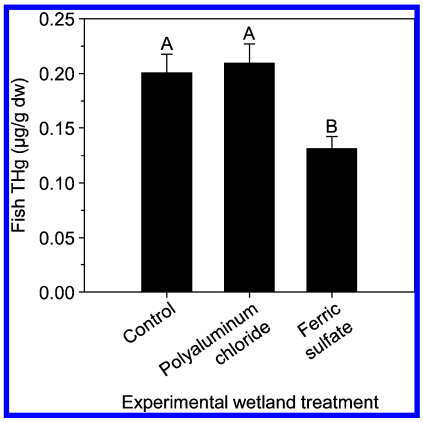

Figure 1. Total mercury concentrations (THg; least-squares means ± SE) in wild mosquitofish from experimental wetland cells that received water that was treated with either polyaluminum chloride coagulant, ferric sulfate coagulant, or untreated water (control) at Twitchell Island, California. Different letters above bars denote significant (p < 0.05) differences between means.

On average, mosquitofish THg concentrations were 35% lower in the ferric sulfate treated wetlands than in the control wetlands. At the time of fish introduction into the experimental wetland cells (4 months prior), THg concentrations in reference mosquitofish from the stock population were very low at 0.01 ± 0.01 μg/g dw (n = 15 reference fish).

In the next stage of our analyses, we compared THg concentrations in fish collected from the source and outlet water canals to those collected from within the experimental wetland cells. THg concentrations in mosquitofish differed among the canal and experimental wetland habitats ($F_{5,7.36}$ = 9.27, p = 0.01), while statistically accounting for the effect of fish length ($F_{1,382.00}$ = 31.80, p < 0.0001). THg concentrations in mosquitofish collected from the canal source water for the experimental wetlands (n = 10 fish; 0.07 ± 0.02 μg/g dw) were lower than in any other habitat type (Figure 2). THg concentrations in mosquitofish collected from the outflow canal for the experimental wetlands (n = 10 fish; 0.20 ± 0.04 μg/g dw) were no different than those in the polyaluminum chloride treated wetlands (n = 118 fish; 0.21 ± 0.02 μg/g dw), the control wetlands (n = 115 fish; 0.20 ± 0.02 μg/g dw), or the ferric sulfate treated wetlands (n = 128 fish; 0.13 ± 0.01 μg/g dw; Figure 2). THg concentrations in mosquitofish collected from the main drainage canal for Twitchell Island (n = 10 fish; 0.42 ± 0.09 μg/g dw) were higher than in any other habitat type (Figure 2).

In the last stage of our fish analyses, we compared THg concentrations in the experimental control wetlands to reference rice fields (Figure 3). THg concentrations in mosquitofish differed among wetland habitats ($F_{1,4.03}$ = 7.57, p = 0.05), subsites ($F_{2,221.00}$ = 4.35, p = 0.01), and fish length ($F_{1,221.10}$ = 4.25, p = 0.04); however, there was a significant habitat × subsite interaction ($F_{2,221.00}$ = 6.91, p = 0.001). THg concentrations in mosquitofish within rice fields (n = 117 fish; 0.47 ± 0.11 μg/g dw) were 139% higher, on average, than those within the

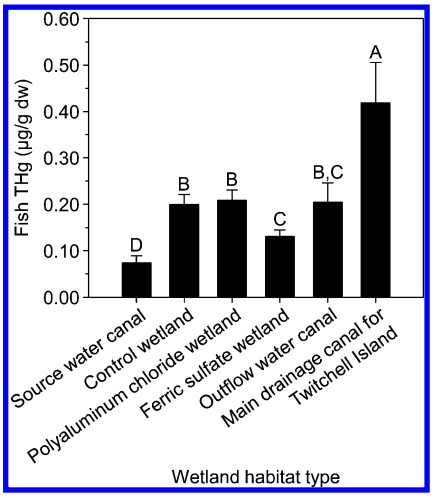

Figure 2. Total mercury concentrations (THg; least-squares means ± SE) in wild mosquitofish differed among the canal and experimental wetland (control, polyaluminum chloride coagulant, or ferric sulfate coagulant) habitat types at Twitchell Island, California. Different letters above bars denote significant (p < 0.05) differences between means.

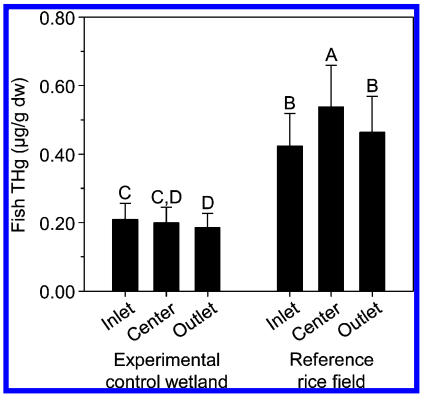

Figure 3. Total mercury concentrations (THg; least-squares means ± SE) in wild mosquitofish within experimental control wetlands and reference rice fields at inlets, centers, and outlets of each wetland type at Twitchell Island, California. Different letters above bars denote significant (p < 0.05) differences between means within each wetland habitat type.

experimental control wetlands (n = 115 fish; 0.20 ± 0.04 μg/g dw), and were consistently higher at each of the subsites (Figure 3). Pairwise comparisons indicated that THg concentrations in mosquitofish collected from the experimental control wetlands did not differ between inlets (n = 40 fish; 0.21 ± 0.05 μg/g dw) and centers (n = 40 fish; 0.20 ± 0.05 μg/g dw), and THg concentrations in mosquitofish at the outlets (n = 35 fish; 0.19 ± 0.04 μg/g dw) were barely lower than those at the inlets (Figure 3). In contrast, THg concentrations in mosquitofish increased in rice fields by 27% from the inlet (n = 39 fish; 0.42 ± 0.10 μg/g dw) to the center (n = 38 fish; 0.54 ± 0.12 μg/g dw), but THg concentrations in mosquitofish at the outlets (n = 40 fish; 0.46 ± 0.10 μg/g dw) were no different from the inlets (Figure 3).

Total and Methylmercury in Whole Water. We collected 72 water samples for Hg analysis. THg concentrations and MeHg concentrations in water differed among experimental wetland treatments (THg: $F_{2,3.30}$ = 32.73, p = 0.01; MeHg: $F_{2,3.82}$ = 8.51, p = 0.04) and months (THg: $F_{3,53.99}$ = 4.47, p = 0.01; MeHg: $F_{3,54}$ = 6.36, p = 0.001), and THg concentrations in water also differed among subsites (THg: $F_{1,53.38}$ = 81.80, p < 0.0001; MeHg: $F_{1,53.90}$

DOI: 10.1021/acs.est.5b00655
Environ. Sci. Technol. 2015, 49, 6304−6311

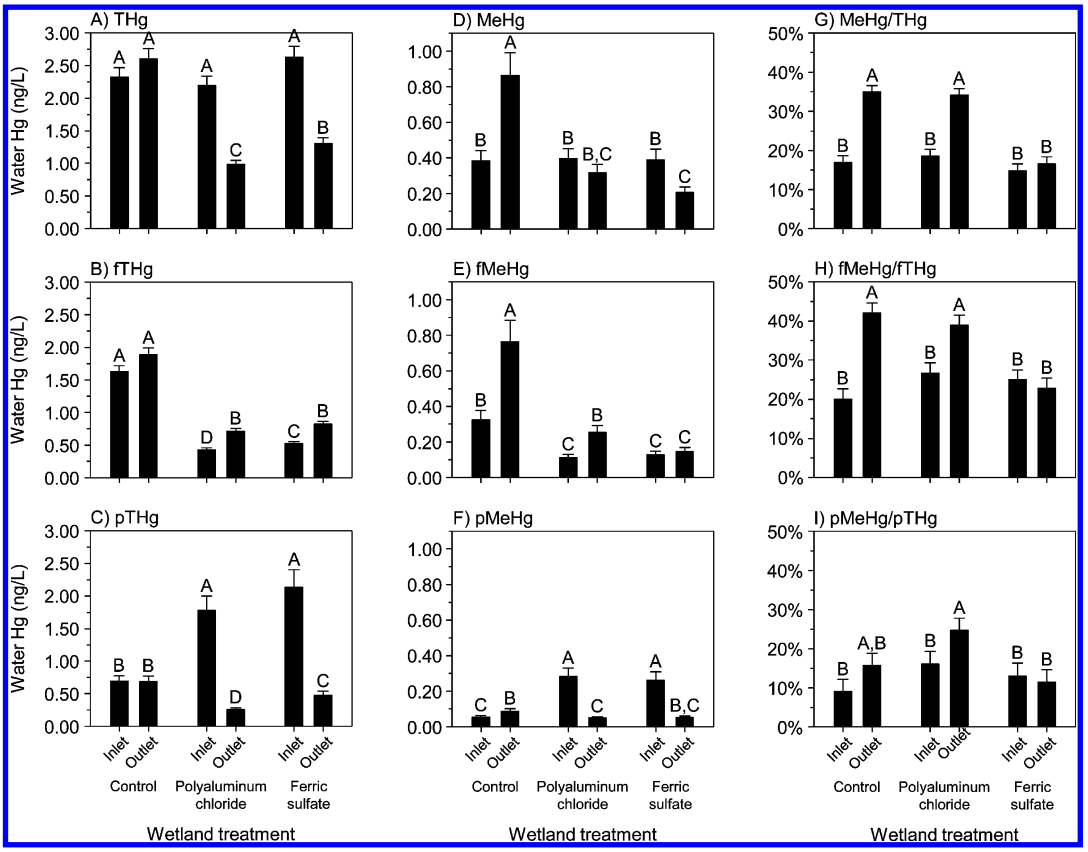

Figure 4. Least squares means ± SE total mercury concentrations (THg), methylmercury concentrations (MeHg), and the percentage of mercury in the methylmercury form (MeHg/THg × 100) in whole water, filtered (f) fraction of water, and particulate (p) fraction of water sampled from water entering (inlets) and exiting (outlets) wetlands treated with different experimental coagulants at Twitchell Island, California. Experimental wetland cells received water that was treated with either polyaluminum chloride coagulant, ferric sulfate coagulant, or untreated water (control). Different letters above bars denote significant ($p < 0.05$) differences between means.

= 0.03, $p = 0.87$), while accounting for block (THg: $F_{2,3.32} = 0.17$, $p = 0.85$; MeHg: $F_{2,3.82} = 0.67$, $p = 0.56$). However, there was a significant treatment × subsite interaction (THg: $F_{2,53.38} = 32.72$, $p < 0.0001$; MeHg: $F_{2,53.95} = 19.22$, $p < 0.0001$).

As expected, pairwise comparisons indicated that THg and MeHg concentrations in water did not differ among inlets of control, polyaluminum chloride, and ferric sulfate treated wetlands (Figure 4a,d). In contrast, at the outlets, THg and MeHg concentrations in water were significantly lower in the polyaluminum chloride (THg: 62% lower; MeHg: 63% lower) and ferric sulfate (THg: 50% lower; MeHg: 76% lower) treated wetlands compared to the control wetlands (Figure 4a,d).

Within wetlands, THg concentrations in water did not differ between inlets and outlets of control wetlands, but THg concentrations in water were 55% and 50% lower at the outlets than at the inlets in the polyaluminum chloride and ferric sulfate treated wetlands, respectively (Figure 4a). MeHg concentrations in water increased by 125% from the inlets to the outlets in the control wetlands, did not differ between inlets and outlets of the polyaluminum chloride treated wetlands, and decreased by 47% from the inlets to the outlets in the ferric sulfate treated wetlands (Figure 4d).

Filtered and Particulate Total Mercury in Water. THg concentrations in water fractions differed among experimental wetland treatments (fTHg: $F_{2,4} = 224.68$, $p < 0.0001$; but not pTHg: $F_{2,3.60} = 5.83$, $p = 0.07$), subsites (fTHg: $F_{1,57} = 4.95$, $p = 0.01$; pTHg: $F_{1,53.70} = 155.10$, $p < 0.0001$), and months (fTHg: $F_{3,57} = 4.95$, $p = 0.01$; pTHg: $F_{3,54.17} = 3.83$, $p = 0.01$), while accounting for block (fTHg: $F_{2,4} = 0.81$, $p = 0.51$; pTHg: $F_{2,3.60} = 0.27$, $p = 0.78$). However, there was a significant treatment × subsite interaction (fTHg: $F_{2,57} = 6.27$, $p = 0.01$; pTHg: $F_{2,53.70} = 41.24$, $p < 0.0001$).

Pairwise comparisons indicated that filtered and particulate THg concentrations in water at the inlets and outlets of control wetlands differed from those in the polyaluminum chloride and ferric sulfate treated wetlands (Figure 4b,c). At the inlets, filtered THg concentrations in water were 73% lower in the polyaluminum chloride treated wetlands and 68% lower in the ferric sulfate treated wetlands compared to the control wetlands (Figure 4b). At the outlets, filtered THg concentrations in water were 62% lower in the polyaluminum chloride treated wetlands and 57% lower in the ferric sulfate treated wetlands compared to the control wetlands (Figure 4b). In contrast, due to the transfer of the dissolved THg into the particulate fraction, particulate THg concentrations in water at the inlets were 157% higher in the polyaluminum chloride treated wetlands and 209% higher in the ferric sulfate treated wetlands compared to the control wetlands (Figure 4c). At the outlets, particulate THg concentrations in water were 63% lower in the polyaluminum chloride treated wetlands and 30% lower in the ferric sulfate treated wetlands compared to the control wetlands (Figure 4c).

Within wetlands, filtered THg concentrations in water did not differ between inlets and outlets of control wetlands, but were 65% and 57% higher at the outlets than at the inlets in the polyaluminum chloride and ferric sulfate treated wetlands, respectively (Figure 4b). Particulate THg concentrations in

DOI: 10.1021/acs.est.5b00655
Environ. Sci. Technol. 2015, 49, 6304−6311

water also did not differ between inlets and outlets of control wetlands, but were 86% and 78% lower at the outlets than at the inlets in the polyaluminum chloride and ferric sulfate treated wetlands, respectively (Figure 4c).

Filtered and Particulate Methylmercury in Water. MeHg concentrations in water fractions differed among experimental wetland treatments (fMeHg: $F_{2,4.00} = 33.12$, $p = 0.01$; but not pMeHg: $F_{2,3.79} = 4.60$, $p = 0.10$), subsites (fMeHg: $F_{1,56.09} = 26.75$, $p < 0.0001$; pMeHg: $F_{1,54.85} = 73.08$, $p < 0.0001$), and months (fMeHg: $F_{3,56.09} = 3.39$, $p = 0.02$; pMeHg: $F_{3,54.91} = 12.97$, $p < 0.0001$), while accounting for block (fMeHg: $F_{2,4.00} = 0.68$, $p = 0.55$; pMeHg: $F_{2,3.79} = 0.03$, $p = 0.97$). However, there was a significant treatment × subsite interaction (fMeHg: $F_{2,56.09} = 4.07$, $p = 0.02$; pMeHg: $F_{2,54.85} = 40.77$, $p < 0.0001$).

Pairwise comparisons indicated that filtered MeHg concentrations in water at the inlets and outlets of control wetlands differed from those in the polyaluminum chloride and ferric sulfate treated wetlands (Figure 4e). Particulate MeHg concentrations in water at the inlets of control wetlands also differed from those in the polyaluminum chloride and ferric sulfate treated wetlands, but differences were smaller at the outlets (Figure 4f). At the inlets, filtered MeHg concentrations in water were 65% lower in the polyaluminum chloride treated wetlands and 60% lower in the ferric sulfate treated wetlands than in the control wetlands (Figure 4e). At the outlets, filtered MeHg concentrations in water were 67% lower in the polyaluminum chloride treated wetlands and 81% lower in the ferric sulfate treated wetlands than in the control wetlands (Figure 4e). In contrast, the transfer of the dissolved MeHg into the particulate fraction resulted in particulate MeHg concentrations in water at the inlets to be 413% higher in the polyaluminum chloride treated wetlands and 377% higher in the ferric sulfate treated wetlands than in the control wetlands (Figure 4f). At the outlets, particulate MeHg concentrations in water were 43% lower in the polyaluminum chloride treated wetlands and 40% lower (but not statistically significant) in the ferric sulfate treated wetlands than in the control wetlands (Figure 4f).

Within wetlands, filtered MeHg concentrations in water did not differ between inlets and outlets for the ferric sulfate treated wetlands, but were 126% and 136% higher at the outlets than at the inlets in the control and polyaluminum chloride treated wetlands, respectively (Figure 4e). Particulate MeHg concentrations in water increased by 58% between inlets and outlets for the control wetlands, but were 83% and 80% lower at the outlets than at the inlets in the polyaluminum chloride and ferric sulfate treated wetlands, respectively (Figure 4f).

Percentage of Total Mercury in the Methylmercury Form in Water. The proportion of THg in the MeHg form in whole and filtered fraction of water differed among experimental wetland treatments (MeHg/THg: $F_{2,2.73} = 33.98$, $p = 0.01$; fMeHg/fTHg: $F_{2,4.06} = 6.59$, $p = 0.05$), subsites (MeHg/THg: $F_{1,51.35} = 54.19$, $p < 0.0001$; fMeHg/fTHg: $F_{1,56.19} = 25.95$, $p < 0.0001$), and months (MeHg/THg: $F_{3,52.74} = 9.73$, $p < 0.0001$; fMeHg/fTHg: $F_{3,56.18} = 5.99$, $p = 0.001$), while accounting for block (MeHg/THg: $F_{2,2.84} = 0.14$, $p = 0.87$; fMeHg/fTHg: $F_{2,4.06} = 0.22$, $p = 0.81$; pMeHg/pTHg: $F_{2,4.08} = 1.06$, $p = 0.42$). However, there was a significant treatment × subsite interaction (MeHg/THg: $F_{2,51.58} = 9.43$, $p = 0.001$; fMeHg/fTHg: $F_{2,56.18} = 11.03$, $p < 0.0001$). The proportion of THg in the MeHg form in the particulate fraction of water did not differ significantly among experimental wetland treatments (pMeHg/pTHg: $F_{2,4.08} = 3.90$, $p = 0.11$), subsites (pMeHg/pTHg: $F_{1,53.34} = 3.69$, $p = 0.06$), months (pMeHg/pTHg: $F_{3,53.74} = 1.18$, $p = 0.32$), or block (pMeHg/pTHg: $F_{2,4.08} = 1.06$, $p = 0.42$), and there was not a treatment × subsite interaction (pMeHg/pTHg: $F_{2,53.29} = 1.64$, $p = 0.20$).

Pairwise comparisons indicated that the proportion of THg in the MeHg form in whole, filtered, or the particulate fraction of water did not differ among treatments at the inlets (Figure 4g,h,i). At the outlets, the proportion of THg in the MeHg form in water was higher in the control wetlands (MeHg/THg: 111% higher; fMeHg/fTHg: 84% higher; pMeHg/pTHg: 37% higher) and polyaluminum chloride treated wetlands (MeHg/THg: 106% higher; fMeHg/fTHg: 70% higher; pMeHg/pTHg: 116% higher) than in the ferric sulfate treated wetlands (Figure 4g,h,i).

Within wetlands, the proportion of THg in the MeHg form in water increased between the inlets and outlets in the control wetlands (MeHg/THg: 107% higher; fMeHg/fTHg: 111% higher; pMeHg/pTHg: 72% higher) and polyaluminum chloride treated wetlands (MeHg/THg: 84% higher; fMeHg/fTHg: 46% higher; pMeHg/pTHg: 54% higher), but were no different in the ferric sulfate treated wetlands (Figure 4g,h,i).

DISCUSSION

Experimentally treating water with metal-based coagulants had large influences on THg and MeHg concentrations in surface water, due to precipitation of dissolved and colloidal forms of Hg and increased settling of particles (formed by the coagulation process) as the surface water passed through the treated wetlands. By the time the water reached the experimental wetland outlets, THg and MeHg concentrations were decreased by 62% and 63% in polyaluminum chloride treated wetlands and 50% and 76% in ferric sulfate treated wetlands compared to control wetlands. The coagulants' largest effect occurred by the time the water reached the experimental wetland inlets, with THg and MeHg being removed from the filtered fraction of water and coagulated into the particulate fraction of water. Because the coagulants were added to achieve a 60% to 80% removal of dissolved organic carbon, we expected to see similar reductions in Hg concentrations in the filtered fraction of water.[11] Accordingly, THg and MeHg concentrations in the filtered fraction of water at the inlets were 73% and 65% lower in the polyaluminum chloride treated wetlands and 68% and 60% lower in the ferric sulfate treated wetlands than in the control wetlands. As a direct consequence of this loss of Hg from the filtered fraction of treated water, there was a corresponding increase in Hg concentrations in the particulate fraction of water at the inlets. In fact, particulate THg and MeHg concentrations in water at the inlets were 157% and 413% higher in the polyaluminum chloride treated wetlands and 209% and 377% higher in the ferric sulfate treated wetlands than in the control wetlands.

Experimentally treating water with ferric sulfate coagulants also influenced Hg bioaccumulation in fish. Whereas THg concentrations in mosquitofish were decreased by 35% in the ferric sulfate treated wetlands compared to the control wetlands, there was no reduction in THg concentrations in mosquitofish within the polyaluminum chloride treated wetlands. Because both the ferric sulfate and polyaluminum chloride treated wetlands showed similar decreases in MeHg concentrations in the filtered fraction of inlet water (i.e., immediately following the addition of the coagulant), the lack of an effect on fish THg concentrations within the polyaluminum chloride treated wetlands may have been caused by greater production of bioavailable MeHg within those wetlands compared to the ferric sulfate treated wetlands. Although THg and MeHg concen-

Environ. Sci. Technol. 2015, 49, 6304−6311

trations in surface water were decreased by the polyaluminum chloride coagulant, the proportion of THg in the MeHg form increased from inlets to outlets in the polyaluminum chloride treated wetlands, just as it did in the control wetlands. Similarly, MeHg concentrations in the filtered fraction of water increased from the inlets to the outlets by 136% within the polyaluminum chloride treated wetlands and 126% in the control wetlands. Yet, in the ferric sulfate treated wetlands, MeHg concentrations in the filtered fraction of water and the proportion of THg in the MeHg form did not differ between inlets and outlets and remained low. Thus, while both coagulants were successful at initially precipitating THg and MeHg into the particulate fraction of water by the time the water reached the inlets, the polyaluminum chloride coagulant was not as successful at reducing MeHg in the filtered fraction of water by the time the water reached the outlet. Although ferric iron and sulfate are both known substrates for MeHg production, when reduced, both iron and sulfide are known to inhibit inorganic Hg availability for MeHg production[24,25] and iron amendments have proven effective at reducing MeHg production.[10] In contrast, the availability of inorganic Hg bound to organo-complexes created in the polyaluminum chloride wetlands may be relatively high compared to the iron-sulfide complexes produced in the ferric sulfate wetlands.[26] Although other explanations are possible, fish were likely exposed through their diet to bioavailable MeHg produced within both the control and polyaluminum chloride treated wetlands whereas minimal net MeHg appeared to be produced in the ferric sulfate treated wetlands. This result underscores the importance of simultaneously considering both the abiotic and biotic compartments of Hg cycling in order to fully understand how management actions, such as applying coagulants, can impact Hg contamination.

Although we found that adding coagulants to wetlands, particularly ferric sulfate, can decrease Hg concentrations in both surface water and fish, wetlands are known to be one of the most effective habitats for producing MeHg.[5,6,27,28] For example, THg concentrations in mosquitofish were 170% higher in the control wetlands than in the source water canal. We therefore used THg concentrations in fish to further examine whether using coagulants in combination with small settling wetlands can decrease THg concentrations in biota more than what they would have been without the coagulation wetlands. Although THg concentrations in mosquitofish were lower in the ferric sulfate treated wetland than those in the control wetlands, they were still 77% higher in the ferric sulfate treated wetland than in the canal source water. This outcome highlights the potential for MeHg production within wetlands relative to canals, but it is also important to note that all the experimental treatment wetlands had significantly lower THg concentrations in mosquitofish than in the main drainage canal for Twitchell Island. Moreover, THg concentrations in mosquitofish were substantially lower (63% lower at field centers) in the experimental treatment wetlands than in the reference rice fields, which were the other main wetland habitat type at Twitchell Island. Indeed, fish within shallowly flooded rice fields are known to have elevated Hg concentrations relative to other wetland habitat types.[17] Overall, 62% of mosquitofish in rice fields at Twitchell Island exceeded a proposed dietary benchmark for behavioral impairment in piscivorous birds (0.10 μg/g ww[29]), and 27% exceeded a proposed dietary benchmark for reproductive impairment in piscivorous birds (0.18 μg/g ww[29]), compared to only 3% and <1%, respectively, of mosquitofish in the experimental wetlands. Only 2% of mosquitofish exceeded 0.10 μg/g ww in the ferric sulfate treated wetlands, compared to 1% of mosquitofish in the control wetlands, and 7% of mosquitofish in the polyaluminum chloride treated wetlands. Thus, although wetlands often increase MeHg production and bioaccumulation, the ferric sulfate treated wetlands produced THg concentrations in mosquitofish that were considerably lower than the majority of other aquatic environments at the study site.

Together with the laboratory study by Henneberry et al.,[11] our results indicate that metal-based coagulation can be an effective technique for removing both inorganic and organic forms of Hg from surface water and reducing MeHg bioaccumulation in fish. Despite similar reductions in surface water Hg concentrations, the two coagulants were not similarly effective at reducing biotic uptake of MeHg likely due to their different effects on MeHg production within the wetlands. Important considerations before large-scale implementation of this potential management practice include (1) identifying coagulants and key factors that optimize reduction of both water Hg concentrations and bioaccumulation, (2) quantifying whether coagulants have any harmful effects on wetland ecosystems and wildlife, and recommendations to mitigate those effects,[30,31] and (3) identifying appropriate operation and management plans, including the fate of flocculants and whether particulate byproducts should be removed from wetlands and disposed of elsewhere.

Mercury Contamination in Forest and Freshwater Ecosystems in the Northeastern United States

CHARLES T. DRISCOLL, YOUNG-JI HAN, CELIA Y. CHEN, DAVID C. EVERS, KATHLEEN FALLON LAMBERT, THOMAS M. HOLSEN, NEIL C. KAMMAN, AND RONALD K. MUNSON

Eastern North America receives elevated atmospheric mercury deposition from a combination of local, regional, and global sources. Anthropogenic emissions originate largely from electric utilities, incinerators, and industrial processes. The mercury species in these emissions have variable atmospheric residence times, which influence their atmospheric transport and deposition patterns. Forested regions with a prevalence of wetlands and of unproductive surface waters promote high concentrations of mercury in freshwater biota and thus are particularly sensitive to mercury deposition. Through fish consumption, humans and wildlife are exposed to methylmercury, which markedly bioaccumulates up the freshwater food chain. Average mercury concentrations in yellow perch fillets exceed the Environmental Protection Agency's human health criterion across the region, and mercury concentrations are high enough in piscivorous wildlife to cause adverse behavioral, physiological, and reproductive effects. Initiatives are under way to decrease mercury emissions from electric utilities in the United States by roughly 70%.

Keywords: atmospheric deposition, bioaccumulation, methylmercury, mercury contamination, northeastern United States

Mercury (Hg) is a potent neurotoxin of significant ecological and public health concern. Human and wildlife exposure to Hg occurs largely through the consumption of contaminated fish. It is estimated that over 410,000 children born each year in the United States are exposed in the womb to methylmercury (MeHg) levels that are associated with impaired neurological development (Mahaffey 2005). Eight percent of US women of childbearing age have blood Hg levels in excess of values deemed safe by the US Environmental Protection Agency (USEPA; Schober et al. 2003). Studies have also linked elevated Hg in the blood or tissue of fish, birds, and mammals with negative effects such as reduced reproductive success, hormonal changes, and motor skill impairment (Wiener and Spry 1996, Nocera and Taylor 1998, Evers et al. 2004).

To protect human health, the USEPA set a fish tissue criterion for MeHg at 0.3 μg per g under section 304(a) of the Clean Water Act (USEPA 2001). Similar criteria for wildlife are under development or promulgation in several states (e.g., Maine, New York). As of 2004, fish consumption advisories regarding Hg contamination have been issued for 44 states, including 21 statewide advisories for fresh waters and 12 for coastal waters. These advisories represent more than 53,000 km^2 of lakes and 1,230,000 km of rivers. The extent of fish consumption advisories underscores the extensive human and ecological health risk posed by Hg pollution.

Important sources of Hg to the environment include electric utilities, incinerators, industrial manufacturing, wastewater treatment plants, and improper disposal of consumer products (e.g., batteries, fluorescent light bulbs, Hg switches). Considerable public policy attention is directed toward airborne Hg emissions, since they constitute the largest source

of Hg in the United States and globally (UNEP 2002). Although estimates suggest that US emissions of Hg peaked in the 1970s and have since declined (Pirrone et al. 1998), atmospheric concentrations remain approximately three times higher than preanthropogenic levels (Mason et al. 1994).

Neither atmospheric Hg emissions nor ambient concentrations of Hg in water constitute a direct public health risk at the levels of exposure usually found in the United States. The risk to humans and wildlife occurs as Hg is transported to watersheds and accumulates in the aquatic food chain. Airborne Hg is transported over variable distances (i.e., local to global scales), depending on the speciation of Hg emissions and reaction pathways, and is deposited to the Earth's surface.

Following deposition, ionic Hg (i.e., oxidized mercuric species, including complexes and particulate forms) may be reduced and reemitted to the atmosphere or converted to a more bioavailable form, MeHg. Through a bioaccumulation factor of about 10 million, MeHg accumulates to toxic levels at the top of the aquatic food chain. This Hg linkage, from air to water to fish and other biota, challenges the state and federal regulators charged with controlling airborne emissions and with decreasing Hg deposition to levels that meet standards for concentrations in water and in fish tissue.

To improve understanding of the Hg air–water–biota connection, the Hubbard Brook Research Foundation convened a team of eight scientists to synthesize scientific information concerning (a) Hg sources and inputs; (b) Hg transport, transformations, exposure, and environmental effects; and (c) Hg policy impacts in the Northeast. This synthesis includes the analysis of a large Hg data set compiled for eastern North America as part of a NERC (Northeastern Ecosystem Research Cooperative) initiative (Evers and Clair 2005). The NERC Hg project published summaries for water, sediment, and major taxonomic groups. Here we distill these studies into a regional overview with policy applications.

Efforts have been under way at state, regional, national, and global scales to reduce Hg emissions. Notably, in May 2005 the USEPA adopted a rule pertaining to Hg emissions from coal-fired power plants (the Clean Air Mercury Rule, or CAMR). This rule calls for a two-phase reduction in emissions through a cap-and-trade approach that is predicted to produce by approximately 2025 a 70% decrease in total US emissions from electric utilities. Rather than imposing an emission rate limit or requiring the use of maximum achievable control technology, the cap-and-trade approach allows facilities to purchase Hg allowances in order to comply with the regulations.

Mercury emissions and deposition in the northeastern United States

The northeastern United States (i.e., New England and New York) is an important region in which to investigate Hg, because it receives elevated Hg deposition and contains ecosystems sensitive to Hg inputs. Mercury-sensitive areas are typically forested areas with shallow surficial materials, abundant wetlands, and low-productivity surface waters. In the Northeast, the fish in many lakes and streams and the associated wildlife have elevated Hg, which in some instances is high enough to constitute a "biological Hg hotspot," which requires special attention from both a scientific and a policy perspective (Evers et al. 2007). A biological Hg hotspot is a location on the landscape that, compared with the surrounding landscape, is characterized by elevated concentrations of MeHg in biota (e.g., fish, birds, mammals) in excess of established human health or wildlife criteria as determined by a statistically adequate sample size.

Mercury emissions. Globally, approximately 6600 metric tons of Hg are emitted to the atmosphere annually, with 33% to 36% attributed to direct anthropogenic emissions. The remainder originates from natural sources or from past anthropogenic emissions that are rereleased (Mason and Sheu 2002). These values suggest that about two-thirds of atmospheric Hg emissions are derived from either direct or reemitted anthropogenic sources. Coal-fired power plants are the largest single category of Hg emissions, with 1450 metric tons per year, comprising about 50% of anthropogenic sources (Pacyna et al. 2003).

Total anthropogenic Hg emissions from all sources in the United States are calculated to be 103 metric tons per year, with the Northeast contributing about 4.7 metric tons per year (USEPA 1999). Mercury emissions in the United States have declined markedly over the past decade (table 1) as a result of federal regulations that mandated large reductions in Hg emissions in medical waste incinerators and in municipal incinerators (USEPA 2005). Unlike incinerator emissions, emissions from electric utilities have remained largely unchanged, and their relative contribution to total US emissions has increased from 25% to 40%. Municipal waste incinerators (23%) and electric utilities (16%) are the largest point-source categories in the Northeast.

Mercury is emitted to the atmosphere from point sources in three forms: elemental Hg (Hg^0), gaseous ionic Hg (reactive gaseous mercury, or RGM), and particulate Hg (PHg). This speciation exerts significant control over the fate of atmospheric Hg emissions and varies widely among sources (table 2). Therefore, Hg can be a local, regional, or global pollutant, depending on the speciation of the emissions and the associated residence times in the atmosphere (Dastoor and Larocque 2004).

In 1999, 57% of calculated point-source Hg emissions in the Northeast occurred as Hg^0, 33% as RGM, and 10% as PHg (USEPA 1999). Studies indicate that emissions from coal combustion in the United States are roughly 50% Hg^0, 40% RGM, and 10% PHg (Pacyna et al. 2003). However, emissions from coal combustion in the northeastern states have a higher percentage of RGM (68%) and a lower percentage of Hg^0 (30%) and PHg (2%; NESCAUM 2005). The actual Hg emission speciation profile for a specific power plant depends on the type of coal used and the air pollution control technology employed (NESCAUM 2003).

Table 1. Mercury (Hg) emissions (in metric tons per year), by source category, in the United States from 1990 through 2002 and in the Northeast region in 2002.

Source	Emissions (metric tons per year)				
	United States				Northeast,
	1990	1996	1999	2002	2002
Utility coal boilers	54	46	44	45	0.74
Medical waste incinerators	46	36	3	0.3	0.015
Municipal waste combustors	52	29	5	4	1.1
Industrial/commercial/ institutional boilers and process heaters	13	11	11	10	0.33
Chlorine production	9	7	6	5	0
Electric arc furnaces	7	–	–	10	–
Hazardous waste incineration	6	4	6	5	0.001
Total	222	168	109	103	4.7

Note: Individual source categories do not sum to the totals because area sources and minor point-source categories are not shown.
Source: USEPA 2002, 2005, NESCAUM 2005.

Elemental Hg, which is relatively unreactive and generally slowly oxidized, constitutes by far the largest pool of Hg in the atmosphere because of its relatively long residence time (0.5 to 2 years) and long-range transport potential (tens of thousands of kilometers). However, under some conditions Hg^0 can be rapidly oxidized and deposited locally or regionally, as observations have shown in the Arctic and Antarctic (Lindberg et al. 2002), at the marine and continental boundary layer, and in areas downwind of urban areas (Weiss-Penzias et al. 2003). Elemental Hg can also be directly deposited to forested ecosystems through stomatal gas exchange (Grigal 2002). As a result, the atmospheric lifetime of Hg^0 is probably closer to 0.5 year than to 2 years.

Reactive gaseous Hg consists predominantly of gaseous chloride and oxide forms of ionic Hg. This species is highly soluble in water and readily deposits to surfaces within tens to a few hundreds of kilometers from emission sources. Because of RGM's short atmospheric residence time (0.5 to 2 days), elevated Hg deposition can occur near RGM emission sources.

The atmospheric residence time of PHg is also relatively short (0.5 to 3 days). Although the fraction of PHg in ambient air in remote areas is generally less than 5% of total atmospheric Hg (Horvat 1996), concentrations may be higher near Hg emission sources and under certain atmospheric conditions (Lu et al. 2001).

Atmospheric deposition. Atmospheric deposition of Hg occurs in two forms: wet deposition (the deposition of Hg associated with rain and snow) and dry deposition (the deposition of PHg and RGM, cloud and fog deposition, and stomatal uptake of Hg^0). Although some areas have been contaminated by land disposal of Hg or discharge of Hg in wastewater effluent, the predominant input of Hg to most watersheds is atmospheric deposition. Fitzgerald and colleagues (1998) systematically rule out alternate hypotheses, such as natural weathering, as a significant cause of the observed widespread Hg contamination.

Judging from global models (Hudson et al. 1995), reconstructions of mass balances (Mason et al. 1994), and paleolimnological techniques (Engstrom and Swain 1997), it appears that deposition of Hg has increased two- to threefold over the past two centuries, following increases in Hg emissions associated with industrialization and Hg use. Paleolimnological studies in the Northeast typically show Hg deposition starting to increase in the late 1800s or early 1900s and increasing 2.5- to 15-fold by the late 20th century (1970s to 1990s) (figure 1; Kamman and Engstrom 2002). Decreases in sediment Hg deposition in the Northeast (approximately 25%) have been evident in recent years, coincident with reductions in US emissions and with static global emissions. Because inventories of Hg emissions have been limited, it is not clear what is responsible for the declines in Hg deposition

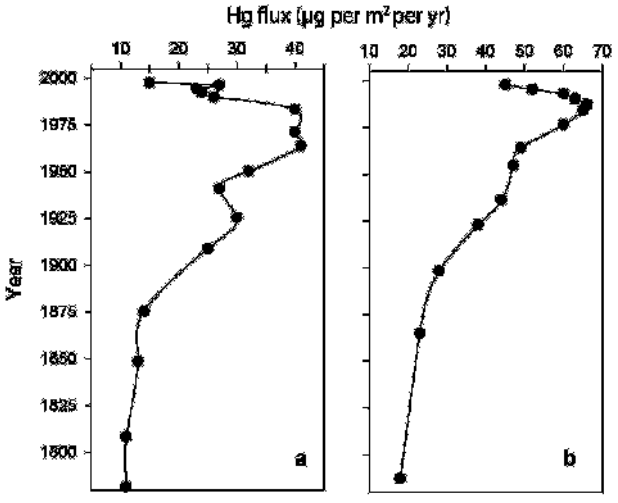

Figure 1. Changes in historical deposition of mercury (Hg) to sediments in (a) Spring Lake and (b) Wallingford Pond, Vermont, from 1820 to the present (after Kamman and Engstrom 2002). The sediment patterns reflect changes in Hg emissions and deposition over time.

Table 2. Percentage of mercury species emitted, by source category.

Source	Particulate mercury (percentage)	Reactive gaseous mercury (percentage)	Elemental mercury (percentage)
Coal-fired electric utilities (United States)	10	40	50
Coal-fired electric utilities (Northeast)	2	68	30
Utility oil boilers	20	30	50
Municipal waste combustors	20	58	22
Medical waste incinerators	20	75	5
Pulp and paper production	20	30	50
Chlorine production	0	5	95
Hazardous waste incinerators	22	20	58
Primary and secondary metal production	10	10	80
Municipal landfills	10	10	80

over the past few decades. However, it seems likely that controls on particulate matter and sulfur dioxide from electric utilities, and reductions in consumer and industrial Hg use, are important factors (Engstrom and Swain 1997).

In the eastern United States, Hg deposition is high (USEPA 1997), but it is difficult to identify its specific sources. Of the estimated 52 metric tons of Hg deposited per year in the United States from US sources, 24 metric tons (46%) are likely to originate from domestic utility coal boilers (half of the 48 metric tons of Hg that the coal-fired utilities emit each year is likely to be deposited within the United States; USEPA 1997). Likewise, for regions of New York it is estimated that 11% to 21% of the Hg deposited is derived from emissions within New York, 25% to 49% originates from other US sources, and 13% to 19% originates from Asia (Seigneur et al. 2003). Given that most coal-fired utilities emit 50% to 70% of Hg as RGM and PHg (table 2), local sources are most likely an important component of the deposition in areas within 50 km of these sources. An analysis of emissions and deposition in southern New Hampshire shows a local region of high deposition associated with local electric utility emissions (Evers et al. 2007).

In the United States and Canada, measurements of wet Hg deposition, which are largely made through the Mercury Deposition Network (MDN), show that wet Hg deposition is highest in the Southeast (e.g., Florida, Mississippi) and lowest in the West. There are currently seven MDN sites in the Northeast, with average annual wet deposition ranging from 3.8 to 12.6 μg per m^2 per year (*http://nadp.sws.uiuc.edu/mdn/*). There do not appear to be broad spatial patterns in wet Hg deposition across the region, but the network is sparse. Because of the placement of collectors in rural areas, the deposition values for the region do not include elevated deposition that would be expected near Hg sources and in urban areas.

Estimates of dry Hg deposition are highly uncertain because of the complex interrelationships of atmospheric conditions, collection surface characteristics and terrain, and chemical properties of the contaminants. Several modeling efforts have been used to estimate dry deposition of Hg, however. In regions of New York, estimated dry Hg deposition was 4 to 10 μg per m^2 per year (Seigneur et al. 2003). Another model estimate specifically for the Northeast suggests that dry deposition of RGM plus Hg^0 was 37 μg per m^2 per year (Xu et al. 2000). Both studies indicate that dry deposition provides a significant pathway of Hg inputs (50% to 75% of total deposition) and agree with USEPA predictions that Hg dry deposition in the Northeast is the highest in the country, in part as a result of the abundant forests whose canopies effectively collect Hg from the atmosphere.

Because of the large surface area associated with canopy foliage, atmospheric deposition of contaminants is elevated in forests compared with other types of ecosystems. Forest studies have indicated that total atmospheric Hg deposition may be estimated using fluxes of throughfall (precipitation that passes through the canopy) plus litterfall (plant material that falls to the forest floor; Rea et al. 2001). Grigal (2002) suggests that the ratio of Hg fluxes resulting from wet deposition, throughfall, and litterfall, respectively, is 1.0 to 1.8 to 2.2. So for the 5 μg per m^2 per year of wet deposition that might be typical of the Northeast, anticipated throughfall would be 9 μg per m^2 per year, and litterfall would be 11 μg per m^2 per year, resulting in total Hg deposition of 20 μg per m^2 per year and dry deposition of 15 μg per m^2 per year (75% of total).

Some portion of the Hg deposited to Earth's surface is reemitted to the atmosphere. However, rates of volatilization vary widely in association with differences in vegetation, soil moisture, temperature, solar radiation, and landscape characteristics. In general, volatilization rates from soil are high immediately after inputs of ionic Hg to the soil (Schluter et al. 1995). On the basis of a review of the literature, Grigal (2002) estimated a mean rate of Hg^0 volatilization from soil of approximately 11 μg per m^2 per hour. This rate is more than adequate to reemit most of the atmospheric Hg deposition. The magnitude and uncertainty of this process demonstrate the acute need for additional research on Hg reemissions.

Transport and transformation of mercury in forest–wetland–lake ecosystems

Following deposition to the landscape, Hg may be sequestered in soil, reemitted to the atmosphere, or transported through the watershed, with a fraction of these inputs ultimately supplied to surface waters. Watershed and water chemistry characteristics influence the transport of Hg to surface waters. Anoxic zones in wetlands and lakes provide suitable conditions for the methylation of ionic Hg to MeHg. The extent to which MeHg is biomagnified in the freshwater food chain depends on the nature and length of the food chain and on water chemistry characteristics.

Mercury transport and fate in upland forest ecosystems. Although there have been few direct studies of soil sequestration of Hg, immobilization of Hg in forest soil is known to correspond with the retention of organic carbon (Schwesig et al. 1999). Pools of Hg in upland soil in northern temperate regions are about 7 mg per m^2, although higher levels have been reported in central Europe (Grigal 2003).

The export of Hg by waters draining upland soils to surface waters is generally low. Concentrations and fluxes of Hg in soil waters, as in soil, are closely related to dissolved organic carbon (DOC; Schwesig et al. 1999). In northern forests, concentrations of total Hg are highest in waters draining the upper soil, coinciding with high concentrations of DOC. Concentrations and fluxes of total Hg decrease as DOC is immobilized with depth in mineral soil (Grigal 2002).

Limited studies suggest that MeHg concentrations in upland soils and groundwaters are generally low, although higher concentrations occur in upper soil waters and decrease with soil depth (Grigal 2002). Low concentrations and fluxes of MeHg in drainage waters suggest that rates of methylation are low, and freely draining upland soils are generally not important in the supply of MeHg to downstream surface waters, with the possible exception of recently harvested forests (Porvari et al. 2003).

Transport and transformation of mercury in wetlands. Wetlands are important features of the landscape that influence the supply of different Hg species to adjacent surface waters. Wetlands are typically net sinks of total Hg and sources of MeHg (Grigal 2002, 2003). Rates of total Hg accumulation are greater in wetlands than in upland soils because of the strong association of Hg with organic matter (Grigal 2003). Annual rates of MeHg production in wetlands are approximately 0.1 to 1 μg per m^2 per year (Galloway and Branfireun 2004). The factors controlling methylation of Hg in wetlands are not completely understood, but they most likely involve the amounts and types of organic matter, hydrologic flow paths, and rates of microbial activity (Galloway and Branfireun 2004). Wetlands are also a major source of DOC. Organic matter produced in wetlands forms complexes with both ionic Hg and MeHg, enhancing the transport of these Hg species to surface waters but decreasing their bioavailability (Hudson et al. 1994). An elevated supply of DOC to downstream surface water could also stimulate methylation and limit photodegradation of MeHg and photoreduction of ionic Hg. Furthermore, wetlands support sulfate-reducing bacteria, which appear to be largely responsible for Hg methylation (Benoit et al. 2003). Concentrations of MeHg in wetland porewaters (waters filling the spaces between solid material in sedimentary deposits) and surface waters vary seasonally, with the highest concentrations evident during the late summer, presumably as a result of warmer temperatures, higher rates of microbial activity, and longer hydraulic residence times (Galloway and Branfireun 2004).

Mercury concentrations and transformations in surface waters. Freshwater ecosystems are among the most sensitive to Hg pollution. Total Hg concentrations in surface waters in the Northeast vary by more than an order of magnitude, from less than 0.5 to 12.7 nanograms per liter (5th to 95th percentile; figure 2; Dennis et al. 2005). Most of the Hg in surface water occurs as ionic Hg, with MeHg ranging from 1% to 35% of total Hg (figure 3). Under conditions of high total Hg loading, MeHg production can vary widely, depending on the methylation efficiency of a particular ecosystem (Krabbenhoft et al. 1999).

Mercury enters remote surface waters through direct atmospheric deposition and through soil water, wetland, or groundwater drainage. Streams and rivers can exhibit marked temporal variation in Hg concentrations, which is associated with variations in concentrations of DOC or suspended matter. Large increases in Hg concentrations can occur during high flow events (Shanley et al. 2005).

Some inputs of Hg to lakes are removed from the water column by the volatilization of Hg^0 and by sediment deposition. In freshwater lakes, photochemical processes are largely responsible for the reduction of ionic Hg to Hg^0 (Amyot et al. 1997). Microbial reduction has been observed in laboratory studies, but only at higher than ambient concentrations of Hg (Morel et al. 1998). Biogeochemical processes in lakes also result in net production of MeHg due to methylation in anoxic sediments and in the water column.

The geographic distribution of average surface water Hg concentrations in the Northeast (figure 2) shows landscape-level heterogeneity in lake and river Hg concentrations, and areas where concentrations are elevated across several contiguous 18-minute grid cells. Areas of elevated Hg concentrations in surface waters can be explained by high concentrations of DOC, as in the Adirondacks; by high inputs of suspended solids, from rivers along Lake Champlain, related to high flow events; and by elevated atmospheric Hg deposition, as in lakes in southeastern New Hampshire and eastern Massachusetts. A large portion of the variation in total Hg and MeHg across the region can be explained by variation in DOC (Dennis et al. 2005). Areas with the highest mean surface water Hg concentrations also have the greatest range in Hg concentrations (figure 2). This variation may be attributed to heterogeneity in watershed characteristics or to high flow events (Shanley et al. 2005).

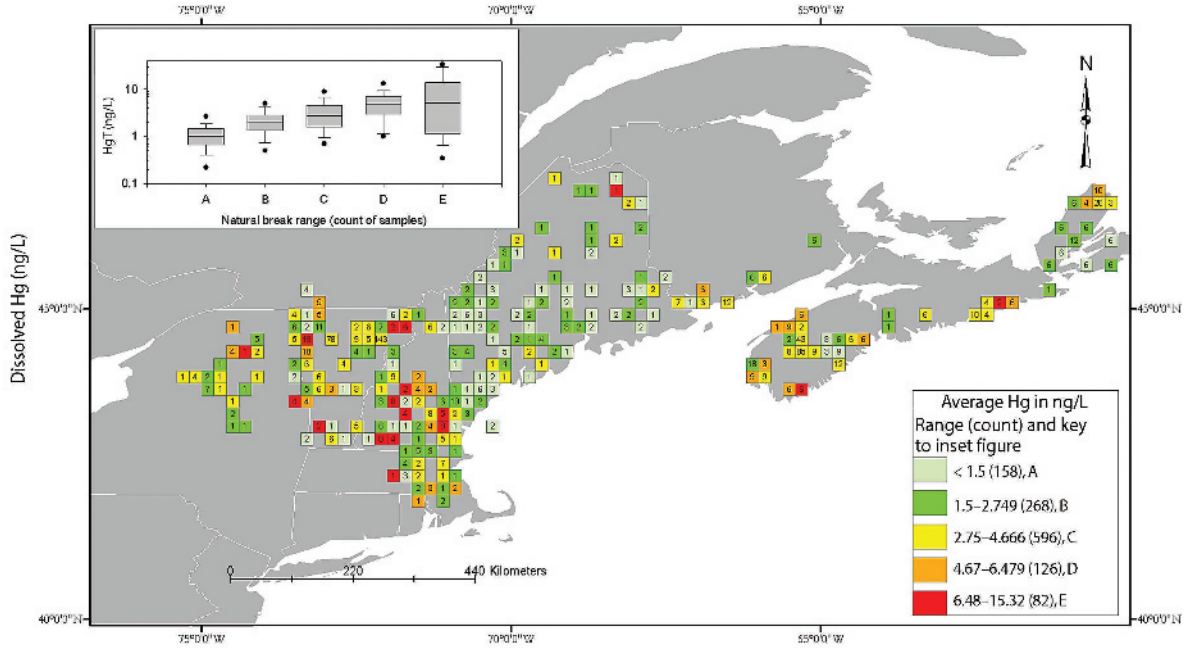

Figure 2. Average water mercury (Hg) concentrations within 18-minute grid cells for lakes and streams across northeastern North America. Inset shows the distribution of Hg concentrations comprising the mean for each quintile.

Other factors controlling mercury dynamics in surface waters. Other factors, such as water chemistry, land cover and land use, and watershed disturbances, alter the transport, transformation, and bioavailability of Hg in surface waters.

The Northeast receives elevated loading of acidic deposition as well as Hg deposition, and contains a relatively large number of acidified surface waters. Acidic deposition and the associated sulfur alter the acid–base status of surface waters, thereby influencing Hg transformation and accumulation in fish. Sulfur transformations are closely coupled with Hg dynamics. The solubility of Hg increases with increasing sulfide concentrations in anoxic waters through complexation reactions, potentially increasing the pool of Hg available for methylation (Benoit et al. 2003). Experimental observations show that when sulfate is added to wetlands or lakes, sulfate reduction is enhanced, leading to increased methylation and MeHg export (Branfireun et al. 1999, Watras et al. 2006).

Widespread observations show an inverse relationship between fish Hg concentrations and surface water pH (e.g., Kamman et al. 2004). Hrabik and Watras (2002) used reference data and observations from a lake experimentally acidified with sulfuric acid to examine the relative contribution of atmospheric Hg deposition and acidic deposition to Hg concentrations in fish. They found that half of the decrease in fish Hg over a six-year period during which the lake was recovering from acidification could be attributed to decreases in sulfuric acid loading.

In a study of 21 river basins nationwide, watersheds with mixed agriculture and forest land cover had the highest methylation efficiency, even where these watersheds had low total Hg in sediments (Krabbenhoft et al. 1999). Some waters draining largely agricultural lands have relatively high concentrations of total Hg and MeHg, but lower concentrations in fish, presumably due to algal "bloom dilution" associated with high phosphorus loading (Kamman et al. 2004; see below) or elevated DOC concentrations (which could stimulate methylation but limit bioaccumulation), or both.

Land disturbance influences Hg export and availability for methylation. Forest harvesting has been shown to increase export of total Hg and MeHg (Porvari et al. 2003). Fire results in a complex pattern of Hg loss from watersheds. During and shortly after fire, elevated Hg losses are associated with volatilization and drainage losses (Grigal 2002). Over the longer term, Hg transport to surface waters is reduced in burned areas as a result of decreases in soil carbon and DOC concentrations.

In reservoirs, rates of Hg methylation can be altered by water level fluctuation associated with hydropower production or flood control. Many large bodies of water in the Northeast are impounded to increase their storage or daily peaking capacity, and these water bodies may fluctuate tens of centimeters on a daily basis or several meters over the course of a summer. As the littoral zone experiences periodic wetting and drying, varying cycles of reduction and oxidation may enhance the production of MeHg, depending on a variety of factors (Sorensen et al. 2005, Evers et al. 2007).

Trophic transfer of mercury in surface waters of the Northeast. Concentrations of total Hg or MeHg in surface waters often do not correlate well with the Hg content of freshwater biota, such as fish. There are many physical, chemical, ecological, and land-use factors controlling the trophic transfer

of MeHg, which are key to predicting MeHg concentrations in fish and other freshwater organisms.

Trophic transfer of Hg in freshwater food webs begins with the bioaccumulation of ionic Hg and MeHg by primary producers. Bioaccumulation factors in the transfer of Hg from water to algae are by far higher (approximately 10^5 to 10^6) than at subsequent trophic levels (figure 3). Although both ionic Hg and MeHg are taken up by aquatic organisms, MeHg is assimilated four times more efficiently than ionic Hg (Mason et al. 1994). However, the absolute and relative assimilation efficiencies of ionic Hg and MeHg vary with trophic level, uptake pathway, and water chemistry conditions. Freshwater grazers and predators acquire MeHg mainly from their food rather than from water (Harris and Bodaly 1998). Methylmercury is efficiently transferred to the higher levels of the food web and largely incorporated within proteins, as in muscle tissue.

The NERC data show that MeHg increases in concentration and comprises a greater percentage of the total Hg in freshwater consumers and predators as it progresses up the food chain (figure 3). Thus organisms consuming prey at higher trophic levels are exposed to higher concentrations of total Hg and MeHg (Vander Zanden and Rasmussen 1996). Fish Hg occurs almost entirely as MeHg.

A variety of physical, chemical, and biological factors influence the biomagnification of MeHg. Fish Hg concentrations tend to vary positively with lake or watershed area and negatively with pH, acid neutralizing capacity (ANC), nutrient concentrations, zooplankton density, and human land use (Chen et al. 2005). Furthermore, the Hg added to the lake surface each year appears to be more available for conversion to MeHg than Hg that has been in the ecosystem for longer periods (Gilmour et al. 2003).

Both experimental and field studies show that nutrient enrichment diminishes Hg bioaccumulation in phytoplankton through the biodilution of Hg under algal bloom conditions (Pickhardt et al. 2002). Mercury concentrations in zooplankton also decrease with increasing zooplankton densities that in turn are correlated with lower Hg concentrations in fish (Chen and Folt 2005). Growth dilution in fish, also under conditions of high productivity and food availability, may be related to lower Hg concentrations in fish (Essington and Houser 2003).

Within given fish populations, Hg burdens increase with the age and size of individuals in part because of the slower rates of elimination and longer exposure in larger individuals, and in part because of the consumption of higher-trophic-level foods by older and larger individuals (Wiener and Spry 1996). Mercury concentrations in top predator fish are higher in food webs with longer chain lengths and less omnivory (Stemberger and Chen 1998).

Indicators of mercury sensitivity. Four simple and common measures of water quality—DOC, ANC, pH, and total phosphorus—have been shown by Chen and colleagues (2005) and many others to be related to fish Hg concentrations. To develop indicators of Hg sensitivity, we combined data from two stratified, random-probability surveys of northeastern lakes (USEPA EMAP [Environmental Monitoring and Assessment Program], Northeast Lakes Program, 1991–1994, and Vermont–New Hampshire REMAP [Regional EMAP], 1998–2000) with the survey data sets of Chen and colleagues (2005) to examine these four water-chemistry characteristics in lakes with standard-age yellow perch (*Perca flavescens*) whose tissue contained mean concentrations of Hg above and below the USEPA criterion (0.3 μg per g; figure 4). The standard age for yellow perch examined in this analysis was 4.6 years (Kamman et al. 2004). This analysis showed that lakes with Hg levels above 0.3 μg per g in yellow perch had significantly higher DOC (t = –3.099, p = 0.003) and lower pH (t = –6.282, $p < 0.001$), ANC (t = 2.835, p = 0.007), and total phosphorus (t = 3.840, $p < 0.001$) than lakes with fish Hg concentrations below 0.3 μg per g. As yellow perch have low to moderate Hg concentrations, these thresholds are conservative and help identify the most sensitive lakes.

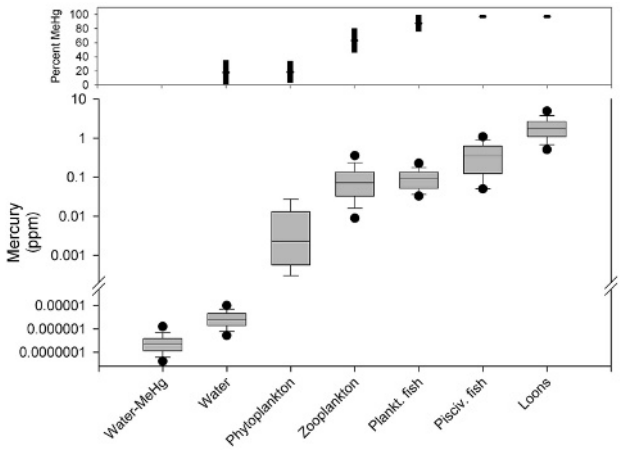

Figure 3. Box and whisker plots of mercury (Hg) concentrations in water and aquatic biota in eastern North America. Also shown are the ranges for the percentage of total Hg occurring as methylmercury (MeHg). All values were obtained from NERC (Northeastern Ecosystem Research Cooperative) data and represent wet weight, except those for phytoplankton, which were obtained from Watras and colleagues (1998).

Twenty percent of lakes in the region had total phosphorus concentrations above 30 μg per L. In those lakes, Hg concentrations in yellow perch were below 0.3 μg per g. In the remaining 80%, we found that most lakes (75%) had yellow perch Hg concentrations exceeding 0.3 μg per g when surface waters had a DOC level of more than 4.0 mg carbon per L, a pH of less than 6.0, or an ANC of less than 100 microequivalents (μeq) per L. These commonly monitored indicators provide natural resource managers with a useful tool for evaluating the likelihood of high fish Hg concentrations in individual lakes.

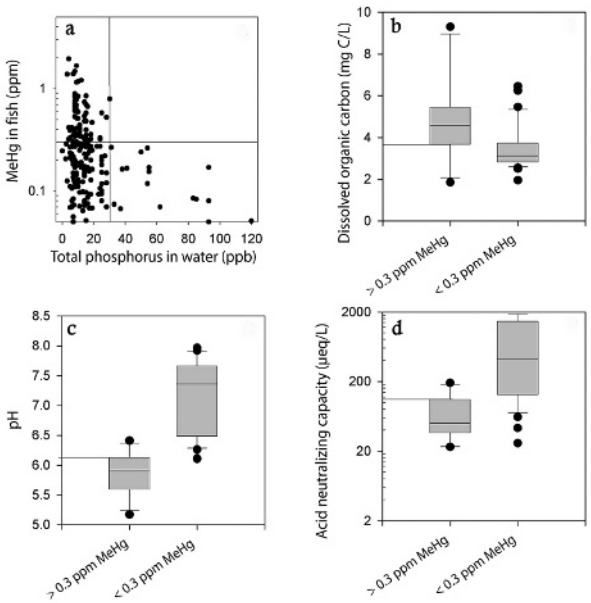

Figure 4. Relationship between methylmercury (MeHg) concentrations in standard-length yellow perch and total phosphorus concentration in lakes (a), and box and whisker plots of concentrations of dissolved organic carbon (b), pH (c), and acid neutralizing capacity (d) for lakes in the northeastern United States containing average concentrations of standard-age yellow perch with MeHg concentrations less than and greater than 0.3 µg per g.

Taxonomic patterns of mercury exposure

Biota are exposed to MeHg primarily through fish and insect consumption. The NERC data establish robust Hg exposure profiles for fish, birds, and mammals (table 3; Evers and Clair 2005), and highlight the importance of habitat type, foraging guild, trophic structure, and demographics on MeHg exposure (Evers et al. 2005).

In general, Hg concentrations vary by taxonomic group, with a higher proportion of MeHg at higher trophic levels. Mercury in benthic invertebrates and larval insects has been extensively studied in northeastern lakes and reservoirs, and is found to increase with trophic level (odonates > hemipterans and coleopterans > trichopterans > dipterans and ephemeropterans; Tremblay et al. 1996). The NERC data on Hg in over 15,000 fish show that the mean fillet Hg levels in 10 of the 13 species are above 0.3 µg per g, with the highest levels in large predatory fish such as walleye (*Sander vitreus*) and lake trout (*Salvelinus namaycush;* figure 5; Kamman et al. 2005).

Habitat type also has an important influence on MeHg concentrations. Data for two-lined salamanders (*Eurycea bislineata*) suggest that amphibians found in headwater streams have significantly higher MeHg concentrations than those in lakes (Bank et al. 2005). Larval insects in reservoirs have total Hg concentrations that are 3 to 10 times higher than those in natural lakes (Tremblay et al. 1996). Northern crayfish (*Orconectes virilis*) in headwater streams have Hg concentrations up to five times greater than those in lakes (Pennuto et al. 2005).

Comprehensive bird studies illustrate differences in MeHg exposure in foraging guilds. Piscivorous species with particularly high MeHg levels include the common loon (*Gavia immer;* Evers et al. 2005), wading birds (Frederick et al. 1999), and the bald eagle (*Haliaeetus leucocephalus;* Bowerman et al. 2002). Exposure studies in common loons have shown hormonal changes, reduced reproductive success, and motor skill impairment, resulting in the establishment of a wildlife criterion for blood Hg of 3.0 µg per g (Evers et al. 2004).

Table 3. Mercury exposure for selected biota in representative habitats in the Northeast.

Major habitat and organism	Sample size	Tissue sampled	Mercury level (µg per g) Mean ± SD	Mercury level (µg per g) Range	Reference
Lakes					
Yellow perch	841	Whole body	0.29 ± 0.07	< 0.05–3.17	Kamman et al. 2005
	2888	Fillet	0.35 ± 0.20	< 0.05–5.03	Kamman et al. 2005
Common loon	770	Adult blood	2.04 ± 1.39	0.05–8.63	Evers et al. 2005
	660	Egg	0.78 ± 0.60	0.01–9.00	Evers et al. 2005
Estuaries					
Saltmarsh sharp-tailed sparrow	108	Adult blood	0.63 ± 0.26	0.18–1.68	Lane and Evers 2005
Rivers					
Belted kingfisher	117	Adult blood	0.99 ± 0.82	0.07–4.57	Evers et al. 2005
Mountains					
Bicknell's thrush	242	Adult blood	0.08 ± 0.38	0.03–0.80	Rimmer et al. 2005
General aquatic					
Bald eagle	108	Juvenile blood	0.30 ± 0.27	0.01–1.20	Evers et al. 2005
Tree swallow	53	Adult blood	0.41 ± 0.21	0.11–1.00	Evers et al. 2005
Mink	126	Fur	20.7	1.78–68.5	Yates et al. 2005
Otter	160	Fur	18.0	1.14–73.7	Yates et al. 2005

SD, standard deviation.

Exposure to MeHg is not limited to piscivorous birds. Data for insectivorous songbirds, such as the northern waterthrush (*Seiurus noveboracensis*) and red-winged blackbird (*Agelaius phoeniceus*), show blood Hg levels that can exceed levels in piscivorous birds (Evers et al. 2005). Moreover, elevated MeHg has been measured in several breeding populations of saltmarsh sharp-tailed sparrows (*Ammodramus caudacutus*) in some New England estuaries (Lane and Evers 2005), and in terrestrial species such as Bicknell's thrush (*Catharus bicknelli*) and other montane songbirds (Rimmer et al. 2005).

Terrestrial mammals, particularly mink (*Mustela vision*) and river otter (*Lontra canadensis;* table 3), also experience elevated MeHg in the Northeast. Yates and colleagues (2005) found that Hg levels tend to be higher in mink than in otter, in interior than in coastal populations, and in females than in males. Recent evidence for MeHg exposure in insectivores has led to ongoing investigations in bats and other nonpiscivorous mammal species.

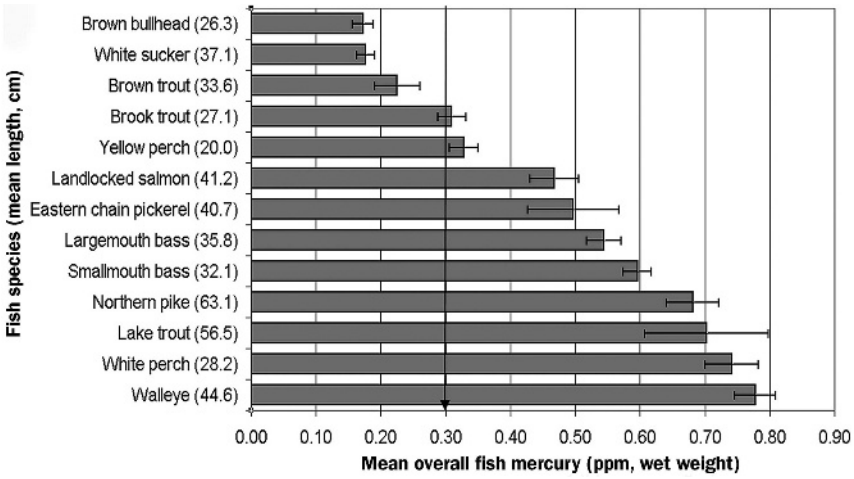

Figure 5. Mean and standard deviation of mercury (Hg) concentrations of 13 species of fish in eastern North America (Kamman et al. 2005). The downward-pointing arrow indicates the US Environmental Protection Agency's criterion for fish Hg concentrations.

Comprehensive data on fish and wildlife exposure are being used to identify species, habitats, and regions that are likely to be at the highest risk for MeHg contamination, and will be useful for measuring progress resulting from future management actions.

Evaluating reductions in mercury emissions

At present, most state and national policy attention is focused on Hg emissions from electric utilities (i.e., coal-fired power plants). Although controlling other sources (e.g., emissions from incinerators, discharges from wastewater treatment plants) and implementing other management options (e.g., biomanipulation, land-use management) may also hold promise for reducing and mitigating Hg bioaccumulation, we focus on the potential effect of reducing Hg emissions from electric utilities, because they are the largest single source of airborne emissions in the United States and the second largest source in the Northeast, and because their emissions have remained unchanged both regionally and nationally over the past decade (NESCAUM 2005). Although municipal waste combustors are the largest Hg emission source in the Northeast, effective strategies for reducing their emissions are under way, as evidenced by the decline of approximately 80% in emissions from this source between 1998 and 2003 (NESCAUM 2005).

Many proposals have been introduced at both the federal and the state level to control Hg emissions from electric utilities. The main differences among them include (a) the level and timing of the cuts, (b) the existence of an emissions cap or emissions rate limit, and (c) whether or not trading is allowed. In general, the level and timing of Hg emission reductions are likely to control the extent and rate of recovery in the region, and the use of trading has prompted questions regarding the persistence or expansion of biological Hg hotspots (Evers et al. 2007).

Here we estimate the changes in emissions and deposition that are associated with the CAMR and discuss the potential effect of these changes on freshwater ecosystems using field data. The USEPA estimates that the CAMR will result in a 70% decrease in Hg emissions from electric utilities by 2025. We estimate that the CAMR, when fully implemented, would result in a decrease of approximately 18% to 30% in deposition in the northeastern United States. This estimate is based on an analysis of US emissions and deposition that assumes (a) that current and reemitted anthropogenic emissions each constitute one-third of the emissions in the United States, and (b) that electric utilities account for 50% of each of these two emission categories. It follows that if electric utilities reduce their emissions by 70%, current and reemitted anthropogenic emissions would each decrease by 35%.

We further assume that US emissions are responsible for 40% to 65% of Hg deposition in the Northeast (Seigneur et al. 2003) and that reemitted US emissions contribute another 10% to 20%. If deposition attributed to these emission categories were reduced by 35% as a result of the CAMR, then total deposition would decline by approximately 18% to 30%. These predictions are consistent with the decrease of approximately 25% in sediment Hg deposition that occurred coincident with decreases in Hg emissions in the United States between 1970 and 1999.

An 18% to 30% decrease in Hg deposition is likely to provide significant ecological benefits in the region. Detailed biological data from a group of nine lakes in New Hampshire show that the Hg concentrations in the blood and eggs of the common loon declined 50% between 1999 and 2002 as emissions in the vicinity were cut 45% between 1997 and 2002, suggesting that some ecosystems in close proximity to large

emissions sources may experience rapid improvement (Evers et al. 2007). Hrabik and Watras (2002) found that Hg fish concentrations declined 30% between 1994 and 2000 as a result of decreased atmospheric Hg loading to a lake in northern Wisconsin; they concluded that modest changes in Hg or acidic deposition can significantly affect Hg bioaccumulation over short timescales. The range and rate of ecosystem response are most likely related to the variation in the physical, chemical, and biological characteristics of lakes and watersheds.

We expect that the CAMR will produce important results, but these changes may not be sufficient to protect human and environmental health. Given that *average* fish Hg concentrations sampled across the region currently exceed the USEPA human health criterion by 10% to 88%, depending on the species, significant additional reductions in Hg emissions from other US and global sources will probably be necessary to bring about widespread recovery to Hg levels that are below this criterion in most fish species in the northeastern United States.

Conclusions

A large Hg database produced by the NERC Hg working group was used to document and examine the widespread Hg contamination across eastern North America. From this synthesis, it is evident that the Northeast receives elevated Hg deposition derived mostly from direct emissions and reemissions of anthropogenic sources. Paleolimnological studies suggest that Hg deposition is substantially influenced by US emissions and responds to reductions in these sources.

Direct anthropogenic emissions of Hg originate largely from electric utilities, incinerators, and industrial processes. Current understanding of speciation and deposition processes suggests that, while speciation exerts important influence over patterns of atmospheric transport and deposition, all forms of Hg have the potential to deposit locally or regionally.

Forest regions are particularly sensitive to Hg inputs as a result of numerous factors: the filtering effects of the canopy and the associated elevated deposition; the prevalence of wetlands, which are critical in the transport of Hg and the production of MeHg; and low-productivity lakes, which promote high concentrations of Hg in fish. Although Hg is highly variable in surface waters across the region, we have identified several chemical thresholds to predict high fish Hg: total phosphorus concentrations of less than 30 μg per L; pH of less than 6.0; ANC of less than 100 μeq per L; and DOC of more than 4 mg carbon per L. Freshwater food chains are characterized by marked bioaccumulation of MeHg (10^6 to 10^7), with the largest increase occurring from water to plankton (10^5). Many freshwater and terrestrial animals in the Northeast exhibit high concentrations of Hg. For the common loon, existing Hg concentrations can cause adverse individual (behavioral and reproductive) and population-level effects.

Our analysis suggests that (a) cuts in Hg emissions from electric utilities in the United States will decrease Hg deposition in the region; (b) decreased Hg deposition will result in lower Hg levels in biota, although significant time lags may exist in many ecosystems; and (c) widespread recovery to Hg levels that no longer pose a human health risk or population risk to the common loon will be a long-term process that is likely to require additional reductions in Hg emissions.

Acknowledgments

This work was convened through the Science Links program of the Hubbard Brook Research Foundation with support from the Henry Luce Foundation, the John Merck Fund, the Merck Family Fund, the Harold Whitworth Pierce Charitable Trust, the New York Energy Research and Development Authority, and the Syracuse Center for Environmental and Energy Systems. This project was also supported through grants from the US Environmental Protection Agency (USEPA) and the National Science Foundation to C. T. D. and the National Institute of Environmental Health Sciences (NIH grant no. P42 ESO7373) to C. Y. C. The Hubbard Brook Experimental Forest is operated and maintained by the Northeastern Research Station, US Department of Agriculture, Newton Square, Pennsylvania. We would particularly like to thank Edward Swain (Minnesota Pollution Control Agency) for serving as an advisor to this project. We also thank several anonymous reviewers. The findings published here are independent and do not necessarily reflect the views of the advisors.

Mercury concentrations in coastal California precipitation: Evidence of local and trans-Pacific fluxes of mercury to North America

Douglas J. Steding and A. Russell Flegal

WIGS Laboratory Group, Department of Environmental Toxicology, University of California at Santa Cruz, Santa Cruz, California, USA

Received 10 January 2002; revised 8 August 2002; accepted 13 August 2002; published 19 December 2002.

[1] Because of mercury's (Hg) relatively high vapor pressure and long (0.5–2 years) atmospheric residence, there is the potential for long-range transport of contaminant Hg. Many studies have focused on that transport and deposition in central and eastern North America, Europe, and the Arctic, but there has been little research on the cycling of Hg in the western coast of North America. That deficiency is addressed in this preliminary study, which indicates there is long-range transport of Hg across the North Pacific. This transport is evidenced by the elevated (relative to equatorial and theoretical baseline) Hg concentrations in rainwater collected on the coast of California, as well as by the positive correlation between North Pacific storm tracks and Hg concentrations, with maximum concentrations associated with storms from 20°–40° latitude. Those tracks trace air masses containing industrial emissions with peak O_3 concentrations moving eastward off the Asian continent. The Asian fluxes appear to enhance Hg concentrations both directly, through the emission of particle-bound Hg and reactive Hg^{2+}, and indirectly, by increasing the rate of oxidation of Hg^0 in the atmosphere. Superimposed on the trans-Pacific background of industrial Hg is a local signal, with elevated concentrations at the urban site relative to the more pristine coastal site in California. This secondary enrichment is tentatively attributed to elevated local emissions of redox species, including O_3 and its precursors, which increase oxidation rates of Hg^0 in the atmosphere and Hg concentrations in precipitation. *INDEX TERMS:* 0365 Atmospheric Composition and Structure: Troposphere—composition and chemistry; 0368 Atmospheric Composition and Structure: Troposphere—constituent transport and chemistry; 0345 Atmospheric Composition and Structure: Pollution—urban and regional (0305); *KEYWORDS:* Mercury, atmosphere, oxidation, precipitation, transport, concentrations

1. Introduction

[2] A large body of evidence has accumulated to support the hypothesis that, due to the relatively long residence time (0.5–2 years) of Hg^0 in the atmosphere [*Lamborg et al.*, 2000; *Lindqvist and Rodhe*, 1985; *Mason et al.*, 1994; *Seiler et al.*, 1980; *Slemr et al.*, 1985], Hg contamination is pandemic [*Fitzgerald et al.*, 1998; *Hudson et al.*, 1995; *Lindqvist et al.*, 1991; *Petersen et al.*, 1995]. The contamination is attributed to the oxidation of Hg^0 from the atmosphere to reactive species (e.g., Hg^{2+}) that are rapidly scavenged by settling particles and rain washout [*Lamborg et al.*, 2000; *Lin and Pehkonen*, 1999; *Munthe*, 1992; *Pleijel and Munthe*, 1995]. Those labile species are then readily available for biologically mediated methylation and accumulation in terrestrial and aquatic food chains [*Fitzgerald et al.*, 1998; *Lamborg et al.*, 1999; *Mason et al.*, 1997a; *Schroeder and Munthe*, 1998].

0148-0227/02/2002JD002081

[3] Recognition of the long-range atmospheric transport and transformation of Hg has coincided with an increased interest in the influence of atmospheric emissions from industrialized Asian countries on the environment. Asia has been identified as the major source of atmospherically deposited metals to the North Pacific [*Merrill*, 1989], and recent studies have evidenced the transport of Asian dust and industrial contaminants across the Pacific to western North America [*Berntsen et al.*, 1999; *Husar et al.*, 2001; *Jaffe et al.*, 1999]. In addition, coal combustion in China accounts for roughly 10% of the total industrial emissions of Hg [*Wang et al.*, 2000]. Consequently, this study was initiated to investigate the influence of Asian industrial emissions on Hg deposition rates in western North America.

2. Methods

[4] Rainwater samples were collected at two sites in central California (Figure 1). One was located on the coast at the University of California Santa Cruz's (UCSC) Long Marine Laboratory (LML), and the other was at Moffett

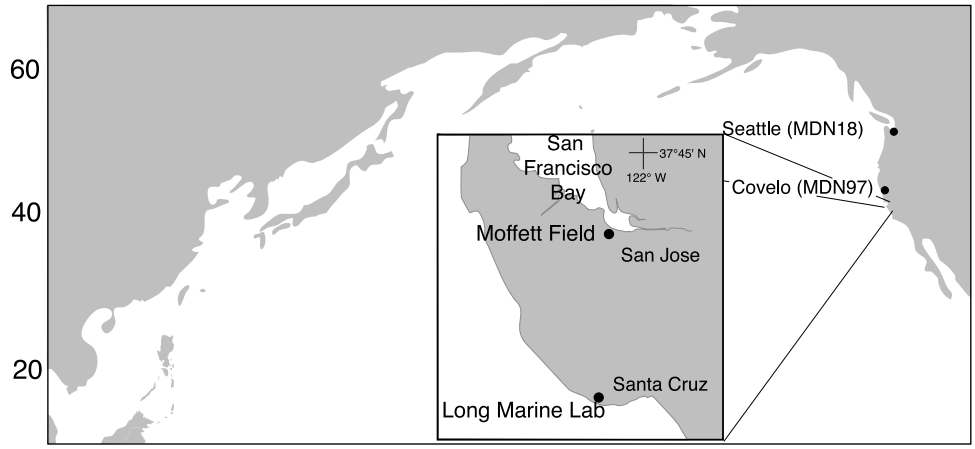

Figure 1. Location of sampling sites (inset) and MDN sites at Covelo, California, and Seattle, Washington.

Field (MF), on the other side (~50 km) of California's coastal range in the southern part of the San Francisco-San Jose-Oakland megalopolis. The coastal site (LML) was chosen to quantify the background concentration of Hg in storms directly off the Pacific, and the more inland site (MF) was chosen to investigate the impacts of local urbanization on Hg concentrations in rainwater. For reference, we compared our results at the two sites to those from two west coast Mercury Deposition Network (MDN) sites, which are located in Covelo (MDN97), California, and Seattle (MDN18), Washington (Figure 1).

[5] Collections were made using modified Aerochem Metrics 301 automated precipitation collectors, glass funnels, and Teflon™ receiving bottles using established methods, with trace metal clean techniques and high-purity reagents [*Dvonch et al.*, 1995; *Mason et al.*, 1992; *Mason et al.*, 1997b]. All sample handling and preparation was done in a HEPA filtered air (Class 100), trace metal clean room. The funnels and bottles were thoroughly cleaned in Trace Metal Grade (TMG, Fisher) acids (8N HNO_3 and 6N HCl) and rinsed (5 times) with Milli-Q (18 MΩ cm) water prior to deployment. Between events, the funnels and receiving bottles were rinsed 5 times with high-purity water, soaked in TMG 1.2N HCl, and then rinsed (5 times) before the next deployment.

[6] Immediately after an event, samples were returned to the lab, subdivided, and frozen prior to Hg analysis. Total Hg was measured after oxidation with 0.5 mL of 0.2 M BrCl using cold vapor atomic fluorescence spectroscopy, using established methods [*Bloom and Crecelius*, 1983; *Bloom and Fitzgerald*, 1988]. Method blanks averaged 10±5 pg, and the detection limit was 0.75 pM for a 100 mL sample.

[7] Aluminum was quantified by high-resolution inductively coupled plasma mass spectrometry (Finnegan Element 1). The analysis followed a HF/HNO_3/HCl (Seastar quartz distilled acids) digestion of 20 mL of sample, which was acidified with 0.5ml 12N HCl prior to digestion. This sample was dried down, digested with 1 mL 14N HF, then dried and digested with 1 mL 18N HNO_3 followed by 1 mL 12N HCl.

[8] Joyce Harris of the Climate Monitoring and Diagnostics Laboratory (CMDL) in Boulder, Colorado, provided air mass trajectory calculations. The calculations were performed using the CMDL isentropic model [*Harris and Kahl*, 1994], with 4 km arrival height for each event. The model was run to provide trajectory data for 10 days prior to each event.

3. Results and Discussion

3.1. Mercury Concentrations in Rain at Long Marine Lab

[9] Concentrations of Hg measured in rain at LML varied from 4–84 pM, with a volume weighted average of 30 pM (Figure 2). The range of concentrations are similar to that measured in the North Pacific (14–85 pM), but are elevated relative to concentrations measured in the equatorial Pacific (6.5–22.5 pM) [*Mason et al.*, 1992]. The volume-weighted concentration at LML was also similar to those (average = 28 pM) measured at the MDN97 in Covelo, California [*NADP*, 2001].

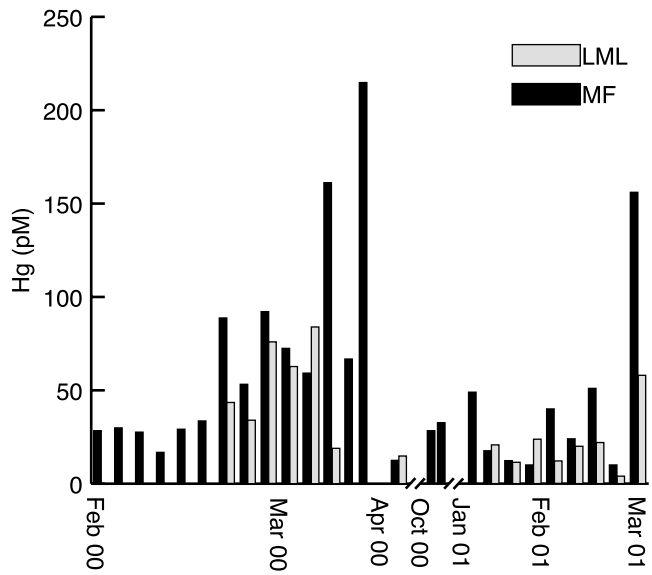

Figure 2. Concentration of Hg (pM) in rainwater at Moffett Field and Long Marine Lab.

Table 1. A Comparison Between Events at Moffett Field and Long Marine Lab[a]

	Moffett Field		Long Marine Lab	
Event Date	Hg, pM	Rainfall, mm	Hg, pM	Rainfall, mm
30 January 2000	28.38	1.51		
3 February 2000	29.89	4.26		
10 February 2000	27.61	2.73		
12 February 2000	16.78	18.73

[a]The RSD on the Hg concentration measurements is ±10%, as determined by duplicate analyses of samples.

[10] Since that latter site is in a very rural location along the California coast, its Hg concentrations are considered to represent the background concentration of Hg in rainwater on the west coast of North America. The similarity between the MDN97 Covelo site and LML substantiates the proposal that Hg concentrations at LML also approach background concentrations, although there is the possibility that some of the Hg at LML is from local emissions.

3.2. Mercury Concentrations in Rain at Moffett Field

[11] Mercury concentrations measured at MF ranged from 4–214 pM and averaged 58 pM, (Figure 2). By comparison, integrated two-week samples collected concurrently at the MF site, at MDN72, averaged 48 pM [*Tsai and Hoenicke*, 2001]. Since other sites in San Francisco Bay have reported averages of 32–36 pM [*Tsai and Hoenicke*, 2001], the marginally higher concentrations observed at MF are tentatively attributed to its downwind location from areas of industrialization and urbanization within the Bay area. The concentrations from MF also compare well to those in samples collected at MDN18 in Seattle, where the long-term (3 years) average is 53 pM [*National Atmospheric Deposition Program*, 2001]. In contrast, the maximum Hg concentrations at all of the west coast sites (MDN18, MDN97, LML, MF) are lower than maximums (~400 pM) observed at the east coast of the United States [*Mason et al.*, 1997b].

3.3. Enrichment in Hg Concentrations at MF Relative to LML

[12] A simple linear, regression analysis comparing MF and LML indicates a highly significant (P = 0.006, paired t-test), 44% enrichment in the Hg concentration of individual rain events at MF compared to LML (Figure 2). Since there is less rainfall at MF than at LML, these higher concentrations might be due to lower dilution of individual events. However, the enrichment is present at MF regardless of relative rainfall at each site (Table 1).

[13] The enrichment, therefore, is tentatively attributed to a combination of factors related to urban activity. These include higher soot particle concentrations, which effectively scavenge reactive mercury species; higher ozone concentrations, which increase atmospheric Hg^0 oxidation rates; and greater local emissions of natural and industrial Hg, from cinnabar deposits and diverse anthropogenic activities in the San Francisco Bay area, respectively.

[14] Another possible explanation for the enrichment at MF is its proximity to San Francisco Bay. Moffett Field, located in the Bay's wetlands, may be influenced by natural processes, which are similar to those observed in oceanic environments [*Mason*, 2001; *Schroeder et al.*, 1998]. Specifically, the influence of Bay surface waters may result in higher Hg deposition rates through boundary layer recycling of Hg^0, which has been hypothesized to react with Cl and Br gas, allowing for local deposition of oxidized Hg [*Mason*, 2001]. This potential source of enrichment, however, does not account for the variability seen in Hg concentrations at both sites, because the consistent magnitude of this enrichment suggests that it is superimposed on another, nonlocal, mechanism, which is governing Hg concentrations in rain on the West Coast.

3.4. Depositional Fluxes

[15] While volume weighted concentrations of Hg in rainwater are lower at LML (30 pM) relative to MF (58 pM), the annual wet deposition at LML (20 nmol m^{-2} yr^{-1}) and MF (22 nmol m^2 yr^{-1}) are similar (Table 2). The similarity is primarily due to the higher amount of rainfall at LML, which is consistent with the relationship between flux and rainfall observed in both terrestrial [*Mason et al.*, 1997a] and open ocean [*Lamborg et al.*, 1999] environments.

[16] The Hg:^{210}Pb correlation in rainwater recently observed in Wisconsin [*Lamborg et al.*, 2000] and the Atlantic Ocean [*Lamborg et al.*, 1999] has been used to calculate Hg deposition using known ^{210}Pb deposition rates [*Lamborg et al.*, 2000]. We have tested the validity of this model at our sites using (1) the ^{210}Pb deposition estimates [*Turekian*, 1977] for the west coast of North America and (2) the slope of the proposed global Hg:^{210}Pb relationship (0.06 ng*m Bq^{-1}). The resultant ratio indicates an annual Hg deposition rate of 25–50 nmol m^{-2} yr^{-1} in this coastal region, comparable with our independent calculations based on measured Hg concentrations in rainwater (Table 2).

[17] Finally, the total pre-industrial flux of Hg to the world's oceans is estimated at 3 Mmol/yr [*Mason et al.*, 1994], which averages 8.3 nmol/m^2/yr [*Mason et al.*, 1994]. Assuming that the pre-industrial flux at LML is comparable to that in the open ocean, the modern value is about twofold to threefold enriched relative to the pre-industrial flux estimate. While there are numerous limitations to this estimate, the twofold to threefold increase in deposition of Hg at LML, compares well to other estimates of the magnitude of the increase (~3 times) of Hg deposition

Table 2. Deposition Estimates of Hg at Long Marine Lab and Moffett Field[a]

Site	Volume Weighted Average Hg Concentration, pM	Annual Average Rainfall, cm	Deposition, μmol/m^2/yr
Moffett Field	58	35	22
Long Marine Lab	30	74	20

[a]Estimates are based on the data collected during the study period, and should be considered representative for that period. A longer study period is necessary to generate long term wet deposition estimates, and to quantify the annual variability in that deposition. In addition, roughly 80% of the events during the study period were sampled at MF and roughly 70% at LML. As a result, there is the potential that the volume-weighted averages used in these calculations are biased by the exclusion of extremely low- or high-concentration events. However, as our data at MF compares well to independent measurements made at MF during the same period as part of the MDN, we do not believe that these estimates are biased.

globally as a result of anthropogenic activities [*Mason et al.*, 1994].

3.5. Enrichment Factors

[18] To assess the relative contribution of natural Hg in crustal material, enrichment factors [*Duce et al.*, 1991] were calculated using published crustal concentrations [*Mason and Moore*, 1982; *Taylor*, 1964]. The enrichment factors, which ranged from 900–5700 at both sites, are much higher than those (4–40) reported in Atlantic rainwater, [*Lamborg et al.*, 1999]. The factors calculated for the Atlantic, however, involved samples with a large component of Saharan dust with a very low Hg/Al ratio that diluted the atmospheric signal.

[19] The relatively high enrichment factors at LML and MF do not necessarily imply enrichment from local anthropogenic fluxes of Hg, as the contribution from industrial emissions and natural oxidation would be difficult to tell apart using enrichment factors alone. The high enrichment factors do indicate that Hg in rainwater is not primarily derived from terrestrial dust. They are also indicative of an atmospheric source of Hg^{2+} to rainwater, which is consistent with the accepted models of Hg cycling in the atmosphere [*Lamborg et al.*, 2000; *Lin and Pehkonen*, 1999; *Munthe and McElroy*, 1992; *Pleijel and Munthe*, 1995].

3.6. Sources of Hg in the North Pacific

[20] In the Pacific basin, the dominant anthropogenic source of Hg to the atmosphere is coal combustion in China, an annual flux of 1.5 Mmol of Hg to the atmosphere [*Wang et al.*, 2000]. For comparison, this flux is double the estimated total anthropogenic Hg emissions (0.78 Mmol/yr) in the United States [*USEPA*, 1997], and accounts for roughly 10% of global industrial emissions (16.5–22 Mmol/yr) [*Mason et al.*, 1994]. With a 0.5–2 year residence time in the atmosphere, Hg^0 emissions from Chinese coal combustion are distributed on a global scale. However, emissions from coal combustion occur in both the vapor (Hg^0) and reactive Hg^{2+} states, and the reactive proportion is likely scavenged and deposited in Asia and the Pacific basin.

[21] Contrasted to anthropogenic emissions, natural emissions in the North Pacific are relatively minor, with the two dominant natural sources of Hg^0 being evasion from surface waters and emissions from volcanoes. In the case of evasion from surface waters, the majority of emissions are the result of reduction of atmospherically deposited Hg^{2+} in surface waters [*Mason et al.*, 1994]. On a global scale, this deposition and resulting evasion is estimated to be enriched 3 times over pre-anthropogenic values; and, as a result, the majority of emissions from surface waters are assumed to have anthropogenic origins [*Mason et al.*, 1994]. While there are few estimates of emissions from volcanoes within the Pacific Basin, the available estimates suggest low emissions (e.g., 5.75 mol/yr, for Kilauea Volcano in Hawaii) relative to anthropogenic emissions in the Pacific basin [*Varekamp and Buseck*, 1986]. Similarly, global emission estimates from volcanic activity range from 0.1–0.45 Mmol/yr [*Fitzgerald*, 1996]. These emissions are minor relative to both total anthropogenic emissions, and the estimated Chinese emissions, especially considering only a fraction of these volcanic emissions occur in the Pacific Basin. Therefore, the majority of Hg^0 in the atmosphere, and the majority of that Hg^0 which is reduced and deposited to land and sea surfaces is anthropogenic in origin.

3.7. Washout of Particle-Bound Hg

[22] A local washout of particle-associated Hg is not seen at MF or LML, with relatively homogenous Hg concentrations over a highly variable precipitation (1–25 mm) event size (Figure 3). Washout of particle-bound Hg is interpreted to be the cause of the strong exponential decrease in Hg concentration with increasing rainfall as observed in both continental [*Mason et al.*, 1997b] and open ocean [*Lamborg et al.*, 1999] environments. The lack of an exponential decrease in concentration with increasing event size in our data suggests that primarily nonlocal processes control the observed variability in Hg concentrations.

[23] The hypothesis that nonlocal processes are the major control on the variability of the concentrations observed was assessed by calculating the particle concentrations required to produce the concentrations observed. This was done with determination of the scavenging ratio [*Duce et al.*, 1991], which defines a relationship between rainwater concentrations and atmospheric particle concentrations as

$$W = [Hg_{rain}]^{*}\rho/[Hg_{atm}],$$

where

W = Scavenging ratio
$[Hg_{rain}]$ = Concentration of Hg in rain
ρ = Density of atmosphere
$[Hg_{atm}]$ = Concentration of Hg in the atmosphere.

Reported scavenging ratios range from 300–600 in midcontinental regions [*Fitzgerald et al.*, 1994; *Lamborg et al.*, 1995], to 1100 on the east coast of the United States [*Mason et al.*, 1997b], and ~1300 in the equatorial Pacific [*Mason et al.*, 1992]. Using a range of 500 to 1000, the volume weighted average concentrations in rainfall could be explained by atmospheric Hg particle concentrations of 71–141 fmol/m^3 at MF and 52–105 fmol/m^3 at LML. These values compare to reported atmospheric Hg particle concentrations of 2–9 fmol/m^3 in the North Pacific [*Fitzgerald*, 1989], 12 fmol/m^3 in the Atlantic [*Lamborg et al.*, 1999] and ~100 fmol/m^3 in continental settings [*Dvonch et al.*, 1995; *Keeler et al.*, 1995; *Lamborg et al.*, 1995; *Mason et al.*, 1997b].

[24] Given the rural, coastal location of LML, and the direction of prevailing winds (from the northwest, off the

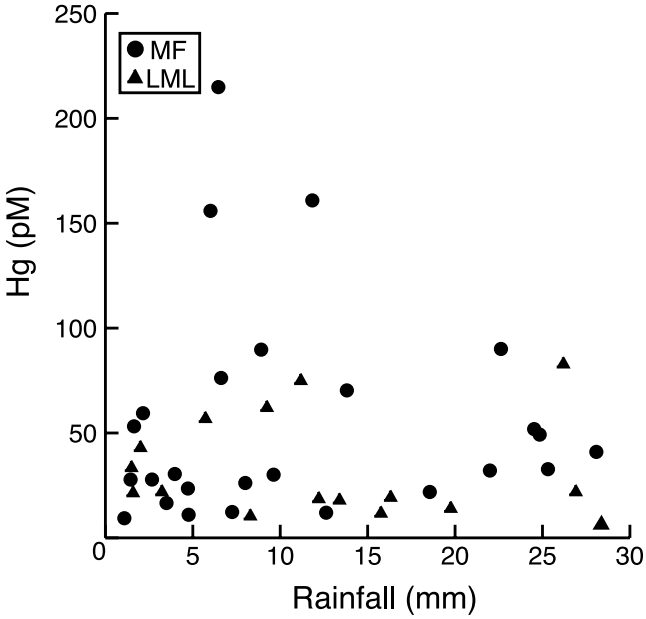

Figure 3. Total Hg versus rainfall for individual events at Long Marine Lab (triangles) and at Moffett Field (circles).

ocean) atmospheric Hg concentrations at LML are, as discussed above, assumed to be similar to those of open ocean sites. With this assumption, the particle concentration needed to account for the observed average rain concentrations is at least double that observed in open ocean environments. This disparity suggests that there is another source of Hg^{2+} to rainwater besides particle-bound Hg, which is consistent with an atmospheric source suggested by the high enrichment factors.

3.8. Air Mass Trajectory Calculations

[25] The preceding analyses indicate that a mechanism, other than local particle washout, is needed to explain the observed variability in rainwater Hg concentrations at both LML and MF. Trajectory calculations of air parcels associated with each event demonstrate a pattern of Hg concentration in rain, which is controlled by storm tracks across the North Pacific (Figure 4). Comparing the data in this study with samples from the North Pacific collected in the 1980s [*Fitzgerald*, 1989] and with equatorial samples collected in 1990 [*Mason et al.*, 1992] reveals a pattern of low Hg concentrations in rainwater in equatorial regions, higher concentrations in the midlatitudes, and slightly decreasing concentrations in the northern latitudes (Figure 4). This latitudinal pattern suggests that large-scale processes are involved in controlling the variability of Hg concentrations observed in this study. Most notably, the peak concentrations at middle latitudes suggest a source in Asia, which appears to influence Hg concentrations in rain on the coast of California.

3.9. Long-Range Sources of Hg

[26] Additional analyses of the sources of Hg in rain in the Pacific Basin are necessary in order assess the validity of the proposal that industrial emissions from Asia are the primary source of Hg in North Pacific rain. The dominant species of Hg in the atmosphere is Hg^0, but reactive Hg^{2+} has been demonstrated to be the dominant species of Hg in rainwater. Given the evidence for a nonlocal atmospheric source of Hg in precipitation, consideration of the atmospheric processes responsible for the generation of Hg^{2+} in the atmosphere is necessary in evaluating potential sources of Hg in rainwater.

[27] While our understanding of the atmospheric chemistry of Hg is far from complete, there are two current accepted processes by which Hg^0 is oxidized and incorpo-

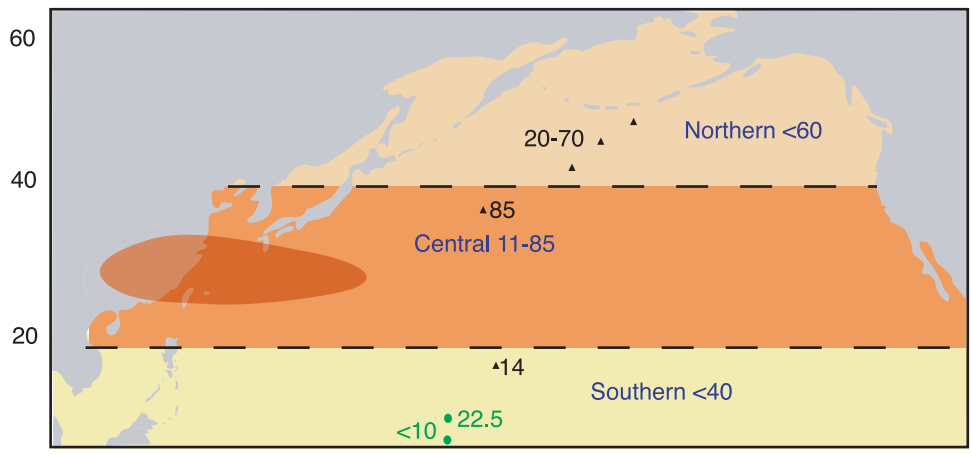

Figure 4. Relationship between storm tracks and Hg concentrations at Long Marine Lab. Storm tracks have been sorted into three categories, represented by dashed lines. Concentrations (pM) are given in blue for each category, with peak concentrations associated with the midlatitude storm tracks. For comparison, previous measurements of Hg in rainwater in the Pacific are given; circles are from *Mason et al.* [1992], triangles from SEAREX [*Fitzgerald*, 1989]. In addition, the area of maximum ozone production and export is plotted [*Mauzerall et al.*, 2000], which corresponds to the peak Hg concentrations observed in this study. See text for discussion.

rated in rainwater. One of these mechanisms, the Cloud Conversion Model (CCM), proposed by Pleijel and Munthe [*Munthe and McElroy*, 1992; *Pleijel and Munthe*, 1995], focuses on the oxidation of Hg^0 in the aqueous phase, and then scavenging of the reactive Hg by soot contained in raindrops. The other mechanism suggests the production of Hg^{2+} in the gas phase (reaction of Hg^0 with either O_3 or H_2O_2) may be the dominant mechanism [*Lamborg et al.*, 2000].

[28] Other models [*Bergan and Rodhe*, 2001] have built on this work, and suggest that the kinetics of O_3 oxidation of Hg^0 is too slow to explain the observed trends in atmospheric Hg speciation and distribution. Work on depletion of Hg^0 during polar sunrise in the Arctic has shown a positive correlation with O_3 [*Schroeder et al.*, 1998], which is attributed to the generation of free halogen species, highly effective oxidizers of Hg^0 [*Schroeder and Munthe*, 1998], during the photodegradation of O_3 [*Lu et al.*, 2001]. The production of halogen species has also been demonstrated to occur during O_3 degradation at lower latitudes [*Dickerson et al.*, 1999], and these halogen species are thought to play an important part in the oxidation of Hg^0 in the marine boundary layer [*Mason*, 2001]. As a result, the oxidation of Hg^0 in the marine environment will be strongly influenced by the concentration of O_3, either directly, through oxidation of Hg^0 or indirectly through the production of reactive halogen species as that O_3 photodegrades.

[29] Asia, and in particular, China, has received a great deal of scientific attention recently as a result of increasing impacts on atmospheric O_3 concentrations due to industrial activities [*Carmichael et al.*, 1998; *Mauzerall et al.*, 2000; *Pochanart et al.*, 1999]. During wintertime, there is a maximum in O_3 production in China as a result of biomass burning, coal combustion and other industrial activities, and, coupled with strong northwesterly continental outflow, these activities result in maximum O_3 concentrations in the western Pacific [*Mauzerall et al.*, 2000]. This O_3 is available for oxidation of ambient Hg^0 through the mechanisms described above, and, if the resulting reactive Hg^{2+} is incorporated in developing storms, it will be effectively transported across the Pacific to the west coast of North America as indicated in Figure 4.

[30] Therefore, O_3 should be considered a tracer for potential oxidation of Hg^0, through both direct and indirect oxidation of Hg^0. The elevated Hg concentrations in rain observed in this study, then, are most likely the result of Asian emissions of both Hg and O_3 and its precursors, although the later may play a more important role in supplying Hg^{2+} to rainwater. These emissions will combine to enhance Hg^0 oxidation rates in the Pacific basin, ultimately resulting in elevated Hg concentrations in rainwater sourced within the basin. This phenomenon has been used to explain Hg deposition in Florida, where recent work suggests that up to 80% of deposition to the Florida Everglades is the result of production of reactive Hg^{2+} species in the marine boundary layer that is then scavenged and deposited by storms in Florida [*Guentzel et al.*, 2001].

4. Conclusions

[31] This initial study demonstrates the impact of Asian industrial emissions on Hg concentrations in rain in western North America. The analyses substantiate previous reports on the influence of those emissions on Hg deposition in the North Pacific, first proposed by Bill Fitzgerald and his colleagues during the SEAREX program [*Fitzgerald*, 1989]. The increased Hg concentrations in rainwater in central California are attributed to a series of atmospheric reactions, and are not dependent solely on emissions of industrial Hg to the atmosphere. Rather, the concentrations may be due to a combination of particle-bound Hg emissions from Asia and a series of redox reactions centered around the destruction of O_3 in the marine troposphere, that increases production of atmospheric Hg^{2+} above background levels. Rainwater, contained in storms forming in the Western Pacific, then transports this contaminant Hg across the Pacific to the west coast of North America.

[32] Superimposed on this long-range transport of Hg in storms are local inputs due to human activities. Those inputs are evidenced by the 44% enrichment of Hg concentrations in precipitation at the urban site (MF) relative to the coastal site (LML). The enrichment could be the result of local industrial Hg emissions, soot, or redox species emissions, which result in higher concentrations of Hg in rainwater at MF relative to LML. Alternatively, the enrichment may be the result of higher O_3 concentrations, which will facilitate direct and indirect oxidation of Hg^0. Additionally, San Francisco Bay, which abuts MF, may supply the sea salt aerosols necessary to generate free halogens during O_3 degradation.

[33] Both of these apparently local and trans-Pacific fluxes demonstrate the increasing importance in understanding the atmospheric chemistry of Hg. Our understanding of the sources of Hg deposited to terrestrial and aquatic environments is directly linked to our understanding of the redox reactions governing the production of Hg^{2+} in the atmosphere, and here we demonstrate how the influence of anthropogenic emissions impact Hg on both regional and hemispheric scales. These data corroborate other recent reports that indicate efforts to regulate Hg concentrations in fish and waterways must focus not only on Hg emissions, but also on emissions of redox species such as O_3 if they are to achieve their desired reductions in concentrations.

[34] **Acknowledgments.** The authors are grateful for the assistance of Pam Tsai at the San Francisco Estuary Institute, Eric Hansen at the City of San Jose, and Kobin Lee, with NASA, at Moffett Field. Rob Mason and his lab at the University of Maryland's Chesapeake Biological Laboratory offered invaluable technical and scientific advice. Joyce Harris and the Climate Monitoring and Diagnostics Laboratory (CMDL) in Boulder, Colorado, provided the trajectory calculations. This study was funded in part by grants from the University of California's Toxic Substances Research and Teaching Program, the San Francisco Estuary Institute's Regional Monitoring Program for Toxic Substances, and the W. M. Keck Foundation.

ZLD	zero liquid discharge

Executive Summary

This study evaluated treatment technologies potentially capable of meeting the State of Washington Department of Ecology's (Ecology) revised effluent discharge limits associated with revised human health water quality criteria (HHWQC). HDR Engineering, Inc. (HDR) completed a literature review of potential technologies and an engineering review of their capabilities to evaluate and screen treatment methods for meeting revised effluent limits for four constituents of concern: arsenic, benzo(a)pyrene (BAP), mercury, and polychlorinated biphenyls (PCBs). HDR selected two alternatives to compare against an assumed existing baseline secondary treatment system utilized by dischargers. These two alternatives included enhanced secondary treatment with membrane filtration/reverse osmosis (MF/RO) and enhanced secondary treatment with membrane filtration/granulated activated carbon (MF/GAC). HDR developed capital costs, operating costs, and a net present value (NPV) for each alternative, including the incremental cost to implement improvements for an existing secondary treatment facility.

Currently, there are no known facilities that treat to the HHWQC and anticipated effluent limits that are under consideration. Based on the literary review, research, and bench studies, the following conclusions can be made from this study:

- Revised HHWQC based on state of Oregon HHWQC (2001) and U.S. Environmental Protection Agency (EPA) "National Recommended Water Quality Criteria" will result in very low water quality criteria for toxic constituents.
- There are limited "proven" technologies available for dischargers to meet required effluent quality limits that would be derived from revised HHWQC.
    - Current secondary wastewater treatment facilities provide high degrees of removal for toxic constituents; however, they are not capable of compliance with water quality-based National Pollutant Discharge Elimination System (NPDES) permit effluent limits derived from the revised HHWQC.
    - Advanced treatment technologies have been investigated and candidate process trains have been conceptualized for toxics removal.
        - Advanced wastewater treatment technologies may enhance toxics removal rates; however, they will not be capable of compliance with HHWQC-based effluent limits for PCBs. The lowest levels achieved based on the literature review were between <0.00001 and 0.00004 micrograms per liter (µg/L), as compared to a HHWQC of 0.0000064 µg/L.
        - Based on very limited performance data for arsenic and mercury from advanced treatment information available in the technical literature, compliance with revised criteria may or may not be possible, depending upon site specific circumstances.
            - Compliance with a HHWQC for arsenic of 0.018 µg/L appears unlikely. Most treatment technology performance information available in the literature is based on drinking water treatment applications targeting a much higher Safe Drinking Water Act (SDWA) maximum contaminant level (MCL) of 10 µg/L.
            - Compliance with a HHWQC for mercury of 0.005 µg/L appears to be potentially attainable on an average basis, but perhaps not if effluent limits are structured on a maximum monthly, maximum weekly or maximum daily basis. Some secondary treatment facilities attain average effluent mercury levels of 0.009 to 0.066 µg/L. Some treatment facilities with effluent filters attain average effluent mercury levels of 0.002 to 0.010 µg/L. Additional

advanced treatment processes are expected to enhance these removal rates, but little mercury performance data is available for a definitive assessment.

- Little information is available to assess the potential for advanced technologies to comply with revised BAP criteria. A municipal wastewater treatment plant study reported both influent and effluent BAP concentrations less than the HHWQC of 0.0013 ug/L (Ecology, 2010).

- Some technologies may be effective at treating identified constituents of concern to meet revised limits while others may not. It is therefore even more challenging to identify a technology that can meet all constituent limits simultaneously.
- A HHWQC that is one order-of-magnitude less stringent could likely be met for mercury and BAP; however, it appears PCB and arsenic limits would not be met.

- Advanced treatment processes incur significant capital and operating costs.
  - Advanced treatment process to remove additional arsenic, BAP, mercury, and PCBs would combine enhancements to secondary treatment with microfiltration membranes and reverse osmosis or granular activated carbon and increase the estimated capital cost of treatment from $17 to $29 in dollars per gallon per day of capacity (based on a 5.0-million-gallon-per-day (mgd) facility).
  - The annual operation and maintenance costs for the advanced treatment process train will be substantially higher (approximately $5 million - $15 million increase for a 5.0 mgd capacity facility) than the current secondary treatment level.
- Implementation of additional treatment will result in additional collateral impacts.
  - High energy consumption.
  - Increased greenhouse gas emissions.
  - Increase in solids production from chemical addition to the primaries. Additionally, the membrane and GAC facilities will capture more solids that require handling.
  - Increased physical space requirements at treatment plant sites for advanced treatment facilities and residuals management including reverse osmosis reject brine processing.
- It appears advanced treatment technology alone cannot meet all revised water quality limits and implementation tools are necessary for discharger compliance.
  - Implementation flexibility will be necessary to reconcile the difference between the capabilities of treatment processes and the potential for HHWQC driven water quality based effluent limits to be lower than attainable with technology

Table ES-1 indicates that the unit NPV cost for baseline conventional secondary treatment ranges from $13 to $28 per gallon per day of treatment capacity. The unit cost for the advanced treatment alternatives increases the range from the low $20s to upper $70s on a per gallon per-day of treatment capacity. The resulting unit cost for improving from secondary treatment to advanced treatment ranges between $15 and $50 per gallon per day of treatment capacity. Unit costs were also evaluated for both a 0.5 and 25 mgd facility. The range of unit costs for improving a 0.5 mgd from secondary to advanced treatment is $60 to $162 per gallon per day of treatment capacity. The range of unit costs for improving a 25 mgd from secondary to advanced treatment is $10 to $35 per gallon per day of treatment capacity.

Table ES-1. Treatment Technology Costs in 2013 Dollars for a 5-mgd Facility

Alternative	Total Construction Cost, 2013 dollars ($ Million)	O&M Net Present Value, 2013 dollars ($ Million)***	Total Net Present Value, 2013 dollars ($ Million)	NPV Unit Cost, 2013 dollars ($/gpd)
Baseline (Conventional Secondary Treatment)*	59 - 127	5 - 11	65 - 138	13 - 28
Incremental Increase to Advanced Treatment - MF/RO	48 - 104	26 - 56	75 - 160	15 - 32
Advanced Treatment - MF/RO**	108 - 231	31 - 67	139 - 298	28 - 60
Incremental Increase to Advanced Treatment - MF/GAC	71 - 153	45 - 97	117 - 250	23 - 50
Advanced Treatment - MF/GAC	131 - 280	50 - 108	181 - 388	36 - 78

* Assumed existing treatment for dischargers. The additional cost to increase the SRT to upwards of 30-days is about $12 - 20 million additional dollars in total project cost for a 5 mgd design flow.

** Assumes zero liquid discharge for RO brine management, followed by evaporation ponds. Other options are available as listed in Section 4.4.2.

*** Does not include the cost for labor.

mgd=million gallons per day
MG=million gallons
MF/RO=membrane filtration/reverse osmosis
MF/GAC=membrane filtration/granulated activated carbon
O&M=operations and maintenance
Net Present Value = total financed cost assuming a 5% nominal discount rate over an assumed 25 year equipment life.

Costs presented above are based on a treatment capacity of 5.0 mgd, however, existing treatment facilities range dramatically across Washington in size and flow treated. The key differences in cost between the baseline and the advanced treatment MF/RO are as follows:

- Larger aeration basins than the baseline to account for the longer SRT (>8 days versus <8 days).
- Additional pumping stations to pass water through the membrane facilities and granulated activated carbon facilities. These are based on peak flows.
- Membrane facilities (equipment, tanks chemical feed facilities, pumping, etc.) and replacement membrane equipment.
- Granulated activated carbon facilities (equipment, contact tanks, pumping, granulated activated carbon media, etc.)
- Additional energy and chemical demand to operate the membrane and granulated activated carbon facilities
- Additional energy to feed and backwash the granulated activated carbon facilities.
- Zero liquid discharge facilities to further concentrate the brine reject.
    - Zero liquid discharge facilities are energy/chemically intensive and they require membrane replacement every few years due to the brine reject water quality.
- Membrane and granulated activated carbon media replacement represent a significant maintenance cost.

- Additional hauling and fees to regenerate granulated activated carbon off-site.

The mass of pollutant removal by implementing advanced treatment was calculated based on reducing current secondary effluent discharges to revised effluent limits for the four pollutants of concern. These results are provided in Table ES-2 as well as a median estimated unit cost basis for the mass of pollutants removed.

Table ES-2. Unit Cost by Contaminant for a 5-mgd Facility Implementing Advanced Treatment using Membrane Filtration/Reverse Osmosis

Component	PCBs	Mercury	Arsenic	BAPs
Required HHWQC based Effluent Quality (µg/L)	0.0000064	0.005	0.018	0.0013
Current Secondary Effluent Concentration (µg/L)	0.002	0.025	7.5	0.006
Total Mass Removed (lbs) over 25 year Period	0.76	7.6	2,800	1.8
Median Estimated Unit Cost (NPV per total mass removed in pounds over 25 years)	$290,000,000	$29,000,000	$77,000	$120,000,000

µg/L=micrograms per liter
lbs=pounds
NPV=net present value

Collateral adverse environmental impacts associated with implementing advanced treatment were evaluated. The key impacts from this evaluation include increased energy use, greenhouse gas production, land requirements and treatment residuals disposal. Operation of advanced treatment technologies could increase electrical energy by a factor of 2.3 to 4.1 over the baseline secondary treatment system. Direct and indirect greenhouse gas emission increases are related to the operation of advanced treatment technologies and electrical power sourcing, with increases of at least 50 to 100 percent above the baseline technology. The energy and air emission implications of advanced treatment employing granulated activated carbon construction of advanced treatment facilities will require additional land area. The availability and cost of land adjacent to existing treatment facilities has not been included in cost estimates, but could be very substantial. It is worthwhile noting residual materials from treatment may potentially be hazardous and their disposal may be challenging to permit. Costs assume zero liquid discharge from the facilities.

1.0 Introduction

Washington's Department of Ecology (Ecology) has an obligation to periodically review waterbody "designated uses" and to modify, as appropriate, water quality standards to ensure those uses are protected. Ecology initiated this regulatory process in 2009 for the human health-based water quality criteria (HHWQC) in Washington's *Surface Water Quality Standards* (Washington Administrative Code [WAC] 173-201A). HHWQC are also commonly referred to as "toxic pollutant water quality standards." Numerous factors will influence Ecology's development of HHWQC. The expectation is that the adopted HHWQC will be more stringent than current adopted criteria. National Pollutant Discharge Elimination System (NPDES) effluent limits for permitted dischargers to surface waters are based on U.S. Environmental Protection Agency (EPA) and state guidance. Effluent limits are determined primarily from reasonable potential analyses and waste load allocations (WLAs) from total maximum daily loads (TMDLs), although the permit writer may use other water quality data. Water quality-based effluent limits are set to be protective of factors, including human health, aquatic uses, and recreational uses. Therefore, HHWQC can serve as a basis for effluent limits. The presumption is that more stringent HHWQC will, in time, drive lower effluent limits. The lower effluent limits will require advanced treatment technologies and will have a consequent financial impact on NPDES permittees. Ecology anticipates that a proposed revision to the water quality standards regulation will be issued in first quarter 2014, with adoption in late 2014.

The Association of Washington Businesses (AWB) is recognized as the state's chamber of commerce, manufacturing and technology association. AWB members, along with the Association of Washington Cities and Washington State Association of Counties (collectively referred to as Study Partners), hold NPDES permits authorizing wastewater discharges. The prospect of more stringent HHWQC, and the resulting needs for advanced treatment technologies to achieve lower effluent discharge limits, has led this consortium to sponsor a study to assess technology availability and capability, capital and operations and maintenance (O&M) costs, pollutant removal effectiveness, and collateral environmental impacts of candidate technologies.

The "base case" for the study began with the identification of four nearly ubiquitous toxic pollutants present in many industrial and municipal wastewater discharges, and the specification of pollutant concentrations in well-treated secondary effluent. The pollutants are arsenic, benzo(a)pyrene (BAP), mercury and polychlorinated biphenyls (PCBs), which were selected for review based on available monitoring data and abundant presence in the environment. The purpose of this study is to review the potential water quality standards and associated treatment technologies able to meet those standards for four pollutants.

A general wastewater treatment process and wastewater characteristics were used as the common baseline for comparison with all of the potential future treatment technologies considered. An existing secondary treatment process with disinfection at a flow of 5 million gallons per day (mgd) was used to represent existing conditions. Typical effluent biochemical oxygen demand (BOD) and total suspended solids (TSS) were assumed between 10 and 30 milligrams per liter (mg/L) for such a facility and no designed nutrient or toxics removal was assumed for the baseline existing treatment process.

Following a literature review of technologies, two advanced treatment process options for toxics removal were selected for further evaluation based on the characterization of removal effectiveness from the technical literature review and Study Partners' preferences. The two tertiary treatment options are microfiltration membrane filtration (MF) followed by either reverse osmosis (RO) or granular activated carbon (GAC) as an addition to an existing secondary treatment facility.

The advanced treatment technologies are evaluated for their efficacy and cost to achieve the effluent limitations implied by the more stringent HHWQC. Various sensitivities are examined, including for less stringent adopted HHWQC, and for a size range of treatment systems. Collateral environmental impacts associated with the operation of advanced technologies are also qualitatively described.

2.0 Derivation of the Baseline Study Conditions and Rationale for Selection of Effluent Limitations

2.1 Summary of Water Quality Criteria

Surface water quality standards for toxics in the State of Washington are being updated based on revised human fish consumption rates (FCRs). The revised water quality standards could drive very low effluent limitations for industrial and municipal wastewater dischargers. Four pollutants were selected for study based on available monitoring data and abundant presence in the environment. The four toxic constituents are arsenic, BAP, mercury, and PCBs.

2.2 Background

Ecology is in the process of updating the HHWQC in the state water quality standards regulation. Toxics include metals, pesticides, and organic compounds. The human health criteria for toxics are intended to protect people who consume water, fish, and shellfish. FCRs are an important factor in the derivation of water quality criteria for toxics.

The AWB/City/County consortium (hereafter "Study Partners") has selected four pollutants for which more stringent HHWQC are expected to be promulgated. The Study Partners recognize that Ecology probably will not adopt more stringent arsenic HHWQC so the evaluation here is based on the current arsenic HHWQC imposed by the National Toxics Rule. Available monitoring information indicates these pollutants are ubiquitous in the environment and are expected to be present in many NPDES discharges. The four pollutants include the following:

- Arsenic
  - Elemental metalloid that occurs naturally and enters the environment through erosion processes. Also widely used in batteries, pesticides, wood preservatives, and semiconductors. Other current uses and legacy sources in fungicides/herbicides, copper smelting, paints/dyes, and personal care products.

- Benzo(a)pyrene (BAP)
  - Benzo(a)pyrene is a polycyclic aromatic hydrocarbon formed by a benzene ring fused to pyrene as the result of incomplete combustion. Its metabolites are highly carcinogenic. Sources include wood burning, coal tar, automobile exhaust, cigarette smoke, and char-broiled food.

- Mercury
  - Naturally occurring element with wide legacy uses in thermometers, electrical switches, fluorescent lamps, and dental amalgam. Also enters the environment through erosion processes, combustion (especially coal), and legacy industrial/commercial uses. Methylmercury is an organometallic that is a bioaccumulative toxic. In aquatic systems, an anaerobic methylation process converts inorganic mercury to methylmercury.

- Polychlorinated Biphenyls (PCBs)
  - Persistent organic compounds historically used as a dielectric and coolant in electrical equipment and banned from production in the U.S. in 1979. Available information indicates continued pollutant loadings to the environment as a byproduct from the use of some pigments, paints, caulking, motor oil, and coal combustion.

2.3 Assumptions Supporting Selected Ambient Water Quality Criteria and Effluent Limitations

Clean Water Act regulations require NPDES permittees to demonstrate their discharge will "not cause or contribute to a violation of water quality criteria." If a "reasonable potential analysis" reveals the possibility of a standards violation, the permitting authority is obliged to develop "water quality-based effluent limits" to ensure standards achievement. In addition, if ambient water quality monitoring or fish tissue assessments reveal toxic pollutant concentrations above HHWQC levels, Ecology is required to identify that impairment ("303(d) listing") and develop corrective action plans to force reduction in the toxic pollutant discharge or loading of the pollutant into the impaired water body segment. These plans, referred to as total maximum daily loads (TMDLs) or water cleanup plans, establish discharge allocations and are implemented for point discharge sources through NPDES permit effluent limits and other conditions.

The effect of more stringent HHWQC will intuitively result in more NPDES permittees "causing or contributing" to a water quality standards exceedance, and/or more waterbodies being determined to be impaired, thus requiring 303(d) listing, the development of TMDL/water cleanup plans, and more stringent effluent limitations to NPDES permittees whose treated wastewater contains the listed toxic pollutant.

The study design necessarily required certain assumptions to create a "baseline effluent scenario" against which the evaluation of advanced treatment technologies could occur. The Study Partners and HDR Engineering, Inc (HDR) developed the scenario. Details of the baseline effluent scenario are presented in Table 1. The essential assumptions and rationale for selection are presented below:

- Ecology has indicated proposed HHWQC revisions will be provided in first quarter 2014. A Study Partners objective was to gain an early view on the treatment technology and cost implications. Ecology typically allows 30 or 45 days for the submission of public comments on proposed regulations. To wait for the proposed HHWQC revisions would not allow sufficient time to complete a timely technology/cost evaluation and then to share the study results in the timeframe allowed for public involvement/public comments.
- Coincident with the issuance of the proposed regulation, Ecology has a statutory obligation to provide a Significant Legislative Rule evaluation, one element of which is a "determination whether the probable benefits of the rule are greater than its probable costs, taking into account both the qualitative and quantitative benefits and costs and the specific directives of the statute being implemented" (RCW 34.05.328(1)(d)). A statutory requirement also exists to assess the impact of the proposed regulation to small businesses. The implication is that Ecology will be conducting these economic evaluations in fourth quarter 2013 and early 2014. The Study Partners wanted to have a completed technology/cost study available to share with Ecology for their significant legislative rule/small business evaluations.
- The EPA, Indian tribes located in Washington, and various special interest groups have promoted the recently promulgated state of Oregon HHWQC (2011) as the "model" for Washington's revisions of HHWQC. The Oregon HHWQC are generally based on a increased FCR of 175 grams per day (g/day) and an excess cancer risk of 10^{-6}. While the Study Partners do not concede the wisdom or appropriateness of the Oregon criteria, or the selection of scientific/technical elements used to derive those criteria, the Study Partners nevertheless have selected the Oregon HHWQC as a viable "starting point" upon which this study could be based.

- The scenario assumes generally that Oregon's HHWQC for ambient waters will, for some parameters in fact, become effluent limitations for Washington NPDES permittees. The reasoning for this important assumption includes:
  - The state of Washington's NPDES permitting program is bound by the *Friends of Pinto Creek vs. EPA* decision in the United States Court of Appeals for the Ninth Circuit (October 4, 2007). This decision held that no NPDES permits authorizing new or expanded discharges of a pollutant into a waterbody identified as impaired; i.e., listed on CWA section 303(d), for that pollutant, may be issued until such time as "existing dischargers" into the waterbody are "subject to compliance schedules designed to bring the (waterbody) into compliance with applicable water quality standards." In essence, any new/expanded discharge of a pollutant causing impairment must achieve the HHWQC at the point of discharge into the waterbody.
  - If a waterbody segment is identified as "impaired" (i.e., not achieving a HHWQC), then Ecology will eventually need to produce a TMDL or water cleanup plan. For an existing NPDES permittee with a discharge of the pollutant for which the receiving water is impaired, the logical assumption is that any waste load allocation granted to the discharger will be at or lower than the numeric HHWQC (to facilitate recovery of the waterbody to HHWQC attainment). As a practical matter, this equates to an effluent limit established at the HHWQC.
  - Acceptance of Oregon HHWQC as the baseline for technology/cost review also means acceptance of practical implementation tools used by Oregon. The HHWQC for mercury is presented as a fish tissue methyl mercury concentration. For the purposes of NPDES permitting, however, Oregon has developed an implementation management directive which states that any confirmed detection of mercury is considered to represent a "reasonable potential" to cause or contribute to a water quality standards violation of the methyl mercury criteria. The minimum quantification level for total mercury is presented as 0.005 micrograms per liter (µg/L) (5.0 nanograms per liter (ng/L)).
  - The assumed effluent limit for arsenic is taken from EPA's *National Recommended Water Quality Criteria* (2012) (inorganic, water and organisms, 10^{-6} excess cancer risk). Oregon's 2011 criterion is actually based on a less protective excess cancer risk (10^{-4}). This, however, is the result of a state-specific risk management choice and it is unclear if Washington's Department of Ecology would mimic the Oregon approach.
  - The assumption is that no mixing zone is granted such that HHWQC will effectively serve as NPDES permit effluent limits. Prior discussion on the impact of the Pinto Creek decision, 303(d) impairment and TMDL Waste Load Allocations processes, all lend support to this "no mixing zone" condition for the parameters evaluated in this study.
- Consistent with Ecology practice in the evaluation of proposed regulations, the HHWQC are assumed to be in effect for a 20-year period. It is assumed that analytical measurement technology and capability will continue to improve over this time frame and this will result in the detection and lower quantification of additional HHWQC in ambient water and NPDES dischargers. This knowledge will trigger the Pinto Creek/303(d)/TMDL issues identified above and tend to pressure NPDES permittees to evaluate and install advanced treatment technologies. The costs and efficacy of treatment for these additional HHWQC is unknown at this time.

Other elements of the Study Partners work scope, as presented to HDR, must be noted:

- The selection of four toxic pollutants and development of a baseline effluent scenario is not meant to imply that each NPDES permittee wastewater discharge will include those pollutants at the assumed concentrations. Rather, the scenario was intended to represent a composite of many NPDES permittees and to facilitate evaluation of advanced treatment technologies relying on mechanical, biological, physical, chemical processes.
- The scalability of advanced treatment technologies to wastewater treatment systems with different flow capacities, and the resulting unit costs for capital and O&M, is evaluated.
- Similarly, a sensitivity analysis on the unit costs for capital and O&M was evaluated on the assumption the adopted HHWQC (and effectively, NPDES effluent limits) are one order-of-magnitude less stringent than the Table 1 values.

Table 1: Summary of Effluent Discharge Toxics Limits

Constituent	Human Health Criteria based Limits to be met with no Mixing Zone (µg/L)	Basis for Criteria	Typical Concentration in Municipal Secondary Effluent (µg/L)	Typical Concentration in Industrial Secondary Effluent (µg/L)	Existing Washington HHC (water + org.), NTR (µg/L)
PCBs	0.0000064	Oregon Table 40 Criterion (water + organisms) at FCR of 175 grams/day	0.0005 to 0.0025[b,c,d,e,f]	0.002 to 0.005[i]	0.0017
Mercury	0.005	DEQ IMD[a]	0.003 to 0.050[h]	0.010 to 0.050[h]	0.140
Arsenic	0.018	EPA National Toxics Rule (water + organisms)[k]	0.500 to 5.0[j]	10 to 40[j]	0.018
Benzo(a)Pyrene	0.0013	Oregon Table 40 Criterion (water + organisms) at FCR of 175 grams/day	0.00028 to 0.006[b,g]	0.006 to1.9	0.0028

3.0 Wastewater Characterization Description

This section describes the wastewater treatment discharge considered in this technology evaluation. Treated wastewater characteristics are described, including average and peak flow, effluent concentrations, and toxic compounds of concern.

3.1 Summary of Wastewater Characterization

A general wastewater treatment process and wastewater characteristics were developed as the common baseline to represent the existing conditions as a starting point for comparison with potential future advanced treatment technologies and improvements. A secondary treatment process with disinfection at a flow of 5 mgd as the current, baseline treatment system for existing dischargers was also developed. Typical effluent biochemical oxygen demand (BOD) and total suspended solids (TSS) were assumed between 10 to 30 mg/L from such a facility and no nutrient or toxics removal was assumed to be accomplished in the existing baseline treatment process.

3.2 Existing Wastewater Treatment Facility

The first step in the process is to characterize the existing wastewater treatment plant to be evaluated in this study. The goal is to identify the necessary technology that would need to be added to an existing treatment facility to comply with revised toxic pollutant effluent limits. Rather than evaluating the technologies and costs to upgrade multiple actual operating facilities, the Study Partners specified that a generalized municipal/industrial wastewater treatment facility would be characterized and used as the basis for developing toxic removal approaches. General characteristics of the facility's discharge are described in Table 2.

Table 2. General Wastewater Treatment Facility Characteristics

Average Annual Wastewater Flow, mgd	Maximum Month Wastewater Flow, mgd	Peak Hourly Wastewater Flow, mgd	Effluent BOD, mg/L	Effluent TSS, mg/L
5.0	6.25	15.0	10 to 30	10 to 30

mgd=million gallons per day
mg/L=milligrams per liter
BOD=biochemical oxygen demand
TSS=total suspended solids

In the development of the advanced treatment technologies presented below, the capacity of major treatment elements are generally sized to accommodate the maximum month average wastewater flow. Hydraulic elements, such as pumps and pipelines, were selected to accommodate the peak hourly wastewater flow.

The general treatment facility incorporates a baseline treatment processes including influent screening, grit removal, primary sedimentation, suspended growth biological treatment (activated sludge), secondary clarification, and disinfection using chlorine. Solids removed during primary treatment and secondary clarification are assumed to be thickened, stabilized, dewatered, and land applied to agricultural land. The biological treatment process is assumed to be activated sludge with a relatively short (less than 10-day) solids retention time. The baseline secondary treatment facility is assumed not to have processes dedicated to removing nutrients or toxics. However, some coincident removal of toxics will occur during conventional treatment.

3.3 Toxic Constituents

As described in Section 2.3, the expectation of more stringent HHWQC will eventually trigger regulatory demands for NPDES permittees to install advanced treatment technologies. The Study Group and HDR selected four specific toxic pollutants reflecting a range of toxic constituents as the basis for this study to limit the constituents and technologies to be evaluated to a manageable level.

The four toxic pollutants selected were PCBs, mercury, arsenic, and BAP, a polycyclic aromatic hydrocarbon (PAH). Mercury and arsenic are metals, and PCBs and PAHs are organic compounds. Technologies for removing metals and organic compounds are in some cases different. Key information on each of the compounds, including a description of the constituent, the significance of each constituent, proposed HHWQC, basis for the proposed criteria, typical concentration in both municipal and industrial secondary effluent, and current Washington state water quality criteria, are shown in Table 1. It is assumed that compliance with the proposed criteria in the table would need to be achieved at the “end of pipe” and Ecology would not permit a mixing zone for toxic constituents. This represents a “worst–case,” but a plausible assumption about discharge conditions.

4.0 Treatment Approaches and Costs

4.1 Summary of Treatment Approach and Costs

Two advanced treatment process options for toxics removal for further evaluation based on the characterization of removal effectiveness from the technical literature review and Study Group preferences. The two tertiary treatment options are microfiltration MF followed by either RO or GAC as an addition to an existing secondary treatment facility. Based on the literature review, it is not anticipated that any of the treatment options will be effective in reducing all of the selected pollutants to below the anticipated water quality criteria. A summary of the capital and operations and maintenance costs for tertiary treatment is provided, as well as a comparison of the adverse environmental impacts for each alternative.

4.2 Constituent Removal – Literature Review

The evaluation of treatment technologies relevant to the constituents of concern was initiated with a literature review. The literature review included a desktop search using typical web-based search engines, and search engines dedicated to technical and research journal databases. At the same time, HDR's experience with the performance of existing treatment technologies specifically related to the four constituents of concern, was used in evaluating candidate technologies. A summary of the constituents of concern and relevant treatment technologies is provided in the following literature review section.

4.2.1 Polychlorinated Biphenyls

PCBs are persistent organic pollutants that can be difficult to remove in treatment. PCB treatment in wastewater can be achieved using oxidation with peroxide, filtration, biological treatment or a combination of these technologies. There is limited information available about achieving ultra-low effluent PCB concentrations near the 0.0000064 µg/L range under consideration in the proposed rulemaking process. This review provides a summary of treatment technology options and anticipated effluent PCB concentrations.

Research on the effectiveness of ultraviolet (UV) light and peroxide on removing PCBs was tested in bench scale batch reactions (Yu, Macawile, Abella, & Gallardo 2011). The combination of UV and peroxide treatment achieved PCB removal greater than 89 percent, and in several cases exceeding 98 percent removal. The influent PCB concentration for the batch tests ranged from 50 to 100 micrograms per liter (µg/L). The final PCB concentration (for the one congener tested) was <10 µg/L (10,000 ng/L) for all tests and <5 µg/L (5,000 ng/L) for some tests. The lowest PCB concentrations in the effluent occurred at higher UV and peroxide doses.

Pilot testing was performed to determine the effectiveness of conventional activated sludge and a membrane bioreactor to remove PCBs (Bolzonella, Fatone, Pavan, & Cecchi 2010). EPA Method 1668 was used for the PCB analysis (detection limit of 0.01 ng/L per congener). Influent to the pilot system was a combination of municipal and industrial effluent. The detailed analysis was for several individual congeners. Limited testing using the Aroclor method (total PCBs) was used to compare the individual congeners and the total concentration of PCBs. Both conventional activated sludge and membrane bioreactor (MBR) systems removed PCBs. The effluent MBR concentrations ranged from <0.01 ng/L to 0.04 ng/L compared to <0.01 ng/L to 0.88 ng/L for conventional activated sludge. The pilot testing showed that increased solids retention time (SRT) and higher mixed liquor suspended solids concentrations in the MBR system led to increased removal in the liquid stream.

Bench scale studies were completed to test the effectiveness of GAC and biological activated carbon (BAC) for removing PCBs (Ghosh, Weber, Jensen, & Smith 1999). The effluent from the

GAC system was 800 ng/L. The biological film in the BAC system was presumed to support higher PCB removal with effluent concentrations of 200 ng/L. High suspended sediment in the GAC influent can affect performance. It is recommended that filtration be installed upstream of a GAC system to reduce solids and improve effectiveness.

Based on limited available data, it appears that existing municipal secondary treatment facilities in Washington state are able to reduce effluent PCBs to the range approximately 0.10 to 1.5 ng/L. It appears that the best performing existing municipal treatment facility in Washington state with a microfiltration membrane is able to reduce effluent PCBs to the range approximately 0.00019 to 0.00063 µg/L. This is based on a very limited data set and laboratory blanks covered a range that overlapped with the effluent results (blanks 0.000058 to 0.00061 µg/L).

Addition of advanced treatment processes would be expected to enhance PCB removal rates, but the technical literature does not appear to provide definitive information for guidance. A range of expected enhanced removal rates might be assumed to vary widely from level of the reference microfiltration facility of 0.19 to 0.63 ng/L.

Summary of PCB Technologies

The literature review revealed there are viable technologies available to reduce PCBs **but no research was identified with treatment technologies capable of meeting the anticipated human health criteria based limits for PCB removal**. Based on this review, a tertiary process was selected to biologically reduce PCBs and separate the solids using tertiary filtration. Alternately, GAC was investigated as an option to reduce PCBs, although it is not proven that it will meet revised effluent limits.

4.2.2 Mercury

Mercury removal from wastewater can be achieved using precipitation, adsorption, filtration, or a combination of these technologies. There is limited information available about achieving ultra-low effluent mercury concentrations near the 5 ng/L range under consideration in the proposed rulemaking process. This review provides a summary of treatment technology options and anticipated effluent mercury concentrations.

Precipitation (and co-precipitation) involves chemical addition to form a particulate and solids separation, using sedimentation or filtration. Precipitation includes the addition of a chemical precipitant and pH adjustment to optimize the precipitation reaction. Chemicals can include metal salts (ferric chloride, ferric sulfate, ferric hydroxide, or alum), pH adjustment, lime softening, or sulfide. A common precipitant for mercury removal is sulfide, with an optimal pH between 7 and 9. The dissolved mercury is precipitated with the sulfide to form an insoluble mercury sulfide that can be removed through clarification or filtration. One disadvantage of precipitation is the generation of a mercury-laden sludge that will require dewatering and disposal. The mercury sludge may be considered a hazardous waste and require additional treatment and disposal at a hazardous waste site. The presence of other compounds, such as other metals, may reduce the effectiveness of mercury precipitation/co-precipitation. For low-level mercury treatment requirements, several treatment steps will likely be required in pursuit of very low effluent targets.

EPA compiled a summary of facilities that are using precipitation/co-precipitation for mercury treatment (EPA 2007). Three of the full-scale facilities were pumping and treating groundwater and the remaining eight facilities were full-scale wastewater treatment plants. One of the pump and treat systems used precipitation, carbon adsorption, and pH adjustment to treat groundwater to effluent concentrations of 300 ng/L.

Adsorption treatment can be used to remove inorganic mercury from water. While adsorption can be used as a primary treatment step, it is frequently used for polishing after a preliminary treatment step (EPA 2007). One disadvantage of adsorption treatment is that when the adsorbent is saturated, it either needs to be regenerated or disposed of and replaced with new adsorbent. A common adsorbent is GAC. There are several patented and proprietary adsorbents on the market for mercury removal. Adsorption effectiveness can be affected by water quality characteristics, including high solids and bacterial growth, which can cause media blinding. A constant and low flow rate to the adsorption beds increases effectiveness (EPA 2007). The optimal pH for mercury adsorption on GAC is pH 4 to 5; therefore, pH adjustment may be required.

EPA compiled a summary of facilities that are using adsorption for mercury treatment (EPA 2007). Some of the facilities use precipitation and adsorption as described above. The six summarized facilities included two groundwater treatment and four wastewater treatment facilities. The reported effluent mercury concentrations were all less than 2,000 ng/L (EPA 2007).

Membrane filtration can be used in combination with a preceding treatment step. The upstream treatment is required to precipitate soluble mercury to a particulate form that can be removed through filtration. According to the EPA summary report, ultrafiltration is used to remove high-molecular weigh contaminants and solids (EPA 2007). The treatment effectiveness can depend on the source water quality since many constituents can cause membrane fouling, decreasing the effectiveness of the filters. One case study summarized in the EPA report showed that treatment of waste from a hazardous waste combustor treated with precipitation, sedimentation, and filtration achieved effluent mercury concentrations less than the detection limit of 200 ng/L.

Bench-scale research performed at the Oak Ridge Y-12 Plant in Tennessee evaluated the effectiveness of various adsorbents for removing mercury to below the NPDES limit of 12 ng/L and the potential revised limit of 51 ng/L (Hollerman et al. 1999). Several proprietary adsorbents were tested, including carbon, polyacrylate, polystyrene, and polymer adsorption materials. The adsorbents with thiol-based active sites were the most effective. Some of the adsorbents were able to achieve effluent concentrations less than 51 ng/L but none of the adsorbents achieved effluent concentrations less than 12 ng/L.

Bench-scale and pilot-scale testing performed on refinery wastewater was completed to determine treatment technology effectiveness for meeting very low mercury levels (Urgun-Demirtas, Benda, Gillenwater, Negri, Xiong & Snyder 2012) (Urgun-Demirtas, Negri, Gillenwater, Agwu Nnanna & Yu 2013). The Great Lakes Initiative water quality criterion for mercury is less than 1.3 ng/L for municipal and industrial wastewater plants in the Great Lakes region. This research included an initial bench scale test including membrane filtration, ultrafiltration, nanofiltration, and reverse osmosis to meet the mercury water quality criterion. The nanofiltration and reverse osmosis required increased pressures for filtration and resulted in increased mercury concentrations in the permeate. Based on this information and the cost difference between the filtration technologies, a pilot-scale test was performed. The 0.04 um PVDF GE ZeeWeed 500 series membranes were tested. The 1.3 ng/L water quality criterion was met under all pilot study operating conditions. The mercury in the refinery effluent was predominantly in particulate form which was well-suited for removal using membrane filtration.

Based on available data, it appears that existing municipal treatment facilities are capable of reducing effluent mercury to near the range of the proposed HHWQC on an average basis. Average effluent mercury in the range of 1.2 to 6.6 ng/L for existing facilities with secondary treatment and enhanced treatment with cloth filters and membranes. The Spokane County plant data range is an average of 1.2 ng/L to a maximum day of 3 ng/L. Addition of

advanced treatment processes such as GAC or RO would be expected to enhance removal rates. Data from the West Basin treatment facility in California suggests that at a detection limit of 7.99 ng/L mercury is not detected in the effluent from this advanced process train. A range of expected enhanced removal rates from the advanced treatment process trains might be expected to ranged from meeting the proposed standard at 5 ng/L to lower concentrations represented by the Spokane County performance level (membrane filtration) in the range of 1 to 3 ng/L, to perhaps even lower levels with additional treatment. For municipal plants in Washington, this would suggest that effluent mercury values from the two advanced treatment process alternatives might range from 1 to 5 ng/L (0.001 to 0.005 µg/L) and perhaps substantially better, depending upon RO and GAC removals. It is important to note that industrial plants may have higher existing mercury levels and thus the effluent quality that is achievable at an industrial facility would be of lower quality.

Summary of Mercury Technologies

The literature search revealed limited research on mercury removal technologies at the revised effluent limit of 0.005 µg/L. Tertiary filtration with membrane filters or reverse osmosis showed the best ability to achieve effluent criteria less than 0.005 µg/L.

4.2.3 Arsenic

A variety of treatment technologies can be applied to capture arsenic (Table 3). Most of the information in the technical literature and from the treatment technology vendors is focused on potable water treatment for compliance with a Safe Drinking Water Act (SDWA) maximum contaminant level (MCL) of 10 µg/L. The most commonly used arsenic removal method for a wastewater application (tertiary treatment) is coagulation/ flocculation plus filtration. This method by itself could remove more than 90 to 95 percent of arsenic. Additional post-treatment through adsorption, ion exchange, or reverse osmosis is required for ultra-low arsenic limits in the 0.018 µg/L range under consideration in the proposed rulemaking process. In each case it is recommended to perform pilot-testing of each selected technology.

Table 3: Summary of Arsenic Removal Technologies[1]

Technology	Advantages	Disadvantages
Coagulation/filtration	• Simple, proven technology • Widely accepted • Moderate operator training	• pH sensitive • Potential disposal issues of backwash waste • As^{+3} and As^{+5} must be fully oxidized
Lime softening	• High level arsenic treatment • Simple operation change for existing lime softening facilities	• pH sensitive (requires post treatment adjustment) • Requires filtration • Significant sludge operation
Adsorptive media	• High As^{+5} selectivity • Effectively treats water with high total dissolved solids (TDS)	• Highly pH sensitive • Hazardous chemical use in media regeneration • High concentration SeO_4^{-2}, F^-, Cl^-, and SO_4^{-2} may limit arsenic removal

Table 3: Summary of Arsenic Removal Technologies[1]

Technology	Advantages	Disadvantages
Ion exchange	• Low contact times • Removal of multiple anions, including arsenic, chromium, and uranium	• Requires removal of iron, manganese, sulfides, etc. to prevent fouling • Brine waste disposal
Membrane filtration	• High arsenic removal efficiency • Removal of multiple contaminants	• Reject water disposal • Poor production efficiency • Requires pretreatment

[1]Adapted from WesTech

The removal of arsenic in activated sludge is minimal (less than 20 percent) (Andrianisa et al. 2006), but biological treatment can control arsenic speciation. During aerobic biological process As (III) is oxidized to As (V). Coagulation/flocculation/filtration removal, as well as adsorption removal methods, are more effective in removal of As(V) vs. As (III). A combination of activated sludge and post-activated sludge precipitation with ferric chloride (addition to MLSS and effluent) results in a removal efficiency of greater than 95 percent. This combination could decrease As levels from 200 µg/L to less than 5 µg/L (5,000 ng/L) (Andrianisa et al. 2008) compared to the 0.018 µg/L range under consideration in the proposed rulemaking process.

Data from the West Basin facility (using MF/RO/AOP) suggests effluent performance in the range of 0.1 to 0.2 µg/L, but it could also be lower since a detection limit used there of 0.15 µg/l is an order of magnitude higher than the proposed HHWQC. A range of expected enhanced removal rates might be assumed to equivalent to that achieved at West Basin in 0.1 to 0.2 µg/L range.

Review of Specific Technologies for Arsenic Removal

Coagulation plus Settling or Filtration

Coagulation may remove more than 95 percent of arsenic through the creation of particulate metal hydroxides. Ferric sulfite is typically more efficient and applicable to most wastewater sources compared to alum. The applicability and extent of removal should be pilot-tested, since removal efficiency is highly dependent on the water constituents and water characteristics (i.e., pH, temperature, solids).

Filtration can be added after or instead of settling to increase arsenic removal. Example treatment trains with filtration are shown in Figures 1 and 2, respectively.

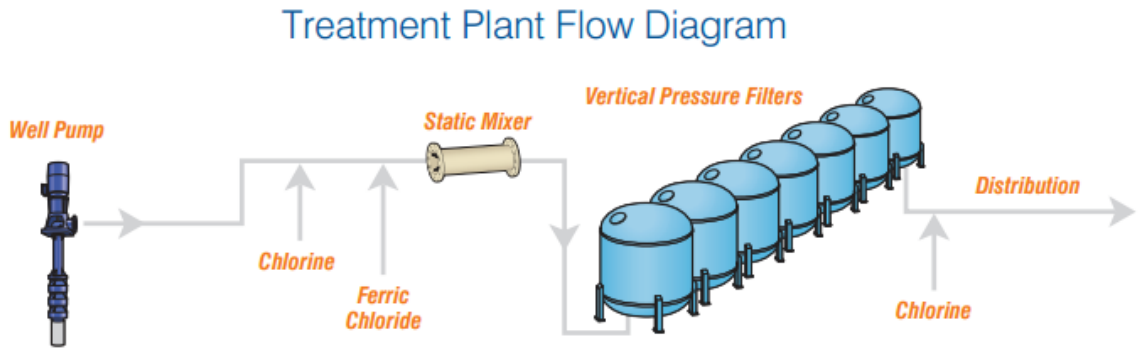

Figure 1. Water Treatment Configuration for Arsenic Removal (WesTech)

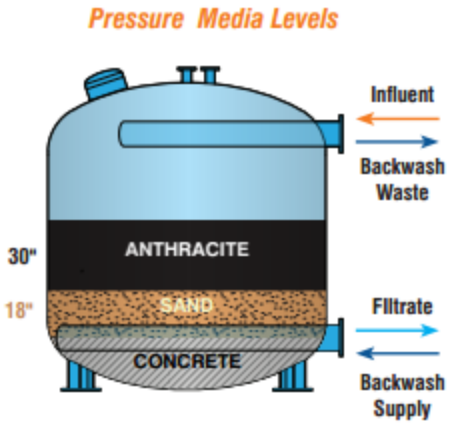

Figure 2. WesTech Pressure Filters for Arsenic Removal

One system for treatment of potable water with high levels of arsenic in Colorado (110 parts per million [ppm]) consists of enhanced coagulation followed by granular media pressure filters that include anthracite/silica sand/garnet media (WesTech). The arsenic levels were reduced to less than the drinking water MCL, which is 10 µg/L (10,000 ng/L). The plant achieves treatment by reducing the pH of the raw water to 6.8 using sulfuric acid, and then adding approximately 12 to 14 mg/L ferric sulfate. The water is filtered through 16 deep bed vertical pressure filters, the pH is elevated with hydrated lime and is subsequently chlorinated and fed into the distribution system.
(http://www.westechinc.com/public/uploads/global/2011/3/Fallon%20NV%20Installation%20ReportPressureFilter.pdf).

Softening (with lime)

Removes up to 90 percent arsenic through co-precipitation, but requires pH to be higher than 10.2.

Adsorption processes

Activated alumina is considered an adsorptive media, although the chemical reaction is an exchange of arsenic ions with the surface hydroxides on the alumina. When all the surface hydroxides on the alumina have been exchanged, the media must be regenerated. Regeneration consists of backwashing, followed by sodium hydroxide, flushing with water and neutralization with a strong acid. Effective arsenic removal requires sufficient empty bed contact time. Removal efficiency can also be impacted by the water pH, with neutral or slightly acidic conditions being considered optimum. If As (III) is present, it is generally advisable to increase empty bed contact time, as As (III) is adsorbed more slowly than As (V). Alumina dissolves slowly over time due to contact with the chemicals used for regeneration. As a result, the media bed is likely to become compacted if it is not backwashed periodically.

Granular ferric hydroxide works by adsorption, but when the media is spent it cannot be regenerated and must be replaced. The life of the media depends upon pH of the raw water, the concentrations of arsenic and heavy metals, and the volume of water treated daily. Periodic backwashing is required to prevent the media bed from becoming compacted and pH may need to be adjusted if it is high, in order to extend media life. For maximum arsenic removal, filters operate in series. For less stringent removal, filters can operate in parallel.

One type of adsorption media has been developed for application to non-drinking water processes for arsenic, phosphate and for heavy metals removal by sorption (Severent Trent Bayoxide® E IN-20). This granular ferric oxide media has been used for arsenic removal from

mining and industrial wastewaters, selenium removal from refinery wastes and for phosphate polishing of municipal wastewaters. Valley Vista drinking water treatment with Bayoxide® E IN-20 media achieves removal from 31-39 µg/L (31,000-39,000 ng/L) to below 10 µg/L MCL (http://www.severntrentservices.com/News/Successful_Drinking_Water_Treatment_in_an_Arsenic__Hot_Spot__nwMFT_452.aspx).

Another adsorptive filter media is greensand. Greensand is available in two forms: as glauconite with manganese dioxide bound ionically to the granules and as silica sand with manganese dioxide fused to the granules. Both forms operate in pressure filters and both are effective. Greensand with the silica sand core operates at higher water temperatures and higher differential pressures than does greensand with the glauconite core. Arsenic removal requires a minimum concentration of iron. If a sufficient concentration of iron is not present in the raw water, ferric chloride is added.

WesTech filters with greensand and permanganate addition for drinking water systems can reduce As from 15-25 µg/L to non-detect. Sodium hypochlorite and/or potassium permanganate are added to the raw water prior to the filters. Chemical addition may be done continuously or intermittently, depending on raw water characteristics. These chemicals oxidize the iron in the raw water and also maintain the active properties of the greensand itself. Arsenic removal is via co-precipitation with the iron.

Ion Exchange

Siemens offers a potable ion exchange (PIX) arsenic water filtration system. PIX uses ion exchange resin canisters for the removal of organic and inorganic contaminants, in surface and groundwater sources to meet drinking water standards.

Filtronics also uses ion exchange to treat arsenic. The technology allows removal for below the SWDA MCL for potable water of 10 µg/L (10,000 ng/L).

Reverse osmosis

Arsenic is effectively removed by RO when it is in oxidative state As(V) to approximately 1,000 ng/L or less (Ning 2002).

Summary of Arsenic Technologies

The current state of the technology for arsenic removal is at the point where all the processes target the SWDA MCL for arsenic in potable water. Current EPA maximum concentration level for drinking water is 10 ug/l; much higher than 0.0018 µg/L target for arsenic in this study. The majority of the methods discussed above are able to remove arsenic to either EPA maximum contaminant level or to the level of detection. The lowest detection limit of one of the EPA approved methods of arsenic measurements is 20 ng/l (0.020 µg/l) (Grosser, 2010), which is comparable to the 0.018 µg/L limit targeted in this study.

4.2.1 Polycyclic Aromatic Hydrocarbons

BAP During Biological Treatment

During wastewater treatment process, BAP tends to partition into sludge organic matter (Melcer et al. 1993). Primary and secondary processing could remove up to 60 percent of incoming PAHs and BAP in particular, mostly due to adsorption to sludge (Kindaichi et al., NA, Wayne et al. 2009). Biodegradation of BAP is expected to be very low since there are more than five benzene rings which are resistant to biological degradation. Biosurfactant addition to biological process could partially improve biodegradation, but only up to removal rates of 50 percent (Sponza et al. 2010). Existing data from municipal treatment facilities in Washington state have

influent and effluent concentrations of BAP of approximately 0.30 ng/L indicating that current secondary treatment has limited effectiveness at BAP removal.

Methods to Enhance Biological Treatment of BAP

Ozonation prior to biological treatment could potentially improve biodegradability of BAP (Zeng et al. 2000). In the case of soil remediation, ozonation before biotreatment improved biodegradation by 70 percent (Russo et al. 2012). The overall removal of BAP increased from 23 to 91 percent after exposure of water to 0.5 mg/L ozone for 30 minutes during the simultaneous treatment process and further to 100 percent following exposure to 2.5 mg/L ozone for 60 minutes during the sequential treatment mode (Yerushalmi et al. 2006). In general, to improve biodegradability of BAP, long exposure to ozone might be required (Haapea et al. 2006).

Sonication pre-treatment or electronic beam irradiation before biological treatment might also make PAHs more bioavailable for biological degradation..

Recent studies reported that a MBR is capable of removing PAHs from wastewater (Rodrigue and Reilly 2009; Gonzaleza et al. 2012). None of the studies listed the specific PAHs constituents removed.

Removal of BAP from Drinking Water

Activated Carbon

Since BAP has an affinity to particulate matter, it is removed from the drinking water sources by means of adsorption, such as granular activated carbon (EPA). Similarly, Oleszczuk et al. (2012) showed that addition of 5 percent activated carbon could remove 90 percent of PAHs from the wastewater.

Reverse Osmosis

Light (1981) (referenced by Williams, 2003) studied dilute solutions of PAHs, aromatic amines, and nitrosamines and found rejections of these compounds in reverse osmosis to be over 99 percent for polyamide membranes. Bhattacharyya et al. (1987) (referenced by Williams, 2003) investigated rejection and flux characteristics of FT30 membranes for separating various pollutants (PAHs, chlorophenols, nitrophenols) and found membrane rejections were high (>98 percent) for the organics under ionized conditions.

Summary of BAP Technologies

Current technologies show that BAP removal may be 90 percent or greater. The lowest detection limit for BAP measurements is 0.006 µg/L, which is also the assumed secondary effluent BAP concentration assumed for this study. If this assumption is accurate, it appears technologies may exist to remove BAP to a level below the proposed criteria applied as an effluent limit of 0.0013 µg/L; however, detection limits exceed this value and it is impossible to know this for certain. A municipal wastewater treatment plant study reported both influent and effluent BAP concentrations less than the HHWQC of 0.0013 ug/L (Ecology, 2010).

4.3 Unit Processes Evaluated

Based on the results of the literature review, a wide range of technologies were evaluated for toxic constituent removal. A listing of the technologies is as follows:

- Chemically enhanced primary treatment (CEPT): this physical and chemical technology is based on the addition of a metal salt to precipitate particles prior to primary treatment, followed by sedimentation of particles in the primary clarifiers. This technology has been

shown to effectively remove arsenic but there is little data supporting the claims. As a result, the chemical facilities are listed as optional.

- Activated sludge treatment (with a short SRT of approximately 8 days or less): this biological technology is commonly referred to as secondary treatment. It relies on converting dissolved organics into solids using biomass. Having a short SRT is effective at removing degradable organics referred to as BOD compounds for meeting existing discharge limits. Dissolved constituents with a high affinity to adsorb to biomass (e.g., metals, high molecular weight organics, and others) will be better removed compared to smaller molecular weight organics and recalcitrant compounds which will have minimal removal at a short SRT.
- Enhanced activated sludge treatment (with a long SRT of approximately 8 days or more): this technology builds on secondary treatment by providing a longer SRT, which enhances sorption and biodegradation. The improved performance is based on having more biomass coupled with a more diverse biomass community, especially nitrifiers, which have been shown to assist in removal of some of the more recalcitrant constituents not removed with a shorter SRT (e.g., lower molecular weight PAHs). There is little or no data available on the effectiveness of this treatment for removing BAP.

  Additional benefits associated with having a longer SRT are as follows:

  - Lower BOD/TSS discharge load to receiving water
  - Improved water quality and benefit to downstream users
  - Lower effluent nutrient concentrations which reduce algal growth potential in receiving waters
  - Reduced receiving water dissolved oxygen demand due to ammonia removal
  - Reduced ammonia discharge, which is toxic to aquatic species
  - Improved water quality for habitat, especially as it relates to biodiversity and eutrophication
  - Secondary clarifier effluent more conditioned for filtration and disinfection
  - Greater process stability from the anaerobic/anoxic zones serving as biological selectors
- Coagulation/Flocculation and Filtration: this two-stage chemical and physical process relies on the addition of a metal salt to precipitate particles in the first stage, followed by the physical removal of particles in filtration. This technology lends itself to constituents prone to precipitation (e.g., arsenic).
- Lime Softening: this chemical process relies on increasing the pH as a means to either volatilize dissolved constituents or inactivate pathogens. Given that none of the constituents being studied are expected to volatilize, this technology was not carried forward.
- Adsorptive Media: this physical and chemical process adsorbs constituents to a combination of media and/or biomass/chemicals on the media. There are several types of media, with the most proven and common being GAC. GAC can also serve as a coarse roughing filter.
- Ion Exchange: this chemical technology exchanges targeted constituents with a resin. This technology is common with water softeners where the hard divalent cations are

exchanged for monovalent cations to soften the water. Recently, resins that target arsenic and mercury removal include activated alumina and granular ferric hydroxides have been developed. The resin needs to be cleaned and regenerated, which produces a waste slurry that requires subsequent treatment and disposal. As a result, ion exchange was not considered for further.

- Membrane Filtration: This physical treatment relies on the removal of particles larger than the membranes pore size. There are several different membrane pore sizes as categorized below.
  - Microfiltration (MF): nominal pore size range of typically between 0.1 to 1 micron. This pore size targets particles, both inert and biological, and bacteria. If placed in series with coagulation/flocculation upstream, dissolved constituents precipitated out of solution and bacteria can be removed by the MF membrane.
  - Ultrafiltration (UF): nominal pore size range of typically between 0.01 to 0.1 micron. This pore size targets those solids removed with MF (particles and bacteria) plus viruses and some colloidal material. If placed in series with coagulation/flocculation upstream, dissolved constituents precipitated out of solution can be removed by the UF membrane.
  - Nanofiltration (NF): nominal pore size range of typically between 0.001 to 0.010 micron. This pore size targets those removed with UF (particles, bacteria, viruses) plus colloidal material. If placed in series with coagulation/flocculation upstream, dissolved constituents precipitated out of solution can be removed by the NF membrane.
- MBR (with a long SRT): this technology builds on secondary treatment whereby the membrane (microfiltration) replaces the secondary clarifier for solids separation. As a result, the footprint is smaller, the mixed liquor suspended solids concentration can be increased to about 5,000 – 10,000 mg/L, and the physical space required for the facility reduced when compared to conventional activated sludge. As with the activated sludge option operated at a longer SRT, the sorption and biodegradation of organic compounds are enhanced in the MBR process. The improved performance is based on having more biomass coupled with a more diverse biomass community, especially nitrifiers which have been shown to assist in removal of persistent dissolved compounds (e.g., some PAHs). There is little or no data available on effectiveness at removing BAP. Although a proven technology, MBRs were not carried further in this technology review since they are less likely to be selected as a retrofit for an existing activated sludge (with a short SRT) secondary treatment facility. The MBR was considered to represent a treatment process approach more likely to be selected for a new, greenfield treatment facility. Retrofits to existing secondary treatment facilities can accomplish similar process enhancement by extending the SRT in the activated sludge process followed by the addition of tertiary membrane filtration units.
- RO: This physical treatment method relies on the use of sufficient pressure to osmotically displace water across the membrane surface while simultaneously rejecting most salts. RO is very effective at removing material smaller than the size ranges for the membrane filtration list above, as well as salts and other organic compounds. As a result, it is expected to be more effective than filtration and MBR methods described above at removing dissolved constituents. Although effective, RO produces a brine reject water that must be managed and disposed.

- Advanced Oxidation Processes (AOPs): this broad term considers all chemical and physical technologies that create strong hydroxyl-radicals. Examples of AOPs include Fenton's oxidation, ozonation, ultraviolet/hydrogen peroxide (UV-H2O2), and others. The radicals produced are rapid and highly reactive at breaking down recalcitrant compounds. Although effective at removing many complex compounds such as those evaluated in this study, AOPs does not typically have as many installations as membranes and activated carbon technologies. As a result, AOPs were not carried forward.

Based on the technical literature review discussed above, a summary of estimated contaminant removal rated by unit treatment process is presented in Table 4.

Table 4. Contaminants Removal Breakdown by Unit Process

Unit Process	Arsenic	BAP	Mercury	Polychlorinated Biphenyls
Activated Sludge Short SRT	No removal	Partial Removal by partitioning		80% removal; effluent <0.88 ng/L
Activated Sludge Long SRT	No removal	Partial removal by partitioning and/or partially biodegradation; MBR could potentially remove most of BAP		>90% removal with a membrane bioreactor, <0.04 ng/L (includes membrane filtration)
Membrane Filtration (MF)	More than 90 % removal (rejection of bound arsenic)	No removal	<1.3 ng/L	>90% removal with a membrane bioreactor, <0.04 ng/L (includes membrane filtration)
Reverse Osmosis (RO)	More than 90% removal (rejection of bound arsenic and removal of soluble arsenic)	More than 98% removal		
Granular Activated Carbon (GAC)	No removal, removal only when carbon is impregnated with iron	90 % removal	<300 ng/L (precipitation and carbon adsorption) <51 ng/L (GAC)	<800 ng/L Likely requires upstream filtration
Disinfection	--	--	--	--

4.4 Unit Processes Selected

The key conclusion from the literature review was that there is limited, to no evidence, that existing treatment technologies are capable of simultaneously meeting all four of the revised discharge limits for the toxics under consideration. Advanced treatment using RO or GAC is expected to provide the best overall removal of the constituents of concern. It is unclear whether these advanced technologies are able to meet revised effluent limits, however these processes may achieve the best effluent quality of the technologies reviewed. This limitation in the findings is based on a lack of an extensive dataset on treatment removal effectiveness in the technical literature for the constituents of interest at the low levels relevant to the proposed criteria, which

approach the limits of reliable removal performance for the technologies. As Table 4 highlights, certain unit processes are capable of removing a portion, or all, of the removal requirements for each technology. The removal performance for each constituent will vary from facility to facility and require a site-specific, detailed evaluation because the proposed criteria are such low concentrations. In some cases, a facility may only have elevated concentrations of a single constituent of concern identified in this study. In other cases, a discharger may have elevated concentrations of the four constituents identified in this study, as well as others not identified in this study but subject to revised water quality criteria. This effort is intended to describe a planning level concept of what treatment processes are required to comply with discharge limits for all four constituents. Based on the literature review of unit processes above, two different treatment trains were developed for the analysis that are compared against a baseline of secondary treatment as follows:

- Baseline: represents conventional secondary treatment that is most commonly employed nationwide at wastewater treatment plants. A distinguishing feature for this treatment is the short solids residence time (SRT) (<8 days) is intended for removal of BOD with minimal removal for the toxic constituents of concern.
- Advanced Treatment – MF/RO: builds on baseline with the implementation of a longer SRT (>8 days) and the addition of MF and RO. The longer SRT not only removes BOD, but it also has the capacity to remove nutrients and a portion of the constituents of concern. This alternative requires a RO brine management strategy which will be discussed in sub-sections below.
- Advanced Treatment – MF/GAC: this alternative provides a different approach to advanced treatment with MF/RO by using GAC and avoiding the RO reject brine water management concern. Similar to the MF/RO process, this alternative has the longer SRT (>8 days) with the capacity to remove BOD, nutrients, and a portion of the toxic constituents of concern. As a result, the decision was made to develop costs for both advanced treatment options.

A description of each alternative is provided in Table 5. The process flowsheets for each alternative are presented in Figure 3 to Figure 5.

4.4.1 Baseline Treatment Process

A flowsheet of the baseline treatment process is provided in Figure 3. The baseline treatment process assumes the current method of treatment commonly employed by dischargers. For this process, water enters the headworks and undergoes primary treatment, followed by conventional activated sludge (short SRT) and disinfection. The solids wasted in the activated sludge process are thickened, followed by mixing with primary solids prior to entering the anaerobic digestion process for solids stabilization. The digested biosolids are dewatered to produce a cake and hauled off-site. Since the exact process for each interested facility in Washington is unique, this baseline treatment process was used to establish the baseline capital and O&M costs. The baseline costs will be compared against the advanced treatment alternatives to illustrate the magnitude of the increased costs and environmental impacts.

Table 5. Unit Processes Description for Each Alternative

Unit Process	Baseline	Advanced Treatment – MF/RO	Advanced Treatment - GAC
Influent Flow	5 mgd	5 mgd	5 mgd
Chemically Enhanced Primary Treatment (CEPT); Optional	--	• Metal salt addition (alum) upstream of primaries	• Metal salt addition (alum) upstream of primaries
Activated Sludge	• Hydraulic Residence Time (HRT): 6 hrs • Short Solids Residence Time (SRT): <8 days	• Hydraulic Residence Time (HRT): 12 hrs (Requires more tankage than the Baseline) • Long Solids Residence Time (SRT): >8 days (Requires more tankage than the Baseline)	• Hydraulic Residence Time (HRT): 12 hrs (Requires more tankage than the Baseline) • Long Solids Residence Time (SRT): >8 days (Requires more tankage than the Baseline)
Secondary Clarifiers	Hydraulically Limited	Solids Loading Limited (Larger clarifiers than Baseline)	Solids Loading Limited (Larger clarifiers than Baseline)
Microfiltration (MF)	--	Membrane Filtration to Remove Particles and Bacteria	Membrane Filtration to Remove Particles and Bacteria
Reverse Osmosis (RO)	--	Treat 50% of the Flow by RO to Remove Metals and Dissolved Constituents. Sending a portion of flow through the RO and blending it with the balance of plant flows ensures a stable non-corrosive, non-toxic discharge.	--
Reverse Osmosis Brine Reject Mgmt	--	Several Options (All Energy or Land Intensive)	--
Granular Activated Carbon (GAC)	--	--	Removes Dissolved Constituents
Disinfection	Not shown to remove any of the constituents	Not shown to remove any of the constituents	Not shown to remove any of the constituents

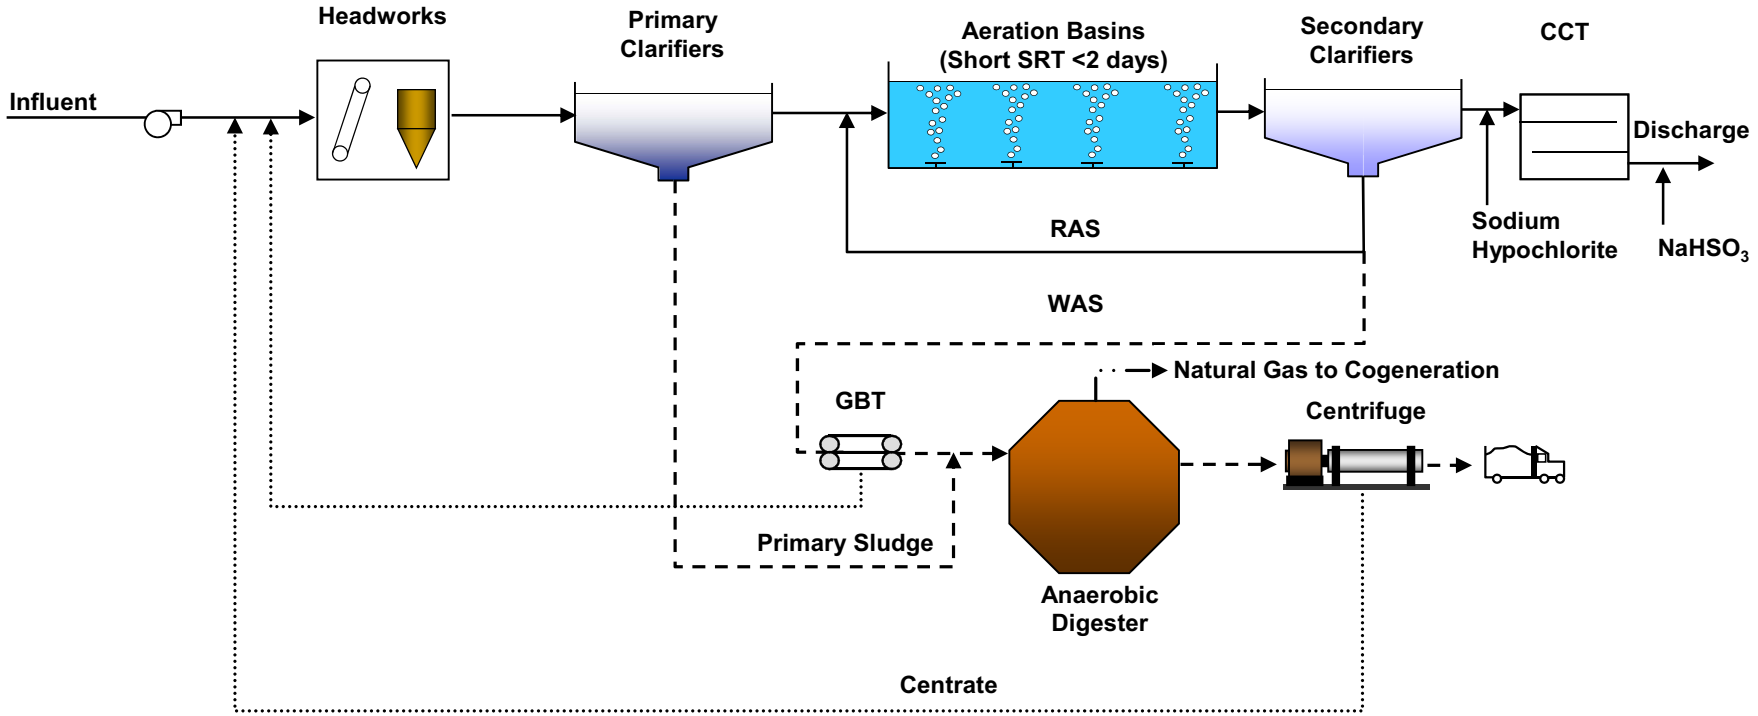

Figure 3. Baseline Flowsheet – Conventional Secondary Treatment

4.4.2 Advanced Treatment – MF/RO Alternative

A flowsheet of the advanced treatment – MF/RO alternative is provided in Figure 4. This alternative builds on the baseline secondary treatment facility, whereby the SRT is increased in the activated sludge process, and MF and RO are added prior to disinfection. The solids treatment train does not change with respect to the baseline. Additionally, a brine management strategy must be considered.

The RO process concentrates contaminants into a smaller volume reject stream. Disposing of the RO reject stream can be a problem because of the potentially large volume of water involved and the concentration of contaminants contained in the brine. For reference, a 5 mgd process wastewater flow might result in 1 mgd of brine reject requiring further management. The primary treatment/handling options for RO reject are as follows:

- Zero liquid discharge
- Surface water discharge
- Ocean discharge
- Haul and discharge to coastal location for ocean discharge
- Sewer discharge
- Deep well injection
- Evaporate in a pond
- Solar pond concentrator

Many of the RO brine reject management options above result in returning the dissolved solids to a “water of the state” such as surface water, groundwater, or marine waters. Past rulings in Washington State have indicated that once pollutants are removed from during treatment they are not to be re-introduced to a water of the state. As a result, technologies with this means for disposal were not considered viable options for management of RO reject water in Washington.

Zero Liquid Discharge

Zero liquid discharge (ZLD) is a treatment process that produces a little or no liquid brine discharge but rather a dried residual salt material. This process improves the water recovery of the RO system by reducing the volume of brine that must be treated and disposed of in some manner. ZLD options include intermediate treatment, thermal-based technologies, pressure driven membrane technologies, electric potential driven membrane technologies, and other alternative technologies.

Summary

There are many techniques which can be used to manage reject brine water associated with RO treatment. The appropriate alternative is primarily governed by geographic and local constraints. A comparison of the various brine management methods and potential costs are provided in Table 6.

Of the listed options, ZLD was considered for this analysis as the most viable approach to RO reject water management. An evaporation pond was used following ZLD. The strength in this combination is ZLD reduces the brine reject volume to treat, which in turn reduces the required evaporation pond footprint. The disadvantage is that evaporation ponds require a substantial amount of physical space which may not be available at existing treatment plant sites. It is also important to recognize that the greenhouse gas (GHG) emissions vary widely for the eight brine management options listed above based on energy and chemical intensity.

Table 6. Brine Disposal Method Relative Cost Comparison

Disposal Method	Description	Relative Capital Cost	Relative O&M Cost	Comments
Zero Liquid Discharge (ZLD)	Further concentrates brine reject for further downstream processing	High	High	This option is preferred as an intermediate step. This rationale is based on the reduction in volume to handle following ZLD. For example, RO reject stream volume is reduced on the order of 50-90%.
Surface Water Discharge	Brine discharge directly to surface water. Requires an NPDES permit.	Lowest	Lowest	Both capital and O&M costs heavily dependent on the distance from brine generation point to discharge. Not an option for nutrient removal.
Ocean Discharge	Discharge through a deep ocean outfall.	Medium	Low	Capital cost depends on location and availability of existing deep water outfall.
Sewer Discharge	Discharge to an existing sewer pipeline for treatment at a wastewater treatment plant.	Low	Low	Both capital and O&M costs heavily dependent on the brine generation point to discharge distance. Higher cost than surface water discharge due to ongoing sewer connection charge. Not an option for wastewater treatment.
Deep Well Injection	Brine is pumped underground to an area that is isolated from drinking water aquifers.	Medium	Medium	Technically sophisticated discharge and monitoring wells required. O&M cost highly variable based on injection pumping energy.
Evaporation Ponds	Large, lined ponds are filled with brine. The water evaporates and a concentrated salt remains.	Low – High	Low	Capital cost highly dependent on the amount and cost of land.
Salinity Gradient Solar Ponds (SGSP)	SGSPs harness solar power from pond to power an evaporative unit.	Low – High	Lowest	Same as evaporation ponds plus added cost of heat exchanger and pumps. Lower O&M cost due to electricity production.
Advanced Thermal Evaporation	Requires a two-step process consisting of a brine concentrator followed by crystallizer	High	Highest	Extremely small footprint, but the energy from H_2O removal is by far the most energy intensive unless waste heat is used.

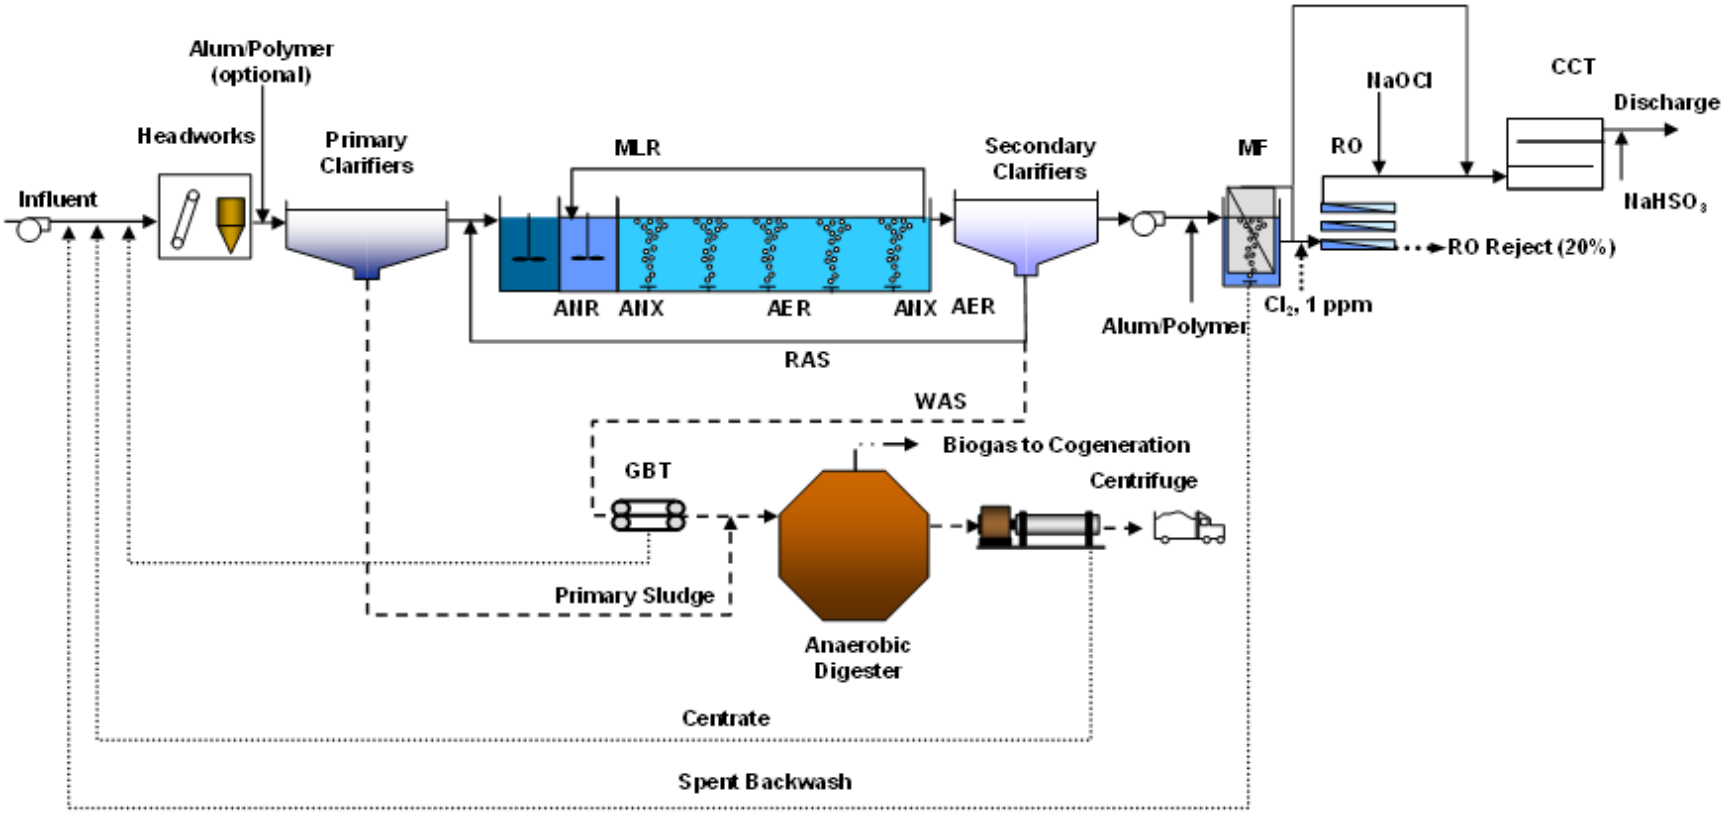

Figure 4. Advanced Treatment Flowsheet – Tertiary Microfiltration and Reverse Osmosis

4.4.3 Advanced Treatment – MF/GAC Alternative

A flowsheet of the advanced treatment – MF/GAC alternative is provided in Figure 5. Following the MF technology, a GAC contactor and media are required.

This alternative was developed as an option that does not require a brine management technology (e.g., ZLD) for comparison to the MF/RO advanced treatment alternative. However, this treatment alternative does require that the GAC be regenerated. A baseline secondary treatment facility can be retrofitted for MF/GAC. If an existing treatment facility has an extended aeration lagoon, the secondary effluent can be fed to the MF/GAC. The longer SRT in the extended aeration lagoon provides all the benefits associated with the long SRT in an activated sludge plant as previously stated:

- Lower BOD/TSS discharge load
- Higher removal of recalcitrant constituents and heavy metals
- Improved water quality and benefit to downstream users
- Less downstream algal growth
- Reduced receiving water dissolved oxygen demand due to ammonia removal
- Reduced ammonia discharge loads, which is toxic to several aquatic species
- Improved water quality for habitat, especially as it relates to biodiversity and eutrophication
- Secondary clarifier effluent more conditioned for filtration and disinfection
- Greater process stability from the anaerobic/anoxic zones serving as a selector

If an existing treatment facility employs a high rate activated sludge process (short SRT) similar to the baseline, it is recommended that the activated sludge process SRT be increased prior to the MF/GAC unit processes. The longer SRT upstream of the MF is preferred to enhance the membrane flux rate, reduce membrane biofouling, increase membrane life, and reduce the chemicals needed for membrane cleaning.

The key technical and operational challenges associated with the tertiary add-on membrane filtration units are as follows:

- The membrane filtration technology is a proven and reliable technology. With over 30 years of experience, it has made the transition in recent years from an emerging technology to a proven and reliable technology.
- Membrane durability dependent on feed water quality. The water quality is individual facility specific.
- Membranes are sensitive to particles, so upstream screening is critical. The newer generations of membranes have technical specifications that require a particular screen size.
- Membrane area requirements based on peak flows as water must pass through the membrane pores. Additionally, membranes struggle with variable hydraulic loading. Flow equalization upstream can greatly reduce the required membrane surface area and provide uniform membrane loading.

- Membrane tanks can exacerbate any foam related issues from the upstream biological process. Foam entrapment in the membrane tank from the upstream process can reduce membrane filtration capacity and in turn result in a plant-wide foam problem.
- Reliable access to the membrane modules is key to operation and maintenance. Once PLC is functionary properly, overall maintenance requirements for sustained operation of the system are relatively modest.
- The membranes go through frequent membrane relaxing or back pulse and a periodic deep chemical clean in place (CIP) process.
- Sizing of membrane filtration facilities governed by hydraulic flux. Municipal wastewaters have flux values that range from about 20 to 40 gallons per square foot per day (gfd) under average annual conditions. The flux associated with industrial applications is wastewater specific.

Following the MF is the activated carbon facilities. There are two kinds of activated carbon used in treating water: powdered activated carbon (PAC) and GAC. PAC is finely-ground, loose carbon that is added to water, mixed for a short period of time, and removed. GAC is larger than PAC, is generally used in beds or tanks that permit higher adsorption and easier process control than PAC allows, and is replaced periodically. PAC is not selective, and therefore, will adsorb all active organic substances making it an impractical solution for a wastewater treatment plant. As a result, GAC was considered for this analysis. The type of GAC (e.g., bituminous and subbituminous coal, wood, walnut shells, lignite or peat), gradation, and adsorption capacity are determined by the size of the largest molecule/ contaminant that is being filtered (AWWA, 1990).

As water flows through the carbon bed, contaminants are captured by the surfaces of the pores until the carbon is no longer able to adsorb new molecules. The concentration of the contaminant in the treated effluent starts to increase. Once the contaminant concentration in the treated water reaches an unacceptable level (called the breakthrough concentration), the carbon is considered "spent" and must be replaced by virgin or reactivated GAC.

The capacity of spent GAC can be restored by thermal reactivation. Some systems have the ability to regenerate GAC on-site, but in general, small systems haul away the spent GAC for off-site regeneration (EPA 1993). For this study, off-site regeneration was assumed.

The basic facilities and their potential unit processes included in this chapter are as follows:

- GAC supply and delivery
- Influent pumping
  - Low head feed pumping
  - High head feed pumping (assumed for this study as we have low limits so require high beds)
- Contactors and backwash facilities
  - Custom gravity GAC contactor
  - Pre-engineered pressure GAC contactor (Used for this study)
  - Backwash pumping
- GAC transport facilities
  - Slurry pumps
  - Eductors (Used for this study)

- Storage facilities
  - Steel tanks
  - Concrete tanks (Used for this study; larger plants would typically select concrete tanks)
- Spent carbon regeneration
  - On-site GAC regeneration
  - Off-Site GAC regeneration

Following the MF is the GAC facility. The GAC contactor provides about a 12-min hydraulic residence time for average annual conditions. The GAC media must be regenerated about twice per year in a furnace. The constituents sorbed to the GAC media are removed during the regeneration process. A typical design has full redundancy and additional storage tankage for spent and virgin GAC. Facilities that use GAC need to decide whether they will regenerate GAC on-site or off-site. Due to challenges associated with receiving air emission permits for new furnaces, it was assumed that off-site regeneration would be evaluated.

The key technical and operational challenges associated with the tertiary add-on GAC units are as follows:

- Nearest vendor to acquire virgin GAC – How frequently can they deliver virgin GAC and what are the hauling costs?
- Contactor selection is typically based on unit cost and flow variation. The concrete contactor is typically more cost effective at higher flows so it was used for this evaluation. The pre-engineered pressure contactor can handle a wider range of flows than a concrete contactor. Additionally, a pressure system requires little maintenance as they are essentially automated
- Periodical contactor backwashing is critical for maintaining the desired hydraulics and control biological growth
- Eductors are preferred over slurry pumps because they have fewer mechanical components. Additionally, the pump with eductors is not in contact with the carbon, which reduces wear.
- Off-site GAC regeneration seems more likely due to the challenges with obtaining an air emissions permit.

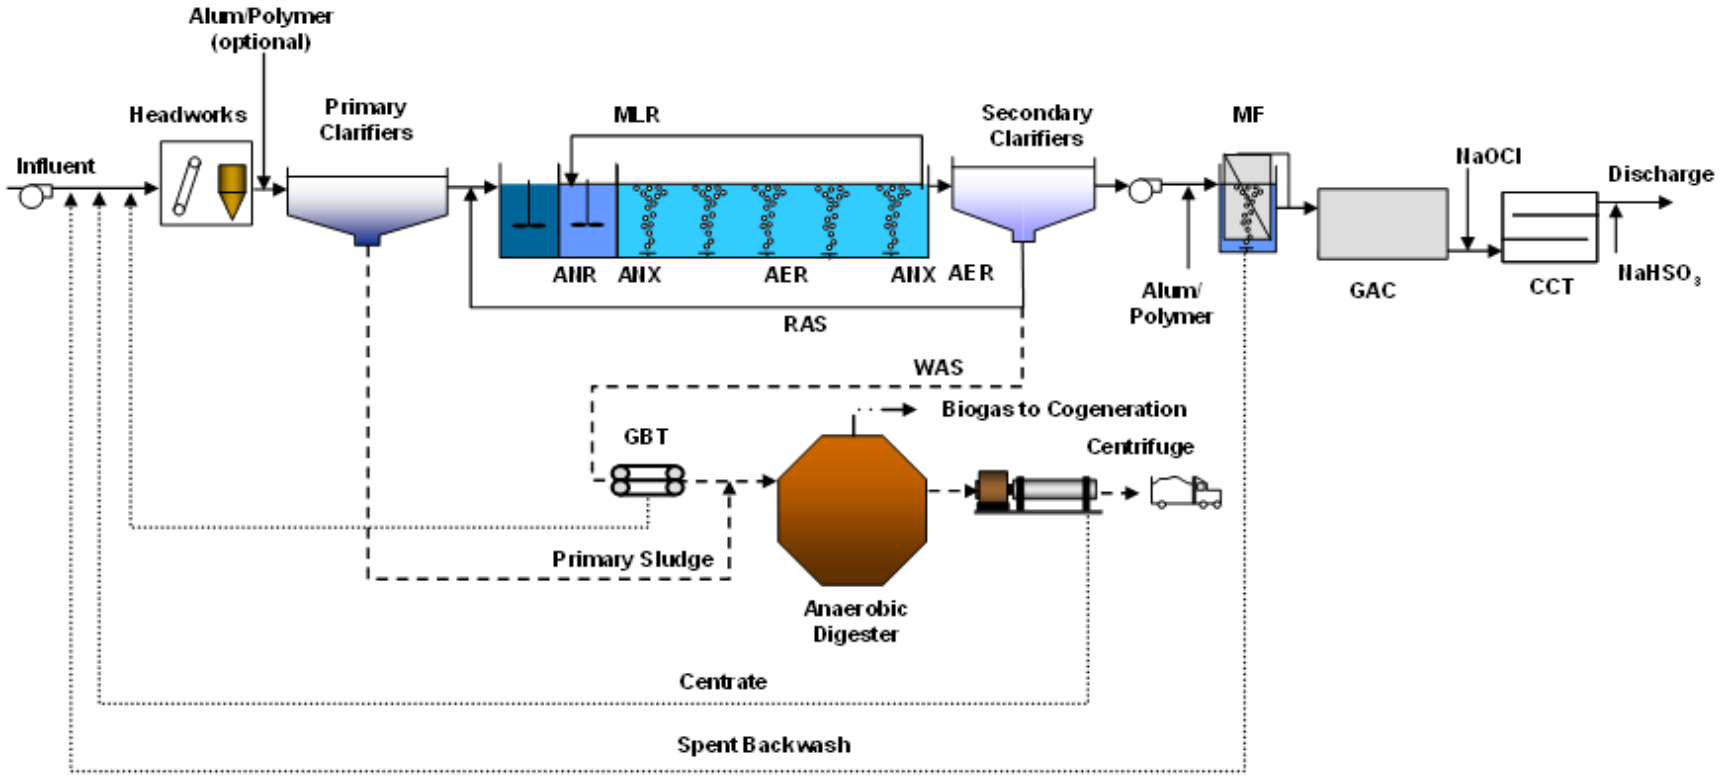

Figure 5. Advanced Treatment Flowsheet – Tertiary Microfiltration and Granular Activated Carbon

4.5 Steady-State Mass Balance

HDR used its steady-state mass balance program to calculate the flows and loads within the candidate advanced treatment processes as a means to size facilities. The design of wastewater treatment facilities are generally governed by steady-state mass balances. For a steady-state mass balance, the conservation of mass is calculated throughout the entire wastewater treatment facility for defined inputs. Dynamic mass balance programs exist for designing wastewater facilities, but for a planning level study such as this, a steady state mass balance program is adequate. A dynamic program is generally used for detailed design and is site-specific with associated requirements for more detailed wastewater characterization.

The set of model equations used to perform a steady-state mass balance are referred to as the model. The model equations provide a mathematical description of various wastewater treatment processes, such as an activated sludge process, that can be used to predict unit performance. The program relies on equations for each unit process to determine the flow, load, and concentration entering and leaving each unit process.

An example of how the model calculates the flow, load, and concentration for primary clarifiers is provided below. The steady-state mass balance equation for primary clarifiers has a single input and two outputs as shown in the simplified Figure 6. The primary clarifier feed can exit the primary clarifiers as either effluent or sludge. Solids not removed across the primaries leave as primary effluent, whereas solids captured leave as primary sludge. Scum is not accounted for.

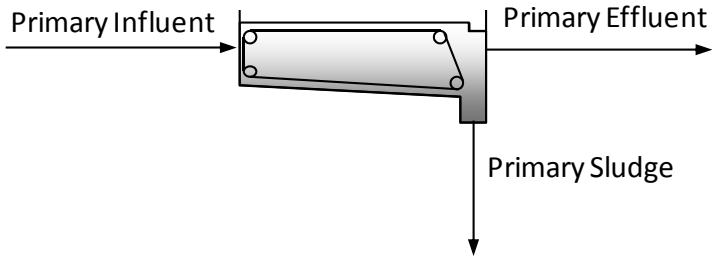

Figure 6. Primary Clarifier Inputs/Outputs

The mass balance calculation requires the following input:

- Solids removal percentage across the primaries (based on average industry accepted performance)
- Primary solids thickness (i.e., percent solids) (based on average industry accepted performance)

The steady-state mass balance program provides a reasonable first estimate for the process performance, and an accurate measure of the flows and mass balances at various points throughout the plant. The mass balance results were used for sizing the facility needs for each alternative. A listing of the unit process sizing criterion for each unit process is provided in Appendix A. By listing the unit process sizing criteria, a third-party user could redo the analysis and end up with comparable results. The key sizing criteria that differ between the baseline and treatment alternatives are as follows:

- Aeration basin mixed liquor is greater for the advanced treatment alternatives which in turn requires a larger volume
- The secondary clarifiers are sized based on hydraulic loading for the baseline versus solids loading for the advanced treatment alternatives

- The MF/GAC and MF/RO sizing is only required for the respective advanced treatment alternatives.

4.6 Adverse Environmental Impacts Associated with Advanced Treatment Technologies

The transition from the baseline (conventional secondary treatment) to either advanced treatment alternatives has some environmental impacts that merit consideration, including the following:

- Land area for additional system components (which for constrained facility sites, may necessitate land acquisition and encroachment into neighboring properties with associated issues and challenges, etc.).
- Increased energy use and atmospheric emissions of greenhouse gases and criteria air contaminants associated with power generation to meet new pumping requirements across the membrane filter systems (MF and RO) and GAC.
- Increased chemical demand associated with membrane filters (MF and RO).
- Energy and atmospheric emissions associated with granulated charcoal regeneration.
- RO brine reject disposal. The zero liquid discharge systems are energy intensive energy and increase atmospheric emissions as a consequence of the electrical power generation required for removing water content from brine reject.
- Increase in sludge generation while transitioning from the baseline to the advanced treatment alternatives. There will be additional sludge captured with the chemical addition to the primaries and membrane filters (MF and RO). Additionally, the GAC units will capture more solids.
- Benefits to receiving water quality by transitioning from a short SRT (<2 days) in the baseline to a long SRT (>8 days) for the advanced treatment alternatives (as previously stated):
    - Lower BOD/TSS discharge load
    - Higher removal of recalcitrant constituents and heavy metals
    - Improved water quality and benefit to downstream users
    - Reduced nutrient loadings to receiving waters and lower algal growth potential
    - Reduced receiving water dissolved oxygen demand due to ammonia removal
    - Reduced ammonia discharge loads, which is toxic to aquatic species
    - Improved water quality for habitat, especially as it relates to biodiversity and eutrophication
    - Secondary clarifier effluent better conditioned for subsequent filtration and disinfection
    - Greater process stability from the anaerobic/anoxic zones serving as a biological selectors

HDR calculated GHG emissions for the baseline and advanced treatment alternatives. The use of GHG emissions is a tool to normalize the role of energy, chemicals, biosolids hauling, and fugitive emissions (e.g., methane) in a single unit. The mass balance results were used to quantify energy demand and the corresponding GHG emissions for each alterative. Energy

demand was estimated from preliminary process calculations. A listing of the energy demand for each process stream, the daily energy demand, and the unit energy demand is provided in Table 7. The advanced treatment options range from 2.3 to 4.1 times greater than the baseline. This large increase in energy demand is attributed to the energy required to pass water through the membrane barriers and/or the granular activated carbon. Additionally, there is energy required to handle the constituents removed as either regenerating the GAC or handling the RO brine reject water. This additional energy required to treat the removed constituents is presented in Table 7.

Table 7. Energy Breakdown for Each Alternative (5 mgd design flow)

Parameter	Units	Baseline	Advanced Treatment – MF/GAC	Advanced Treatment – MF/RO
Daily Liquid Stream Energy Demand	MWh/d	11.6	23.8	40.8
Daily Solids Stream Energy Demand	MWh/d	-1.6	-1.1	-1.1
Daily Energy Demand	MWh/d	10.0	22.7	39.7
Unit Energy Demand	kWh/MG Treated	2,000	4,500	7,900

MWh/d = megawatt hours per day
kWh/MG = kilowatt hours per million gallons

Details on the assumptions used to convert between energy demand, chemical demand and production, as well as biologically-mediated gases (i.e., CH4 and N2O) and GHG emissions are provided in Appendix B.

A plot of the GHG emissions for each alternative is shown in Figure 7. The GHG emissions increase from the baseline to the two advanced treatment alternatives. The GHG emissions increase about 50 percent with respect to baseline when MF/GAC is used and the GHG emissions increase over 100 percent with respect to baseline with the MF/RO advanced treatment alternative.

The MF/GAC energy demand would be larger if GAC regeneration was performed on-site. The GHG emissions do not include the energy or air emissions that result from off-site GAC regeneration. Only the hauling associated with moving spent GAC is included. The energy associated with operating the furnace would exceed the GHG emissions from hauling spent GAC.

The zero liquid discharge in the MF/RO alternative alone is comparable to the Baseline. This contribution to increased GHG emissions by zero liquid discharge brine system highlights the importance of the challenges associated with managing brine reject.

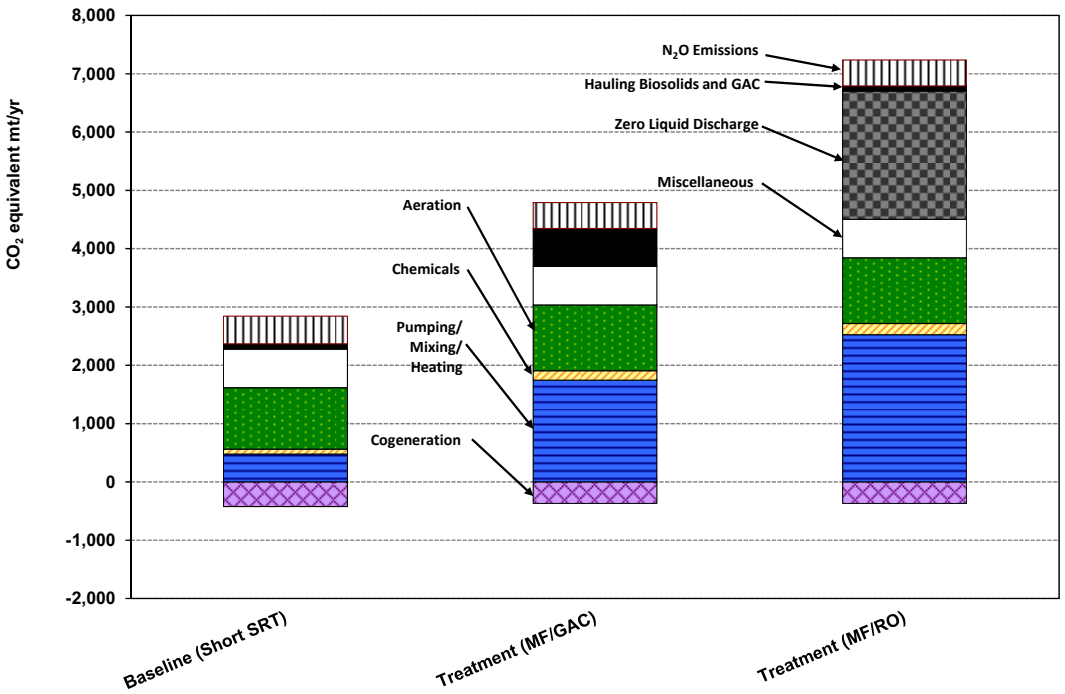

Figure 7. Greenhouse Gas Emissions for Each Alternative

The use of GHG emissions as a measure of sustainability does not constitute a complete comparison between the baseline and advanced treatment alternatives. Rather, it is one metric that captures the impacts of energy, chemical demand and production, as well as biologically-mediated gases (i.e., CH_4 and N_2O). The other environmental impacts of advanced treatment summarized in the list above should also be considered in decision making beyond cost analysis.

4.7 Costs

Total project costs along with the operations and maintenance costs were developed for each advanced treatment alternative for a comparison with baseline secondary treatment.

4.7.1 Approach

The cost estimates presented in this report are planning level opinions of probable construction costs for a nominal 5 mgd treatment plant design flow representing a typical facility without site specific details about local wastewater characteristics, physical site constraints, existing infrastructure, etc. The cost estimates are based on wastewater industry cost references, technical studies, actual project cost histories, and professional experience. The costs presented in this report are considered planning level estimates. A more detailed development of the advanced treatment process alternatives and site specific information would be required to further refine the cost estimates. Commonly this is accomplished in the preliminary design phase of project development for specific facilities following planning.

The cost opinion includes a range of costs associated with the level of detail used in this analysis. Cost opinions based on preliminary engineering can be expected to follow the Association for the Advancement of Cost Engineering (AACE International) Recommended Practice No. 17R-97 Cost Estimate Classification System estimate Class 4. A Class 4 estimate is based upon a 5 to 10 percent project definition and has an expected accuracy range of -30 to +50 percent and typical end usage of budget authorization and cost control. It is considered an

"order-of-magnitude estimate." The life-cycle costs were prepared using the net present value (NPV) method.

The cost associated for each new unit process is based on a unit variable, such as required footprint, volume, demand (e.g., lb O_2/hr), and others. This approach is consistent with the approach developed for the EPA document titled "Estimating Water Treatment Costs: Volume 2-Cost Curves Applicable to 1 to 200 mgd Treatment Plants" dated August 1979. The approach has been updated since 1979 to account for inflation and competition, but the philosophy for estimating costs for unit processes has not changed. For example, the aeration system sizing/cost is governed by the maximum month airflow demand. Additionally, the cost associated constructing an aeration basin is based on the volume. The cost considers economies of scale.

The O&M cost estimates were calculated from preliminary process calculations. The operations cost includes energy and chemical demand. For example, a chemical dose was assumed based on industry accepted dosing rates and the corresponding annual chemical cost for that particular chemical was accounted for. The maintenance values only considered replacement equipment, specifically membrane replacement for the Advanced Treatment Alternatives.

4.7.2 Unit Cost Values

The life-cycle cost evaluation was based on using the economic assumptions shown in Table 8. The chemical costs were based on actual values from other projects. To perform detailed cost evaluations per industry, each selected technology would need to be laid out on their respective site plan based on the location of the existing piping, channels, and other necessary facilities.

Table 8. Economic Evaluation Variables

Item	Value
Nominal Discount Rate	5%
Inflation Rate:	
General	3.5%
Labor	3.5%
Energy	3.5%
Chemical	3.5%
Base Year	2013
Project Life	25 years
Energy	$0.06/kWh
Natural Gas	$0.60/therm
Chemicals:	
Alum	$1.1/gal
Polymer	$1.5/gal
Hypochlorite	$1.5/gal
Salt	$0.125/lb
Antiscalant	$12.5/lb
Acid	$0.35/lb
Deionized Water	$3.75/1,000 gal
Hauling:	

Table 8. Economic Evaluation Variables

Item	Value
Biosolids Hauling Distance	100 miles (one way)
Biosolids Truck Volume	6,000 gal/truck
Biosolids Truck Hauling	$250/truck trip
GAC Regeneration Hauling Distance	250 miles (round trip)
GAC Regeneration Truck Volume	$20,000 lb GAC/truck
GAC Regeneration Truck Hauling	Included in cost of Virgin GAC

kWh= kilowatt hours; lbs=pounds; GAC=granulated activated carbon; gal=gallon

4.7.3 Net Present Value of Total Project Costs and Operations and Maintenance Cost in 2013 Dollars

An estimate of the net present value for the baseline treatment process and the incremental cost to implement the advanced treatment alternatives is shown in Table 9. The cost for the existing baseline treatment process was estimated based on new construction for the entire conventional secondary treatment process (Figure 3). The incremental cost to expand from existing baseline secondary treatment to advanced treatment was calculated by taking the difference between the baseline and the advanced treatment alternatives. These values serve as a benchmark for understanding the prospective cost for constructing advanced treatment at the planning level of process development.

Table 9. Treatment Technology Total Project Costs in 2013 Dollars for a 5 mgd Facility

Alternative	Total Construction Cost, 2013 dollars ($ Million)	O&M Net Present Value, 2013 dollars ($ Million)*	Total Net Present Value, 2013 dollars ($ Million)	NPV Unit Cost, 2013 dollars ($/gpd)
Baseline (Conventional Secondary Treatment)*	59 - 127	5 - 11	65 – 138	13 - 28
Advanced Treatment – MF/RO**	108 - 231	31 - 67	139 - 298	28 - 60
Advanced Treatment – MF/GAC	131 - 280	50 - 108	181 - 388	36 - 78
Incremental Increase to Advanced Treatment MF/RO	48 - 104	26 - 56	75 - 160	15 - 32
Incremental Increase to Advanced Treatment MF/GAC	71 - 153	45 - 97	117 - 250	23 - 50

* The additional cost to increase the SRT to upwards of 30-days is about $12 - 20 million additional dollars in total project cost for a 5 mgd design flow

** Assumes zero liquid discharge for RO brine management, followed by evaporation ponds. Other options are available as listed in Section 4.4.2.

O&M=operations and maintenance; MF/RO=membrane filtration/reverse osmosis; MF/GAC=membrane filtration/granulated activated carbon; gpd=gallons per day

4.7.4 Unit Cost Assessment

Costs presented above are based on a treatment capacity of 5.0 mgd, however, existing treatment facilities range dramatically across Washington in size and flow treated. Table 9 indicates that the unit capital cost for baseline conventional secondary treatment for 5.0 mgd ranges between $13 to 28 per gallon per day of treatment capacity. The unit cost for the advanced treatment alternatives increases the range from the low $20s to upper $70s on a per-gallon per-day of capacity. The increase in cost for the advanced treatment alternatives is discussed in the sub-sections below.

Advanced Treatment MF/RO

The advanced treatment MF/RO alternative has a total present worth unit cost range of $28 to $60 million in per gallon per day of capacity. This translates to an incremental cost increase with respect to the baseline of $15 to $32 million dollars in per gallon per day treatment capacity. The key differences in cost between the baseline and the advanced treatment MF/RO are as follows:

- Larger aeration basins than the baseline to account for the longer SRT (<8 days versus >8 days).
- Additional pumping stations to pass water through the membrane facilities (MF and RO). These are based on peak flows.
- Membrane facilities (MF and RO; equipment, tanks chemical feed facilities, pumping, etc.) and replacement membrane equipment.
- Additional energy and chemical demand to operate the membrane facilities (MF and RO) and GAC.
- Zero liquid discharge facilities to further concentrate the brine reject.
- Zero liquid discharge facilities are energy/chemically intensive and they require membrane replacement every few years due to the brine reject water quality.
- An evaporation pond to handle the brine reject that has undergone further concentration by zero liquid discharge.

The advanced treatment MF/RO assumes that 100 percent of the flow is treated by MF, followed by 50 percent of the flow treated with RO. Sending a portion of flow through the RO and blending it with the balance of plant flows ensures a stable water to discharge. The RO brine reject (about 1.0 mgd) undergoes ZLD pre-treatment that further concentrates the brine reject to about 0.1-0.5 mgd. The recovery for both RO and ZLD processes is highly dependent on water quality (e.g., silicate levels).

ZLD technologies are effective at concentrating brine reject, but it comes at a substantial cost ($17.5 per gallon per day of ZLD treatment capacity of brine reject). The zero liquid discharge estimate was similar in approach to the demonstration study by Burbano and Brandhuber (2012) for La Junta, Colorado. The ability to further concentrate brine reject was critical from a management standpoint. Although 8 different options were presented for managing brine reject in Section 4.4.2, none of them is an attractive approach for handling brine reject. ZLD provides a viable pre-treatment step that requires subsequent downstream treatment. Evaporation ponds following ZLD were used for this study. Without ZLD, the footprint would be 3-5 times greater.

Roughly 30 acres of evaporation ponds, or more, may be required to handle the ZLD concentrate, depending upon concentrator effectiveness, local climate conditions, residuals

accumulation, residual removal, etc. Precipitation throughout Washington is highly variable which can greatly influence evaporation pond footprint. The approach for costing the evaporation pond was in accordance with Mickley et al. (2006) and the cost was about $2.6 million.

Recent discussions with an industry installing evaporation ponds revealed that they will use mechanical evaporators to enhance evaporation rates. The use of mechanical evaporators was not included in this study, but merits consideration if a facility is performing a preliminary design that involves evaporation ponds. The mechanical evaporators have both a capital costs and annual energy costs.

Advanced Treatment MF/GAC

The advanced treatment MF/GAC alternative has a total present worth unit cost range of $36 to $78 million in per gallon per day capacity. This translates to an incremental cost increase with respect to the baseline of $23 to $50 million dollars on a per gallon per day of treatment capacity basis. The key differences in cost between the baseline and the advanced treatment MF/GAC are as follows:

- Larger aeration basins than the baseline to account for the longer SRT (<8 days versus >8 days).
- Additional pumping stations to pass water through the MF membrane and GAC facilities. These are based on peak flows.
- GAC facilities (equipment, contact tanks, pumping, GAC media, etc.)
- Additional energy to feed and backwash the GAC facilities.
- GAC media replacement was the largest contributor of any of the costs.
- Additional hauling and fees to regenerate GAC off-site.

The advanced treatment MF/GAC assumes that 100 percent of the flow is treated by MF, followed by 100 percent of the flow treated with GAC. The GAC technology is an established technology. The costing approach was in accordance with EPA guidelines developed in 1998.

The critical issue while costing the GAC technology is whether a GAC vendor/regeneration facility is located within the region. On-site regeneration is an established technology with a furnace.

However, there are several concerns as listed in Section 4.4.3:

- Ability to obtain an air emissions permit
- Additional equipment to operate and maintain
- Energy and air emissions to operate a furnace on-site
- Operational planning to ensure that furnace is operating 90-95 percent of the time. Otherwise, operations is constantly starting/stopping the furnace which is energy intensive and deleterious to equipment
- If not operated properly, the facility has the potential to create hazardous/toxic waste to be disposed

If located within a couple hundred miles, off-site regeneration is preferred. For this study, off-site regeneration was assumed with a 250-mile (one-way) distance to the nearest vendor that can provide virgin GAC and a regeneration facility.

Incremental Treatment Cost

The difference in costs between the baseline and the advanced treatment alternatives is listed in Table 10. The incremental cost to retrofit the baseline facility to the advanced treatment was calculated by taking the difference between the two alternatives. These values should serve as a planning level benchmark for understanding the potential cost for retrofitting a particular facility. The incremental cost is unique to a particular facility. Several reasons for the wide range in cost in retrofitting a baseline facility to advanced treatment are summarized as follows:

- Physical plant site constraints. A particular treatment technology may or may not fit within the constrained particular plant site. A more expensive technology solution that is more compact may be required. Alternately, land acquisition may be necessary to enlarge a plant site to allow the addition of advanced treatment facilities. An example of the former is stacking treatment processes vertically to account for footprint constraints. This is an additional financial burden that would not be captured in the incremental costs presented in Table 10.
- Yard piping. Site specific conditions may prevent the most efficient layout and piping arrangement for an individual facility. This could lead to additional piping and pumping to convey the wastewater through the plant. This is an additional financial burden that would not be captured in the incremental costs presented in Table 10.
- Pumping stations. Each facility has unique hydraulic challenges that might require additional pumping stations not captured in this planning level analysis. This is an additional financial burden that would not be captured in the incremental costs presented in Table 10.

A cursory unit cost assessment was completed to evaluate how costs would compare for facilities with lower (0.5 mgd) and higher capacity (25 mgd), as presented in Table 10. Capital costs were also evaluated for a 0.5 mgd and 25 mgd facility using non-linear scaling equations with scaling exponents. The unit capital cost for baseline conventional secondary treatment for 0.5 mgd and 25 mgd is approximately $44 and $10 per gallon per day of treatment capacity, respectively. The incremental unit costs to implement an advanced treatment retrofit for 0.5 mgd would range between $30 to $96 per gallon per day of treatment capacity and would be site and discharger specific. The incremental unit costs to implement an advanced treatment retrofit for 25 mgd would range between $10 to 35 per gallon per day of treatment capacity and would be site and discharger specific. The larger flow, 25 mgd, is not as expensive on a per gallon per day of treatment capacity. This discrepancy for the 0.5 and 25 mgd cost per gallon per day of treatment capacity is attributed to economies of scale. Cost curve comparisons (potential total construction cost and total net present value) for the baseline and the two tertiary treatment options (MF/RO and MF/GAC) are shown in Figure 8 and Figure 9 between the flows of 0.5 and 25 mgd. It is important to note that while the economies of scale suggest lower incremental costs for the larger size facilities, some aspects of the advanced treatment processes may become infeasible at larger capacities due to factors such as physical space limitations and the large size requirements for components such as RO reject brine management.

Table 10. Treatment Technology Total Project Costs in 2013 Dollars for a 0.5 mgd Facility and a 25 mgd Facility

Alternative	Total Construction Cost, 2013 dollars ($ Million)	O&M Net Present Value, 2013 dollars ($ Million)*	Total Net Present Value, 2013 dollars ($ Million)	NPV Unit Cost, 2013 dollars ($/gpd)
0.5 mgd:				
Baseline (Conventional Secondary Treatment)	15 - 32	0.5 - 1.1	15 - 33	31 - 66
Advanced Treatment – MF/RO**	27 - 58	3.2 - 6.8	30 - 65	60 - 130
Advanced Treatment – MF/GAC	33 - 70	5 - 10.8	38 - 81	76 - 162
Incremental Increase to Advanced Treatment MF/RO	12 - 26	2.7 - 5.7	15 - 32	30 - 64
Incremental Increase to Advanced Treatment MF/GAC	18 - 38	4.6 - 9.8	22 - 48	45 - 96
25 mgd:				
Baseline (Conventional Secondary Treatment)	156 - 335	25 - 54	182 - 389	7 - 16
Advanced Treatment – MF/RO**	283 - 606	157 - 336	440 - 942	18 - 38
Advanced Treatment – MF/GAC	343 - 735	252 - 541	595 - 1276	24 - 51
Incremental Increase to Advanced Treatment MF/RO	127 - 272	131 - 281	258 - 553	10 - 22
Incremental Increase to Advanced Treatment MF/GAC	187 - 401	226.9 - 486	414 - 887	17 - 35

* Does not include the cost for labor.
** Assumes zero liquid discharge for RO brine management, followed by evaporation ponds. Other options are available as listed in Section 4.4.2.
MF/RO=membrane filtration/reverse osmosis
MF/GAC=membrane filtration/granulated activated carbon

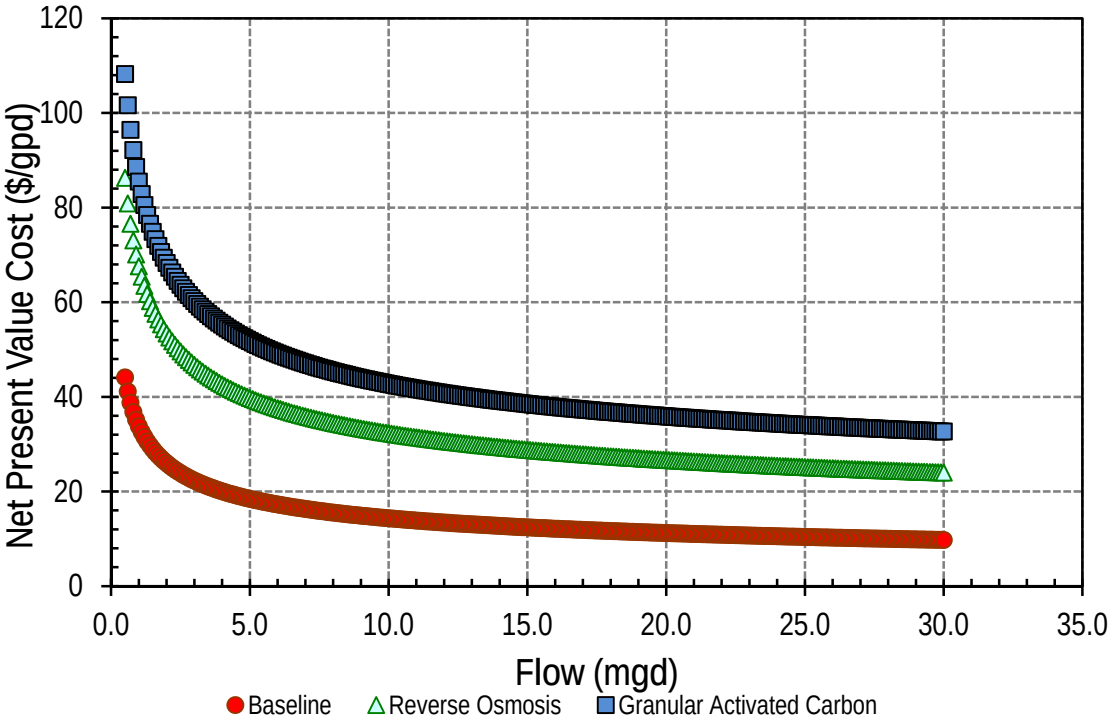

Figure 9: NPV Cost Curve Comparison for Baseline Treatment, MF/RO, and MF/GAC

4.8 Pollutant Mass Removal

An estimate of the projected load removal for the four constituents of concern was developed and is presented in Table 11. The current secondary effluent and advanced treatment effluent data is based on the only available data to HDR and is from municipal treatment plant facilities. Data is not available for advanced treatment facilities such as MF/RO or MF/GAC. Due to this lack of data, advanced treatment using MF/RO or MF/GAC was assumed to remove an additional zero to 90 percent of the constituents presented resulting in the range presented in Table 11. It is critical to note these estimates are based on limited data and are presented here simply for calculating mass removals. Current secondary effluent for industrial facilities would likely be greater than the data presented here and as a result, the projected effluent quality for industrial facilities would likely be higher as well. Based on the limited actual data from municipal treatment facilities, Table 11 indicates that mercury and BAP effluent limits may potentially be met using advanced treatment at facilities with similar existing secondary effluent quality.

Table 11. Pollutant Mass Removal by Contaminant for a 5 mgd Facility

Component	PCBs	Mercury	Arsenic	BAP
Required HHWQC based Effluent Quality (µg/L)	0.0000064	0.005	0.018	0.0013
Current Secondary Effluent Concentration (µg/L)*	0.0015	0.025	7.5	0.00031
Projected Effluent Quality (µg/L) from Advanced Treatment (MF/RO or MF/GAC)*	0.000041 – 0.00041	0.00012 – 0.0012	0.38 – 3.8	0.000029 - 0.00029
Mass Removed (mg/d)**	21 - 28	451 - 471	71,000 – 135,000	0.4 – 5.0
Mass Removed (lb/d)**	0.000045 – 0.000061	0.00099 – 0.0010	0.16 – 0.30	0.0000010 – 0.0000012

* Based on or estimated for actual treatment plant data from municipal facilities. Data sets are limited and current secondary effluent for industrial facilities would likely be greater than the data presented here.
** 1 lb = 454,000 mg
HHWQC=human health-based water quality criteria
MF/RO=membrane filtration/reverse osmosis
MF/GAC=membrane filtration/granulated activated carbon
µg/L=micrograms per liter
mg/d=milligrams per day
lb/d=pounds per day

Unit costs were developed based on required mass removal from a 5 mgd facility for each of the four constituents of concern to reduce discharges from current secondary effluent quality to the assumed required effluent quality (HHWQC). It important to note that this study concludes it is unclear if existing technology can meet the required effluent quality, however, the information presented in Table 12 assumes HHWQC would be met for developing unit costs. The unit costs are expressed as dollars in NPV (over a 25 year period) per pound of constituent removed over the same 25 year period using advanced treatment with MF/RO. The current secondary effluent quality data presented are based on typical secondary effluent quality expected for a municipal/industrial discharger. Table 12 suggests unit costs are most significant in meeting the PCB, mercury, and PAH required effluent quality.

Table 12. Unit Cost by Contaminant for a 5 mgd Facility Implementing Advanced Treatment using MF/RO

Component	PCBs	Mercury	Arsenic	PAHs
Required HHWQC based Effluent Quality (µg/L)	0.0000064	0.005	0.018	0.0013
Current Secondary Effluent Concentration (µg/L)*	0.002	0.025	7.5	0.006
Total Mass Removed (lbs) over 25-year Period	0.76	7.6	2,800	1.8
Unit Cost (NPV per total mass removed in pounds over 25 years)	$290,000,000	$29,000,000	$77,000	$120,000,000

*Derived from data presented in Table 3.
**Based on assumed 25-year NPV of $219,000,000 (average of the range presented in Table 10) and advanced treatment using MF/RO.
NPV=net present value
HHWQC=human health-based water quality criteria
µg/l=micrograms per liter

4.9 Sensitivity Analysis

The ability of dischargers to meet a HHWQC one order of magnitude less stringent (than HHWQC presented in Table 3 and used in this report) was considered. The same advanced treatment technologies using MF/RO or MF/GAC would still be applied to meet revised effluent quality one order-of-magnitude less stringent despite still not being able to meet less stringent effluent limits. As a result, this less stringent effluent quality would not impact costs. Based on available data, it appears the mercury and BAP limits would be met at a less stringent HHWQC. PCB effluent quality could potentially be met if advanced treatment with RO or GAC performed at the upper range of their projected treatment efficiency. It does not appear the less stringent arsenic HHWQC would be met with advanced treatment. It is important to note that a discharger's ability to meet these less stringent limits depends on existing secondary effluent characteristics and is facility specific. Facilities with higher secondary effluent constituent concentrations will have greater difficulty meeting HHWQC.

5.0 Summary and Conclusions

This study evaluated treatment technologies potentially capable of meeting revised effluent discharge limits associated with revised HHWQC. HDR completed a literature review of potential technologies and engineering review of their capabilities to evaluate and screen treatment methods for meeting revised effluent limits for four constituents of concern: arsenic, BAP, mercury, and PCBs. HDR selected two alternatives to compare against a baseline, including enhanced secondary treatment, enhanced secondary treatment with MF/RO, and enhanced secondary treatment with MF/GAC. HDR developed capital costs, operating costs, and a NPV for each alternative, including the incremental cost to implement from an existing secondary treatment facility.

The following conclusions can be made from this study.

- Revised HHWQC based on state of Oregon HHWQC (2001) and EPA "National Recommended Water Quality Criteria" will result in very low water quality criteria for toxic constituents.
- There are limited "proven" technologies available for dischargers to meet required effluent quality limits that would be derived from revised HHWQC.
    - Current secondary wastewater treatment facilities provide high degrees of removal for toxic constituents; however, they will not be capable of compliance with water quality-based NPDES permit effluent limits derived from revised HHWQC.
    - Advanced treatment technologies have been investigated and candidate process trains have been conceptualized for toxics removal.
        - Advanced wastewater treatment technologies may enhance toxics removal rates, however they will not be capable of compliance with HHWQC based effluent limits for PCBs. The lowest levels achieved based on the literature review were between <0.00001 and 0.00004 µg/L, as compared to a HHWQC of 0.0000064 µg/L.
        - Based on very limited performance data for arsenic and mercury from advanced treatment information available in the technical literature, compliance with revised criteria may or may not be possible, depending upon site specific circumstances.
            - Compliance with a HHWQC for arsenic of 0.018 µg/L appears unlikely. Most treatment technology performance information available in the literature is based on drinking water treatment applications targeting a much higher SDWA MCL of 10 µg/L.
            - Compliance with a HHWQC for mercury of 0.005 µg/L appears to be potentially attainable on an average basis but perhaps not if effluent limits are structured on a maximum monthly, weekly or daily basis. Some secondary treatment facilities attain average effluent mercury levels of 0.009 to 0.066 µg/L. Some treatment facilities with effluent filters attain average effluent mercury levels of 0.002 to 0.010 µg/L. Additional advanced treatment processes are expected to enhance these removal rates, but little mercury performance data is available for a definitive assessment.
        - Little information is available to assess the potential for advanced technologies to comply with revised benzo(a)pyrene criteria. A municipal wastewater treatment plant study reported both influent and effluent BAP concentrations less than the HHWQC of 0.0013 ug/L (Ecology, 2010).

  - Some technologies may be effective at treating identified constituents of concern to meet revised limits while others may not. It is therefore even more challenging to identify a technology that can meet all constituent limits simultaneously.
  - A HHWQC that is one order-of-magnitude less stringent could likely be met for mercury and PAHs however it appears PCB and arsenic limits would not be met.
- Advanced treatment processes incur significant capital and operating costs.
  - Advanced treatment process to remove additional arsenic, benzo(a)pyrene, mercury, and PCBs would combine enhancements to secondary treatment with microfiltration membranes, reverse osmosis, and granular activated carbon and increase the estimated capital cost of treatment from $17 to $29 in dollars per gallon per day of capacity (based on a 5.0 mgd facility).
  - The annual operation and maintenance costs for the advanced treatment process train will be substantially higher (approximately $5 million - $15 million increase for a 5.0 mgd capacity facility) than the current secondary treatment level.
- Implementation of additional treatment will result in additional collateral impacts.
  - High energy consumption.
  - Increased greenhouse gas emissions.
  - Increase in solids production from chemical addition to the primaries. Additionally, the membrane and GAC facilities will capture more solids that require handling.
  - Increased physical space requirements at treatment plant sites for advanced treatment facilities and residuals management including reverse osmosis reject brine processing.
- It appears advanced treatment technology alone cannot meet all revised water quality limits and implementation tools are necessary for discharger compliance.
  - Implementation flexibility will be necessary to reconcile the difference between the capabilities of treatment processes and the potential for HHWQC driven water quality based effluent limits to be lower than attainable with technology

APPENDIX A - UNIT PROCESS SIZING CRITERIA

Table A-1. Unit Processes Sizing Criteria for Each Alternative

Unit Process	Units	Baseline Treatment	Advanced Treatment	Comment
Influent Pumping Station	unitless	3 Times Ave Flow	3 Times Ave Flow	This is peaking factor used to size the pumps (peak flow:average flow)
Alum Dose for CEPT (optional)	mg/L	20	20	This is the metal salt upstream of the primaries
Primary Clarifiers	gpd/sf	1000	1000	This is for average annual flows
Primary Solids Pumping Station	unitless	1.25 Times Ave Flow	1.25 Times Ave Flow	This is peaking factor used to size the pumps (maximum month flow:average flow)
Aeration System Oxygen Uptake Rate (OUR)	mg/L/hr	25	25	Average annual OUR is used in tandem with mixed liquor to determine the required aeration basin volume (the limiting parameter governs the activated sludge basin volume)
Aeration Basin Mixed Liquor	mg/L	1250	2500	Average annual mixed liquor is used in tandem with OUR (see next row) to determine the required aeration basin volume (the limiting parameter governs the activated sludge basin volume)
Secondary Clarifiers Hydraulic Loading	gpd/sf	650	--	Only use for Baseline as clarifiers governed hydraulically with short SRT (<2 days)
Secondary Clarifiers Solids Loading	lb/d/sf	--	24	Only use for Advanced Treatment as clarifiers governed by solids with long SRT (>8 days)
Return Activated Sludge (RAS) Pumping Station	unitless	1.25 Times Ave Flow	1.25 Times Ave Flow	RAS must have capacity to meet 100% influent max month Flow. The influent flow is multiplied by this peaking factor to determine RAS pumping station capacity.
Waste Activated Sludge (WAS) Pumping Station	gpm	1.25 Times Ave Flow	1.25 Times Ave Flow	WAS must have capacity to meet max month WAS flows. The average annual WAS flow is multiplied by this peaking factor to determine WAS pumping station capacity.
Microfiltration (MF) Flux	gfd	--	25	Based on average annual pilot experience in Coeur D'Alene, ID
MF Backwash Storage Tank	unitless	--	1.25	Storage tanks must have capacity to meet maximum month MF backwash flows. The average annual MF backwash volume is multiplied by this peaking factor to determine required volume.

Table A-1. Unit Processes Sizing Criteria for Each Alternative

Unit Process	Units	Baseline Treatment	Advanced Treatment	Comment
MF Backwash Pumps	unitless	--	1.25	Backwash pumps must have capacity to meet maximum month MF backwash flows. The average annual MF backwash flow is multiplied by this peaking factor to determine required flows.
Reverse Osmosis (RO)	gallon per square foot per day (gfd)	--	10	
RO Reject	%	--	20	This represents the percentage of feed flow that is rejected as brine
Chlorination Dose	mg/L	15	15	
Chlorination Storage Capacity	days	14	14	
Chlorine Contact Tank	min	30	30	This is for average annual conditions.
Dechlorination Dose	mg/L	15	15	
Dechlorination Storage Capacity	days	14	14	
Gravity Belt Thickener	gpm/m	200	200	This is for maximum month conditions using the 1.25 peaking factor from average annual to maximum month
Anaerobic Digestion	Hydraulic residence time (HRT)	18	18	This is for average annual conditions
Dewatering Centrifuge	gpm	120	120	This is for maximum month conditions using the 1.25 peaking factor from average annual to maximum month

gpd=gallons per day; sf=square feet; gpm=gallons per minute

Appendix B – Greenhouse Gas Emissions Calculation Assumptions

The steady state mass balance results were used to calculate GHG emissions. The assumptions used to convert between energy demand, chemical demand and production, as well as biologically-mediated gases (i.e., CH4 and N2O) and GHG emissions are provided in Table B-1. The assumptions are based on EPA (2007) values for energy production, an adaptation of the database provided in Ahn et al. (2010) for N2O emissions contribution, Intergovernmental Panel on Climate Change (IPCC) (2006) for fugitive CH4 emissions, and various resources for chemical production and hauling from production to the wastewater treatment plant (WWTP). Additionally, the biogas produced during anaerobic digestion that is used as a fuel source is converted to energy with MOP8 (2009) recommended waste-to-energy values.

Table B-1. Greenhouse Gas Emissions Assumptions

EXECUTIVE SUMMARY

Fish in the Sacramento-San Joaquin River Delta Estuary (Delta) have elevated levels of methylmercury that pose a risk for human and wildlife consumers. As a result, the Delta is on the Clean Water Act Section 303(d) List of Impaired Water Bodies. Section 303(d)(1)(A) of the Clean Water Act requires the Central Valley Water Board to develop a water quality management strategy – a.k.a. total maximum daily load (TMDL) – to lower fish mercury levels in the Delta so that the beneficial uses of fishing and wildlife habitat are attained.

Although methylmercury is less than 1% of all mercury discharged to the Delta, methylmercury is the chemical that accumulates in the food web. Available science indicates that reducing methylmercury in ambient water is the most direct way to reduce methylmercury in biota. The need for methylmercury effluent data for facilities permitted by the National Pollutant Discharge Elimination System (NPDES) program arose during the development of the TMDL source analysis for the Delta. There was a substantial amount of concentration and load data for inorganic mercury; however, there was limited information about methylmercury. Although inorganic mercury in effluent is a concern because of the potential for it to be methylated in downstream aquatic ecosystems, methylmercury also is a concern because it is immediately available for uptake by aquatic biota.

The Central Valley Water Board issued a California Water Code Section 13267 Order (13267 Order) in 2004 that required municipal wastewater treatment plants (WWTPs) and other non-municipal NPDES-permitted dischargers located in the Delta and its source region to monitor their methylmercury discharges. Effluent methylmercury data were submitted by 111 facilities. Although not required by the 13267 Order, thirty-six of those facilities also submitted influent methylmercury data. In addition, the Sacramento Regional Count Sanitation District submitted influent and effluent methylmercury concentration data for a six-year period.

This report provides a literature review and summary of NPDES influent and effluent methylmercury and inorganic mercury data along with available treatment process information for municipal WWTPs. No policy or regulation is either expressed or intended. This report is not a required element of the Delta methylmercury TMDL. However, this report includes a wealth of effluent and influent data and treatment process information that may be useful for future characterization and control studies in the Central Valley and elsewhere nationwide.

Overall, NPDES facilities account for about 4% of the methylmercury load to the Delta; NPDES facilities within the Delta contribute about 205 grams per year (g/year) while facilities in upstream watersheds that are downstream of major dams contribute about 24 g/year. The Delta TMDL divides the Delta into hydrologically-defined subwatershed

areas; different sources supply the different areas. For example, NPDES facilities within the San Joaquin River and Sacramento River subareas contribute about 7-9% of all methylmercury loading to those subareas, while NPDES facilities within the Central Delta, West Delta, and Yolo Bypass subareas contribute less than 0.2% of all methylmercury loading to these subareas. This report evaluates how the different NPDES categories contribute to methylmercury loading to the Delta.

Twelve categories of non-municipal facilities submitted effluent data: aggregate, aquaculture, drinking water treatment, food processing, groundwater remediation, heating/cooling, manufacturing, mines, paper/saw mill, power generation, power generation/domestic WWTP and a miscellaneous category. A few of the aquaculture and power generation facilities were neither significant sources nor sinks of methylmercury. More influent and effluent data are necessary to determine if other facilities in these two categories and heating/cooling facilities are net methylmercury sources or sinks. Aggregate, drinking water treatment, groundwater remediation, paper/saw mills and the other non-municipal facilities were sources of methylmercury but typically had low effluent methylmercury concentrations (average of 0.05 nanograms per liter [ng/l]). Eight of the twelve categories of non-municipal facilities had average effluent methylmercury concentrations less than or equal to 0.05 ng/l (the lowest calibration standard for methylmercury). Of the 198 effluent methylmercury samples submitted by all non-municipal facilities, 134 were less than or equal to 0.05 ng/l, and 80 of those were below the method detection limit (typically < 0.025 ng/l). The highest effluent methylmercury concentration observed at a non-municipal facility was 1.19 ng/l from a stormwater detention pond at the Sierra Pacific Industries Shasta Lake Mill, which is in the paper/saw mill category; all other samples from the paper/saw mills and other non-municipal facilities were less than 0.2 ng/l.

In contrast, municipal WWTPs contribute the most discharge (by discharge volume and methylmercury load) to the Delta source region of any one of the NPDES discharger categories monitored and have the most variability in effluent methylmercury concentrations. Individual effluent samples collected from WWTPs had methylmercury concentrations that ranged from below the detection limit to 4 ng/l, a 200-fold difference. Twenty of the 61 WWTPs that submitted effluent data had an average concentration less than or equal to 0.05 ng/l, and 13 of the WWTPs had an average concentration less than 0.03 ng/l. In contrast, 18 WWTPs had an average effluent methylmercury concentration greater than 0.2 ng/l, and seven had mean concentrations greater than 1 ng/l.

Staff grouped the municipal WWTPs into mutually exclusive treatment categories based on their secondary, tertiary and disinfection treatment types to determine if trends existed between treatment processes and effluent methylmercury concentrations. The facilities that use treatment pond systems (oxidation, facilitative, settling or stabilization ponds) had the highest effluent methylmercury concentrations. The median effluent

methylmercury values of all pond treatment categories were statistically higher than all other treatment categories, with one exception; the “Pond + Filtration + Chlorination/Decholorination” category did not have significantly higher effluent methylmercury concentrations than the “Secondary + Chlorination/Decholorination” (secondary treatment without nitrification/denitrification and filtration) category. WWTPs that use one or more of the following treatment processes generally had lower effluent methylmercury concentrations: nitrification/denitrification, filtration, and ultraviolet (UV) disinfection. Treatment categories that include one or more of these processes had statistically lower effluent methylmercury concentrations than both the pond and “Secondary + Chlorination/Dechlorination” categories.

Seasonal variability was observed in effluent methylmercury concentrations at several municipal WWTPs in the Central Valley and elsewhere. Studies were conducted at the City of Winnipeg WWTP (Canada) and Onondaga County WWTP (New York); both WWTP studies demonstrated that effluent methylmercury concentrations increase as ambient temperatures increase, particularly when treatment ponds are used. Effluent methylmercury concentrations were also higher in the warm season (e.g., May through November) than the cool season at several of the Central Valley WWTPs. The Central Valley WWTPs that showed seasonal patterns in their effluent methylmercury concentrations had many different types of treatment processes, indicating that there was no trend between the type of treatment process and seasonality.

These and other possible trends between treatment processes and effluent methylmercury concentrations identified by the Central Valley facility data and literature reviews merit additional investigation. There are many factors that affect the concentrations of methylmercury in effluent and subsequent methylation/demethylation processes in the receiving waters. Additional studies are required to understand the mercury/methylmercury relationships between different treatment processes and mercury methylation/demethylation processes in the receiving water. Chapter 5 of this report suggests preliminary ideas for future analyses and key questions to be addressed by treatment plant analyses.

LIST OF TABLES

1. Summary of Literature Review 55
2. Inorganic mercury and Methylmercury Concentrations at the San Jose / Santa Clara WWTP 57
3. Phase 1A and 1B Inorganic mercury Concentrations, Mass Loads and Particulate Concentrations at the SRCSD Sacramento WWTP 57
4. Phase 1A and 1B Methylmercury Concentrations, Mass Loads and Particulate Concentrations at SRCSD 58
5. Average Inorganic mercury, Methylmercury and TSS concentrations at the Onondaga County WWTP for the Entire Sampling Period (October 1995 to September 1996) 58
6. Seasonal Average Methylmercury Concentrations at the Onondaga County WWTP 59
7. Inorganic mercury and Methylmercury Concentrations in the Fritz Island WWTP Inputs and Outputs 59
8. Inorganic mercury and Methylmercury Loads in the Inputs and Outputs of the Fritz Island WWTP 59
9. Inorganic Mercury and Methylmercury Concentrations in the Influent and Effluent of Various Components of the Fritz Island WWTP Treatment Processes 60
10. Summary of Total and Methylmercury Concentrations in Samples Collected in October 1987 at the Whitlingham Sewage Treatment Works 60
11. Methylmercury Data Excluded from Calculations in this Report 61
12. Relative Percent Differences (RPD) of Field Duplicate Samples Analyzed for Methylmercury 62
13. Anomalous Values Observed in the Methylmercury and Inorganic Mercury Data 63
14. Sum of Average Daily Discharges (mgd) for Facilities within Each Discharger Type for NPDES Facilities in the Delta Source Region 64
15. Number of NPDES Facilities That Received the 13267 Order Categorized by Facility Type and Geographical Region 64
16. NPDES Facility Receiving Water Information and Map Labels for Figures 1 through 3 65
17. Summary of all Effluent Methylmercury Concentration Data for the Non-Municipal Facility Categories 73
18. Available Intake and Outfall Methylmercury Concentration Data for Aquaculture, Power and Heating/Cooling Facilities in the Delta Region 74
19. Comparison of Delta Municipal WWTP Effluent Methylmercury Concentrations to Methylmercury Concentrations in Drinking Water Supplies for Delta Communities 76
20. Municipal WWTP Treatment Processes in Place at the Time of Methylmercury Sampling 79
21. Treatment Categories and Effluent Methylmercury Descriptive Statistics for the Municipal WWTPs 82
22. Description of Treatment Categories 85
23. Descriptive Statistics for the Effluent Methylmercury Concentrations for the Municipal WWTP Treatment Categories 86

24. Kruskal-Wallis Multiple Comparison Results for Median Effluent Methylmercury Concentrations of the Treatment Categories 87
25. Subcategories Based upon Secondary Treatment for the Municipal WWTPs 88
26. Descriptive Statistics for the Effluent Methylmercury Concentrations for the Municipal WWTP Subcategories 89
27. Kruskal-Wallis Multiple Comparison Results for Median Effluent Methylmercury Concentrations of the Subcategories within the "Filtration + C/D" category 90
28. Two-sided Significance Levels (p-values) for WWTP Treatment Subcategories 90
29. Kruskal-Wallis Multiple Comparison Results for Median Effluent:Influent Methylmercury Ratios of the Treatment Categories 91
30. Regression Coefficients (R^2) and Two-sided Significance Levels (p-values) for Influent versus Effluent Methylmercury Concentration Scatter Plots for Each WWTP with Five or More Paired Data Points 92
31. Kruskal-Wallis Multiple Comparison Results for Median Effluent Methylmercury:Total Mercury Ratios of the Treatment Categories 93
32. Regression Coefficients (R^2) and Two-sided Significance Levels (p-values) for Inorganic Mercury versus Methylmercury Effluent Concentration Scatter Plots for Each WWTP with Five or More Paired Data Points 94
33. Regression Coefficients (R^2) and Two-sided Significance Levels (p-values) for Influent Inorganic Mercury versus Effluent Methylmercury Concentration Scatter Plots for Each WWTP with Five or More Paired Data Points 94
34. Regression Coefficients (R^2) and Two-sided Significance Levels (p-values) for Influent versus Effluent Inorganic Mercury Concentration Scatter Plots for Each WWTP with Five or More Paired Data Points 95
35. Sum of Annual Total Mercury Loads (g/yr) Discharged by Facilities within Each Discharger Category for NPDES Facilities in the Delta Source Region Downstream of Major Dams 95
36. Sum of Annual Methylmercury Loads (g/yr) Discharged by Facilities within Each Discharger Category for NPDES Facilities in the Delta Source Region Downstream of Major Dams 96
37. Comparison of Annual Methylmercury Loads (g/yr) Discharged by NPDES Facilities to The Sum of All Point and Nonpoint Source Methylmercury Loading to Each Delta Subarea Identified in The February 2010 Delta TMDL Staff Report 97

ACRONYMS

Basin Plan	Central Valley Region Water Quality Control Plan for the Sacramento River and San Joaquin River Basins
CTR	California Toxics Rule
CVRWQCB	Central Valley Regional Water Quality Control Board (a.k.a. Central Valley Water Board)
CWA	Federal Clean Water Act
EC	Electrical conductivity
GIS	Geographic Information System
GW	Groundwater
Hg	Mercury
ID	Irrigation District
mgd	Million gallons per day
MeHg	Monomethyl mercury (also referred to as methylmercury in this report)
NPDES	National Pollutant Discharge Elimination System
O	Oxygen
PUD	Public Utilities District
SD	Sanitation District
SFBRWQCB	San Francisco Bay Regional Water Quality Control Board (a.k.a. San Francisco Bay Water Board)
SFEI	San Francisco Estuary Institute
SRCSD	Sacramento Regional County Sanitation District
TMDL	Total maximum daily load
TSS	Total suspended solids
USEPA	U.S. Environmental Protection Agency
UV	Ultraviolet radiation
WTP	Water treatment plant (drinking water filtration or groundwater treatment)
WWTP	Wastewater treatment plant
WY	Water Year[1]

[1] A "water year" (WY) is defined as the period between 1 October and 30 September of the following year; for example, WY2001 is the period between 1 October 2000 and 30 September 2001. The California Department of Water Resources (DWR) developed the Hydrologic Classification Index (HCI) to evaluate the distribution of wet and dry years in the Central Valley. DWR classifies water year types according to the natural water production of the major basins. See the following website for more information about the HCI: http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST

UNITS OF MEASURE

μg	microgram
μg/g	microgram per gram
μg/l	microgram per liter
μm	micrometer
cfs	cubic feet per second
cm	centimeter
g	Gram
g/day	gram per day
g/l	gram per liter
in/yr	inches per year
kg	kilogram
L	Liter
m	Meter
mg	milligram
mg/g	milligram per gram
ml	milliliter
mm	millimeter
ng	nanograms
ng/l	nanograms per liter
o/oo	parts per thousand (salinity)
ppb	parts per billion; usually µg/kg
ppm	parts per million; usually mg/kg or μg/g
ppt	parts per trillion; usually ng/kg

Page intentionally left blank.

1 INTRODUCTION

In 1990, the Central Valley Regional Water Quality Control Board (Central Valley Water Board) identified the Delta as impaired by mercury because fish had elevated levels that posed a risk for human and wildlife consumers. This is a concern because fishing is a popular activity in the Delta. About 300,000 licensed sport and subsistence anglers fish in the Delta each year, along with an unknown number of unlicensed anglers. Wildlife species of concern that consume Delta fish include California least tern, bald eagle, and river otter. Eating fish with high levels of mercury is a problem, especially for the young, because mercury is a potent neurotoxicant that impairs nervous systems in both humans and wildlife (National Research Council (NRC), 2000). In addition, it affects their reproductive and immune system function; examples of negative effects include deficits in memory and motor control in humans and reductions in physical abilities in wildlife (Wolfe *et al.*, 1998; Whitney, 1991 in Huber, 1997; Dansereau *et al*., 1999; Huber, 1997; Wiener and Spry, 1996).

As stated in CalFed's 2003 Mercury Strategy: "The problem with mercury in the Delta's aquatic ecosystems can be defined as biotic exposure to methylmercury." Methylmercury is the most toxic and bioaccumulated form of mercury. Methylmercury concentrations in aquatic ecosystems are the result of two competing processes: methylation and demethylation. Methylation is the addition of a methyl group to an inorganic mercury molecule. Sulfate reducing bacteria in sediment are the primary agents responsible for the methylation of mercury in aquatic ecosystems. Maximum methylmercury production occurs at the oxic-anoxic boundary in sediment, usually several centimeters below the surface. Although less common, methylmercury also may be formed in anaerobic water (Regnell *et al.*, 1996 and 2001).

Demethylation is both a biotic and abiotic process. Both sulfate reducing and methanogen-type bacteria have been reported to demethylate mercury in sediment with maximum demethylation co-occurring in the same zone where maximum methylmercury production is located (Marvin-DiPasquale *et al*., 2000). Photodegradation of methylmercury in the water column also has been observed (Sellers *et al*., 1996; Byington *et al*., 2005; Gill, 2008). The rate of both biotic and abiotic demethylation appear quantitatively important in controlling net methylmercury concentrations in aquatic ecosystems (Sellers and Kelly, 2001; Marvin-DiPasquale *et al*., 2000; Foe *et al*., 2008).Several published papers provide comprehensive reviews of the methylmercury cycle in the Delta and elsewhere (e.g., Wiener *et al.*, 2003a and 2003b; Tetra Tech, Inc., 2005; Larry Walker Associates (LWA), 2002). Board staff and others have found that in some waterways, processes of methylmercury production and transport downstream in the water column are dominant (e.g., in the lower Sacramento and San Joaquin Rivers upstream of the Delta) and in others, processes that remove

methylmercury from the water column such as photodegradation and sedimentation are dominant (e.g., in the Central Delta) (Stephenson *et al.*, 2008).

Once in the water column, methylmercury bioaccumulates in the food web. That is, very low methylmercury levels in water lead to high methylmercury levels in fish. For example, largemouth bass in the Delta have more than 6 million times the methylmercury as the water in which they swim. As a result, human and wildlife exposure to methylmercury is primarily through consumption of fish and shellfish, rather than drinking water.

Although processes that remove methylmercury from the water column may be dominant in some water bodies, there is no information that suggests that methylmercury discharged into a water body would disappear so rapidly that none of it would be accumulated, at least in part, into the food chain immediately downstream of the discharge. For example, in its Localized Mercury Bioaccumulation Study, SRCSD concluded that SRCSD WWTP effluent contributes about the same percentage of methylmercury to Sacramento River biota downstream of its discharge as it does to the methylmercury loading in the river. SRCSD found that four out of six fish and clams species sampled had methylmercury concentrations about 10% greater downstream from the discharge than upstream. The ratio of SRSCD WWTP methylmercury loads to river methylmercury loads was also about 10% during the study period. Also, as demonstrated by extensive spatial and temporal sampling of large and small fish in the Delta and its tributary watersheds (e.g., Slotton *et al*., 2003 and 2007; Davis *et al*., 2000, 2003 and 2008), methylmercury persists long enough in tributary and Delta waters to be reflected in fish uptake with regional patterns that stay consistent over years.

Although methylmercury is less than 1% of the inorganic mercury input to the Delta (Wood *et al*., 2010b), methylmercury is the form of mercury that accumulates in the food web. Available science indicates that reducing methylmercury in ambient water is the most direct way to reduce methylmercury in biota. Methylmercury produced by many modern-day activities may potentially be managed so that less methylmercury is discharged. Chapters 3 and 5 in the February 2008 draft staff TMDL report (Wood *et al*., 2010b) provides information about the relationship between methylmercury in Delta fish and water and potentially controllable methylation processes in the Delta region. Methylmercury in Delta waterways comes from many sources, such as wetlands, agricultural drains, urban runoff, wastewater treatment plant effluent and tributary inflows, in addition to methylmercury production in and flux from open-water sediments in Delta waterways.

Section 303(d)(1)(A) of the federal Clean Water Act requires States to establish a “Total Maximum Daily Load” (TMDL) for each impaired water body to attain water quality standards. Section 13240 of the State of California Porter-Cologne Water Quality

Control Act requires Regional Boards to develop water quality control plans to meet reasonable protection of beneficial uses, including establishing water quality objectives and a program of implementation to achieve the water quality objectives. A TMDL represents the maximum load (usually expressed as a rate, such as kilograms per day (kg/day) or other appropriate measure) of a pollutant that a water body can receive and still meet water quality objectives. A TMDL describes the reductions needed to meet water quality objectives and allocates those reductions among the sources in the watershed. Central Valley Water Board staff has proposed a mercury TMDL control program for the Delta that addresses sources of both inorganic mercury and methylmercury (Wood *et al.*, 2010a and 2010b). The proposed program focuses on methylmercury source reduction because available information indicates that methylmercury levels in water may be a primary factor determining methylmercury concentrations in fish. A inorganic mercury load reduction strategy also is part of the proposed program for several reasons: to reduce sediment mercury levels and associated water methylmercury levels in the Delta; to maintain compliance with the USEPA's criterion of 50 ng/l; and to comply with the San Francisco Bay mercury control program adopted by the San Francisco Bay Regional Water Quality Control Board.

The need for methylmercury data for discharges permitted by the National Pollutant Discharge Elimination System (NPDES) arose during the development of the source analysis for the Delta methylmercury TMDL. At the beginning of the TMDL development, only one NPDES-permitted facility in the Central Valley had collected effluent methylmercury data. Between December 2000 and June 2003, the Sacramento Regional County Sanitation District (SRCSD) collected 60 samples to characterize its effluent methylmercury levels. In February and March 2004, Central Valley Water Board staff conducted two sampling events at four other municipal facilities to determine whether the SRCSD data are representative of other WWTPs. The 2004 sampling results, along with data available in the published literature, indicated that the effluent methylmercury data for the SRCSD facility might not be representative of all facilities in the Delta. Therefore, the Central Valley Water Board issued a California Water Code Section 13267 Order (13267 Order) in 2004 that required NPDES dischargers, including municipal WWTPs and non-municipal facilities to monitor methylmercury discharges for one year.

Specifically, the 13267 Order required the following:

- Instantaneous, unfiltered grab samples collected from the facilities effluent for one year (generally September 2004 to August 2005) at a monthly, quarterly or biannual frequency, depending on facility size and whether there was a discharge to surface water;
- Use of clean hands/dirty hands sampling procedures and U.S. Environmental Protection Agency (USEPA) Method 1630/1631 (Revision E) with a method detection limit of 0.02 ng/l;

- Analysis of a matrix spike and matrix spike duplicate with either the first or second set of samples to ensure an acceptable methylmercury recovery rate; and
- Analysis of a travel blank with every other set of samples.

The 13267 Order did not require the collection of inorganic mercury data. However, if the facility was already collecting samples for inorganic mercury analysis, then it was required to collect the methylmercury samples concurrently. Also all inorganic mercury data and any other methylmercury monitoring data collected by a facility must be reported to the Central Valley Water Board. While not required by the 13267 Order, collection of instantaneous grab samples from the facilities' upstream receiving water and main influent were recommended to calculate methylmercury treatment efficiency. Appendix A provides an example of the 13267 Order letter and a list of facilities that received the Order.

This technical staff report presents a summary of the methylmercury data submitted by the NPDES dischargers. Because of the file size, data for individual facilities are not attached to this report; a Microsoft Excel file containing all data is available upon request. This report also includes an evaluation of the quality assurance/quality control results, a literature review, a description of the treatment processes in place at the municipal WWTPs when their methylmercury data were collected, a discussion of treatment processes and their possible relation to effluent methylmercury levels, and recommendations for further research. An administrative draft report was sent in December 2008 to all of the NPDES facilities whose data was summarized in this report. Staff addressed comments submitted for the December 2008 draft report and made the revised draft report available for public review in May 2009. Staff incorporated corrections and comments on the December 2008 and May 2009 draft reports into this final version of the report. Comments submitted by facilities and staff responses are in Appendix D.

As part of the proposed Delta mercury control program (Wood *et al.*, 2010a), Central Valley Water Board staff is currently recommending that methylmercury dischargers in the Delta and its source region conduct collaborative methylmercury control studies to develop methods to reduce their methylmercury discharges. This report and the associated database are a first step in that process, particularly for the municipal WWTPs.

The literature review of studies that investigated methylmercury in WWTPs is presented in Chapter 2. The quality assurance/quality control evaluation is presented in Chapter 3. The summary of effluent and influent methylmercury data is provided in Chapter 4. In response to comments from the Sacramento Regional County Sanitation District on the May 2009 draft report, an additional chapter (Chapter 5) was added to this report to assess the relative contribution of methylmercury load to the Delta by NPDES facilities in and upstream of the Delta. The discussion of treatment processes

and their possible relation to effluent methylmercury levels and recommendations for further research are provided in Chapter 6.

In this report, mercury, inorganic mercury, and total mercury are used synonymously.

2 LITERATURE REVIEW

Several published reports have evaluated wastewater treatment plant mercury fate and transport. Results and conclusions from these studies are summarized below and in Table 1.

2.1 San Jose / Santa Clara Water Pollution Control Plant

From October 2004 to March 2006, the City of San Jose conducted a sampling program to study the fate and transport of mercury within its wastewater treatment facility in compliance with its NPDES waste discharge permit (SJ/SC, 2007). The treatment process of the San Jose/Santa Clara Water Pollution Control Plant (SJ/SC WPCP) consists of screening and grit removal, primary sedimentation, secondary treatment (activated sludge with nitrification/denitrification), secondary clarification, filtration, chlorination, and dechlorination before the wastewater is discharged. During the secondary treatment process the waste stream is split between two parallel units, which are identical in function. Aqueous samples were collected from the raw influent after grit removal, primary effluent, settled sewage influent to nitrification units (secondary influent), secondary effluent, tertiary filter influent and effluent, and final effluent. City staff collected and analyzed over 140 aqueous samples for total and dissolved mercury, methylmercury, and parallel samples for total suspended solids (TSS), sulfide, chloride, and sulfate. Total and dissolved mercury and methylmercury results for the aqueous sampling are summarized in Table 2.

In addition, City staff collected and analyzed 32 biosolids samples for inorganic mercury, methylmercury, sulfide, sulfate, pH and moisture content. Sludge samples were collected from the primary sludge, waste activated sludge from secondary units, returned activated sludge, thickened activated sludge and digested sludge. Inorganic mercury concentrations in sludge were higher than in the water due to the strong particle association of mercury. Inorganic mercury and methylmercury concentrations in sludge were roughly uniform throughout the treatment process.

In this study, the removal of TSS corresponded with the removal of inorganic mercury. Raw influent contained approximately 190 mg/l TSS and 168 ng/l inorganic mercury. After primary settling, the TSS concentration was approximately 85 mg/l and the inorganic mercury concentration was 92 ng/l. Secondary effluent, which is a combined flow from identical and parallel activated sludge units, continued to show a close correlation between TSS and inorganic mercury removal with concentrations of about 5 mg/l and 5.2 ng/l, respectively. The TSS was reduced to approximately 2 mg/l in the treated tertiary effluent, but increased to 3 mg/l in the final effluent. The corresponding inorganic mercury concentration for the tertiary treated effluent was 1.6 ng/l, and for the final effluent was 2.0 ng/l. The study states that this slight increase in inorganic mercury

and TSS in the final effluent may be attributed to the addition of the filter backwash water, treated by flocculation and clarification, to the filter effluent prior to disinfection. The final effluent represented an overall removal of 99% of the inorganic mercury.

The secondary treatment process proved to be a catalyst for the removal of methylmercury, indicated by a primary effluent concentration of 1.5 ng/l and a reduction to 0.05 ng/l in the secondary effluent. Although anoxic conditions are present during some process steps of secondary treatment, the conditions were not sufficient to promote methylation of mercury. The authors of the study noted that little apparent sulfate reduction occurred within the treatment process, which could explain why significant methylation did not occur. Final effluent concentrations of methylmercury showed a decrease to 0.04 ng/l, representing an overall removal efficiency of 97%.

The study found no significant seasonal trend in influent inorganic mercury concentrations; however, the study observed a diurnal trend, with higher concentrations in the afternoon and early evening. There were no observed diurnal patterns for methylmercury in the influent. The study concluded that methylmercury concentrations in the influent were relatively uniform over the course of a day. The study did not discuss seasonal or diurnal patterns or variability in effluent inorganic mercury and methylmercury concentrations.

2.2 Sacramento Regional County Sanitation District Wastewater Treatment Plant

The Sacramento Regional County Sanitation District (SRCSD) WWTP is a 181 mgd pure oxygen activated sludge secondary treatment plant (Parmer *et al.*, 2005). The SRCSD also operates a 5 mgd tertiary treatment plant for water recycling. The SRCSD study investigated both inorganic mercury and methylmercury fate and transport for the wastewater and solids treatment trains. The tertiary effluent (recycled water) was not tested. This study used a two-phased approach, identified as Phase 1A and 1B.

Phase 1A included nine sampling days that occurred from October to November 2004. Samples were taken from the influent, primary effluent, secondary effluent prior to chlorination, dechlorinated final effluent, and solids storage basin return flow to the plant influent structure. The liquid supernatant from the digested sludge and three different solids storage basins (SSB) named green, black and harvest were also sampled. The parameters measured in Phase 1A were inorganic mercury (total and dissolved), methylmercury (total and dissolved), total dissolved solids, TSS, pH and dissolved oxygen.

Phase 1B involved more extensive sampling of the treatment process from the end of Phase 1A to May 2005. Phase 1B sampling locations included all locations sampled in Phase 1A, except for the supernatant from the SSB Ponds. In addition, the mixed liquor (mixture of the influent flow to the secondary clarifiers and the return activated sludge),

the waste activated sludge from the secondary clarifiers, the biosolids recycling facility (BRF) influent from the sludge digesters and the BRF return flow to the plant influent structure were sampled during Phase 1B. The same analytes were measured in both Phases 1A and 1B. The concentrations, mass loads and particulate concentrations for the inorganic mercury and methylmercury samples collected during both phases of the study are summarized in Tables 3 and 4.

There was a strong correlation between solids removal and inorganic mercury removal. The inorganic mercury concentration was reduced by an average of 94% from the influent to the secondary effluent, and 95% from the influent to the final dechlorinated effluent. The TSS was reduced by an average of 95% from the influent to the secondary effluent, and 96% from the influent to the final effluent. Overall, it appeared that the treatment process removed inorganic mercury more efficiently than methylmercury. The methylmercury concentration was reduced by an average of 75% from the influent to the secondary effluent, and 70% from the influent to the dechlorinated final effluent.

The highest methylmercury loading in the liquid train of the plant occurred in the mixed liquor channel, which comprises primary effluent and 40% return activated sludge. The highest methylmercury concentration (not including digested sludge and return flows) of about 31 ng/l occurred in the return activated sludge stream, which is recycled to the mixed liquor (activated sludge unit process). The secondary process achieved the greatest reduction of methylmercury concentrations and loads in the liquid train as observed from the primary and secondary effluents; however, it also had the greatest methylmercury concentration (in the waste activated sludge stream) of all the liquid train unit processes in this study.

An increase in methylmercury concentration occurred between the secondary effluent (0.38 ng/l) and the dechlorinated final effluent (0.55 ng/l). The study authors noted the increase was consistent with the slightly increased TSS concentration in the final effluent. According to the authors, no backwash or other return flow is added to the waste stream between the secondary effluent and the dechlorinated final effluent. The report authors concluded that both inorganic mercury and methylmercury removals correlated with TSS removal due to strong particle affinity.

2.3 Concentrations and Fluxes of Inorganic mercury and Methylmercury within the Onondaga County Metropolitan Wastewater Treatment Plant

The Onondaga County Metropolitan Wastewater Treatment Plant discharges its effluent to Onondaga Lake, a mercury-contaminated lake in Syracuse, New York (McAlear, 1996). A study at the Onondaga County Metropolitan WWTP investigated the concentrations and fluxes of inorganic mercury and methylmercury within the plant and in its discharge. The WWTP treatment processes consist of screening and grit removal,

primary clarification, conventional activated sludge, secondary clarification, chlorination, and phosphorous removal (coagulation by addition of iron salts followed by clarification) before the wastewater is discharged.

Monthly samples were collected from the plant influent, primary effluent, secondary effluent, “tertiary” effluent from the phosphorous removal clarifiers and final plant effluent between October 1995 and September 1996 and analyzed for inorganic mercury and methylmercury. Daily composite total dissolved solids concentrations and daily inorganic mercury concentrations in sludge also were evaluated. The average concentrations of inorganic mercury, methylmercury and TSS at each treatment process are summarized in Table 5.

The authors determined that seasonal conditions play an important role in the methylation process, and in particular, that warm temperatures may be a catalyst for methylation. The influent methylmercury concentrations were much lower during cold weather (November through April) than during warm weather (May through October), and further, methylmercury concentrations remained relatively constant throughout the treatment process during cold weather (Table 6). However, during the warm weather months, an increase in the average methylmercury concentrations occurred between primary effluent and secondary effluent (from 1.8 ng/l to 3.5 ng/l), followed by a decrease in the “tertiary” and final effluents (2.9 ng/l and 1.6 ng/l, respectively). Despite this apparent methylation during secondary treatment in warm weather months, the study found that the average final effluent methylmercury concentration in the warm weather months was only slightly higher than during the cold weather months (1.6 ng/l compared to 1.4 ng/l).

There was a strong correlation between the mean concentrations of inorganic mercury and TSS throughout the treatment processes. In contrast, a weak correlation was evident between the mean methylmercury and TSS concentrations. The ratios of methylmercury versus inorganic mercury concentrations for the entire study period (includes warm and cold weather months) were highest during secondary treatment at 20.5%, decreasing to 8.3% in the final effluent.

During the cold weather months, November through April, the influent and final effluent methylmercury averaged 2.3 and 1.4 ng/l, respectively. Primary and secondary treatment effluent had concentrations near 2.0 ng/l. The highest methylmercury concentration during the cold weather months was in the “tertiary” effluent (2.4 ng/l). The percentage of inorganic mercury as methylmercury during the same period increased gradually throughout the treatment process from about 1% (influent), 2% (primary), 6% (secondary), and 12% (“tertiary”), before decreasing in the outfall to 3%.

The influent and final plant effluent methylmercury averaged 7.8 and 1.6 ng/l, respectively, in the warm weather months. The percentage of inorganic mercury as

methylmercury during warm weather months varied from approximately 2 to 3% in the influent and primary effluent, to a high of 35% in secondary treatment, and then decreasing to 15% in tertiary treatment and 13% in the final effluent measured at the outfall. Although activated sludge is an aerobic treatment process, the study author hypothesized that methylation of mercury likely occurred during secondary treatment in anaerobic microenvironments.

2.4 City of Winnipeg, Manitoba, Canada

The City of Winnipeg, Manitoba operates three secondary treatment plants that discharge to two local rivers, the Red and Assiniboine Rivers (Bodaly *et al.*, 1998). Two of the plants (the North End and South End plants) use pure oxygen activated sludge in their secondary treatment process. The West End plant, in contrast, uses conventional activated sludge with diffusers. The West End facility also is the only WWTP of the three to use lagoons after secondary treatment and before final effluent discharge.

Samples were collected from the influent and effluent of the three plants. Five sampling events took place from early summer to autumn 1994 and one event took place in spring 1995, for a total of six sampling events. The unfiltered water samples were analyzed for inorganic mercury and methylmercury.

Influent methylmercury concentrations observed at the three treatment plants ranged from 0.5 to greater than 4 ng/l and averaged 2.2 ng/l. Effluent methylmercury concentrations observed at the North and South End plants ranged from 0.13 to 0.56 ng/l. However, effluent methylmercury concentrations observed at the West End Plant, which utilizes conventional activated sludge and lagoons after secondary treatment, were significantly higher, varying from about 0.2 to greater than 2 ng/l. A seasonal trend was apparent only in the West End facility; effluent methylmercury concentrations increased as ambient temperatures increased, with the highest concentration occurring in August. The authors noted that the high concentrations of methylmercury in 1994 may have been related to the fact that the West End facility had begun operations within the year and experienced start-up problems. Also, this facility was the only one of the three plants to use final polishing lagoons, which could be sites of substantial methylmercury production, especially if anoxic conditions exist.

Overall removal rates for the three treatment plants were 88% of inorganic mercury and 90% of methylmercury. However, this methylmercury removal rate does not include the summer period at the West End Plant when methylmercury concentrations in the effluent were elevated. The study authors did not observe a seasonal pattern in the concentration of inorganic mercury in effluent from any of the plants.

2.5 Fritz Island Wastewater Treatment Plant

The City of Reading signed a consent decree with the State of Pennsylvania agreeing to remove three mercury-filled trickling filter center column seals used in the Fritz Island WWTP (Gilmour and Bloom, 1995). This allowed researchers to examine the extent of inorganic mercury and methylmercury contamination within the plant and its receiving water body, the Schuylkill River. Each filter seal initially contained 340 kg of mercury, some of which was lost from the seals due to excessive pressure and equipment failures and escaped to the rock media and underbed of the trickling filters. The mobility and fate of the mercury contaminating the Fritz Island WWTP was determined by evaluating inorganic mercury and methylmercury concentrations of the inflow to and outflow from a number of individual treatment components in the WWTP.

The Fritz Island WWTP is a secondary treatment facility that employs trickling filters (TFs) for secondary treatment. The treatment process consists of primary settling before the 1st stage TFs, 1st stage trickling filters (TF# 1-3), intermediate settling before the 2nd stage TFs, 2nd stage trickling filters (TF# 4-6), settling after the 2nd stage TFs, aeration and then a final settling process. There are six trickling filters involved in the treatment process. Four of these (TF# 1, 3, 5 and 6) originally used mercury-containing center seals. The contaminated seal in trickling filter #5 was replaced with a mechanical seal in 1984, and the rock media and underbed was cleaned or replaced.

Researchers collected aqueous samples from the plant influent and effluent, and sludge samples from the belt press, from July to December 1993. The aqueous and sludge samples were analyzed for inorganic mercury and methylmercury. A summary of the inorganic mercury and methylmercury concentration data and calculated mass balances are presented in Tables 7 and 8, respectively. During a one-time sampling event in August 1993, researchers collected inorganic mercury and methylmercury samples from the inputs and outputs from each treatment process within the WWTP. A summary of those results is provided in Table 9.

With the exception of TF# 5, all of the trickling filters were measurable sources of both inorganic mercury and methylmercury, demonstrated by greater concentrations in the effluent than in the influent of the contaminated trickling filters. In TF# 1, the inorganic mercury concentration of the effluent was 25 times higher than the influent, and the methylmercury concentration was four times higher. Inorganic mercury in the wastewater was lost to the sludge during the settling steps. More than 90% of the inorganic mercury in the effluent of the first stage trickling filters was removed to the sludge during the intermediate settling process. A similar trend was observed in the post 2nd stage and final settling processes.

An average of 157 grams of inorganic mercury was released from the plant per day, with less than 10% in the effluent and more than 90% released in the sludge. Only

about 20 grams of the 157 grams was derived from the plant influent, with the remainder generated inside the plant. However, the WWTP was an overall sink for inorganic mercury in the wastewater, demonstrated by lower inorganic mercury concentrations and loads in the plant effluent than in the plant influent.

Methylmercury production was closely related to the mercury concentration in each of the trickling filters. The contaminated trickling filters were the main sites of methylmercury production. Methylmercury concentrations decreased during aeration, which the study authors hypothesized was attributed to chemical or microbial demethylation of methylmercury to inorganic mercury during this process. Overall, about 0.4 g/day of methylmercury was released from the plant, with about 25% of this amount introduced from the plant influent and the rest generated inside the plant. Of the 0.4 g/day of methylmercury released from the plant, 30% was in the sludge, and 70% was released to the river in the effluent. The WWTP was an overall source of methylmercury in the wastewater. Both the methylmercury concentrations and loads in the effluent were higher than in the plant influent.

2.6 Whitlingham Sewage Treatment Works

Between May 1986 and June 1988, a study was conducted at Whitlingham Sewage Treatment Works in Norwich, England to evaluate the behavior of heavy metals during wastewater treatment and to investigate the occurrence of mercury methylation throughout the treatment plant (Goldstone *et al.*, 1990). The wastewater treatment processes at the Whitlingham facility consisted of primary clarification followed by secondary activated sludge treatment before discharge as effluent.

The study consisted of two sampling events, the first in May 1986 and the second in October 1987. The constituents evaluated during both sampling events were inorganic mercury, dissolved mercury, total solids and total suspended solids (TSS). Methylmercury was sampled throughout the treatment process only during the second sampling event. Raw sewage (influent), settled sewage (primary effluent), picket fence thickener overflow, returned activated sludge, and final effluent were sampled during the second event. Table 10 provides a summary of the inorganic mercury and methylmercury concentration results for the second sampling event.

Methylation of mercury within the treatment plant was observed, especially in the presence of bacterial solids. Methylmercury and inorganic mercury concentrations were highest in the return activated sludge. However, the average methylmercury concentration of the final effluent was below the 10 ng/l detection limit; the study authors assumed that the seven samples with methylmercury concentrations below the detection limit were equal to zero when they calculated the average methylmercury concentration of the final effluent.

The effects of centrifugation and filtration on additional return activated sludge samples were investigated to determine whether methylmercury has a greater affinity for the soluble or particulate phase of the return activated sludge. Results indicated that methylmercury was predominantly associated with solids. The study authors determined that the absence of detectable methylmercury in the influent and primary effluent indicates that all methylmercury in the return activated sludge had been produced by *in situ* biological methylation. However, the authors noted that the aerobic conditions of the activated sludge could be considered unfavorable to the production and accumulation of methylmercury. The authors hypothesized that the high concentrations of bacterial solids and other organic material in the waste activated sludge may have outweighed the aerobic conditions and permitted the establishment of an equilibrium concentration of methylmercury. Correlations performed on the data confirmed a relationship between high concentrations of biological solids and aerobic methylation.

2.7 Determination of Methylmercury in a Pilot-Scale Activated Sludge Wastewater Treatment Plant

Pavlogeorgatos and others (2006) investigated methylation in a pilot-scale activated sludge plant supplied with synthetic wastewater enriched with mercury. The wastewater was spiked with mercury concentrations of 10, 100 and 500 µg/l. The initial methylmercury concentration of the synthetic wastewater was not evaluated. Duplicate samples from the aeration tank, treatment plant effluent, and sludge were analyzed for inorganic mercury and methylmercury. The results indicated that all of the samples had methylmercury concentrations below the detection limit of 0.07 µg/l. The highest inorganic mercury concentration of 17.8 mg/l was found in the sludge sample associated with the 500 µg/l mercury spike. On average, 82.8% of the mercury entering the treatment plant was adsorbed to the particulate matter in the aeration tank.

While no conclusion could be drawn regarding methylation because of the high method detection limit (0.7 µg/l, compared to the MDL of 0.02 ng/l required for the 13267 Order monitoring), this investigation confirmed that the reduction and volatilization of mercury is the primary pathway to its removal. In the aeration tank, this pathway becomes secondary when the microorganisms and mercury reach equilibrium. Adsorption of mercury onto the biosolid flocs becomes the primary removal mechanism. The study theorized that methylmercury was not detectable because the conditions were aerobic, or because demethylation predominated. Methylation may have occurred but was not detectable given the method detection limit used in the study. The authors also discovered that spiking the wastewater with increased mercury concentrations reduced the removal effectiveness of organic matter in the treatment process.

3 QUALITY ASSURANCE AND QUALITY CONTROL

The 13267 Order required NPDES facilities to submit effluent methylmercury monitoring data collected using the clean hands/dirty hands technique described in USEPA Method 1669 and analyzed using USEPA Method 1630/1631 (Revision E) with a method detection limit (MDL) of 0.02 ng/l. In addition, the facilities were required to have a matrix spike/matrix spike duplicate (MS/MSD) performed on their first or second set of effluent samples, and travel blanks performed with every other set of samples. The MS/MSD is designed to determine if the effluent matrix causes interferences in methylmercury recovery and to provide an estimate of analytical precision. The travel blank is used to determine if there is any contamination during transport. Other quality assurance/quality control (QA/QC) parameters not required by the 13267 Order but evaluated by some of the facilities include field duplicates, MS/MSD of other matrixes, and field blanks. Staff used guidelines described in the CALFED Mercury Program Quality Assurance Project Plan (Puckett, 2000) to assess the quality of the data presented in this report.

3.1 Method Detection Limit

Since Frontier GeoSciences laboratory has a minimum reporting limit of 0.025 ng/l and Frontier conducted many of the analyses for the facilities, staff considered non-detects to be reported as less than 0.025 ng/l or lower. Only on six occasions were MDLs greater than 0.025 ng/l; the maximum MDL reported was 0.05 ng/l. The concentration data submitted by the dischargers overall appear to be of high quality and analyzed by laboratories able to perform the latest methods for analyzing methylmercury.

3.2 Sample Handling and Preservation

USEPA Method 1630 requires samples to be preserved with acid within 48 hours to a pH of less than two. The analytical laboratories verify the pH of the samples upon receipt, and the laboratories acid-preserve the samples if the pH is found to be greater than two. The laboratories flag samples when the samples are preserved after the 48-hour hold time. Thirty-four percent of the samples analyzed for methylmercury were preserved before being received by the analytical laboratories (field), 37% were preserved at the laboratories, and 29% of the samples had no acid preservation information provided (unknown). All data from samples known to have pH hold time exceedences were flagged so. Data for samples whose hold times exceeded 60 hours were flagged and excluded from calculations made in this report. Table 11 shows the data for these excluded samples. All samples with no preservation information provided were assumed to meet their pH hold times and their data were accepted.

Twenty-two samples exceeded the 48-hour hold time, and of those, 21 samples exceeded 60 hours (Table 11). Acid preservation stops the bacterial activity in the water that produces methylmercury from inorganic mercury. Samples without preservation may not be representative of the conditions at the time of sampling if bacterial activity continues after sampling. However, because bacterial activity is believed to be minimal in samples that are kept cold (0 to 4°C), data from samples with minimal hold time exceedences (<60 hours) were considered acceptable.

The USEPA Method 1630 states that unpreserved samples should be kept at 0 to 4°C until preserved, after which samples can be stored at cool temperatures. The analytical laboratory reports state the optimal temperature is 4 ±2°C for unpreserved samples; as a result, all data derived from samples received by the laboratories above 6°C and unpreserved were flagged for being out of optimal temperature range. A review of the data indicated that temperature did not likely affect the samples; therefore, staff incorporated the flagged data in this report's calculations.

3.3 Matrix Spike/Matrix Spike Duplicates

MS/MSD results were submitted by 93 facilities (see Appendix C, Table C.1). The facilities were not required to submit the laboratory reports from the analysis laboratories; consequently, eight facilities submitted summaries only of their methylmercury data. Ninety-two facilities had MS/MSDs performed on their effluent at least once for a total of 161 effluent MS/MSDs performed. On eight occasions, the MS/MSDs were not within the criteria of acceptability.[2] For three events the MS/MSD had relative percent differences (RPD) greater than 25%, and the associated effluent data were flagged "not reproducible" for high variability. In addition, there were three times where the MS/MSD had recoveries below 70% and twice the recovery was greater than 130%, hence the associated effluent data were flagged "low bias" for low recoveries and "high bias" for high recoveries, respectively.

Influent and receiving water had MS/MSDs performed on 25 and 32 occasions, respectively. One of the influent MS/MSDs exhibited a recovery above 130%, and the data were flagged "high bias". Five of the influent MS/MSDs (20% of the MS/MSDs performed on influent samples) exhibited recoveries below 70%, and their data were flagged "low bias". The USEPA Method 1630 may underestimate the methylmercury concentration in wastewater influent samples. Receiving water MS/MSD experienced recoveries below 70% once and above 130% once, hence the associated data were flagged accordingly. In all instances that the MS/MSDs experienced recoveries below 70% or above 130%, the laboratories' analyses of laboratory control samples were

[2] Acceptable MS/MSD recovery per the CalFed QAPP: >70% and <130% recovery.
Acceptable MS/MSD RPD: ≤25%.

within acceptable limits, indicating that the laboratories performed the method appropriately.

One laboratory reported that high levels of chloride in effluent could interfere with recoveries, and that a special preparation of the sample could remedy the problem. However, the small occurrence of low recoveries in effluent indicates that there is little interference caused by the effluent matrix. In addition, the low occurrence of MS/MSD RPD exceedences greater than 25% indicates the high precision of the laboratory analyses and the high quality of data produced.

3.4 Travel Blanks

The facilities were required to submit travel blanks with every other set of samples submitted. Some facilities submitted trip blanks or field blanks, in addition to or instead of travel blanks. Travel blanks are bottles filled with deionized (DI) water that are transported to the site but not opened (CDFG, 2002). Travel blanks are synonymous to trip blanks, which is defined by USEPA as, "A clean sample of a matrix that is taken from the laboratory to the sampling site and transported back to the laboratory without being exposed to the sampling procedures" (USEPA, 2002). Conversely, one of the laboratories contracted to collect water samples defined trip blanks as, "…Trip blanks should be handled the same as the sample; however, they only need to be exposed to the atmosphere. Do not put sample in the bottle. Trip blanks are designed to measure the amount of methyl mercury in the air…" This suggests that this laboratory's trip blanks were performed to test parameters typically assessed with field blanks. Field blanks are considered acceptable substitutes because they assess contamination introduced by field sampling conditions in addition to all of the contamination assessed by travel blanks.

Approximately 85% of the facilities that submitted data fulfilled their requirements for blanks submittal, 4% partially fulfilled their requirements, and 11% did not submit any blank analysis. Approximately 5% of the combined number of trip and field blanks had methylmercury concentrations detected above the MDL; however, the majority of the detections were less than two times the detection limit or less than five times the sample concentration. These deviations are not considered to affect the quality of the sample concentration data. The analytical laboratories reported that concentration detections less than two times the MDL have high variability and are considered estimates. Only 3% of the blank concentration detections were greater than two times the MDL and proportionately high when compared to their respective sample concentrations. Because these data could be affected by contamination they were flagged. Blanks are designed to be used as an interactive QA/QC tool, where sources of reoccurring contaminations can be identified and eliminated. Because most of the contaminations

were isolated events, the concentration data accuracy should not be greatly affected; therefore, the flagged data were used in this report's calculations.

3.5 Field Duplicates

Field duplicates are used to examine field homogeneity and sampling handling. Though not required by the 13267 Order, field duplicates were collected on 35 occasions (Table 12). Field duplicate mean RPD was 12.7%. On four occasions the RPD was greater than 25%; however, the methylmercury concentrations for each of the samples and their duplicates were less than 10 times the MDL. Sample concentrations at or near the MDL have higher variability, suggesting that these field duplicates' high RPD cannot be completely attributed to field variability. All of the field duplicates met the criterion for data acceptability, indicating that the facilities performing field duplicates had acceptable field collection precision. Field duplicates were not incorporated into the calculations of this report.

3.6 Anomalous Values

Several anomalous values were observed in the methylmercury and inorganic mercury dataset when compared to the remainder of the values observed at a facility (Table 13). When an analytical laboratory report was available, staff was able to confirm the anomalous values. None of the available laboratory reports indicated that contamination or any other error or misreporting occurred. Otherwise, if no laboratory information was provided, staff assumed that all data including anomalous values were correct. As a result, Board staff included all anomalous values in the report calculations since staff could not conclude definitively that errors were made.

SRCSD staff identified three methylmercury results that failed their quality assurance review. Influent and effluent samples collected on 13 July 2001 had methylmercury concentrations of 1.05 and 2.93 ng/l, respectively; SRCSD staff commented in their data review notes, "highly unlikely that there is more MeHg in effluent than influent". Likewise, an effluent sample collected on 18 June 2006 had a methylmercury concentration of 0.077 ng/l; SRCSD noted, "highly unlikely that effluent concentration is this low". As a result, these three samples were not included in the calculations in this report.

There were three instances when a municipal WWTP had a higher effluent methylmercury concentration than the influent value collected on the same day. This occurred one time at each of the Colusa, SRCSD Walnut Grove and Mariposa WWTPs. Staff carefully reviewed available information to determine the likelihood of some type of data or reporting error. The influent and effluent values were confirmed by analytical

laboratory reports and chain of custody documents; hence, staff assumed that the data was correct and the data was included in the report calculations.

3.7 Summary

The data presented in this report meets the overall QA/QC requirements of the NPDES 13267 Order. Less than 1% of the analyses for methylmercury had method detection limits greater than 0.025 ng/l, with 0.05 ng/l being the highest, indicating that the samples were analyzed using the latest methods. Only 3% of the effluent matrix spikes resulted in recoveries exceeding the criterion, and less than 2% of the MS/MSD analyses resulted in RPDs greater than 25%. Wastewater treatment plant effluent appears to exhibit little to no interference with Method 1630. These results agree with Caltest Analytical Laboratory staff's review of Method 1630 performance on wastewater they have analyzed, where their last 200 matrix spikes averaged 93% recovery in matrix and MS/MSD relative percent differences averaged 9% in their last 100 MS/MSD performed (SFEI, 2007). In contrast, 20% of the MS/MSD performed on influent samples submitted by Central Valley facilities exhibited low recoveries; therefore, Method 1630 may underestimate the methylmercury concentration in wastewater influent samples. Less than 3% of the combined travel and field blanks resulted in detections above the criterion of acceptability, suggesting that there was little cross contamination between bottles and/or contamination from field procedures.

Twenty-five methylmercury samples were excluded from calculations and graphs in this report. Twenty-two of these excluded samples had acid preservation hold times that exceeded 60 hours. In addition, 6 of the samples excluded due to hold time exceedences, were also contaminated with mercury in the laboratory and were not believed to be representative of site influent or effluent. These contaminated samples were from General Electric Co. GWCS (NPDES No. CA0081833) and were collected on 18 October 2004. The three other methylmercury samples excluded from calculations in this report failed the SRCSD staff quality assurance review.

Page intentionally left blank.

4 REVIEW OF METHYLMERCURY CONCENTRATION DATA FROM CENTRAL VALLEY DISCHARGERS

There are currently 124 NPDES-permitted dischargers in the Delta source region[3] representing a variety of discharger types, primarily: aggregate, aquaculture, food processing, heating/cooling, manufacturing, mines, municipal WWTPs, paper/saw mills, power generation, water filtration (e.g., for drinking water), and groundwater remediation. The approximate discharge volumes of each of these NPDES categories are provided in Table 14.

A total of 134 Central Valley NPDES-permitted dischargers received the 13267 Order (see Appendix A, Table A.1). Staff did not send the 13267 Order to every NPDES-permitted discharger in the Delta source region. In addition, some of the facilities that received the Order discharge upstream of major dams, some were not discharging to surface waters during the study period, and some no longer discharge. Of the 134 dischargers that received the Order, 18 facilities discharge upstream of major dams, 22 facilities discharge directly to the Delta/Yolo Bypass, 17 discharge to other waterways that are 303(d)-listed as mercury impaired as of 2006, and 12 discharge to small waterways that, although not 303(d)-listed, drain directly to the Delta/Yolo Bypass. Table 15 summarizes the number of facilities that received the Order, categorized by discharger type and geographical region.

Effluent methylmercury data were submitted by 111 facilities as a result of the 13267 Order monitoring requirements. Although not required by the Order, thirty-six of those facilities also submitted influent methylmercury data. In addition, the Sacramento Regional County Sanitation District submitted influent and effluent methylmercury concentration data for a six-year period (December 2000 – March 2007). Central Valley Water Board staff compiled influent and effluent inorganic mercury concentration data available in SRCSD monitoring reports. The abundance of inorganic mercury and methylmercury data for the SRCSD Sacramento River WWTP influent and effluent allowed for more analysis of the SRCSD data. Figures 1, 2 and 3 illustrate the locations of the Central Valley facilities that submitted methylmercury data and Table 16 provides the map codes, receiving water information, approximate discharge volumes and facility types discussed in this report.

Tables G.3a and G.3b in Appendix G of the Delta methylmercury TMDL report summarize the number of effluent methylmercury samples collected by each facility, along with their average, minimum and maximum methylmercury concentrations. Tables in the Delta methylmercury TMDL report appendix provide average concentrations only for discharges to surface water. The graphs and calculations in this

[3] The "Delta Source Region" is a geographic area that includes the Delta and the watershed areas upstream that drain into the Delta but are downstream of major dams.

report incorporate all available data, including samples collected when facilities did not discharge to surface water. Of the approximately 700 effluent methylmercury samples collected, nine samples were taken from reclaimed effluent that was not discharged to surface water.

Available influent and effluent data are summarized by discharger type in the following sections. Summaries of effluent and influent methylmercury data for each NPDES facility are presented in Appendix B, Tables B.1 through B.4, at the end of this report.

4.1 Non-Municipal Discharges

Section 4.1 is divided into six subsections that describe non-municipal discharges:

1. Aggregate;
2. Aquaculture, power generation and heating/cooling;
3. Paper, pulp and saw mills;
4. Groundwater remediation;
5. Drinking water treatment; and
6. Food processing, manufacturing, and other non-municipal discharges.

A summary of the effluent methylmercury concentration data categorized by discharger type for the non-municipal NPDES facilities is provided in Table 17.

4.1.1 Aggregate

Discharge from aggregate plants, which process rock and gravel from quarries, is typically storm water after it is settled in sedimentation basins. These facilities were a small source of methylmercury with an average effluent concentration of 0.026 ng/l (Table 17). Five aggregate facilities submitted discharge methylmercury concentration data; one of the facilities is no longer active. Six of the eight samples collected by the active aggregate plants had methylmercury concentrations less than the method detection limit, and the other two samples had concentrations of 0.062 and 0.081 ng/l. Discharges from aggregate plants comprise about 2% of NPDES discharges (by volume) to the Delta source region.

The Oakwood Lake Subdivision Mining Reclamation NPDES permit (CA0082783; formerly known as the Brown Sand, Inc., Manteca Aggregate Sand Plant) allows for the discharge of water from Oakwood Lake to the San Joaquin River for flood control. Oakwood Lake is a former excavation pit filled primarily by groundwater. The results from discharge sampling in August and November 2004, nondetect (<0.02 ng/l) and 0.043 ng/l, respectively, are comparable to results for groundwater remediation plant discharges (Section 4.1.4). Furthermore, these effluent values are substantially lower

than the monthly average methylmercury concentrations observed in the adjacent San Joaquin River at Vernalis during August and November (0.167 and 0.130 ng/l, respectively; Wood *et al.*, 2010b).

4.1.2 Aquaculture, Power Generation & Heating/Cooling

Aquaculture, power generation, and heating/cooling facilities typically use ambient surface water, domestic water or groundwater for hatchery flow-through water or cooling water. Wastewater from these types of facilities may be untreated, filtered to remove solids and/or metals, or clarified in sedimentation basins prior to discharge. The combined discharge volume from all of these facility categories is about 50% of the total discharged by NPDES facilities to the Delta source region (Table 14).

Aquaculture, power generation and heating/cooling facilities had average effluent methylmercury concentrations of 0.041 ng/L, 0.061 ng/L and 0.11 ng/L, respectively (Table 17). The intake water of many of these facilities is taken from the same water body that the effluent is discharged to; therefore, a comparison of intake and effluent concentrations is necessary to determine whether a facility is a net source or sink of methylmercury.

Ten of the twenty-four facilities that submitted methylmercury data collected paired intake/outfall samples (Table 18). The power and heating/cooling facilities did not appear to be a source of methylmercury to the Delta. However, staff was unable to do statistical analyses of the paired influent-effluent samples of these facilities because sample sizes were too small for all facilities except for Mirant Delta CCPP (CA0004863), a power generation facility. Furthermore, many of these facilities had influent and effluent samples that were below the detection limit, making it impossible to statistically compare those paired samples. Methylmercury concentrations of outfalls 1 and 2 from Mirant Delta CCPP were not significantly different than intake 2 when compared individually (Outfall 1 vs. Intake 2: $p=0.26$; Outfall 2 vs. Intake 2: $p=0.37$, paired t-test). Therefore, outfalls 1 and 2 were neither significant sources nor sinks of methylmercury. More data is necessary to determine if the other power and heating/cooling facilities are methylmercury sources or sinks.

Effluent methylmercury concentrations of the aquaculture facilities were not significantly different than the paired influent concentrations ($p=0.21$, paired t-test). Even though the effluent concentrations typically exceeded intake concentrations (see Table 18), aquaculture facilities were neither a source nor sink of methylmercury. This comparison is based upon five paired influent-effluent samples from three facilities; therefore, more paired data is necessary to determine if aquaculture facilities are net sources or sinks. Almost all the aquaculture facilities had average effluent methylmercury concentrations equal to or less than 0.05 ng/l.

Until recently, the SMUD Rancho Seco Nuclear Generating Station (CA0004758) discharged a combination of treated liquid radioactive wastewater, secondary treated domestic wastewater, stormwater and irrigation runoff. It is the only facility in the power generation/ domestic WWTP category and was a small source of methylmercury. Methylmercury concentrations in the combined effluent ranged from nondetect (<0.025 ng/l) to 0.104 ng/l with an average of 0.040 ng/l.

4.1.3 Paper, Pulp & Saw Mills

Paper, pulp and saw mills discharge a combination of process wastewater and storm water after it is typically clarified in settling basins. These facilities were a source of methylmercury with an average effluent concentration of 0.117 ng/l (Table 17). However, 15 of the 21 effluent samples collected at these facilities were less than 0.10 ng/l. Paper, pulp and saw mills account for about 0.4% of the volume discharged by NPDES facilities to the Delta source region.

Five of the 12 effluent samples collected at the Pactiv Molded pulp mill (CA0004821) had methylmercury concentrations less than the method detection limit, and the other seven samples were between the detection limit and 0.085 ng/l. Eight of the nine samples collected at the two other mills had concentrations between the detection limit and 0.18 ng/l. The SPI Shasta Lake saw mill (CA0081400) had the highest effluent methylmercury concentration of 1.19 ng/l, collected from “Discharge 002” on 30 December 2004. The concentration of the other effluent sample collected from “Discharge 002” on 23 March 2005 at this facility was 0.023 ng/l. Discharge 002 is from a stormwater retention pond, and rainfall occurred on both sample dates and on previous days; it is conceivable that a “first flush” effect could be the cause of the highly variable results.

4.1.4 Groundwater Remediation

Groundwater remediation facilities extract contaminated groundwater for treatment prior to discharge to surface waters. These facilities had very low levels of methylmercury in their discharge. Nineteen of the 20 effluent samples collected by four facilities had methylmercury concentrations less than the method detection limit, and one sample was just slightly above the detection limit (0.033 ng/l). One plant collected nine influent samples, all of which had methylmercury concentrations less than the detection limit. Groundwater remediation plants account for about 1.4% of the volume discharged by PDES facilities to the Delta source region.

4.1.5 Drinking Water Treatment

Drinking water treatment plants account for about 0.1% of the volume discharged by NPDES facilities to the Delta source region. Drinking water treatment plants typically

discharge settled filter backwash water from their treatment process to surface waters. Six drinking water treatment facilities submitted effluent methylmercury concentration data and two of those submitted influent data. These facilities had an average effluent concentration of 0.033 ng/l (Table 17). Five of the facilities had effluent samples with methylmercury concentrations ranging from below the detection limit to 0.043 ng/l. One of these facilities collected an intake sample with a methylmercury concentration of 0.084 ng/l. The other facility had two effluent samples with methylmercury concentrations measuring 0.045 ng/l and 0.066 ng/l, and two influent samples with concentrations measuring less than the detection limit (0.02 ng/l) and 0.033 ng/l.

4.1.6 Food processing, Manufacturing, and other Non-Municipal Discharges

Food processing, manufacturing, and publishing facilities were not a substantial source of methylmercury. Fifteen of the 20 effluent samples collected by facilities in these categories had methylmercury concentrations less than the method detection limit, and the other five samples had concentrations between the detection limit and calibration standard (0.05 ng/l). One of the manufacturing facilities collected 12 influent samples. Eleven of these samples had methylmercury concentrations less than the detection limit, and one was just above the detection limit.

The one laboratory and one mine facility that submitted data were both small sources of methylmercury. The three samples collected by the laboratory facility had methylmercury concentrations between 0.038 ng/l and 0.082 ng/l. The four samples collected by the mine ranged from 0.025 ng/l to 0.091 ng/l. Permitted discharges from food processing, mining, publishing, and laboratory facilities comprise about 0.3% of the total NPDES discharge volume to the Delta source region. The two manufacturing plants in the Delta source region have since ceased discharge to surface waters.

4.2 Municipal WWTPs

More information is available for municipal WWTPs than for other types of NPDES facility discharges, so staff was able to conduct a more extensive data analysis for WWTPs. Municipal WWTPs contribute about 44% of the total discharge volume (see Table 14) and about 99% of methylmercury loading contributed to the Delta source region by NPDES facilities (see Chapter 5 and Table 36). While the loads from all WWTPs may be a small fraction of the total and methylmercury loads from tributary and Delta sources (see Chapter 5 and Tables 35, 36 and 37), some municipal WWTPs may contribute substantial methylmercury loads to individual water bodies. For example, a six-year comparison of the SRCSD Sacramento River WWTP effluent methylmercury loads as a percentage of its receiving water loads was as high as 30 to 43% during the warm seasons of 2001 and 2002 and less than 1% during the wet seasons of 2005 and 2006 (Figure 4; Bosworth, 2008), ranging from 4.2% to 17% on an annual basis.

Between October 2002 and October 2006 most of the loading was less than 10% during the winter through summer seasons. For some receiving waters, reducing municipal WWTP methylmercury discharges, along with reductions from other point and nonpoint sources, may be an important component in reducing methylmercury levels in Delta water.

Sixty-one municipal WWTPs submitted effluent methylmercury concentration data representing 63 discharges (two facilities had two discharge locations). Twenty-three treatment plants also submitted influent methylmercury data. In addition, inorganic mercury influent and effluent data are available for 9 and 29 discharges, respectively. Hence, Section 4.2 is divided into subsections describing the different types of concentration data and data comparisons:

1. Effluent methylmercury;
2. Influent methylmercury;
3. Effluent inorganic mercury;
4. Influent inorganic mercury;
5. Ratio between effluent methylmercury and influent methylmercury;
6. Ratio between effluent methylmercury and effluent inorganic mercury;
7. Ratio between effluent methylmercury and influent inorganic mercury; and
8. Ratio between effluent inorganic mercury and influent inorganic mercury.

To begin the process of evaluating methylmercury discharges from municipal WWTPs, Board staff conducted a preliminary evaluation of municipal treatment process information available in NPDES permits and project files. Table 20 provides treatment process information with the WWTPs sorted by average effluent methylmercury concentration. Using this treatment process information, staff grouped the Central Valley WWTPs into mutually exclusive categories based on the maximum level of wastewater treatment that the facilities were using in 2005, including the secondary, tertiary and disinfection treatment types (Table 21). A description of the treatment categories is provided in Table 22 and descriptive statistics for these categories are provided in Table 23. For calculations involving inorganic mercury and methylmercury concentration results that were less than the method detection limit (MDL), one half of the MDL was used for those results.

Staff attempted to identify obvious differences and seasonal trends in influent and effluent data between facilities and evaluated those differences in terms of the treatment categories. Identifying the reasons why some WWTPs discharge effluent with higher methylmercury concentrations than others, and why some facilities have seasonal or other treatment-related variability in their methylmercury discharges, could be critical components to the development of methylmercury controls.

4.2.1 Effluent Methylmercury

Municipal WWTPs had the most variability in effluent methylmercury concentrations of any of the NPDES discharger categories evaluated. Individual effluent methylmercury concentrations ranged from nondetect (<0.02 ng/l at 31 WWTPs) to 4 ng/L at the Colusa WWTP, a 200-fold difference. As illustrated by Figure 5, 20 (33%) of the WWTPs had average effluent methylmercury concentrations less than 0.05 ng/l, and 13 (21%) plants had average concentrations less than 0.03 ng/l. In contrast, 18 (30%) WWTPs had average effluent methylmercury concentrations greater than 0.2 ng/l, and 7 of these averaged between 1 and 2.9 ng/l. The highest average effluent methylmercury concentration (2.86 ng/l) observed at a facility was nearly 150 times that of the lowest average concentrations (e.g., facilities with effluent concentrations approaching or less than the detection limit). As shown in Table 1, the variability in the methylmercury concentrations observed in effluent from different municipal WWTPs in the Central Valley is comparable to WWTP effluent concentrations observed elsewhere.

Municipal WWTPs with higher average effluent methylmercury concentrations generally had higher variability, as indicated by a positive relationship ($R^2 = 0.7167$, $p<0.0001$) between the WWTPs' average methylmercury concentrations and corresponding standard deviations (Figure 6).

Seasonal variability was observed in effluent methylmercury concentrations at several municipal WWTPs. Anderson, Cottonwood, Davis, Grass Valley, Lincoln, Oroville, Placer Co. SMD #1, Redding Clear Creek and SRCSD Sacramento River WWTPs had higher effluent methylmercury concentrations in the warm season (e.g., May through November) than the cool season (see Figures 7 and 8). The exception was the Stockton WWTP, which had higher concentrations in the cool season. No obvious relationship between seasonality and treatment processes exists.

The SRCSD Sacramento River WWTP has a six-year methylmercury monitoring record for both the influent and effluent. Monthly averages of all the effluent methylmercury concentrations collected during the six-year period were higher during the warm season than during cold weather (Figure 8). However, the most recent data collected during WY2005-2007 show much less seasonal variability and lower methylmercury concentrations during warm months (May – November) than in earlier years ($p<0.0001$ for both the non-parametric Mann-Whitney U test and the parametric two sample t-test). Overall, SRCSD effluent methylmercury concentrations showed a marked decrease from WY2001 to 2007 (Figure 9).

Staff used statistical tests to determine if significant differences in effluent methylmercury concentrations exist between the treatment categories. Descriptive statistics and normality tests indicate that the treatment categories do not meet the assumptions of parametric hypothesis tests, including homoscedasticity (constant

variance) among all groups and data normality (Table 23). Differences in effluent methylmercury concentrations between the treatment categories were analyzed with non-parametric statistics as transformations could not be found to produce homoscedasticity and data normality among the all of the categories. The "Statistica" software was employed for all the statistical analyses.[4]

Statistically significant differences in effluent methylmercury concentrations exist among the treatment categories ($p<0.0001$, Kruskal-Wallis test). A pair-wise multiple comparison test was conducted to determine which treatment categories had higher concentrations. The two-sided significance levels (p-values) for each treatment category are presented in Table 24.

Facilities that use treatment pond systems as part of their treatment process had the highest effluent methylmercury concentrations (Figures 10 and 11; Table 23). The "Pond + Chlorination/Dechlorination (C/D)" and "Pond + Filtration + C/D" treatment categories had median effluent methylmercury concentrations of 0.52 ng/l and 0.81 ng/l, respectively. Conversely, facilities that have some combination of nitrification/denitrification (N/D), filtration, and ultraviolet (UV) disinfection generally had lower effluent methylmercury concentrations. The "N/D + Filtration + C/D", "Secondary w/ N/D + UV", "N/D + Filtration + UV", "Filtration + UV", "Secondary w N/D + C/D" and "Filtration + C/D" categories had median effluent methylmercury concentrations of 0.06 ng/l or less (Table 23).

These observed trends are confirmed by the multiple comparison p-values for the treatment categories. The "Pond + C/D" and "Pond + Filtration + C/D" categories had significantly higher effluent methylmercury concentrations than the "N/D + Filtration + C/D", "Secondary w/ N/D + UV", "N/D + Filtration + UV", "Filtration + UV", "Secondary w/ N/D + C/D" and "Filtration + C/D" categories ($p<0.00001$; Table 24). In addition, the "Secondary + C/D" category had significantly higher concentrations than every other category ($p<0.01$), excluding the "Pond + C/D" and "Pond + Filtration + C/D" categories (Table 24). Other statistically significant differences in effluent methylmercury concentrations include: the "Pond + C/D" category had higher values than the "Secondary + C/D" category, and the "N/D + Filtration + C/D" category had lower values than the "Secondary w/ N/D + C/D" and "Filtration + C/D" categories.

As indicated by Figure 10, two WWTPs had different effluent methylmercury concentrations than other WWTPs in the same treatment category:

- The Modesto WWTP had lower effluent methylmercury concentrations than other WWTPs in the "Pond + C/D" category ($p<0.0001$ for both the Mann-Whitney U test and the two sample t-test);

[4] Statistica StatSoft, http:// www.statsoft.com

- The Rio Alto WWTP had higher effluent methylmercury concentrations than other WWTPs in the “Filtration + C/D” category. Since only two effluent samples were collected at this WWTP, more data is needed to determine if these concentrations are representative of this facility’s effluent.

These differences suggest that other unique processes are acting at these two facilities that significantly modify methylmercury production or degradation. Staff’s review of the other treatment processes and data for these facilities (e.g., Tables 20 and 21, Figure 7) gave no straightforward reasons for the differences. The Rio Alto WWTP had more variability (i.e., coefficient of variation) than all but one of the 17 WWTPs in the "Filtration +C/D" category. The Modesto WWTP had the lowest average effluent methylmercury concentration and coefficient of variation of all of the 11 WWTPs in the “Pond + C/D” category. It could be helpful to obtain more information about conditions during each of the sampling events for these WWTPs (e.g., variations in treatment methods and differences in nitrate concentrations and temperature) and, in the future, to sample both influent and effluent to assess whether the variability in effluent is due to influent variability or treatment variability.

Nitrification/denitrification, filtration, ultraviolet disinfection or a combination of these treatments may play a role in decreasing effluent methylmercury concentrations. The “N/D + Filtration + C/D” category had significantly lower effluent methylmercury concentrations than the “Secondary w/ N/D + C/D” and “Filtration + C/D” categories (Table 24). This suggests that both filtration and nitrification/denitrification treatment processes may have been responsible for the lower concentrations discharged by the facilities in the “N/D + Filtration + C/D” category.

During the nitrification process, aerobic bacteria convert ammonia to nitrate with the assistance of oxygen (Metcalf and Eddy, Inc., 1972). The denitrification process involves anoxic bacteria converting nitrate to nitrogen gas with the help of a carbon source such as methanol (Metcalf and Eddy, Inc., 1972). The denitrification bacteria potentially could assist in the demethylation of methylmercury to inorganic mercury, because the methyl group is the best carbon source for the conversion of nitrate to nitrogen gas (Pirondini, 2008a). This potential methylmercury demethylation could occur in a fully-nitrified wastewater (low ammonia), but likely not in a partially-nitrified or non-nitrified wastewater (high ammonia) (Pirondini, 2008a). Additional analysis that directly evaluates effluent ammonia/nitrate/nitrite levels and effluent methylmercury concentrations needs to take place.

The “Filtration + C/D” and “Secondary + C/D” treatment categories both contained numerous WWTPs with a variety of secondary treatment types. Staff assigned the WWTPs in each of these groups into three mutually exclusive subcategories based upon their secondary treatment (Table 25). The three subcategories were “Activated Sludge” (includes conventional, pure oxygen and extended aeration activated sludge,

oxidation ditch and sequencing batch reactor treatments), “Activated Sludge + Trickling Filter” and “Fixed Media” (includes trickling filter and rotating biological contactor treatments). Descriptive statistics and normality tests indicate that the subcategories within each treatment grouping do not meet the assumptions of parametric hypothesis tests (Table 26). Differences in effluent methylmercury concentrations between the treatment subcategories were analyzed with non-parametric statistics as transformations could not be found to produce homoscedasticity and data normality among the all of the categories.

Within the “Secondary + C/D” category, no significant differences in effluent methylmercury concentrations exist between the three subcategories ($p=0.07$, Kruskal-Wallis test). However, within the “Filtration + C/D” category, significant differences exist between the subcategories ($p<0.01$, Kruskal-Wallis test). A pair-wise multiple comparison test indicated that the “Activated Sludge” subcategory had lower effluent methylmercury concentrations than the “Fixed Media” subcategory ($p<0.01$; Table 27). Descriptive statistics for the subcategories within each treatment category are presented in Table 26.

Each subcategory within the “Filtration + C/D” category had lower average and median effluent methylmercury concentrations than the same subcategory within the “Secondary + C/D” category (Table 25). These differences are statistically significant as shown by the two-sided significance levels (p-values) in Table 28. This indicates that the filtration treatment process may have assisted in the reduction of methylmercury in the effluent of these facilities.

4.2.2 Influent Methylmercury

A seasonal pattern was observed in influent methylmercury concentrations at a few municipal WWTPs. Several plants appeared to experience a decrease in influent methylmercury concentrations during cool weather months (Chico, Deer Creek and El Dorado Hills WWTPs); while some showed a sharp increase in the spring (Williams and Woodland WWTPs) or the summer (Rio Vista and UC Davis WWTPs) (see Figure 13). The approximately six-year influent methylmercury monitoring record for the SRCSD Sacramento River facility also showed an increase in average influent concentrations during the summer months (Figure 14). As for effluent methylmercury, there appeared to be a decreasing trend in influent methylmercury concentrations at the SRCSD Sacramento River facility between WY2001 to WY2007 (Figure 9).

Average influent methylmercury concentrations ranged from 0.068 at Mariposa WWTP to 14.6 ng/l at Maxwell WWTP, a 215-fold difference (Figure 12). Of the 23 municipal WWTPs that collected influent methylmercury data, three had average influent methylmercury concentrations less than 1 ng/l, ten had average concentrations between 1 ng/l and 2 ng/l, and two had average concentrations greater than 7 ng/l.

4.2.3 Effluent Inorganic Mercury

Effluent inorganic mercury concentrations ranged from non-detect (less than 0.2 ng/l) at the Modesto WWTP to 53.1 ng/l at the Woodland WWTP, which is about a 260-fold difference (Figure 15). The high value observed at the Woodland WWTP was an anomaly when compared to the remainder of the Woodland WWTP data. Of the 28 WWTPs where effluent inorganic mercury data were collected, 10 had average effluent inorganic mercury concentrations less than 3 ng/l, 11 had average concentrations between 3 ng/l and 7 ng/l, and two had average concentrations greater than 10 ng/l. The highest average effluent inorganic mercury concentration (22 ng/l) observed at a WWTP was about 44 times that of the lowest average concentration (0.5 ng/l; Figure 15).

Several WWTPs had higher effluent inorganic mercury concentrations during the winter (Davis [Discharge 1], Manteca, Placer County SMD #1 and Stockton WWTPs) or spring (Redding Stillwater WWTP) (see Figure 16). No obvious relationship between seasonality and treatment processes seemed to exist. The effluent inorganic mercury monitoring record for the SRCSD Sacramento River facility showed relatively constant monthly averages (between 5 ng/l and 7 ng/l) with no apparent seasonal trend (Figure 17). However, effluent inorganic mercury data collected from December 2000 to March 2007 showed an obvious decreasing trend, particularly after 2004 (Figure 18). Furthermore, the effluent inorganic mercury concentrations from 2005 to 2007 had much less variability than the prior years.

4.2.4 Influent Inorganic Mercury

Of the 61 municipal WWTPs that monitored effluent methylmercury, nine WWTPs monitored influent inorganic mercury. Influent inorganic mercury concentrations ranged from 29.0 ng/l at Roseville Pleasant Grove WWTP to 6,100 ng/l at SRCSD Sacramento River WWTP, which is about a 210-fold difference (Figure 19). Two of the nine facilities that collected data had average influent inorganic mercury concentrations less than 100 ng/l, four facilities were between 100 ng/l and 300 ng/l, and 3 facilities had average influent concentrations greater than 300 ng/l. The highest average influent inorganic mercury (2,100 ng/l) observed at a municipal WWTP was about 60 times that of the lowest average concentration (35.5 ng/l).

Because of the limited data set, there was not enough information to discern any seasonal patterns. The Lodi White Slough WWTP had higher influent inorganic mercury concentrations in the fall and winter, the Roseville Pleasant Grove WWTP had higher concentrations in the summer, and two WWTPs (Roseville Dry Creek and Woodland WWTPs) had no discernable pattern (Figure 20).

Board staff compiled influent inorganic mercury data for the SRCSD Sacramento River WWTP collected from December 2000 – December 2004 that were available in a variety of monitoring reports and special study documents in the permit files (SRCSD, 2004; SRCSD, 2005). The influent inorganic mercury data for this four-year period had no interannual (Figure 21) or seasonal trends (Figure 22). The monthly averages for the SRCSD Sacramento River WWTP varied between 120 ng/l and 300 ng/l, with the exception for two months, January and March (Figure 22). These were observably higher than other months as a result of two anomalously high values. One of these two values was collected on 6 January 2004 (6,100 ng/l) and the other on 11 March 2004 (3,400 ng/l). Three other influent samples collected during the four-year period had inorganic mercury concentrations greater than 1,000 ng/l, one each in 2001, 2002 and 2004.

4.2.5 Ratio between Effluent Methylmercury and Influent Methylmercury

The ratios between paired effluent and influent methylmercury concentrations were calculated to determine the methylmercury removal efficiencies of the municipal WWTPs. A percent value less than 100% for a given municipal WWTP indicates that its treatment processes caused a net reduction in methylmercury; a percent value greater than 100% indicates that the plant was a net methylmercury source. Average ratios ranged from 1.1% at El Dorado Hills WWTP (Discharge 2) to 803% at Mariposa WWTP. Of the 23 WWTPs where both effluent and influent methylmercury data were collected, 14 had average effluent:influent methylmercury ratios less than or equal to 10%, and 11 of those had average ratios less than or equal to 5% (Figure 23). In contrast, five WWTPs had average ratios greater than 30%. Municipal WWTPs in the "Secondary + C/D" and "Pond + C/D" treatment categories had lower methylmercury removal efficiencies indicated by higher effluent:influent ratios than WWTPs in all other treatment categories (Figure 24; Table 29; $p<0.04$, Kruskal-Wallis test).

Three facilities (Colusa, Mariposa and SRCSD Walnut Grove WWTPs) had average ratios greater than 100%, indicating that these facilities were net producers of methylmercury. As seen in Figure 23, two of these average effluent:influent methylmercury ratios (254% for Colusa and 803% for Mariposa) were much higher than the average ratios of the remainder of the facilities. The closest value to these is from the SRCSD Walnut Grove WWTP, which had an average ratio of 101%. The Colusa and SRCSD Walnut Grove WWTPs are both in the "Pond + C/D" treatment category, while the Mariposa WWTP is in the "Secondary + C/D" category. These average ratios are based upon one or two paired influent and effluent samples collected at the WWTP. More data is needed to determine if these removal efficiencies are representative of these facilities.

Several facilities exhibited seasonal variability in methylmercury removal (Figures 25 and 26). Lower removal efficiencies indicated by higher ratios occurred during the

summer or fall for some facilities (Grass Valley, Rio Vista, Roseville Dry Creek, Roseville Pleasant Grove and SRCSD Sacramento River WWTPs), and during winter for others (Chico, Deer Creek and El Dorado Hills [Discharge 1] WWTPs). No relationship was apparent between seasonal variability and the type of treatment process.

The methylmercury removal efficiency for SRCSD Sacramento River WWTP's six-year record showed an increasing trend indicated by a decrease in its ratios (Figure 27). These ratios differed temporally, in that the WY2001-2004 period showed much more seasonal variability with higher ratios in the warm season (May – November) than did the ratios for the WY2005-2007 period (Figure 26; $p<0.001$ for both the Mann-Whitney U test and the two sample t-test). This trend between earlier and later time periods was similarly seen in the effluent methylmercury concentrations for SRCSD Sacramento River WWTP and may be the reason for the observed trend in the ratios (Figure 8).

As mentioned in sections 4.2.1 and 4.2.2, decreasing trends were observed both in influent and effluent methylmercury concentrations for the SRCSD Sacramento River WWTP between WY2001 and WY2007 (Figure 9). The decrease in effluent methylmercury concentrations could be partially due to the concurrent decrease in influent concentrations; however, the regression for effluent methylmercury has a steeper decreasing slope (-0.0001) than does the influent line (-0.00008) indicating an improved methylmercury removal efficiency since WY2001 (Figure 9). Furthermore, Figure 27 shows an increasing trend in methylmercury removal efficiency between WY2001 and WY2007.

Staff reviewed scatter plots of paired influent and effluent methylmercury concentrations to determine whether there was a relationship between the two. The paired samples may not represent the same parcels of water due to in-plant residence time. The scatter plot of all paired data from all WWTPs excluding SRCSD Sacramento River WWTP showed a significant positive relationship ($R^2 = 0.1347$, $p<0.0001$; Figure 28a). The scatter plot including data from SRCSD Sacramento River WWTP also showed a statistically significant positive relationship ($R^2 = 0.0715$, $p<0.0001$; Figure 28b). Staff analyzed scatter plots with and without data from SRCSD Sacramento River WWTP because the number of paired data points from the SRCSD Sacramento River WWTP (n=107) was relatively high compared to other WWTPs (n=1 to 16). These significant relationships indicate that reductions in methylmercury in the effluent were in part due to lower influent concentrations. However, only 7-13% of the variability in effluent methylmercury concentrations was explained by influent concentrations, indicating that effluent concentrations were substantially affected by other factors. Influent methylmercury concentrations alone were not a good predictor of effluent concentrations.

Of the 23 WWTPs that submitted both influent and effluent methylmercury concentration data, 10 WWTPs submitted paired data for five or more sampling events (Figures 29 and 30). When analyzed individually, none of these facilities had significant relationships between influent and effluent methylmercury concentrations except Lodi WWTP ($R^2 = 0.404$, $p<0.03$), UC Davis WWTP ($R^2 = 0.388$, $p<0.04$) and SRCSD Sacramento River WWTP ($R^2 = 0.174$, $p<0.0001$; see Table 30 for R^2 and p-values for each WWTP). All three facilities exhibited positive relationships; however, the significant positive relationship for Lodi WWTP appeared to be driven by one paired data point collected on 13 April 2005 (influent 2.74 ng/l, effluent 1.24 ng/l). When this point was removed, no significant relationship exists ($R^2 = 0.090$, $p>0.05$). Influent versus effluent methylmercury scatter plots for SRCSD Sacramento River WWTP indicated a significant positive relationship for the paired data collected during the cool season (December through April; $R^2 = 0.262$, $p<0.001$), but not during the warm season (May through November; $R^2 = 0.015$, $p>0.05$; Figure 30). Again, only about 26% of the variability in cool season effluent methylmercury concentrations was explained by influent concentrations, which indicates that effluent methylmercury concentrations were affected by other factors as well.

4.2.6 Ratio between Effluent Methylmercury and Effluent Inorganic Mercury

The ratios between paired effluent methylmercury and effluent inorganic mercury concentrations were calculated to estimate the percentage of inorganic mercury as methylmercury in the effluent and to see if differences exist between treatment types. Average ratios ranged from 0.60% at Discovery Bay WWTP to 28% at Nevada County Sanitation District #2 Lake of the Pines WWTP. Of the 28 WWTPs where both methylmercury and inorganic mercury were analyzed in the effluent, 24 had average effluent methylmercury:inorganic mercury ratios less than or equal to 10%, and 19 of those had average ratios less than or equal to 5% (Figure 31). Only four discharges had average ratios greater than 10%. The average effluent methylmercury:inorganic mercury ratio for SRCSD Sacramento River WWTP was 10%; the ratio appeared to increase slightly from WY2001 to WY2007 (Figure 32).

Municipal WWTPs in the "Pond + Filtration + C/D" maximum treatment category had higher effluent methylmercury:inorganic mercury ratios than WWTPs in all other treatment categories except for the "Pond + C/D" category (Figure 33; Table 31; $p<0.03$, Kruskal-Wallis test). In addition, the "Pond + C/D" and "Secondary + C/D" categories had higher ratios than the "Secondary w/ N/D + UV", "N/D + Filtration + C/D" and "Filtration + UV" categories ($p<0.01$, Kruskal-Wallis test).

Five municipal WWTPs appeared to have well-defined seasonal variability in their effluent methylmercury:inorganic mercury ratios (Figures 34 and 35). The following WWTPs appeared to experience an increase in their ratio in the spring and/or summer: Davis (Discharges 1 and 2), Manteca, Placer County SMD #1, SRCSD Sacramento

River, and Stockton. No discernable relationship between the seasonal variability of the ratios and the types of treatment processes were apparent.

Staff reviewed scatter plots to determine whether there was a relationship between effluent methylmercury and inorganic mercury concentrations. The scatter plot of all paired data from all WWTPs excluding SRCSD Sacramento River WWTP showed a significant positive relationship ($R^2 = 0.0431$, $p<0.01$; Figure 36a). The anomalous value collected at Woodland WWTP on 9 December 2004 (THg: 53.1 ng/l, MeHg: below detection limit of 0.025 ng/l) appeared to strongly influence the trend-line. The scatter plot after removing the anomalous paired data-point continued to indicate a statistically significant positive relationship ($R^2 = 0.0779$, $p<0.0001$). The scatter plots including data from SRCSD Sacramento River WWTP also showed significant positive relationships with ($R^2 = 0.0704$, $p<0.0001$) and without the Woodland WWTP outlier ($R^2 = 0.1155$, $p<0.0001$; Figure 36b). Only 4-12% of the variability in effluent methylmercury concentrations was explained by effluent total mercury concentrations for the different WWTPs, indicating that effluent concentrations were substantially affected by other factors.

Of the 28 WWTPs that submitted effluent methylmercury and inorganic mercury concentration data for a total of 29 discharges, 20 WWTPs submitted paired data for five or more sampling events (Figures 37 and 38). Some WWTPs appeared to have positive relationships between effluent methylmercury and inorganic mercury, however only four facilities (Discovery Bay, Stockton, SRCSD Sacramento River and Davis WWTPs) had a statistically significant relationship (Discovery Bay : $R^2 = 0.551$, $p<0.03$; Stockton: $R^2 = 0.67$, $p<0.01$; SRCSD: $R^2 = 0.0775$, $p<0.01$; Davis: $R^2 = 0.4445$, $p<0.02$; Table 32). Seasonal scatter plots for SRCSD Sacramento River WWTP did not indicate significant positive relationships for all of the paired data collected from WY2001 to WY2007 for both the warm (May through November; $R^2 = 0.061$, $p>0.05$) and cool (December through April; $R^2 = 0.071$, $p>0.05$) seasons (Figure 38).

4.2.7 Ratio between Effluent Methylmercury and Influent Inorganic Mercury

The ratios between paired effluent methylmercury and influent inorganic mercury concentrations were calculated to determine if a relationship existed between influent inorganic mercury and effluent methylmercury, and to explore how the ratios may relate to treatment processes. Ultimately, it would be very useful to know whether reducing influent inorganic mercury concentrations (e.g., by implementing mercury source minimization measures[5]) would result in reductions in effluent methylmercury, and if so, by how much.

[5] For example, residential drop-off programs for mercury-containing products and best management practices for hospitals, dentists, other medical facilities, laboratories, and pottery studios.

Average ratios ranged from 0.0005% at the Lincoln WWTP to 1.85% at the Davis WWTP (Discharge 1) (Figure 39). The average effluent methylmercury:influent inorganic mercury ratio for SRCSD Sacramento River WWTP was 0.45%; the ratio did not appear to change from December 2000 to December 2004 (Figure 40). Two of the five facilities with more than six paired samples (Lodi White Slough and SRCSD Sacramento River WWTPs) had an apparent seasonal pattern, with an increase in effluent methylmercury:influent inorganic mercury ratio in the summer (see Figures 41 and 42).

Staff reviewed scatter plots to determine whether there was any relationship between effluent methylmercury and influent inorganic mercury concentrations. The scatter plots of all paired data for all WWTPs with and without the SRCSD Sacramento River WWTP data showed no relationship (with SRCSD: $R^2 = 0.0026$, $p>0.05$, Figure 43a; without SRCSD: $R^2 = 0.0206$, $p>0.05$, Figure 43b). The relationship between effluent methylmercury and influent inorganic mercury loads may present a different conclusion, but was not assessed in this report.

Of the nine municipal WWTPs that submitted effluent methylmercury and influent inorganic mercury concentration data, five facilities submitted paired data for five or more sampling events. No relationships between effluent methylmercury and influent inorganic mercury were observed for any of these five facilities individually (Figures 44 and 45a; Table 33). Scatter plots for SRCSD Sacramento River WWTP showed no relationship for data collected from December 2000 to December 2004 (all data: $R^2 = 0.0017$, $p>0.05$; warm season: $R^2 = 0.0311$, $p>0.05$; cool season: $R^2 = 0.0182$, $p>0.05$; Figure 45a). After removing the paired data that included the anomalously high value collected on 6 January 2004 (6,100 ng/l) at the SRCSD Sacramento River WWTP, the scatter plots still indicated no significant relationships (all data: $R^2 = 0.0045$, $p>0.05$; warm season: $R^2 = 0.0311$, $p>0.05$; cool season: $R^2 = 0.0044$, $p>0.05$; Figure 45b).

The SRCSD District Engineer presented a chart of annual influent inorganic mercury and effluent methylmercury loads for 2001 through 2007 during testimony for the April 2008 hearing for the Delta mercury control program (see Figure 46). The SRCSD District Engineer indicated that the WWTP's effluent inorganic mercury and methylmercury decreased as a result of influent inorganic mercury decreases associated with the initiation of their "Be Mercury Free" source control program. This additional influent inorganic mercury data from 2005 to 2007 was not available at the time this report was written.

4.2.8 Ratio between Effluent Inorganic Mercury and Influent Inorganic Mercury

The ratios between paired effluent and influent inorganic mercury concentrations were calculated to determine by how much the municipal WWTPs reduced inorganic mercury- the lower the ratio, the higher the removal efficiency. Average ratios ranged

from 0.6% at the Woodland WWTP to 27% at the Merced WWTP (Figure 47). Of the eight WWTPs that submitted paired influent and effluent inorganic mercury data, five of the facilities had average effluent:influent inorganic mercury ratios less than or equal to 5%, and two had average ratios greater than 15%. No discernable relationship between removal efficiency and the types of treatment processes were observed.

Two of the five facilities with six or more paired samples had an apparent seasonal pattern (Figures 48 and 49). The Lodi White Slough WWTP appeared to have a lower inorganic mercury removal efficiency during the summer, while the Roseville Dry Creek appeared to have a lower removal efficiency during the winter-spring. The ratios for the SRCSD Sacramento River WWTP showed no seasonal patterns (Figure 49).

Scatter plots of all paired data for all WWTPs with and without the SRCSD Sacramento River WWTP data showed no relationships between effluent and influent inorganic mercury concentrations (with SRCSD: $R^2 = 0.0004$, $p>0.05$; without SRCSD: $R^2 = 0.0029$, $p>0.05$; Figure 50). No relationships were indicated by individual WWTP scatter plots as well, though some facilities were more effective at removing inorganic mercury (Figure 51 and Table 34). Scatter plots for SRCSD Sacramento River WWTP showed no significant relationships for the paired data collected from December 2000 to December 2004 (all data: $R^2 = 0.0004$, $p>0.05$; warm season: $R^2 = 0.0038$, $p>0.05$; cool season: $R^2 = 0.0045$, $p>0.05$; Figure 52); however, the scatter plots indicate that as influent concentrations increased, effluent concentrations did not increase.

The average effluent:influent inorganic mercury ratio for SRCSD Sacramento River WWTP was 5.1%; the ratio did not appear to change from December 2000 to December 2004 (Figure 53). The inorganic mercury removal efficiency during this period was consistently high with an average of about 95%, indicating that the SRCSD Sacramento River WWTP was effective in removing most of the inorganic mercury from the waste stream. As mentioned in Section 4.2.3, there was an observed decreasing trend in effluent inorganic mercury from WY2001-2007, particularly from 2005 to 2007. However, as indicated earlier, Board staff does not have influent inorganic mercury data after 2004 and was unable to compare effluent and influent concentrations during this later period.

Page intentionally left blank.

5 ESTIMATION OF METHYLMERCURY LOADS FROM CENTRAL VALLEY DISCHARGERS

In response to comments from the Sacramento Regional County Sanitation District on the May 2009 draft report, an additional chapter was added to this report to assess the relative contribution of methylmercury loading to the Delta from NPDES facilities in and upstream of the Delta. This chapter describes the methods used to calculate methylmercury and total mercury loads discharged by the different types of NPDES facilities and provides a brief review of loads by facility type and watershed.

All of the mass load calculations are based on the following equation:

$M_x = C_x * V$

Where: M_x = Mass of constituent, X

C_x = Concentration of constituent, X, in mass per volume

V = Volume of effluent

For example, the annual methylmercury load discharged for the Stockton WWTP was calculated as follows:

$M_x = (0.935 \text{ ng/l} \div 10^9) * (28 \text{ mgd} * 365 * 10^6 * 3.7854118) =$ **36 g/year**

Where: M_x = Mass of methylmercury (grams per year)

C_x = Concentration of methylmercury (ng/l) converted to grams per liter

V = Volume of effluent (million gallons per day) converted to liters per year

Not all facilities in the Central Valley were required to collect methylmercury and/or total mercury by the 2004 13267 Order or by their existing permit requirements. In addition, some facilities only recently began to discharge to surface water; some of these have collected effluent methylmercury and total mercury data and others have not. Table B.5 in Appendix B includes the effluent concentration and volume values used to estimate the loads discharged by each facility. For facilities that have not yet collected effluent total mercury or methylmercury concentration data, staff used the average of concentration data available for similar facilities to calculate the loads and noted where this was done in Table B.5.

Some facilities have ceased to discharge to surface water since effluent methylmercury and total mercury concentration data were collected. Data for such facilities, as well as data for facilities upstream of major dams, were included in the calculation of average methylmercury and total mercury concentrations by facility type used to estimate effluent loads for facilities with no effluent concentration data. Table B.5 does not

include all facilities located upstream of major dams because few of these were required to collect methylmercury data by the 2004 13267 Order. Also, Table B.5 includes several facilities for which total mercury data were available but methylmercury data were not, especially in the tributary watersheds upstream of major dams.

Tables 35 and 36 provide the sums of the annual total mercury loads and methylmercury loads, respectively, discharged by NPDES facilities within each discharger category in the Delta/Yolo Bypass and its tributary watersheds downstream of major dams. Table 37 compares the sum of annual methylmercury loads discharged by NPDES facilities to the sum of all point and nonpoint source methylmercury loading to each Delta subarea identified in the February 2010 Delta TMDL Staff Report (Wood *et al.*, 2010b, Table 8.4). As noted earlier, power, heating/cooling, and aquaculture facilities that use ambient water for cooling water do not appear to act as a net source of methylmercury to receiving waters and therefore are not included. GWF Power Systems is included because it acquires its intake water from sources other than ambient surface water. Only facilities that were discharging during the TMDL methylmercury load evaluation period (WY2000-2003) and/or the total mercury load evaluation period (WY1984-2003) were included in Tables 35, 36 and 37.

Effluent total mercury concentration data were not available for any of the facilities within the food, laboratories, and port terminal categories, and consequently these categories are not included in the load summaries described in Table 35. Because these facilities account for only about a quarter of a percent of the discharge volume from NPDES facilities in the Delta source region, they likely do not affect our understanding of relative contributions from different point and nonpoint sources.

As shown in Tables 35 and 36, about 96% (3,435 g/yr) of the total mercury loading from all NPDES facilities (3,586 g/yr) and more than 99% (228 g/yr) of the methylmercury loading from all NPDES facilities (229 g/yr) comes from municipal WWTPs. About 67% of the total mercury loading from all NPDES facilities and about 89% of the methylmercury loading from all NPDES facilities comes from facilities within the Delta/Yolo Bypass. A comparison of Table 36 to Table B.5 in Appendix B indicates that nearly 90% of the methylmercury loading from the 61 municipal WWTPs that discharge to the Delta and its tributary watersheds downstream of major dams comes from two WWTPs, the SRCSD Sacramento River WWTP (161 g/yr, 71%) and Stockton WWTP (36 g/yr, 16%). This is not surprising given the most populous urban areas in the Sacramento and San Joaquin Basins (the Delta's primary source region) – Sacramento in Sacramento County and Stockton in San Joaquin County – are adjacent to and within the Delta (CDOF, 2007; Wood *et al*., 2010b, Figure 6.9).

The Delta methylmercury TMDL divides the Delta into eight subareas based on the hydrologic characteristics and mixing of the source waters (Wood *et al.*, 2010b). A separate methylmercury reduction strategy was developed for each subarea because

the levels of impairment and the methylmercury sources in the subareas are substantially different (Wood *et al.*, 2010a and 2010b). Table 37 compares the methylmercury loads discharged by NPDES facilities within the Delta and its tributary watersheds downstream of major dams to the total methylmercury loading to each subarea from point and nonpoint sources within the Delta and its tributary inputs.

Overall, NPDES facilities account for about 4% of the methylmercury load to the Delta; NPDES facilities within the Delta contribute about 205 grams per year (g/year) while facilities in upstream watersheds that are downstream of major dams contribute about 24 g/year. The Delta TMDL divides the Delta into hydrologically-defined subwatershed areas; different sources supply the different areas. For example, NPDES facilities within the San Joaquin River and Sacramento River subareas contribute about 7-9% of all methylmercury loading to those subareas, while NPDES facilities within the Central Delta, West Delta, and Yolo Bypass subareas contribute less than 0.2% of all methylmercury loading to these subareas. For some receiving waters (e.g., in the Sacramento and San Joaquin subareas), reducing municipal WWTP methylmercury discharges, along with reductions from other point and nonpoint sources, may be an important component in reducing methylmercury levels in ambient water. For example, the Sacramento River is the largest river in California and drains a 27,000 square-mile area – almost one fifth of the State of California and about one half of the Central Valley – that contains numerous reservoirs and a myriad of point and nonpoint sources downstream of the reservoirs. As noted as early as 1997 in the Sacramento River Mercury Control Planning Project report prepared for SRCSD by Larry Walker Associates, "… mercury sources in the study area appear to be diffusely distributed without any significant "hotspots" …" (LWA, 1997, page 31). As a result, any individual discharge from a point or nonpoint source that provides a notable percentage (e.g., more than 1%) of methylmercury loading to the Sacramento River warrants evaluation.

Page intentionally left blank.

6 DISCUSSION & NEXT STEPS

The non-municipal NPDES facilities in the Delta source region typically had low effluent methylmercury concentrations (Table 17). Aquaculture and power generation facilities appeared to be neither significant sources nor sinks of methylmercury. More data is necessary to determine if the other facilities in these two categories and heating/cooling facilities are net methylmercury sources or sinks. The aggregate, paper/saw mills, groundwater remediation, drinking water treatment, and other non-municipal facilities were sources of methylmercury but typically had very low effluent methylmercury concentrations (average of 0.05 ng/L; see Table 17). Of the 198 effluent methylmercury samples submitted by non-municipal facilities, 134 were less than or equal to 0.05 ng/l, and 80 of those were below the method detection limit (typically less than 0.025 ng/l). The highest effluent methylmercury concentration observed in the non-municipal facilities was 1.91 ng/l from a stormwater detention pond at the SPI Shasta Lake Mill; all other sample results from the mill and other non-municipal facilities were less than 0.2 ng/l.

Municipal WWTPs contribute the most discharge (by volume and methylmercury load) to the Delta source region of any one facility category and had average effluent methylmercury concentrations that ranged from non-detect (<0.02 ng/l) to 2.9 ng/l, about a 150-fold difference. Twenty of the 61 Central Valley municipal WWTPs that submitted effluent data had average effluent concentrations less than 0.05 ng/l, and 13 WWTPs had averages less than 0.03 ng/l. In contrast, 18 WWTPs had average effluent methylmercury concentrations greater than 0.2 ng/l, and seven had averages greater than 1 ng/l.

To begin the process of evaluating whether and how methylmercury discharges from municipal WWTPs may be reduced, Board staff conducted a literature review. In addition, staff evaluated treatment process information for Central Valley municipal WWTPs and available methylmercury and inorganic mercury concentration data for influent and effluent. The reviews indicate several trends that merit additional investigation:

- Central Valley WWTPs that use treatment pond systems (oxidation, facilitative, settling or stabilization ponds) as a significant part of their treatment process had the highest effluent methylmercury concentrations. The “Pond + C/D” and “Pond + Filtration + C/D” treatment categories had significantly higher effluent methylmercury values than all other treatment categories, with one exception. The “Pond + Filtration + C/D” category did not have significantly higher effluent methylmercury concentrations than the “Secondary + C/D” category. Similarly in Canada, the West End WWTP, which was the only facility of the three City of Winnipeg treatment plants that has treatment ponds in its treatment process, also had higher effluent methylmercury concentrations than the other two City of Winnipeg treatment plants.

- Municipal WWTPs in the “Secondary + C/D” and “Pond + C/D” treatment categories had lower methylmercury removal efficiencies indicated by significantly higher effluent:influent ratios than WWTPs in all other treatment categories.
- Mercury-contaminated trickling filters at the Fritz Island WWTP in Pennsylvania acted as a substantial source of both inorganic mercury and methylmercury to the plant’s effluent. The average effluent methylmercury concentration at the Fritz Island WWTP was approximately 4 ng/l. Likewise in Central Valley WWTPs, within the “Secondary + C/D” and “Tertiary + C/D” treatment categories, the “Fixed Media” subcategory, which includes trickling filters, had average effluent methylmercury concentrations of 0.22 ng/l and 0.12 ng/l, respectively. Within the “Filtration + C/D” category, the “Fixed Media” subcategory had significantly higher effluent methylmercury concentrations than the “Activated Sludge” subcategory.
- Central Valley WWTPs that have some combination of nitrification/denitrification (N/D), filtration, and ultraviolet (UV) disinfection generally had lower effluent methylmercury concentrations. The “N/D + Filtration + C/D”, “Secondary w/ N/D + UV”, “N/D + Filtration + UV”, “Filtration + UV”, “Secondary w N/D + C/D” and “Filtration + C/D” treatment categories all had significantly lower effluent methylmercury concentrations than the “Secondary + C/D”, “Pond + C/D” and “Pond + Filtration +C/D” categories. In addition, the “N/D + Filtration + C/D” category had significantly lower effluent methylmercury concentrations than the “Secondary w/ N/D + C/D” and “Filtration + C/D” categories, suggesting that both the filtration and nitrification/denitrification treatment processes may have played a role in the decrease in the methylmercury concentrations of these facilities.
- Each secondary treatment subcategory within the “Filtration + C/D” category had significantly lower average and median effluent methylmercury concentrations than the same subcategory within the “Secondary + C/D” category, which suggests that the filtration treatment process may have assisted in the reduction of methylmercury in the effluent of these facilities.
- Several published studies investigated methylmercury at WWTPs that use conventional activated sludge treatment. The effluent methylmercury concentrations were variable with averages of 0.04 ng/l at the San Jose/Santa Clara WWTP, 0.2 ng/l to greater than 2 ng/l at the West End WWTP in Canada, and 1.53 ng/l at the Onondaga County Metropolitan WWTP in New York. Treatment ponds are used at the West End WWTP in Winnipeg, which could explain the elevated effluent methylmercury. The Onondaga County WWTP had an average influent methylmercury concentration of 5.05 ng/l and a removal efficiency of 70%. The methylmercury removal efficiency of the SJ/SC WWTP was 97%. The higher methylmercury removal efficiency of the SJ/SC WWTP could have been due to differences in other treatment processes. Nitrification and denitrification are incorporated in the activated sludge process of the SJ/SC WWTP and tertiary filtration is used as well, while neither is used in the Onondaga County WWTP.
- The SRCSD Sacramento River WWTP and SJ/SC WWTP had similar average influent methylmercury concentrations (1.55 ng/l and 1.6 ng/l, respectively).

However, the SJ/SC WWTP secondary treatment resulted in a much lower average secondary effluent methylmercury concentration (0.05 ng/l) than the SRCSD WWTP (0.38 ng/l). The secondary treatment process of the SRCSD Sacramento River facility is pure oxygen activated sludge without nitrification and denitrification. The differences in methylmercury removal efficiency between the two WWTPs may be either due to the pure oxygen activated sludge, nitrification/denitrification or both.

- The San Jose/Santa Clara WWTP study observed a methylmercury removal efficiency of 40% between the tertiary filter influent (0.05 ng/l) and final effluent (0.03 ng/l). Given the low concentrations, this is a small reduction when compared to the methylmercury removal efficiency of 96% between the secondary influent (1.3 ng/l) and secondary effluent (0.05 ng/l) (see Table 2). This suggests that most of the methylmercury removal occurred during the secondary treatment process.
- Significant relationships between influent and effluent methylmercury concentrations existed for all the paired data from the Central Valley WWTPs. This indicates that reductions in methylmercury in the effluent were in part due to lower influent concentrations. However, 7-13% of the variability in effluent methylmercury concentrations was explained by influent concentrations, indicating that effluent concentrations were affected by other factors as well.
- Seasonal variability was observed in effluent methylmercury concentrations at several Central Valley WWTPs, as well as WWTPs evaluated elsewhere. The City of Winnipeg's West End Plant, which utilizes conventional activated sludge and treatment ponds, had a seasonal trend in its effluent methylmercury concentrations, while its two other plants, which use pure oxygen activated sludge and no treatment ponds, did not have a seasonal trend. At the West End Plant, methylmercury concentrations increased as ambient temperatures increased, with the highest concentration occurring in August. The Onondaga County Metropolitan WWTP, which uses conventional activated sludge, demonstrated that warm temperatures were a catalyst for the methylation process to occur, apparently in both the environment as well as through the treatment process. For the several Central Valley WWTPs where seasonal variability was observed, the effluent methylmercury concentrations were higher in the warm season (e.g., May through November), and lower in the cool season. No obvious relationship between seasonality and the treatment processes of the Central Valley WWTPs seemed to exist.
- Methylmercury production occurred during the secondary activated sludge treatment process at the Onondaga County WWTP. McAlear (1996) hypothesized that mercury methylation occurred in anoxic micro-zones within the activated sludge flocs. A correlation between high concentrations of biological solids and mercury methylation during the activated sludge process was discovered at the Whitlingham Sewage Treatment Works (Goldstone *et al.*, 1990).
- The SRCSD study demonstrated that the removal of solids may have been a removal mechanism for methylmercury; however, inorganic mercury had a greater particle affinity than methylmercury and was removed more efficiently by solids

removal (Parmer *et al.*, 2005). In the Whitlingham Sewage Treatment Works study, the centrifugation and filtration of return activated sludge samples indicated that methylmercury had a greater affinity for the particulate phase of the return activated sludge than for the soluble phase. From the literature reviewed, it appears that the inorganic mercury and methylmercury removed from wastewater is partially due to the removal of solids, with the mechanism being more efficient for inorganic mercury. Board staff did not evaluate this relationship further for the Central Valley WWTPs because of their limited data set; however, this merits additional investigation.

- SRCSD WWTP's influent methylmercury concentrations and effluent inorganic mercury and methylmercury concentrations and loads decreased between 2001 and 2007. This decrease was attributed to a decrease in influent inorganic mercury associated with the initiation of SRCSD's "Be Mercury Free" source control program. No similar pattern was noted between influent inorganic mercury and effluent methylmercury at any other WWTP in the Central Valley.

Municipal WWTPs have multiple treatment processes and the factors affecting methylmercury production and degradation are complex. As a result, the differences in effluent methylmercury concentrations among the Central Valley WWTPs are most likely due to multiple factors and different combinations of treatment processes. Furthermore, a few of the treatment categories evaluated contained only one or two WWTPs, resulting in a limited data set for those categories. Therefore, the data of some of the treatment categories may not be representative of other WWTPs that utilize the same treatment processes. Also, of the 61 WWTPs that submitted effluent methylmercury data, only 23 submitted influent methylmercury data, and only nine submitted influent inorganic mercury data. Therefore, comparisons among WWTPs and treatment categories were done without correcting for influent inorganic mercury and methylmercury concentrations. In addition, influent inorganic mercury and methylmercury concentrations often had substantial day-to-day variability. As a result, comparisons between influent and effluent samples collected on the same day may not be appropriate, depending on the residence time of the wastewater in a particular plant.

The Central Valley Clean Water Association (CVCWA) has conducted a preliminary evaluation of effluent methylmercury data for a subset of WWTPs evaluated in this report. CVCWA's preliminary evaluation similarly found that WWTPs that incorporate any significant effluent storage (e.g., ponds) have higher methylmercury concentrations, and WWTPs with activated sludge treatment processes that result in a fully-denitrified, low ammonia effluent also have lower effluent methylmercury concentrations (Pirondini, 2008b). After completing the QA/QC review of the available effluent and influent methylmercury concentration data (see Chapter 3), Board staff forwarded the completed database to CVCWA so that they could continue a more detailed evaluation.

Additional analyses are needed to continue the evaluation of potential relationships between WWTP treatment processes, mercury minimization measures for mercury

sources to WWTP influent, and effluent methylmercury levels. Board staff and WWTP staff and consultants have informally discussed several ideas for future analyses and key questions to be addressed by those analyses. Some analyses would not require additional influent and effluent sampling, for example:

- Conduct more detailed, focused analyses of the data presented in this report.
- Gather more information about the influent and effluent samples described in this report, for example (but not limited to): specific sampling locations, depths, and time of day; influent inorganic mercury concentrations; pH, alkalinity, dissolved oxygen, temperature, and nitrate, sulfate and ammonia concentrations; and specific treatment processes in place at the time of sample collection.
- Do other factors impact reported concentrations, such as sampling protocols including location, time of day, holding time and composite vs. grab samples?

In addition, the data set presented in this report needs to be updated, with special attention given to facilities that have recently completed treatment process upgrades. For example, the City of Stockton WWTP was upgraded to meet new ammonia effluent limits and Title 22 (or equivalent) tertiary requirements since the data presented in this report were collected. The average effluent methylmercury and total mercury concentrations for January-July 2009 are about 91% and 83% lower than the annual average methylmercury and total mercury concentrations, respectively, observed in 2004/2005. It is not known if the treatment plant upgrades are responsible for the total mercury and methylmercury reductions, or if the reductions are a result of other operational or physical changes. Additional sampling may be needed to determine the cause of the decrease. In addition, methylmercury results for only seven monthly effluent samples have been submitted since the upgrades were completed. As more data are collected, Board staff will work with City of Stockton staff to evaluate whether the above trends are representative of current conditions.

Also, at the time this report was receiving final review, reports for Phases 1 and 2 of the WERF-funded project, "Estimation of Mercury Bioaccumulation Potential from Wastewater Treatment Plants in Receiving Waters", were released (Dean and Mason, 2009a and 2009b). This project assessed changes in mercury bioavailability in wastewater effluents and receiving waters and developed a guidance document for wastewater treatment professionals who want to assess the bioavailability of mercury in their wastewater, compare it to other point and nonpoint sources, and assess changes in bioavailability in their effluent when it is mixed in a receiving water body. The Phase 1 and 2 reports should be considered by future wastewater analyses and control studies, as well as when the Delta mercury TMDL control program goes through future reviews during its implementation.

After additional analyses of existing data are completed, it may be useful to conduct targeted monitoring and pilot scale studies where actual sewage flow may be used to evaluate specific treatment processes and variations.

Possible questions that could be addressed by future analyses include, but are not limited to, the following:

- Do relationships exist between nitrate, ammonia, sulfate, sulfite and TSS concentrations and methylmercury concentrations throughout the treatment process? If so, could treatment processes designed to reduce effluent ammonia also reduce effluent methylmercury?
- Are tertiary treatment processes effective in significantly reducing methylmercury concentrations within a WWTP? What are the affects of filtration and UV treatment on effluent methylmercury?
- Why do some WWTPs have seasonality in their effluent methylmercury concentrations and others do not? What are the causes behind the seasonality observed in methylmercury concentrations?
- Do influent and effluent methylmercury concentrations have any diurnal variability, and if so, what are the causes?
- Is it feasible to modify the biological secondary processes at some plants to increase methylmercury degradation? If so, can "real-time" indicators (e.g., pH or alkalinity) be developed so that plant operators can make immediate adjustments (versus having to wait several weeks for methylmercury analyses)?
- Do WWTPs that use pond systems or other treatments act as greater sources of inorganic mercury and/or methylmercury than WWTPs that utilize other treatment systems?
- How much are effluent inorganic mercury and methylmercury concentrations reduced by reducing influent inorganic mercury concentrations and/or loads (e.g., by implementing inorganic mercury source minimization measures)?

Several Central Valley WWTP staff and consultants have noted that it would be very helpful to establish a working group that coordinates efforts between CVCWA, San Francisco Bay area facilities, and other regional efforts to develop more detailed analyses of the existing information, further evaluate treatment processes, and design additional monitoring studies and pilot projects. Board staff is supportive of this concept and will work with dischargers and working groups to design and review studies.

TABLES

Table 1: Summary of Literature Review

Facility	Citation	Secondary Treatment	Tertiary Treatment (if any)	Influent MeHg (ng/l)	Influent MeHg: TotHg Ratio [(a)]	Post-Secondary Treatment MeHg (ng/l)	Post-Secondary Treatment MeHg:TotHg Ratio [(a)]	Final Effluent MeHg (ng/l)	Final Effluent MeHg: TotHg Ratio [(a)]	Comments
San Jose / Santa Clara Water Pollution Control Plant	SJ/SC, 2007	Activated sludge with nitrification/ denitrification	Filtration	1.57	0.94%	0.05	0.87%	0.04	2.0%	
Sacramento Regional Wastewater Treatment Plant	Parmer and others, 2005	Pure oxygen activated sludge		1.55	0.80%	0.38	7.7%	0.55	12%	180 MGD activated sludge plant. Slight rise in final effluent MeHg.
City of Winnipeg: North End, West End & South End Water Pollution Control Centres	Bodaly and others, 1998	North and South End: Pure oxygen activated sludge West End: Conventional diffused air activated sludge	West End only: Treatment lagoons	Average of all three plants: 2.2 (range: 0.5 - >4)		Not reported		North and South End: 0.13 - 0.56 West End: 0.2 - >2		Pure oxygen aeration exhibited greater removal efficiency of MeHg in effluent.
Pilot-scale activated sludge plant	Pavlogeor-gatos and others, 2006	Activated sludge		<70 (MDL: 0.07 µg/l)				<70 (MDL: 0.07 µg/l)		Pilot scale activated sludge study using synthetic wastewater containing glucose and ammonia. Spiked Hg concentrations of 10, 100, and 500 µg/l added directly to aeration tanks. No RAS; secondary sludge returned to aeration tanks.
Onondaga County Metropolitan Wastewater Treatment Plant	McAlear, 1996	Activated sludge	Phosphorous removal (addition of $FeSO_4$)	5.05	1.84%	2.76	21%	1.53	8.3%	
Fritz Island Wastewater Treatment Plant	Gilmore and Bloom, 1995	Trickling filters		3.0	1.92%	9.1	3.2%	4.0	3.7%	

Table 1: Summary of Literature Review

Facility	Citation	Secondary Treatment	Tertiary Treatment (if any)	Influent MeHg (ng/l)	Influent MeHg: TotHg Ratio [(a)]	Post-Secondary Treatment MeHg (ng/l)	Post-Secondary Treatment MeHg:TotHg Ratio [(a)]	Final Effluent MeHg (ng/l)	Final Effluent MeHg: TotHg Ratio [(a)]	Comments
Whitlingham Sewage Treatment Works	Goldstone and others, 1990	Activated sludge		11		120		< 10		

[(a)] Staff calculated the MeHg:TotHg ratios for the SJ/SC WWTP and Fritz Island WWTP studies using the average inorganic mercury and methylmercury data provided in their respective reports. The ratios for the SRCSD WWTP and Onondaga County WWTP studies were obtained from the reports.

Table 2: Total Mercury and Methylmercury Concentrations at the San Jose/Santa Clara WWTP

Sample Location	Average TotHg Conc. (ng/l)	Average Dissolved TotHg Conc. (ng/l)	Average MeHg Conc. (ng/l)	MeHg:TotHg Ratio [c]
Raw Sewage	168	2.9	1.6	0.9%
Primary Effluent	92	4.0	1.5	1.6%
Secondary Influent [a]	79	3.6	1.3	1.6%
Secondary Effluent [b]	5.2	1.1	0.05	0.87%
Filter Influent	5.1	1.2	0.05	0.98%
Tertiary Filter Effluent	1.6	1.2	0.03	1.9%
Filter Backwash	1.9	2.1	0.11	5.8%
Final Effluent	2.0	1.4	0.04	2.0%

[a] The SJ/SC WWTP study refers to the secondary influent as "Settled Sewage Influent to Secondary Units".
[b] The secondary treatment process consists of two pathways that are identical in function (biological nutrient removal) and receive the same influent. These numbers are averages of the effluent concentrations of the two pathways.
[c] Staff calculated the MeHg:TotHg ratio from the inorganic mercury and methylmercury data provided in the report.

Table 3: Phase 1A and 1B Total Mercury Concentrations, Mass Loads and Particulate Concentrations at the SRCSD Sacramento WWTP

Location [a]	Average TotHg Conc. (ng/l)	TotHg Mass Load (g/day)	TotHg Particulate Concentration (ng/g) [b]
Influent	192.33	131	1100
Primary Effluent	50.91	35	490
Mixed Liquor	693.33	660	408
Secondary Effluent	4.92	3.3	300
Dechlorinated Final Effluent	4.64	3	305
Waste Activated Sludge	1800	35.13	
Digested Sludge	12,333	60.36	800
Green SSB	170		350
Black SSB	430		770
Harvest SSB	990		1700
BRF Influent	13,166.67	23.92	800
SSB Return Flow	253.33	4.24	740
BRF Return Flow	150.67	0.47	580

[a] SSB: Solids Storage Basins BRF: Biosolids Recycling Facility
[b] Inorganic mercury particulate concentrations obtained from Table 9 in the SRCSD report.

Table 4: Phase 1A and 1B Methylmercury Concentrations, Mass Loads and Particulate Concentrations at SRCSD

Location [a]	Average MeHg Conc. (ng/l)	MeHg Mass Load (g/day)	MeHg Particulate Conc. (ng/g) [b]	MeHg:TotHg Ratio
Influent	1.55	1.06	4.93	0.80%
Primary Effluent	1.34	0.91	7.3	2.6%
Mixed Liquor	11.77	11.2	6.5	
Secondary Effluent	0.38	0.26	20.4	7.7%
Dechlorinated Final Effluent	0.55	0.36	33	12%
Waste Activated Sludge	30.72	0.5988	6.2	
Digested Sludge	245.88	1.176	13.01	
Green SSB	4.66		9.5	
Black SSB	18.35		32.4	
Harvest SSB	13.05		22	
BRF Influent	208.2	0.3585	13.5	
SSB Return Flow	7.39	0.1207	19	2.9%
BRF Return Flow	7.21	0.0215	24.2	5.5%

[a] SSB: Solids Storage Basins BRF: Biosolids Recycling Facility
[b] Methylmercury particulate concentrations obtained from Table 9 in the SRCSD report.

Table 5: Average Total Mercury, Methylmercury and TSS concentrations at the Onondaga County WWTP for the Entire Sampling Period (October 1995 to September 1996)

Location	Average TotHg Conc. (ng/l)	Average MeHg Conc. (ng/l)	MeHg:TotHg Ratio	Average TSS Conc. (mg/l)
Plant Influent	308	5.05	1.8%	206
Primary Effluent	112	1.92	2.2%	88.5
Secondary Effluent	24.0	2.76	21%	26.2
“Tertiary” Effluent	32.9	2.63	14%	9.48
Final Effluent	36.8	1.53	8.3%	11.7

Table 6: Seasonal Average Methylmercury Concentrations at the Onondaga County WWTP [a]

Location	Average Cold Weather (November to April) MeHg Conc. (ng/l)	Average Warm Weather (May to October) MeHg Conc. (ng/l)
Plant Influent	2.34	7.76
Primary Effluent	2.03	1.77
Secondary Effluent	1.94	3.49
"Tertiary" Effluent	2.40	2.87
Final Effluent	1.43	1.63

[a] Staff calculated the primary, secondary and "tertiary" effluent average concentrations for both the warm and cold weather periods from raw data provided in the Appendix of the report.

Table 7: Total Mercury and Methylmercury Concentrations in the Fritz Island WWTP Inputs and Outputs

Location	Total Mercury			Methylmercury		
	# of Samples [a]	Conc. Range (ng/l)	Average Conc. (ng/l)	# of Samples [a]	Conc. Range (ng/l)	Average Conc. (ng/l)
Plant Influent	3	185 - 556	358	3	1.36 - 2.45	1.91
Plant Effluent	3	108 - 448	228	3	4.03 - 5.69	4.74
Plant Sludge	3	3.96 - 4.09 [b]	4.02 [b]	3	1.6 - 5.2 [b]	3.23 [b]

[a] Each sample was a triplicate sample.
[b] The unit of measure for the wet weight sediment concentrations is μg/g.

Table 8: Total Mercury and Methylmercury Loads in the Inputs and Outputs of the Fritz Island WWTP

Site	TotHg Load (g/day)	Percent of TotHg Output Load from WWTP [a]	MeHg Load (g/day)	Percent of MeHg Output Load from WWTP [a]
Plant Influent	19.3		0.104	
Effluent	12.8	8%	0.269	68%
Sludge	144	92%	0.125	32%
Output Load from WWTP (Effluent + Sludge)	157	100%	0.394	100%
Net Output Load generated inside the WWTP (Output - Influent)	138	88%	0.29	74%

[a] The output load from the WWTP is equal to the sum of the effluent and sludge loads.

Table 9: Total Mercury and Methylmercury Concentrations in the Influent and Effluent of Various Components of the Fritz Island WWTP Treatment Processes

Site	TotHg Conc. (ng/l)	MeHg Conc. (ng/l)	MeHg:TotHg Ratio [(a)]
Plant Influent	**156**	**3**	**1.9%**
1st Stage Trickling Filters			
Input	229	7.8	3.4%
Output TF# 1	5660	31.9	0.56%
Output TF# 3	1540	24	1.6%
Intermediate Settling			
Input	2670	29.4	1.1%
Output	215	13	6.1%
Sludge	114,000 mg/kg	71 mg/kg	0.06%
2nd Stage Trickling Filters			
Input	215	13	6.1%
Output TF# 4	629	33.9	5.4%
Output TF# 5	291	10.8	3.7%
Output TF# 6	394	13.1	3.3%
Post 2nd Stage Settling			
Input	288	9.1	3.2%
Output	167	11.1	6.7%
Sludge	39,600 mg/kg	287 mg/kg	0.72%
Aeration			
Input	167	11.1	6.7%
Output	148	4.7	3.2%
Final Settling			
Input	148	4.7	3.2%
Output	76	6.9	9.1%
Sludge	124,000 mg/kg	205 mg/kg	0.17%
Final Effluent	**108**	**4**	**3.7%**

[(a)] Staff calculated the MeHg:TotHg ratio from the inorganic mercury and methylmercury data provided in the report.

Table 10: Summary of Total and Methylmercury Concentrations in Samples Collected in October 1987 at the Whitlingham Sewage Treatment Works

Location	Average TotHg Conc. (ng/l)	Average MeHg Conc. [(a)] (ng/l)	MeHg Conc. Range (ng/l)	Number of MeHg Samples	Number of MeHg Results below the MDL [(a)]
Raw Sewage	200	11	< MDL - 83	11	9
Settled Sewage	100	<10	all < MDL	11	11
Picket Fence Thickener Overflow	300	23	16 - 36	5	0
Returned Activated Sludge	5900	120	68 - 200	4	0
Final Effluent	100	<10	< MDL - 20	13	7

[(a)] The method detection limit was 10 ng/l. The average concentrations were calculated by the study authors assuming that values below the detection limit were zero.

[a] Facilities upstream of a major dam.
[b] Facilities for which NPDES permits were rescinded sometime after the facilities completed 13267 Order monitoring.
[c] Facilities that do not discharge to 303(d) Listed mercury-impaired waterways but do discharge to small tributaries that drain directly to the Delta.
[d] The City of Davis WWTP (CA0079049) has two seasonal discharge locations; wastewater is discharged from Discharge 001 to the Willow Slough Bypass upstream of the Yolo Bypass and from Discharge 002 to the Conaway Ranch Toe Drain in the Yolo Bypass. The latitude and longitude coordinates and other information provided in the table are for Discharge 001. The coordinates for Discharge 002 are 38.575833, -121.633889.

Table 17: Summary of all Effluent Methylmercury Concentration Data for the Non-Municipal Facility Categories [a]

Facility Type	# of Effluent MeHg Samples	Average MeHg Conc (ng/l) [b]	# of Nondetect samples	MeHg Conc. Range (ng/l)
Aggregate	10	0.026	7	ND - 0.081
Aquaculture	38	0.041	12	ND - 0.243
Drinking Water Treatment	10	0.033	3	ND - 0.066
Food Processing	12	0.014	9	ND - 0.027
Groundwater Remediation	20	0.012	19	ND - 0.033
Heating/Cooling	14	0.110	3	ND - 0.919
Manufacturing	5	0.023	3	ND - 0.050
Mines	4	0.064	1	ND - 0.091
Miscellaneous	6	0.034	3	ND - 0.082
Paper/Saw Mills	21	0.117	5	ND - 1.190
Power Generation	46	0.061	11	ND - 0.178
Power Generation/ Domestic WWTP	12	0.040	4	ND – 0.104

[a] This table summarizes all of the effluent methylmercury data submitted by non-municipal facilities including multiple discharge locations (e.g., effluents 1-4).

[b] One-half of the MDL was used in calculations for methylmercury concentration results that were less than the MDL.

Table 19 Footnotes:

[a] Except where otherwise noted, all water supply information was obtained from the Water Education Foundation's 2006 website, "Where does my water come from?" [http://www.water-ed.org/watersources/]. This site lists the drinking water sources for incorporated cities with a population of 10,000 or greater, as determined from the 2005 Water Education Foundation survey, water agencies, and annual water quality reports.

[b] If methylmercury data were not available for the local surface water supply, data for nearby waterways were included. Methylmercury data for the Central Valley Project (CVP), State Water Project (SWP) and Delta outflows to San Francisco Bay (X2) were used to represent drinking water intakes in the Central and West Delta, such as the Rock Slough and Old River intakes for the Randall-Bold Water Treatment Plant located in Oakley (see footnote "d"). Average methylmercury values were obtained from the February 2008 Delta TMDL draft staff report (Wood *et al.*, 2008b) for all surface water locations with four exceptions. Central Valley Water Board staff collected methylmercury samples from the American River at Discovery Park and Stanislaus River at Caswell State Park as part of a broader CalFed-funded study (Foe *et al.*, 2007; 2008 draft report in peer review). The Sacramento Coordinated Monitoring Program sampled the Sacramento River at Veteran's Bridge (CMP, 2004).

[c] The Deuel Vocational Institute WWTP services the Deuel Vocational Institute (DVI), which is about two miles south of Mossdale and ten miles south of Stockton. Information about its water supply was obtained from a case study described in: Corrollo Engineers, 2007, Drinking Water with Emphasis on Desalination and Membrane Softening Qualifications, available at: http://www.carollo.com/356/section.aspx/333

[d] Groundwater from eight active wells provides approximately 67% of the Discovery Bay water supply; the remaining water comes from the Randall-Bold Water Treatment Plant located in Oakley, which is jointly owned by Contra Costa Water District (CCWD) and Diablo Water District (DWD) and receives water from Rock Slough, Old River, and Los Vaqueros Reservoir. Information about the Discovery Bay water supply is from: Brown and Caldwell, 2006. City of Brentwood 2005 Urban Water Management Plan - Final. Prepared for the City of Brentwood by Department of Public Works by Brown and Caldwell, Walnut Creek, California. January 2006. Available at: http://www.ci.brentwood.ca.us/pdf/new/publicworks/2005_urban_water_plan.pdf

[e] The Water Education Foundation listed Manteca water sources as both groundwater and local streams/reservoirs. The City of Manteca Water Division website [http://www.ci.manteca.ca.us/eng/water/] stated that as of 2005, 100% of the Manteca drinking water supply came from groundwater sources and that in the near future some of its supply will come from the South County Surface Water Supply Project, which will draw water from Woodward Reservoir. The Woodward Reservoir is supplied by the Stanislaus River. The South County Surface Water Supply Project is a project to supply the cities of Tracy, Lathrop, Manteca and Escalon with water from the South San Joaquin Irrigation District and includes construction of a new water treatment plant at Woodward Reservoir and pipelines to supply water to the cities. Currently no methylmercury data are available for Woodward Reservoir.

[f] The City of Rio Vista relies on groundwater sources and has the right to obtain a specified amount of North Bay Aqueduct (NBA, a component of the State Water Project) water in the future, but as of 2003, had no facility to take NBA water. [Information from: Solano County Water Agency, 2002. SWCA Briefing Book. January 2002. Available at: http://www.scwa2.com/briefing_book.html]

[g] County Service Area 31 is an 80-acre parcel that includes Flag City, a collection of hotels, gas stations and restaurants at Interstate 5 and Highway 12 near Lodi.

[h] Per California American Water's 2005 Annual Water Quality Report for Walnut Grove [PWS ID: 3410047], water in the Walnut Grove system comes from wells that pump groundwater from aquifers in the Walnut Grove area. [Report available at: http://www.illinoisamerican.com/awpr1/caaw/pdf/CA-WalnutGrove-web.pdf]

Table 19 Footnotes, *continued*:

[i] According to the City of Tracy Public Works website, 2005 sources of the City of Tracy's water supply include the Delta-Mendota Canal [a.k.a. Central Valley Project] (50%), the Stanislaus River (17%), and groundwater pumped from wells (33%). [http://www.ci.tracy.ca.us/departments/public_works/water_quality/]

[j] In 2005, the City of Stockton obtained about 58% of their drinking water from surface water supplied by the Stockton East Water District (SEWD) and 42% from groundwater sources [City of Stockton / OMI Thames Water 2005 Annual Drinking Water Quality Report, California Water System No. 3910012.] SEWD obtains water from the New Hogan Reservoir in the Calaveras River watershed, and from the New Melones Reservoir in the Stanislaus River watershed. [Report available at: http://www.stocktongov.com/MUD/General/water/documents/2005CCRWaterQualityReport.pdf] Currently no methylmercury data are available for the reservoirs.

[k] The West Sacramento 2006 Water Quality Consumer Confidence Report states that the City of West Sacramento's main water supply is the Sacramento River, with an intake structure at Bryte Bend, upstream of the confluence of the Sacramento and American rivers. The City maintains water supply contracts with the federal Bureau of Reclamation, the Central Valley Project and the North Delta Water Agency. In addition to surface water, the City has five ground water wells that are available to supply additional water during emergencies. The City did not utilize ground water in 2005.

[l] The 2005 City of Sacramento Water Quality Report states that 85% of its water supply comes from the American and Sacramento Rivers and 15% comes from groundwater. [Report available at: http://www.cityofsacramento.org/utilities/pubs/DOU_CCR_2005.pdf] According to the November 2006 City of Sacramento Urban Water Management Plan prepared by West Yost Associates, the City diverts water from the American River downstream from the Howe Avenue Bridge, and from the Sacramento River downstream of the confluence of the American and Sacramento Rivers. [Report available at: http://www.cityofsacramento.org/utilities/urbanwater/] According to available water quality reports for urban areas outside of the City of Sacramento serviced by other water districts and private corporations, water supply for unincorporated areas is a mixture of surface water (e.g., Sacramento River, American River, and Folsom Lake) and groundwater. The effluent methylmercury data used in this analysis was collected from December 2000 to June 2003, since the surface drinking water supply data was collected during the same time period.

[m] Groundwater treatment plant intake and discharge monitoring (Tables B.1 through B.4) indicate that methylmercury concentrations in groundwater are at or below method detection limits (typically < 0.02 ng/l).

[n] The Modesto Irrigation District (ID) Water Treatment Plant (WTP), which supplements groundwater drinking water supplies for the Modesto community, obtains water from the Tuolumne River at Modesto Reservoir. The Modesto ID collected intake samples and analyzed them for methylmercury as part of their 13267 Order monitoring effort (see Table B.3). Modesto ID WTP water supply information is available at: http://www.mid.org/water/drnkwtr.htm

[a] One-half of the method detection limit (MDL) was used in calculations for methylmercury concentration results that were less than the MDL.

[b] The California Department of Public Health (DPH) has developed reclamation criteria (CCR, Division 4, Chapter 3 (Title 22)) for the reuse of wastewater. Title 22 requires that for spray irrigation of food crops, parks, playgrounds, schoolyards, and other areas of similar public access, wastewater be adequately disinfected, oxidized, coagulated, clarified, and filtered, and that the effluent total coliform levels not exceed 2.2 MPN/100 mL as a 7-day median. The regulatory criteria include numerical limitations and requirements, treatment method requirements, and provisions and requirements related to sampling and analysis, engineering reports, design, operation, maintenance and reliability of facilities.

[c] RBC's: Rotating Biological Contactors SBR's: Sequencing Batch Reactors

[d] *Tertiary, no Title 22. ** No tertiary. *** No Title 22. **** No tertiary, no Title 22.

[e] If two values are provided, the first is design average dry weather flow and the second is design peak wet weather flow.

(a) The municipal WWTPs placed in the pond treatment categories use treatment pond systems (oxidation, facilitative, settling or stabilization ponds) as a significant part of their treatment process. These facilities may also use other types of secondary treatment in addition to the treatment ponds.

[a] One-half of the MDL was used in calculations for methylmercury concentration results that were less than the MDL.
[b] The standard error is estimated standard deviation of the sample mean. It is calculated by dividing the sample standard deviation by the square root of the sample size.
[c] The 25th percentile (P_{25}) is a value which exceeds no more than 25 percent of the data and is exceeded by no more than 75 percent.
[d] The 75th percentile (P_{75}) is a value which exceeds no more than 75 percent of the data and is exceeded by no more than 25 percent.
[e] The interquartile range (IQR) is the 75th percentile minus the 25th percentile. The IQR is a measure of variability that is more resistant to outliers than the standard deviation.
[f] A positive coefficient of skewness (g) indicates that the distribution is right-skewed (i.e. the distribution is asymmetric with extreme values extending out longer to the right side or larger value side). Conversely, a negative coefficient of skewness indicates that the distribution is left-skewed. As the coefficient of skewness increases from zero in either the negative or positive direction, the more extreme the skewness of the distribution.
[g] If the Shapiro-Wilk W statistic is statistically significant (p-value is less than 0.05), then the hypothesis that the data distribution is normal is rejected. Therefore, a p-value less than 0.05 indicates that the distribution is most likely not normal.

[a] Due to the small sample size and unusual treatment type, the "Filtration + Ozonation" treatment category was not included in this analysis.

[b] The comparison p-values between pairs were calculated with Statistica software. The p-values are two-sided significance levels multiplied by the number of possible combination pairs [k*(k-1)/2, where k is the total number of groups in the comparison]. The number of possible combination pairs in this comparison analysis is 36. P-values less than 0.05 are highlighted in ***bold and italics*** to identify statistically significant differences between treatment categories.

[(c)] P-value for two sample t-test assuming unequal variances.

Table 29: Kruskal-Wallis Multiple Comparison Results for Median Effluent:Influent Methylmercury Ratios of the Treatment Categories

2005 Treatment Category [a]	Average Effluent:Influent MeHg Ratio	Median Effluent:Influent MeHg Ratio	Comparison p-values [b]						
			N/D + Filtration + Chlor./ Dechlor.	N/D + Filtration + UV	Filtration + Chlor./ Dechlor.	Filtration + UV	Secondary w/ N/D + Chlor./ Dechlor.	Secondary + Chlor./ Dechlor.	Pond + Chlor./ Dechlor.
N/D + Filtration + Chlor./ Dechlor.	2.4%	1.2%	--	1.0000	1.0000	1.0000	1.0000	***0.0000***	***0.0000***
N/D + Filtration + UV	2.7%	1.5%	1.0000	--	1.0000	1.0000	1.0000	***0.0000***	***0.0019***
Filtration + Chlor./ Dechlor.	4.1%	1.6%	1.0000	1.0000	--	1.0000	1.0000	***0.0109***	***0.0365***
Filtration + UV	6.0%	2.0%	1.0000	1.0000	1.0000	--	1.0000	***0.0004***	***0.0153***
Secondary w/ N/D + Chlor./ Dechlor.	10.2%	2.1%	1.0000	1.0000	1.0000	1.0000	--	***0.0006***	***0.0344***
Secondary + Chlor./ Dechlor.	36.8%	28.1%	***0.0000***	***0.0000***	***0.0109***	***0.0004***	***0.0006***	--	1.0000
Pond + Chlor./ Dechlor.	65.5%	36.4%	***0.0000***	***0.0019***	***0.0365***	***0.0153***	***0.0344***	1.0000	--

[a] The "Pond + Filtration + Chlor./ Dechlor." treatment category was not included in this analysis due to it having a sample size of one. Additionally, the "Secondary w/ N/D + UV" and "Filtration + Ozonation" treatment categories were not included since the facilities with these treatment types did not collect influent samples.

[b] The comparison p-values between pairs were calculated with Statistica software. The p-values are two-sided significance levels multiplied by the number of possible combination pairs [k*(k-1)/2, where k is the total number of groups in the comparison]. The number of possible combination pairs in this comparison analysis is 21. P-values less than 0.05 are highlighted in ***bold and italics*** to identify statistically significant differences between treatment categories.

Table 30: Regression Coefficients (R^2) and Two-sided Significance Levels (p-values) for Influent versus Effluent Methylmercury Concentration Scatter Plots for Each WWTP with Five or More Paired Data Points. [Significant relationships are in bold.]

NPDES #	WWTP	# of paired data points	R^2 value for linear regression	p-value for linear regression

ORDER FOR UNFILTERED METHYLMERCURY WASTE DISCHARGE DATA PURSUANT TO CALIFORNIA WATER CODE SECTION 13267 (*MONTHLY* SAMPLING) NPDES NO. «NPDES_NO»

Section 303(d) of the federal Clean Water Act requires States to list water bodies that do not meet water quality objectives to protect their beneficial uses and to develop and implement Total Maximum Daily Load (TMDL) control programs to eliminate the impairment of beneficial uses.

The Sacramento and San Joaquin Rivers and associated Delta Estuary were placed on the 303(d) list because of elevated methylmercury concentrations in fish. Recent data demonstrate a statistically significant correlation between methylmercury concentrations in water and fish, i.e., as concentrations of methylmercury increase in the water column, concentrations of methylmercury also increase in fish resident in that water column. The data thus suggest that the annual median methylmercury concentration of a water body is a major factor determining resident fish tissue methylmercury levels. The proposed TMDL goal to protect Delta beneficial uses is 0.05 nanograms per liter (ng/l) methylmercury in water.

Limited methylmercury effluent data are available for local NPDES facilities. A recent survey by the Regional Board found considerable variability between facilities and demonstrated that some plants were discharging methylmercury above the proposed TMDL goal. Table 1 summarizes data collected by the Regional Board in February and March of 2004 as well as data collected by the Sacramento Regional County Sanitation District from a year-long study in 2001.

Section 13267 of the California Water Code states in part that a regional board may investigate the quality of waters within its region, and in doing so may require dischargers to furnish technical or monitoring reports which the regional board requires. The burden, including costs, of these reports must bear a reasonable relationship to the need for the report and the benefits to be obtained from the reports.

The monitoring reports required by this letter are necessary to determine the extent to which NPDES facilities are contributing methylmercury in concentrations that impair beneficial uses of receiving waters. Preliminary load calculations using the information shown in Table 1 estimate that POTWs discharge significant portions of the total methylmercury loading to the Delta. Accurate discharge information will be required from treatment facilities to complete the TMDL.

Table 1. Summary of unfiltered methylmercury concentrations in effluent from POTW's located in the Central Valley of California.

Facility	# of Sampling Events	Mean Concentration (ng/l)	Range (ng/l)
Sacramento Regional County Sanitation District	45	0.73	0.14-2.93
Stockton STP	2	0.34	0.13-0.59
Vacaville Easterly STP	2	0.10	0.09-0.11
West Sacramento STP	2	0.04	0.03-0.05
City of Roseville	2	0.01	0.01-0.01

Therefore pursuant to Section 13267 of the California Water Code, you are required to submit effluent methylmercury monitoring data for your facility. In most cases, this monitoring will be in addition to monitoring required in your NPDES Permit.

Instantaneous grab samples shall be collected monthly for one year (August 2004-July 2005) from the facility's effluent. Intermittent or seasonal dischargers shall collect monthly samples during those months for which a discharge occurs. The samples must be collected downstream from the last connection through which wastes can be admitted into the outfall, and shall be representative of the quality of the discharge from the treatment plant. Unfiltered methylmercury samples shall be taken using clean hands/dirty hands procedures[1] and shall be analyzed by U.S. EPA method 1630/1631 (Revision E) with a method detection limit of 0.02 ng/l. A matrix spike/matrix spike duplicate shall also be analyzed with either the first or second set of samples to insure an acceptable methylmercury recovery rate in your effluent. A travel-blank must also be collected and analyzed with every other set of samples. Any other methylmercury monitoring data collected by your plant during the above period shall also be reported to the Regional Board. If your facility is currently collecting total mercury data, methylmercury samples should be collected concurrently. A partial list of laboratories performing U.S. EPA method 1630/1631 is attached as Table 2.

While not required by this letter, we are also recommending that instantaneous grab samples be collected from the facility's upstream receiving water and the main influent to determine the methylmercury treatment efficiency of your facility.

Please submit quarterly reports summarizing the monitoring results to the Regional Board. The reports are due by 31 October 2004, 31 January 2005, 30 April 2005, and 31 July 2005. Your cooperation with this special discharge monitoring requirement is sincerely appreciated. However, we must advise that failure or refusal to comply with this request as required by Section 13267 of the California Water Code or falsifying any information provided may be subject to an administrative civil liability of up to $1,000 per day of violation in accordance with Section 13268.

[1] Described in U.S. EPA method 1669: Sampling Ambient Water for Trace Metals at EPA Water Quality Criteria Levels for collection of equipment blanks (section 9.4.4.2)

Please contact your regular Regional Board staff representative if you have any questions regarding this order.

THOMAS R. PINKOS
Executive Officer

APPENDIX B
SUMMARY OF NPDES FACILITY EFFLUENT AND INFLUENT METHYLMERCURY AND TOTAL MERCURY CONCENTRATIONS

Many facilities have multiple discharge locations and influent sources (intakes). Therefore, there are separate tables that summarize the methylmercury concentrations for each discharge and intake:

- Table B.1: Summary of Effluent 1 and Effluent 2 Methylmercury Concentrations
- Table B.2: Summary of Effluent 3 and Effluent 4 Methylmercury Concentrations
- Table B.3: Summary of Influent/Intakes 1 and 2 Methylmercury Concentrations
- Table B.4: Summary of Influent/Intakes 3 and 4 Methylmercury Concentrations

Table B.1: Summary of Effluent 1 and Effluent 2 Methylmercury Concentrations

Table B.1 Footnotes:

a. Sample MeHg concentration <MDL; half the detection limit was used for calculations.

b. Lehigh Southwest Cement Co. EFF 1: Outfall #1, Shale Quarry Tunnel Road. Effluent 2: Lehigh Southwest Cement Co., 002B: Shale Quarry

c. Darrah Springs Fish Hatchery EFF 1: Upper Springs. EFF 2: Darrah Springs Fish Hatchery - Lower Springs

d. UCD Center for Aquatic Biology & Aquaculture, EFF 1: CABA Aquatic Center. EFF 2: CABA Putah Creek Facility

e. Proctor & Gamble, Pond EFF 2: Effluent PTI-660

f. Aerojet Sacramento Facility, EFF 1 Sample collected from West Detention Pond because there was no discharge to the American River during the rainy season.

g. City of Turlock WWTP, EFF 1: R5

h. Mirant Delta CCPP EFF 1:Outfall 001, EFF 2: Outfall 002

i. Defense Logistics Agency, Sharp Groundwater Cleanup; EFF 1: CBCGWTPEFF = Central Area B/C Aquifer Zone, EFF 2: NBGWTPEFF = North GWTP effluent

j. General Electric Co., GWCS: EFF 1: Air Stripper Effluent, EFF 2: 100-foot Zone Effluent

k. Results for the following facilities and sample dates were not incorporated in the calculations due to sample preservation hold times exceeding EPA recommendations: Aerojet Interim GW WTP (18 November 2005, EFF 1 and EFF 2 were both <MDL); Aerojet Sacramento Facility (18 March 2005, 0.057 ng/l); Corning Industries/ Domestic WWTP (22 September 2004, 0.041 ng/l); Deuel Vocational Institute WWTP (26 October 2004, <MDL); DGS Office of State Publishing (8 July 2005, <MDL); El Dorado Hills WWTP (9 August 2005, 0.057 ng/l); Lincoln WWTP (25 August 2005, 0.034 ng/l); Modesto ID Regional WWTP (8 October 2004, 0.038 ng/l); South Feather Water & Power Agency Miners Ranch WTP (9 September 2004, <MDL); and SRCSD Walnut Grove WWTP (CSD1) (29 December 2004, 0.759 ng/l).

l. El Dorado Hills WWTP sampled effluent when discharging to land and to surface water. Only samples collected when the plant discharged to surface water (December 2004 through April 2005) were used in the February 2008 Delta TMDL Report (Wood *et al.*, 2008b). However, this summary includes samples that were collected when the plant discharged to land and to surface water.

m. General Electric Co. GWCS conducted four sampling events. However, results for samples collected on 8 October 2004 were not incorporated in the calculations due to sample contamination with mercury in the laboratory and preservation hold times at the laboratory exceeding EPA recommendations.

n. Lodi White Slough WWTP sampled effluent when discharging to land and to surface water. Only samples collected when the plant discharged to surface water (September 2004 through June 2005) were used in the TMDL Report. However, this summary includes samples that were collected when the plant discharged to land and to surface water.

o. Davis WWTP: EFF 1: Willow Slough, EFF 2: Conaway Ranch Toe Drain in the Yolo Bypass

p. Tables 6.5 and 8.4 in the main text of the February 2008 TMDL Report and Tables B and C in the draft Basin Plan amendment provide average concentration values rounded to two decimal places based on un-rounded calculations. For example, the Tracy WWTP had an average methylmercury concentration of 0.014465 ng/l, which rounds to 0.0145 ng/l in this table, and 0.14 ng/l in Table 6.5.

Footnotes for Table B.5:

(a) U/S: Upstream.

(b) An asterisk (*) indicates that effluent total mercury and/or methylmercury concentration date were not available for these facilities. Average effluent concentrations observed at similar facilities were used to estimate their effluent loads. The average concentrations shown in this table for non-municipal WWTPs for which effluent total mercury and/or methylmercury concentration data were not available are based on the average of average effluent concentrations observed at facilities within their respective facility categories. Average total mercury concentrations for municipal WWTPs with tertiary and secondary treatment processes for which effluent data were not available are based on the average of the average total mercury concentrations observed at tertiary and secondary municipal WWTPs, 4.1 and 8.7 ng/l, respectively. Average methylmercury concentrations for municipal WWTPs for which effluent data were not available are based on the average concentrations observed at municipal treatment plants with a similar suite of treatment processes, as shown in Tables 17, 23 and 26.

(c) Altamont Landfill and Resource discharge: average wet weather/dry weather design prior to 1999; there has been no discharge since 1999.

(d) Shasta Paper Co Shasta Mill discharge: stormwater discharges only; there has been no discharge of treated process and domestic wastewater from the treatment plant to Sacramento River since 31 August 2001.

(e) SRCSD Walnut Grove WWTP discharge: The WWTP no longer discharges; as of March 2010, the NPDES permit has not yet been rescinded.

(f) Yuba City WWTP discharge: average daily flow for dates effluent was sampled for methylmercury.

(g) Metropolitan Stevedore discharge: the facility's discharge volume was not specified by its permit.

(h) Mountain House CSD WWTP discharge: Phase 1 dry weather design capacity; the WWTP began to discharge to surface water in 2007.

(i) Rio Vista Northwest WWTP discharge: start-up capacity; the WWTP began to discharge to surface water in 2007.

(j) Roseville Pleasant Grove WWTP discharge: the WWTPbegan to discharge to surface water in June 2004.

[a] Effluent and influent data for municipal WWTPs is annotated with "(Mun-WW)".
[b] The Manteca Aggregate Sand Plant is now known as Oakwood Lake Subdivision Mining Reclamation.

APPENDIX D
COMMENTS AND RESPONSES SUBMITTED DURING THE ADMINISTRATIVE DRAFT REVIEW AND PUBLIC DRAFT REVIEW

Following are comments submitted during the Administrative Draft Report and Public Draft Report reviews and staff responses. Comments are in **bold** and staff responses are in plain text.

1. Mike Paulucci (Laboratory Manager), City of Yuba City Utilities Department, Yuba City WWTP (CA0079260) – E-mail dated December 15, 2008

2. William T. Aravanis PE REA (Senior Engineer) and Paul C. Deutsch (Principal Scientist), General Electric Company, Former Kendall Site, Merced, California (CA0081833) – Letter dated December 22, 2008

3. Art O' Brien PE (Wastewater Utility Manager), City of Roseville, Roseville Pleasant Grove and Dry Creek WWTPs (CA0084573 and CA0079502) – Letter dated January 14, 2009

4. Linda Dorn (Business Citizen's Assistant), Sacramento Regional County Sanitation District, Sacramento River and Walnut Grove WWTPs (CA0077682 and CA0078794) – Letter dated January 15, 2009

5. Lysa Voight PE (Senior Civil Engineer), Sacramento Regional County Sanitation District, Sacramento River and Walnut Grove WWTPs (CA0077682 and CA0078794) – Letter dated March 18, 2009

6. Airy Krich-Brinton, Larry Walker Associates – Email dated June 11, 2009

7. Lysa Voight PE (Senior Civil Engineer), Sacramento Regional County Sanitation District, Sacramento River and Walnut Grove WWTPs (CA0077682 and CA0078794) – Letter dated 15 June 2009

1. Mike Paulucci (Laboratory Manager), City of Yuba City Utilities Department, Yuba City WWTP (CA0079260) – Letter dated December 15, 2008

Table 11 on page 52 is missing the Field Duplicate data from our August 2004 sample event. I have attached a copy of the laboratory report. The table should include for the City's August 24, 2004 sample event a duplicate 1 value of 0.036 ng/L and duplicate 2 value of 0.038 ng/L (RPD 5.4%). Yuba City did not conduct field duplicates for September 2004 as properly noted in Table 11.

Table 11 on page 52 also lists both values for the July 5, 2005 sample event as 0.025 ng/L; however, the values should indicate that both sample were not detected at a reporting limit (RL) of 0.025 ng/L or"<0.025 ng/L".

Table 15 on page 62 lists Yuba City's discharge flow as 5.50 MGD. The flow for the sample dates is 5.22 MGD.

Table 19 on page 70 lists Yuba City's discharge flow as 5.50 MGD. The flow for the sample dates is 5.22 MGD.

Table C.1 on page 183 indicates Yuba City collected an influent sample on July 5, 2005. The City did not collect any influent methylmercury samples for this study as influent samples were voluntary as listed in the 13267 Order. The data listed in Table C.1 is from a sample location not related to the methylmercury study and should be removed.

R-1: Staff incorporated all of the corrections into the report.

2. William T. Aravanis PE REA (Senior Engineer) and Paul C. Deutsch (Principal Scientist), General Electric Company, Former Kendall Site, Merced, California (CA0081833) – Letter dated December 22, 2008

Table A.1 includes data for the National Pollutant Discharge Elimination System (NPDES) number CA0083739. That NPDES number was discontinued when NPDES number CA0081833 was issued in July 2004 with provisions to include discharges originally permitted under NPDES number CA0083739. The first round of methylmercury samples were collected in October 2004. Consequently, samples included in the December 2008 letter were not collected subject to NPDES number CA0083739 and reference to this NPDES number should be removed from Table A.1.

R-2: Staff removed the record of the NPDES # CA0083739 from Table A.1, since at the time the 13267 letter was sent, discharges originally covered under permit CA0083739 were included under the permit CA0081833.

Tables B.1 through B.4 contain footnotes (footnotes m, f, g, and c of tables B.1, B.2, B.3, and B.4, respectively)describing reasons that results of samples collected from the site on October 8, 2004, were not included in the tables. These footnotes indicate the samples were contaminated at the laboratory and that hold times were exceeded. However, the footnotes do not clearly indicate that the location where the hold time was exceeded was at the laboratory. For example, footnote m of table B.1 says "However, results for samples collected on 8 October 2004 were not incorporated in the calculations due to sample contamination with mercury in the laboratory and preservation hold times exceeding EPA recommendations." GE requests that the RWQCB revise

the footnote to read "However, results for samples collected on 8 October 2004 were not incorporated in the calculations due to sample contamination with mercury in the laboratory and preservation hold times at the laboratory exceeding EPA recommendations for reanalyzing the samples." This change in wording would remove any ambiguity concerning where the samples were located when hold times were exceeded.

R-3: After looking at the Semiannual Monitoring Report sent on 21 February 2005, it does not appear that Brooks Rand was able to reanalyze the contaminated samples after the GE request because the remaining sample was contaminated as well. Therefore, staff revised the footnotes in Tables B.1 through B.4 to state: "However, results for samples collected on 8 October 2004 were not incorporated in the calculations due to sample contamination with mercury in the laboratory and preservation hold times at the laboratory exceeding EPA recommendations."

3. Art O' Brien PE (Wastewater Utility Manager), City of Roseville, Roseville Pleasant Grove and Dry Creek WWTPs (CA0084573 and CA0079502) – Letter dated January 14, 2009

Thank you for the opportunity to comment on the subject report. The comments are outlined below:

1. Page 26, 2nd full paragraph: "The denitrification process involves anaerobic bacteria converting nitrate to nitrogen gas with the help of methanol (Metcalf and Eddy, Inc., 1972)." This is likely an incorrect reference quote. First, at our WWTPs, the anoxic bacteria convert the nitrate to nitrogen gas. Second, not all WWTPs use methanol as the carbon source for the denitrification process. We do not add methanol as a carbon source. Third, a carbon source is only needed when the denitrification process follows the nitrification process. This sentence should be changed to: "The denitrification process involves anoxic bacteria converting nitrate to nitrogen gas with the help of a carbon source such as methanol (Metcalf and Eddy, Inc., 1972)."

R-4: Staff agrees with the suggested sentence change and modified the sentence in the report accordingly.

2. Table 19 (page 69): PGWWTP should have box 15 and 19 marked off
DCWWTP should have box 15 marked off

R-5: Staff made the suggested changes in Table 19. The Roseville Pleasant Grove WWTP was already placed in the "N/D + Filtration + Chlor./ Dechlor." treatment category, so the effluent methylmercury analysis for the various categories did not need to be redone.

3. Some of the data and statistical analyses do not support the conclusions:

- **Section 4.2.5, pg 30, 2nd full paragraph: the authors conclude there is a "significant positive relationship (R^2=0.1347, Figure 28a and R^2=0.0715, Figure 28b)" between influent methylmercury and effluent methylmercury. The authors go on to state: "These significant relationships indicate that reductions in methylmercury in the effluent were in part due to lower influent concentrations." This conclusion is not supported by the statistical analysis. The extremely low R^2 value would draw the exact opposite conclusion. R^2 is the square of the correlation coefficient or coefficient of determination. This statistical method is a good way of evaluating the strength of the relationship**

between 2 variables and is measure between 0 and 1. When R^2=1, there is a very strong relationship, conversely when R^2=0, a weak relationship exists. Therefore, it appears that these data demonstrates a very weak relationship at best.

R-6: Staff agrees that there is a weak relationship between influent methylmercury and effluent methylmercury indicated by the low R^2 values (square of the correlation coefficient). R^2 is the proportion of the variance of "variable y" that can be explained by the "variable x". Staff discussed this in the last sentence of the 2nd full paragraph on page 30: "…7-13% of the variability in effluent methylmercury concentrations was explained by influent concentrations, indicating that effluent concentrations were affected by other factors as well." Even though both of the relationships shown in Figures 28a and 28b have low R^2 values, they are statistically significant with p-values (two-sided levels of significance) less than 0.0001 using the one-sample t-test for the correlation coefficient (R). Typically, p-values less than 0.05 are considered statistically significant. The reason that the relationships have low R^2 values and are still significant is in part due to the large number of paired data points in each relationship. Figure 28a, which is the scatter plot of all paired data from all WWTPs excluding SRCSD Sacramento River WWTP, has 131 paired data points. Figure 28b, which includes the SRCSD Sacramento River WWTP paired data, has 238.

- **Section 4.2.6, pages 31 and 32: the authors draw the same "significant positive relationship" conclusion as was done in section 4.2.5. These data, again, resulted in extremely low R^2 values indicating that there is very low correlation between effluent methylmercury and effluent total mercury.**

R-7: Staff agrees that the relationships referred to in this comment are weakly correlated. However, all of these relationships have p-values less than 0.01 using the one-sample t-test for the correlation coefficient (R), which indicates statistical significance. See comment R-6 for further explanation.

- **Section 4.2.7, 3rd paragraph, page 32 and Section 4.2.8, 3rd paragraph, page 33: the authors conclude that there is no relationship between effluent methylmercury and influent total mercury. However, no statistical analysis (i.e. R^2 values) is presented that support these conclusions.**

R-8: Staff added the R^2 values and p-values to the text in the report referring to these relationships. All of the effluent methylmercury vs. influent inorganic Mercury and effluent vs. influent inorganic Mercury relationships had p-values greater than 0.05, indicating no statistical significance.

4. General observations:

- **The authors appear to work very hard at trying to draw statistically "significant" conclusions from this data using statistical modeling. This leaves the impression they are trying to make the data support a preconceived conclusion. Based on the data and the statistical analysis performed, the only conclusions that can be drawn are:**

    1. **Low levels of methylmercury exist in some WWTP's influent and effluent; however, a relationship can not be drawn.**

    2. **Low levels of total methylmercury exist in some WWTP's influent and effluent. Removal efficiencies can be determined.**

3. **The type of WWTP treatment process may influence the removal efficiency.**

4. **Seasonality may or may not play a role in methylmercury concentrations.**

R-9: One of the questions the Central Valley Water Board (Board) staff posed and analyzed in this report was: "Does a relationship exist between WWTP treatment processes and effluent methylmercury concentrations? Do WWTPs with a particular treatment process have higher effluent concentrations than WWTPs with other treatment processes?" In order to answer these questions, staff developed 10 mutually exclusive treatment categories based on secondary, tertiary and disinfectant treatment types. Pond and nitrification/denitrification treatments were considered separately from other types of secondary treatment types because they are significantly different from other treatments and could have an effect on effluent methylmercury concentrations. The categories were internally reviewed and verified by multiple Board engineers in the NPDES permitting unit who are very knowledgeable about WWTP treatment processes. Each WWTP that submitted effluent methylmercury data was assigned to one of these 10 categories and the data for all of the WWTPs in each category were grouped together for the analysis. Differences between the treatment categories were analyzed using a nonparametric multiple comparison procedure and the results were presented in the report. Staff allowed for the robust statistical test used to conclude the differences between the treatment categories and did not bias the test and results in any way. A similar procedure was used to compare effluent:influent methylmercury ratios, effluent inorganic Mercury:methylmercury ratios and the 3 secondary subcategories within the "Secondary + C/D" and "Filtration + C/D" categories.

- **The last paragraph of the report is of great concern (pg 38, 39): "additional monitoring studies and pilot projects". To require municipalities, under the auspices of AB13267, to provide personnel and funding to support this massive data acquisition could be problematic. Due to the limited resources and reduced budgets we are operating under, it would present real challenges to support this project both financially and from a personnel standpoint. Sampling for these constituents and performing the associated analyses is very expensive.**

R-10: The full paragraph (pg 38, 39) is: "Several Central Valley WWTP staff and consultants have noted that it would be very helpful to establish a working group that coordinates efforts between CVCWA, San Francisco Bay area facilities, and other regional efforts to develop more detailed analyses of the existing information, further evaluate treatment processes, and design additional monitoring studies and pilot projects. Board staff is supportive of this concept and will work with dischargers and working groups to design and review studies." Board staff appreciates the financial and personnel challenges of conducting additional studies and pilot projects. It is possible that this report's results may be used to support additional studies during the implementation phase of the Delta mercury control program and other upstream mercury control programs. As noted in the February 2008 draft Basin Plan amendment staff report[1] and in later responses to public comments,[2] Board staff recommends that, during the implementation phase of the Delta mercury control program, entities responsible for point and nonpoint sources conduct collaborative and coordinated control studies. During the time of this report, Board staff has been working with stakeholders to develop an efficient and cost effective mercury control program.

[2] Available at: http://www.waterboards.ca.gov/centralvalley/water_issues/tmdl/central_valley_projects/delta_hg/stakeholder_meetings/25nov08_hearing_rtc.pdf

- **Our overarching concern is that further study and/or further regulation of WWTPs regarding methylmercury will not reduce the concentrations of mercury in fish tissue. It is important to provide a clear conclusion on this point in this report. As research has shown, and the authors actually cite in the second sentence of the Executive Summary, methylmercury only accounts for 1% of all mercury discharged to the Delta. Therefore removing 100% of the 1% isn't even statistically significant and wouldn't begin to address the problem. Also it should be noted, that all the WWTPs that discharge to the Delta account for less than 2% of the total mercury in the Delta. Again if 100% of the 2% were removed, no significant impact in reducing the mercury in the Delta would be realized.**

R-11: Of the approximately 400 kg inorganic Mercury that enters the Delta each year, about 2.2 kg is methylmercury. Although methylmercury is less than 1% of all mercury discharged to the Delta, methylmercury is the form that accumulates in the food web. If there were no methylmercury in Delta waters (i.e., if the 1% of all mercury discharged to the Delta that is in the form of methylmercury were demethylated), there would be no fish impairment.

The best available science indicates that reducing methylmercury in ambient water is the most direct way to reduce methylmercury in biota. Methylmercury is produced by many modern-day activities that humans may be able to modify so that less methylmercury is discharged. The Delta control program could focus on reducing methylmercury sources by reducing the inorganic mercury that supplies the methylation sites (i.e., reduce the inorganic mercury levels in Delta sediments by reducing discharges from mine sites and other legacy and modern sources) and by managing the methylation sources themselves to reduce methylmercury discharges. As part of their recommendations for a Delta mercury control program, Board staff recommended that WWTPs, MS4s, wetlands, irrigated agriculture, and new water management activities evaluate and develop management practices to reduce their methylmercury loads, such that each takes responsibility for its contribution to the impairment. As noted earlier, staff does not recommend that every individual NPDES, MS4, and agricultural and wetland landowner individually conduct a study, but instead recommends coordinated studies.

The stakeholder process for the Delta mercury control program will be developing an adaptive management approach to address the methylmercury impairment. Without the completion of point and nonpoint methylmercury control studies, it is not yet possible to define which sources are "important" or "insignificant" or which are feasible or make sense to control. When discussing the importance of different sources, many stakeholders have focused on the amount of loading by source category and by individual discharge. However, there are additional factors that should be considered. Given the number of individual discharges there are in each source category in the Delta, almost all of the individual discharges are small. Although the tributary inputs are substantial, available information indicates that they also contain a similar distribution of individual discharges. As determined as early as 1997 in the Sacramento River Mercury Control Planning Project report prepared for SRCSD by Larry Walker Associates, "… mercury sources in the study area appear to be diffusely distributed without any significant "hotspots" …" (LWA, 1997, page 31). Examples of small discharges include most wastewater treatment plants (which comprise about 4% of methylmercury inputs to the Delta), individual farm fields, and wetlands where water flow is managed in discrete units. It is the sum of all of the individual discharges (point and non-point) in the Delta and its tributary watersheds that impairs the Delta. The "importance" or "insignificance" of different methylmercury and inorganic Mercury sources could be defined by: (a) their load, (b) their distance from an impaired area, (c) how big of a reduction is needed to achieve safe fish mercury levels in a given impaired area, (d) whether they can be controlled, (e) whether they can be controlled without impacting habitat or operational function, (f) the cost to control them, and (g) the resources available to the

responsible parties to implement controls. It is conceivable that the control program for the Delta will need to focus on just a few large projects in some watersheds, but many small projects in other watersheds, to reduce methylmercury levels throughout the Delta.

Please refer to the February 2008 draft Basin Plan amendment and Delta TMDL staff reports[3] and the follow-up document, "Staff's Initial Responses to Board and Stakeholder Questions and Comments at the April 2008 Hearing"[4], for additional discussion on this topic.

4. Linda Dorn (Business Citizen's Assistant), Sacramento Regional County Sanitation District, Sacramento River and Walnut Grove WWTPs (CA0077682 and CA0078794) – Letter dated January 15, 2009

SRCSD submitted two letters (attached), which included three lab reports, to the RWQCB within the required monitoring period. The three sampling dates are: 12/29/2004, 1/20/2005, and 4/6/2005. The data presented in the report only includes two sampling results rather than the three submitted. The sample result for 12/29/04 is missing. Including this result will decrease the average effluent methylmercury concentration from 2.16 ng/L to 1.69 ng/L. The average methylmercury concentration in discharge is presented in Tables 18 and 19 of the administrative draft of the staff report.

R-12: The sample collected on 29 December 2004 was excluded from calculations made in the report because the hold time between collection and preservation exceeded 60 hours. This is consistent with all other samples that exceeded 60 hours hold times. The effluent sample collected on 29 December 2004 arrived at Frontier Geosciences on 3 January 2005 and was preserved with acid upon receipt. This is approximately 120 hours between collection and preservation. USEPA Method 1630 (methylmercury analysis in water) requires samples to be preserved with acid within 48 hours to a pH of less than two. Acid preservation stops the bacterial activity in the water that produces methylmercury from inorganic mercury. Samples without preservation may not be representative of the conditions at the time of sampling if bacterial activity continues after sampling. Therefore, staff excluded data for all samples whose hold times exceeded 60 hours.

5. Lysa Voight PE (Senior Civil Engineer), Sacramento Regional County Sanitation District, Sacramento River and Walnut Grove WWTPs (CA0077682 and CA0078794) - Letter dated March 18, 2009

Page 116, Figure 25 and Page 122 Figure 29B: SRCSD requests that a note be added to the figures indicating that three points of data were provided, but only two were used in this report for the SRCSD Walnut Grove WWTP. This might also be explained in section 3.6 anomalous values. A suggested wording for the footnote is: "Three data points were provided, but only two data points were used. The third data point was not considered in this report due to receipt of the

[3] Available at: http://www.waterboards.ca.gov/centralvalley/water_issues/tmdl/central_valley_projects/delta_hg/staff_report_feb08/index.shtml

[4] Available at: http://www.waterboards.ca.gov/centralvalley/water_issues/tmdl/central_valley_projects/delta_hg/stakeholder_meetings/25nov08_hearing_rtc.pdf

sample beyond the 48 hour holding period at an elevated temperature as noted on the lab's transmittal memo."

R-13: Staff added a new table (Table 11) to the report to provide the methylmercury data that were excluded from the report's calculations due to quality control concerns (e.g., hold time exceedances greater than 60 hours and laboratory contamination). This table includes the effluent sample collected at SRCSD Walnut Grove WWTP on 29 December 2004. Section 3.2 (page 13) in the revised report refers to Table 11. Samples that do not meet quality control requirements may not be representative of the conditions at the time of sampling. Therefore, including excluded data in calculations could be misleading.

P.22: The statement "Municipal WWTPs may contribute significant methylmercury loads to receiving water" perpetuates the misperception that WWTPs are major sources of the total methylmercury to the river. This report and its analysis are focused on NPDES permit holders which are a small portion of the total and methylmercury loading. All loads to receiving water are not compared in this report so care should be used when referencing whether or not WWTP loading is significant. A more appropriate statement that SRCSD suggests is: "Municipal WWTPs appear to contribute a greater methylmercury load to receiving water when compared to the other permitted sources investigated in this report but are a small fraction of the total and methylmercury load in the Sacramento River and the Delta."

R-14: Staff edited the beginning of Section 4.2.

P.29-30: The paired influent-effluent samples should be qualified more by mention of the following note that SRCSD recommends adding to the second paragraph of page 30: "The paired samples do not necessarily represent the same parcels of water due to in-plant residence time."

R-15: Staff added the suggested text to the report.

P.38: An additional question that might be addressed by future analysis is suggested as follows: "Do other factors impact reported concentrations, such as sampling protocols including location, time of day, holding time, composite vs. grab samples?"

R-16: Staff added the suggested text to the report.

Executive Summary: SRCSD suggests that the following comment be added to the executive summary so that readers understand the relationship between discharge and receiving waters: "The concentration of mercury and methylmercury in waters is dynamic. Mercury methylates and demethylates as a function of several factors including the characteristics of the effluent stream and the characteristics of the receiving waters. The mercury/methylmercury inter-relationships are currently being studied by various stakeholders but are not fully understood at the time of the completion of this report."

R-17: Staff edited the Executive Summary.

6. Airy Krich-Brinton, Larry Walker Associates – Email dated June 11, 2009 sent to Michelle Wood (Environmental Scientist, Central Valley Water Board)

I have been using the data file you sent and checking the statistical calculations shown in the methyl mercury report, and I have a question. In Table 24 (and similar tables), the title indicates that a Kruskal-Wallis Multiple Comparison was performed on median values. However, that test only produces a single p-value, and the table is populated with multiple p-values, one for each

treatment category pair. Can you explain further how those p-values were calculated? The footnote states that they are two-sided significance levels multiplied by 36, but it does not tell how the significance levels are determined (what test was used). Can you help me find out which test was used to calculate the p-values in tables like Table 24?

R-18: Table 24 and similar tables report the p-values for the Kruskal-Wallis Multiple Comparison test run in the Statistica software. Basically, you run a Kruskal Wallis test and if you find that there are significant differences between medians then you have to run a multiple comparison test to identify which medians are responsible for the statistical difference. The documentation from Statistica (see attached) is the best way to determine the type of multiple comparison test used. Most likely it is a Dunn's comparison procedure. With Statistica you can set the test for a default p value. We used a traditional value of $p < 0.05$ as the cut off. However, the program will give you actual p-values, which is what we reported. Also, Table 24 and similar tables report two p-values for each pair comparison, which are actually identical when looking closely. We set the table up this way to make it easier to identify the p-values for a particular pair of treatment categories. [Response provided in a 12 June 2009 email.]

7. Lysa Voight PE (Senior Civil Engineer), Sacramento Regional County Sanitation District, Sacramento River and Walnut Grove WWTPs (CA0077682 and CA0078794) – Letter dated June 15, 2009

Thank you for the opportunity to review the final version of the subject document and for taking into account our comments from the previous draft version of the document. The following comments are being provided by SRCSD to help put the report's findings in a context that is useful for policy and regulatory efforts such as the Delta Mercury TMDL.

In the Executive Summary and in the Introduction, the low aggregate contribution of methylmercury to the Delta by NPDES permitted facilities should be clearly stated. The report refers to the relative contributions from different NPDES permitted sources, but does not provide important information regarding the numerical or quantitative significance of the sum of the point sources in the Delta relative to the entire methylmercury impairment.

R-19: The Administrative and Public Review drafts of this report focused on a review of effluent methylmercury concentrations and did not attempt to calculate effluent methylmercury loads for the more than 100 facilities in the Central Valley. However, staff agrees that having load estimates will be useful for the Delta and upstream TMDL development efforts. To address SRCSD's comment, staff added a new chapter to the report (Chapter 5) that includes a method for calculating methylmercury loads discharged by NPDES facilities within the Delta and its upstream watersheds, and compares the sum of those loads to overall methylmercury loading to the Delta by watershed.

Page 22, Section 4.2: The report cites older data for the SRWTP and states that methylmercury loads as a percentage of receiving water loads "was as high as 30 to 43% during the warm seasons of 2001 and 2002". Page 91 of the report shows a graphical representation of the percentage of methylmercury in SRWTP discharge compared to the Sacramento River. The two points selected for discussion are not typical values for the stated time period. Many of the points reported for years 2000-2006 indicate the SRWTP contribution to methylmercury is under 10%.

R-20: The entire sentence in the report is, "For example, a six-year comparison of the SRCSD Sacramento River WWTP effluent methylmercury loads as a percentage of its receiving

water loads was as high as 30 to 43% during the warm seasons of 2001 and 2002 and less than 1% during the wet seasons of 2005 and 2006 (Figure 4; Bosworth, 2008), ranging from 4.2% to 17% on an annual basis." The purpose of the text is to highlight the range of conditions as well as typical conditions. Also, although the three high points mentioned in the text (30%, 31%, and 43%) are not typical values, they are not anomalously high, given that there were 14 other points that fell between 20% and 30%. No changes were made to the text.

In the absence of an actual conclusive analysis, a general statement regarding the ability to reduce methylmercury levels in water through point source controls is questionable.

R-21: Staff assumes that SRCSD is referring to the sentence that follows the above mentioned percent range, at the end of the last paragraph on Page 22 of the draft report: "For some receiving waters, reducing municipal WWTP methylmercury discharges, along with other point and nonpoint sources, may be an important component in reducing methylmercury levels in water." Staff was careful to include both point and nonpoint sources in this general sentence. Until the proposed Phase 1 control studies are conducted, we cannot know for certain which point and nonpoint sources can be feasibly and reasonably reduced. However, it seems reasonable to note that reducing municipal WWTP methylmercury discharges may be an important component, especially for individual water bodies that are dominated by effluent from municipal WWTPs or for which municipal WWTP discharges comprise a substantial source. For example, the Sacramento River is the largest river in California and drains a 27,000 square-mile area – almost one fifth of the State of California and about one half of the Central Valley – that contains numerous reservoirs and a myriad of point and nonpoint sources downstream of the reservoirs. As noted as early as 1997 in the Sacramento River Mercury Control Planning Project report prepared for SRCSD by Larry Walker Associates, "… mercury sources in the study area appear to be diffusely distributed without any significant "hotspots" …" (LWA, 1997, page 31). As a result, any individual discharge from a point or nonpoint source that provides a notable percentage (e.g., more than 1%) of methylmercury loading to the Sacramento River warrants evaluation.

It should be noted in the report that methylmercury is not strictly bioavailable mercury nor is it conservative.

R-22: Staff edited the Introduction to reflect that methylmercury is the most bioaccumulated form of mercury, rather than most bioavailable. In addition, staff added text to further describe degradation processes, as well as how in some waterways processes of methylmercury production and transport downstream in the water column are dominant and in others, processes that remove methylmercury from the water column such as photodegradation and sedimentation are dominant, and included the results of SRCSD's 2008 Localized Mercury Bioaccumulation Study.

The Water Environment Research Foundation (WERF) recently completed a study of mercury bioavailability discharged from conventional municipal wastewater treatment plants. The WERF research is part of the difficult process of understanding the relationship between total mercury methylmercury and bioavailable mercury, all of which should be considered when evaluating the TMDL.

R-23: Staff agrees and, in response to this comment, staff added the following text to Chapter 6: "… at the time this report was receiving final review, reports for Phases 1 and 2 of the WERF-funded project, "Estimation of Mercury Bioaccumulation Potential from Wastewater

Treatment Plants in Receiving Waters", were released (Dean and Mason, 2009a and 2009b). This project assessed changes in mercury bioavailability in wastewater effluents and receiving waters and developed a guidance document for wastewater treatment professionals who want to assess the bioavailability of mercury in their wastewater, compare it to other point and nonpoint sources, and assess changes in bioavailability in their effluent when it is mixed in a receiving water body. The Phase 1 and 2 reports should be considered by future wastewater analyses and control studies, as well as when the Delta mercury TMDL control program goes through future reviews."

SRCSD previously commented with an objection to the use of the term "significant positive relationship" between paired influent and effluent data with low R^2 values (low model reliability). The Regional Board responded by stating that the low p-values associated with the results allow this term. While it is correct to say that a low p-value indicates statistical significance, the low R-values indicate that the fit of the model cannot be trusted more than "R-value" percent of the time. Thus, the model is not a good predictor on an individual basis.

R-24: Staff assumes that SRCSD is referring to the comment made by Art O' Brien (Wastewater Utility Manager, City of Roseville), and staff's response regarding how paired influent/effluent data with low R^2 values can have low p-values, indicating statistical significance (staff response R-6, page 192 in this appendix). As noted in staff's response, staff agrees that there is a weak relationship between influent methylmercury and effluent methylmercury indicated by the low R^2 values, and further that influent methylmercury concentration alone is not a good predictor of effluent methylmercury on an individual basis. This is why staff had included the following text in earlier drafts, "…7-13% of the variability in effluent methylmercury concentrations was explained by influent concentrations, indicating that effluent concentrations were affected by other factors as well." Staff added the word "substantially" ("were substantially affected") in attempt to more clearly indicate that staff is not stating that influent methylmercury alone is a good predictor, and carefully included similar text wherever low R^2 values were associated with paired data that also had low p values.

Our New Evolution in Wastewater Treatment

Regional San is undertaking a monumental effort—called the EchoWater Project—to take our region's wastewater treatment to a whole new level.

In 2010, Regional San was issued stringent new treatment requirements from the State of California that require us to make the most significant upgrade to our wastewater treatment plant since its original construction. This new system, which must be in place by 2021-2023, will produce cleaner water for discharge to the Sacramento River, as well as for potential reuse as recycled water (e.g., for landscape and agricultural irrigation).

We're calling this major upgrade the "EchoWater Project" to reflect how it will take our wastewater and return it to a clean, natural state—much like an "echo" returning to its original source.

The EchoWater Project is among the largest public works projects in Sacramento's history. When completed, it will keep Regional San in compliance with its regulatory permits and improve water quality by resulting in a nearly 95 percent reduction in ammonia discharged to the Sacramento-San Joaquin River Delta. Ultimately, EchoWater will be capable of meeting our region's needs and protecting our region's waterways for generations to come.

Construction Underway

The project is now in the construction phase—get current construction updates here.

Low-Interest Financing Approved

In early April, the project was approved to receive nearly $1.6 billion in low-interest financing from the State of California's Clean Water State Revolving Fund. The favorable loan terms will save ratepayers more than a half billion dollars in interest costs. Read more here.

This low-interest financing for the EchoWater Project has been provided in part by the Clean Water State Revolving Fund through an agreement with the State Water Resources Control Board. The contents of this document do not necessarily reflect the views and policies of the State Water Resources Control Board, nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

EchoWater Fact Sheet

☐ View the Fact Sheet

Regulatory Permit Conditions

For all wastewater treatment plants, the level of treatment required before the water can be released back into the environment is dictated by a National Pollutant Discharge Elimination System (NPDES) permit. For Regional San, this wastewater discharge permit is issued by the Central Valley Regional Water Quality Control Board (Regional Water Board), the state agency that regulates wastewater dischargers in our region.

New Treatment Processes

Regional San's 2010 discharge permit contains strict mandates that require us to construct costly new "tertiary" treatment processes for ammonia and nitrate removal, filtration and enhanced disinfection:

Ammonia and nitrate removal: Using a process called "biological nutrient removal" (BNR), this will eliminate nearly all ammonia and most nitrate from the effluent (treated water), addressing concerns about possible impacts these constituents may have on the ecosystem, both here and downstream.

Impacts to Customer Rates

The requirements of our new discharge permit will cost our region's ratepayers about $1.5-2.1 billion to build. On top of that, about $50 million per year in ongoing maintenance and operations costs are anticipated.

Gradual annual rate increases to fund these improvements have already begun and will continue to be necessary until the project is completed in 2021-2023. For more information on the anticipated rate impacts of the EchoWater Project, please visit Monthly Rates.

On March 7, 2001, the State Water Resources Control Board (State Water Board) adopted a precedential decision on two refinery permits. The decision, in Order WQ 2001-06, addresses "interim permits." Interim permits are permits that regulate pollutant discharges to waters identified on the Clean Water Act section 303(d) impaired waters list prior to TMDL (total maximum daily load) development.

The two permits under review contained 10-year compliance schedules for impairing pollutants (except for dioxin and furan compounds). The schedules were based on the schedules for TMDL development. The permit findings stated that final water quality-based effluent limitations for these pollutants would be based on waste load allocations in the TMDLs. The permits also included alternative final limits findings, stating that if TMDLs were not available, final limits for bioaccumulative pollutants would be "no net loading" and for non-bioaccumulative pollutants would be the applicable criterion or water quality objective applied end-of-pipe. The permits also included interim, performance-based effluent limitations regulating both the mass and concentration of impairing pollutants.

On interim permitting, the State Water Board held:

- A Regional Water Quality Control Board (Regional Water Board) cannot rely solely on a Section 303(d) listing as the basis for concluding that a receiving water lacks assimilative capacity for an impairing pollutant. Rather, the Regional Water Board must base assimilative capacity determinations on the relevant water quality-related data. This includes the data supporting the 303(d) listing.

- Under the circumstances, the alternative final limits findings were unnecessary and inappropriate. The decision held that a finding stating that final effluent limitations for impairing pollutants will be based on the wasteload allocations in the TMDLs satisfied the Clean Water Act requirement for water quality-based effluent limitations. The alternative final limits findings were inappropriate because the discharges were considered insignificant to the impairment, the alternative final limits may be technically infeasible, TMDLs appeared to be the most appropriate method to address the problems, and development of TMDLs appeared to be on schedule. In addition, the decision held that the State Water Board's Policy for Implementation of Toxics Standards for Inland Surface Waters, Enclosed Bays, and Estuaries of California (2000) does not require alternative final limits findings for TMDL-based compliance schedules for priority pollutants.

- Interim, performance-based mass limits, in the context of a compliance schedule, are legal.

- Interim, performance-based mass limits for impairing pollutants that are discharged by industrial facilities at concentrations above the applicable criteria/objectives are a reasonable step to preserve the status quo pending TMDL development. The decision does not address interim mass limits for publicly owned treatment works (POTW) permits.
- Regional Water Boards should calculate interim, performance-based mass limits, by developing frequency distributions from available, representative data. The Regional Water Boards can select the percentiles or number of standard deviations, based on balancing the risk of a violation with the need to protect receiving water quality.

The decision also addressed other topics. These included the need for effluent limitations for pollutants not detected in the effluent, pollution prevention plans, antibacksliding, and a compliance schedule for dioxin and furan compounds. The decision held that it was inappropriate to include effluent limitations in permits for pollutants that were not detected in the effluent because all detection limits were above the applicable criteria or objectives, absent any additional information that the pollutants were expected to be present.

Regarding the Migden bill (Water Code § 13263.3), the decision held that permits could require that dischargers prepare pollution prevention plans but cannot require that they "implement" the plans. Additionally, it is inappropriate for permits to require these plans for the pollutants discussed in the preceding paragraph (i.e. pollutants not detected and not expected to be in the effluent).

On antibacksliding, the decision held that the proscription does not apply to interim limits in a compliance schedule.

The decision also held that the regional water quality control plan (basin plan) provision authorizing compliance schedules for new criteria or objectives could be interpreted to allow compliance schedules for new interpretations of existing objectives. One permit contained a 12-year compliance schedule for dioxin and furan compounds. The basin plan allowed compliance schedules of up to 10 years. Therefore, the compliance schedule length had to be revised.

Abstract: Effects of mercury (Hg) on birds have been studied extensively and with increasing frequency in recent years. The authors conducted a comprehensive review of methylmercury (MeHg) effects on bird reproduction, evaluating laboratory and field studies in which observed effects could be attributed primarily to Hg. The review focuses on exposures via diet and maternal transfer in which observed effects (or lack thereof) were reported relative to Hg concentrations in diet, eggs, or adult blood. Applicable data were identified for 23 species. From this data set, the authors identified ranges of toxicity reference values suitable for risk-assessment applications. Typical ranges of Hg effect thresholds are approximately 0.2 mg/kg to >1.4 mg/kg in diet, 0.05 mg/kg/d to 0.5 mg/kg/d on a dose basis, 0.6 mg/kg to 2.7 mg/kg in eggs, and 2.1 mg/kg to >6.7 mg/kg in parental blood (all concentrations on a wet wt basis). For Hg in avian blood, the review represents the first broad compilation of relevant toxicity data. For dietary exposures, the current data support TRVs that are greater than older, commonly used TRVs. The older diet-based TRVs incorporate conservative assumptions and uncertainty factors that are no longer justified, although they generally were appropriate when originally derived, because of past data limitations. The egg-based TRVs identified from the review are more similar to other previously derived TRVs but have been updated to incorporate new information from recent studies. While important research needs remain, a key recommendation is that species not yet tested for MeHg toxicity should be evaluated using toxicity data from tested species with similar body weights. *Environ Toxicol Chem* 2017;36:294–319. © 2016 SETAC

Keywords: Methylmercury Avian toxicity Ecological risk assessment Reproductive toxicity Wildlife toxicology

INTRODUCTION

Effects of mercury (Hg) on the survival and reproduction of birds have been studied extensively over the last 50 yr [1–3]. Birds can be among the most highly exposed organisms in Hg-contaminated areas as a result of biomagnification of methylmercury (MeHg) through the food web, particularly in aquatic systems. Early research on the effects of Hg on birds was initiated by evidence of bird fatalities related to the use of Hg (often MeHg dicyandiamide) as an agricultural seed dressing [4,5]. With the decline in agricultural Hg uses, ecological risk assessments for Hg now more typically focus on diffuse regional contamination related to atmospheric transport and deposition of Hg and on industrial or mining sites where Hg remains in soil or sediment from historical activities. In its contaminated sediment remediation guidance, the US Environmental Protection Agency (USEPA) [6] estimated that Hg wholly or partially drove decisions at more than 15% of sediment sites remediated under the US Superfund program. Artisanal gold mining is also of concern as an ongoing source of Hg contamination in Africa and South America [7,8].

The predominant practice for predicting risks of adverse effects of Hg on birds involves measuring or estimating Hg exposure in a population of interest and then comparing that exposure to 1 or more toxicity reference values (TRVs). Depending on the application, a TRV may be an exposure level previously shown or estimated to be without deleterious effects, or it may represent a low level of adverse effects. In most cases, TRVs are derived from the peer-reviewed scientific literature, although site-specific avian studies may be conducted to derive TRVs for sites where data indicate that Hg bioaccumulation may be limited by site-specific conditions or where the accuracy of predicted risks has large financial consequences. As an example of the consequences of TRV selection, the Oregon Department of Environmental Quality [9] advises that where Hg concentrations exceed background levels in sediment and specified "acceptable tissue levels" in fish, sediment remedial action should be evaluated. However, sediment remediation, particularly dredging, can itself result in adverse environmental effects as a result of aquatic and riparian habitat disturbance, increased contaminant bioavailability and exposure from sediment resuspension and transport, and carbon emissions from heavy equipment and dredged material transportation. If a TRV is inaccurate, perhaps because it is based on data from an outdated or low-quality study, then significant risks may be overlooked or risks may be significantly overestimated leading to unnecessary environmental costs, which can be substantial.

Extensive data have become available over the past decade to inform the development of Hg TRVs for avian risk assessment. In addition to new studies on aquatic-feeding species [10–14], songbirds have increasingly become a subject of investigation [15]. Another recent development is increasing reliance on blood Hg analyses as a primary tool for monitoring avian Hg exposures [13,14]. Many of the recent studies reflect improvements in study design, analytical methods, effects endpoints, and statistical interpretation compared with older studies that

DOI: 10.1002/etc.3606

historically have been relied on for TRV derivation. In this context, a critical review is warranted to support updated TRVs.

The present article reviews avian ecotoxicology data for Hg, focusing on reproduction as a sensitive endpoint that is directly related to the maintenance of wild bird populations. We comprehensively reviewed the relevant literature and developed criteria for study inclusion in the TRV data set. Because extrapolation of toxicity data to new contexts is inherent in the ecological risk-assessment process, we also reviewed issues relevant to understanding similarities and differences among studies and among species. Based on these findings, we identified ranges of effect thresholds for Hg-related reproductive impairment in birds. These threshold ranges are reviewed in comparison with previously developed TRVs as well as with estimates of naturally occurring, preindustrial background Hg concentrations in avian prey.

LITERATURE REVIEW METHODS

Avian toxicity studies and related literature were identified using Google Scholar and other online searches, reference lists of relevant articles, and direct inquiry to researchers. The literature review methodology was consistent with the principles of systematic review [16], including application of criteria for study inclusion and exclusion; evaluation of the strengths, uncertainties, and potential biases of each study; identification of confidence ratings for each study result; meta-analysis of data where applicable; and transparent documentation of findings. Criteria for inclusion of avian toxicity studies were based on the type of effect measured, specificity in attributing the observed effect to Hg exposure rather than to other stressors, chemical form of Hg, exposure pathways, exposure measures, and data quality. Paired exposure and effects data were compiled for the studies that met the designated criteria.

Study inclusion criteria

Effect endpoints. All studies included in the data compilation measured effects of Hg on reproduction, reflecting a focus on potential population-level effects. Broadly speaking, population success depends on the successful reproduction and survival of individuals, and reproductive effects are more sensitive than mortality in Hg-exposed birds [17,18]. Growth is also sometimes considered for TRV development, but growth effects in Hg-exposed birds are not particularly sensitive [19–21]; and from a population perspective, growth is primarily of interest as a surrogate for reproductive fitness. An alternative option would be to include data for survival, growth, and reproduction in the TRV derivation process [22]; but this approach can add uncertainty if safety factors are applied to results for less sensitive endpoints. For Hg, the available data for avian toxicity are sufficiently robust to support TRVs based specifically on reproductive effects. Although effects on reproductive success can be mediated by various mechanisms (e.g., behavioral or physiological effects), our focus is on the net effect of such processes on reproductive outcomes.

Where available, we considered production of independent offspring (e.g., number surviving through fledging) to be the preferred measure of reproductive success. This endpoint integrates effects on various components of the reproductive process (i.e., fertility, clutch size, hatching success, and fledging success) and is most directly relevant to protection of bird populations. If no measure of the production of independent offspring was reported, we considered various measures of offspring survival, hatching success, fledging success, or nest success. A successful nest is typically defined as a nesting attempt that produces at least 1 fledgling, although in some cases nest success is reported based only on successful hatching of at least 1 egg [23]. Studies that considered multiple avian reproductive endpoints suggested that fecundity expressed as clutch size is relatively insensitive to Hg exposure [4,24,25]; for this reason, studies that evaluated egg production but no other reproductive endpoints were excluded.

Causality. We compiled data from studies where observed effects (if any) could be attributed solely or primarily to Hg exposure, including both controlled experiments and field studies. Although there are unavoidable uncertainties associated with both laboratory and field studies, each provides unique and useful information. Laboratory studies provide controlled conditions to isolate MeHg as the cause of any observed effects. However, laboratories cannot fully replicate natural conditions, and laboratory artifacts can interfere with the interpretation of results. Field studies directly examine effects in the wildlife population of interest, but observed effects may be fully or partially caused by other stressors, such as co-occurring chemicals, low prey availability, poor habitat, depredation, or competition. These factors complicate the attribution of observed adverse effects to Hg and, conversely, can contribute to high variability, which can hinder detection of adverse effects. To assess whether Hg is causing adverse effects in the field, investigators should conduct an equally thorough and transparent analysis of all reasonable candidate causes [26], considering factors such as strength and consistency of association and biological plausibility [27]. Few field studies include any investigation of causality. However, field studies designed to detect effects related to Hg-contaminated sites generally involve observations across a site-related gradient of Hg exposure in which habitat and prey types are intended to be similar in Hg-contaminated and reference locations. Causality is more uncertain in cases where gradients in Hg exposure among birds are not a function of a localized contaminant source but rather a function of factors that influence Hg methylation and/or bioaccumulation (e.g., lake pH, primary productivity, availability of different prey types). For this reason, most of the studies that present a reasonably compelling case for effects caused by Hg were designed to investigate Hg-contaminated sites.

Field studies were excluded from the review if dichlorodiphenyldichloroethylene (DDE) or other chemicals probably caused or contributed substantially to observed effects [28–41], except in 1 case where the authors were able to establish a Hg egg concentration below which adverse effects were not expected despite the observation of DDE-related effects [42]. Certain other studies also were excluded even though Hg was associated with reproductive differences and other chemicals were not identified as likely toxicants. In a study of Bonelli's eagles (*Aquila fasciata*), Ortiz-Santaliestra et al. [43] found greater Hg exposures associated with nests supporting single chicks compared with nests with multiple chicks. This difference was attributed to the confounding effect of coincidentally lower Hg concentrations in the eagles' preferred prey; where the preferred prey species was less abundant, fewer chicks could be supported [43]. We also excluded a study of Hg effects on Acadian flycatchers (*Empidonax virescens*) in central Ohio [44] because the authors did not sufficiently evaluate whether habitat conditions contributed to effects on fledgling production that were marginally correlated with Hg exposure, despite demonstrated adverse effects of urbanization on this species' reproductive success in the same study area [45]. Finally, we excluded studies of black-legged kittiwakes

(*Rissa tridactyla*) in Svalbard, Norway [46,47]. Average prebreeding blood Hg levels were greater in birds that did not breed compared with those that bred; but the differences in average Hg levels between birds with different reproductive outcomes were very small (approximately 0.05 mg/kg wet wt), and there was a high degree of overlap in Hg levels between the 2 exposure groups. Therefore, it appears that Hg is at most a cofactor influencing reproductive outcomes in this kittiwake population. Such a result is consistent with effects related to diet and nutritional factors such as those observed by Ortiz-Santaliestra et al. [43].

Chemical form. In field studies, the form of Hg in avian diets is assumed to vary depending on the type of prey consumed. Mercury in fish is usually 95% to 100% MeHg [48,49], whereas the proportion of total Hg present as MeHg is lower and more variable in invertebrates [1,50,51]. We included controlled experiments in which Hg was administered as MeHg because this form of Hg is environmentally relevant and much more toxic and bioaccumulative than inorganic Hg. Specific MeHg forms included MeHg dicyandiamide, MeHg chloride, and MeHg cysteine. We excluded studies of inorganic Hg toxicity as well as studies using other organomercury forms (e.g., ethylmercury p-toluene sulfonanilide [52]). Total Hg exposures were identified for all field studies, as MeHg often was not measured; however, MeHg exposures are also noted in the data compilation, if measured. Mercury in bird eggs and blood is assumed to be almost exclusively MeHg [53,54].

Exposure pathways. The present review includes studies in which Hg exposures occurred via diet and/or via maternal transfer. Studies using egg injection to expose bird embryos to Hg were excluded because injected MeHg induces adverse effects at lower concentrations than maternally transferred Hg [55,56]. Egg injection is not an environmentally relevant exposure pathway in wild bird populations. Studies that applied Hg externally to eggs also were excluded because the absorbed dose cannot be determined and because it is unknown whether this exposure method would produce dose–response relationships comparable to those observed for Hg exposure via maternal transfer.

Exposure measures. We considered studies in which Hg exposure concentrations were reported for diet, eggs, or parental blood. Food consumption is the major pathway by which birds are exposed to Hg, and dietary Hg is often the primary measure of exposure characterized at Hg-contaminated sites. For laboratory studies, we used measured Hg concentrations if available; otherwise, nominal concentrations were used, and this study limitation is noted. For field studies, uncertainty in characterizing Hg exposure based on dietary Hg lies primarily in prey tissue sampling, which may imperfectly represent true avian dietary preferences. Egg Hg has the advantage of directly representing the exposure of embryos, a particularly sensitive life stage in birds. Parental blood Hg directly represents short-term Hg exposure of parents, with measurable changes occurring within weeks in response to changes in exposure [57]. Parental blood Hg concentrations during breeding provide a nondestructive measure of exposure that may be correlated with egg Hg exposures [14]. Parental blood Hg can also be related to behavioral effects on incubation or provisioning that may affect reproductive outcomes [58,59].

Although trends in avian Hg exposures are sometimes evaluated based on concentrations in feathers, this measure of exposure is generally a poor basis for TRVs. Deposition of Hg in feathers is a protective mechanism that sequesters Hg in nonliving tissue. Birds depurate Hg in their feathers only during feather growth; thus, Hg concentrations in the feathers of migratory birds that molt outside the breeding season reflect exposures in wintering grounds, rather than the more toxicologically important exposure incurred during the breeding season [60]. We also considered nestling blood Hg concentrations to be a poor basis for TRV development. Nestling and parental blood Hg concentrations are not comparable because of rapid nestling growth and MeHg depuration in growing feathers [61]. Too few studies are available to develop TRVs specifically for Hg in nestling blood; and, in any case, nestling blood Hg changes relatively rapidly during development [62], which would be expected to limit comparability among studies.

Data quality. All studies were reviewed for appropriate study design, documentation, and data quality. Although secondary references were reviewed, data were compiled only from primary references. Abstracts were not considered. The present review was consistent with the USEPA's [63] assessment factors for evaluating the quality of scientific information, which include soundness (i.e., the extent to which the study design and methods are appropriate to the researchers' intended application), applicability and utility (i.e., the extent to which the study is appropriate to our intended application), clarity and completeness, appropriate consideration of uncertainty and variability (e.g., through statistical analysis), and evaluation and review by others. Consistent with USEPA guidance for evaluation of ecological toxicity data [64], control performance and documentation of test conditions were reviewed for laboratory studies. Additionally, field studies that lacked a comparable reference site or a wide exposure gradient were excluded because in such cases the study design did not provide a basis to determine whether reproductive outcomes differed from what would be expected in the absence of elevated Hg exposure (i.e., [37,65–73], also osprey [*Pandion haliaetus*] data from Anderson et al. [74] and double-crested cormorant [*Phalacrocorax auritus*] data from Henny et al. [75]).

Study interpretation

Paired exposure and effects data were compiled based on reported Hg concentrations in dietary items, eggs, or blood. We report all Hg concentrations on a wet weight basis. In some cases, it was necessary to estimate wet weight concentrations from dry weight data. If the wet or dry weight basis of Hg concentrations was not reported, we assumed a wet weight basis because that is the most common basis used in the scientific literature for reporting concentrations in biological tissue. All such estimates and assumptions are reported in Tables 1 and 2. Concentrations of MeHg were given stoichiometrically on the basis of Hg content.

Dietary exposures were compiled based on reported Hg concentrations in the diet (as milligrams of Hg per kilogram of food) and on a dose basis (as milligrams of Hg ingested per kilogram of body weight per day). Doses are often calculated in wildlife risk assessments to facilitate integration of exposures experienced through multiple exposure pathways (e.g., food ingestion and sediment ingestion) [76]. Doses were estimated as the product of dietary Hg concentrations and body weight–normalized food ingestion rates. In a few cases, study-specific food ingestion rates were available from Hg toxicity studies [25,77,78], but for most studies it was necessary to estimate a food ingestion rate for the species tested. Species-specific food ingestion rates were identified if available. Otherwise, food ingestion rates were estimated from body weights using regressions developed by Nagy [79] or Kushlan [80]. Adult female body weights were study-specific if available and

Table 1. Methylmercury effects on avian reproduction in controlled experiments

Species	Chemical form	Exposure duration	Diet Hg (mg/kg wet wt)	Hg dietary dose (mg/kg-d)	Egg Hg (mg/kg wet wt)	Parental blood Hg (mg/kg wet wt)	Reproductive endpoint	Effect[a]	Reference	Comments
American kestrel (*Falco sparverius*)	Methylmercury chloride	ca. 60 d	0.16	0.05	1.3	2.5	Expected number of fledglings	EC20	[24]	Blood concentration estimated from diet–blood regression [163]. Exposure to Hg through incubation only. Moderate confidence.
Zebra finch (*Taeniopygia guttata*)	Methylmercury cysteine	2 generations	0.75	0.24	2.7	10	Average no. of offspring	EC20	[85]	Fledging success was more sensitive than clutch size, hatching success, time to renest, and adult survival. Egg Hg from Ou et al. [164]. Companion study reported high intraspecies variability in Hg sensitivity [102]. High confidence.
Ring-necked pheasant (*Phasianus colchicus*)	Methylmercury dicyandiamide	12 wk	0.92	0.06	—	—	Surviving chicks/hen	EC20	[25]	No significant effects on chick mortality. Eggs incubated artificially; does not account for any effects related to incubation behavior. Diet Hg unmeasured. Wet or dry weight basis not reported, but uncertainty is minimal because of low moisture content of grain. Moderate confidence.
Ring-necked pheasant (*P. colchicus*)	Methylmercury dicyandiamide	6–9 d	—	—	0.8/1.35	—	Hatching success	NOAEL/ LOAEL	[4]	Constant dietary dose; egg concentrations increased and hatching decreased over time. Does not account for any posthatching effects. Moderate confidence.
Japanese quail (*Coturnix japonica*)	Methylmercury chloride	2 generations	3.3	0.4	3.9	—	Surviving chicks/egg laid	EC20	[86]	Egg production, fertility, and hatchability were less sensitive than chick mortality. Egg Hg from Eskeland et al. [87]. Egg Hg for experiment 2 estimated from reported concentrations in yolk and albumen. Eggs incubated artificially; does not account for any effects related to incubation behavior. Diet Hg not measured. Wet or dry weight basis not reported for diet or eggs; wet weight assumed. Moderate confidence.
Japanese quail (*C. japonica*)	Methylmercury chloride	16 wk	10	1.2	—	15	Surviving chicks/egg laid	EC80	[96]	Chicks not fed Hg diet; mortality was the result of maternal transfer only. Diet Hg unmeasured. Wet or dry weight basis not reported, but uncertainty is minimal because of low moisture content of grain. Parental blood Hg reported for males only. Moderate confidence.
Black duck (*Anas rubripes*)	Methylmercury dicyandiamide	2 breeding seasons	2.6	0.41	3.86	—	Surviving ducklings/pair	EC80–EC90	[165]	Diet Hg converted to wet weight assuming 10% moisture in feed. Moderate confidence.
Mallard (*Anas platyrhynchos*)	Methylmercury dicyandiamide	2 breeding seasons	2.5	0.4	5.0	5.2	Surviving ducklings/egg	EC20	[77,88–90]	Chick mortality associated with neurological signs of Hg toxicity [104]. No significant effect on fertility or hatching success. Eggs incubated artificially; does not account for any effects related to incubation behavior. Blood Hg estimated from egg–blood regression [166]. Moderate confidence.
Mallard (*A. platyrhynchos*)	Methylmercury chloride	71 d	9.3	1.5	16	17	Surviving ducklings/egg	EC20	[10,92]	Eggs incubated artificially; does not account for any effects related to incubation behavior. Blood Hg estimated from egg–blood regression [166]. High confidence.
Chicken (*Gallus gallus domesticus*)	Methylmercury dicyandiamide	54 d	4.6	0.27	9.5	—	Hatching success	EC70	[78]	Diet Hg (nominal) calculated from Hg in grain and proportion of diet as grain. Wet or dry weight basis not reported for diet, but uncertainty is minimal because of low moisture content of grain. Egg Hg calculated from average Hg mass per egg and egg mass. Moderate confidence.

[a]Doses and EC20s are derived in the present study. Other effects are as reported by authors.
ECx = x% effect concentration; Hg = mercury; NOAEL = no-observed-adverse-effect level; LOAEL = lowest-observed-adverse-effect level.

Table 2. Mercury effects on avian reproduction in field studies[a]

Species	Site and Hg source	Diet Hg (mg/kg wet wt)	Hg dietary dose (mg/kg-d)	Egg Hg (mg/kg wet wt)	Parental blood Hg (mg/kg wet wt)	Reproductive endpoint	Effect	Reference	Comments[b]
American dipper (*Cinclus mexicanus*)	Upper Willamette River watershed, Oregon, USA; mining source	0.04	0.02	0.04	—	Young/territory	NOAEL	[167]	Diet Hg converted from dry weight using study-specific moisture content. In invertebrate prey Hg was 57% MeHg. Small sample size. Unbounded NOAEL below range of effects for all species; limits utility for TRV derivation.
Western/Clark's grebe (*Aechmophorus occidentalis*/*A. clarkii*)	Clear Lake, California, USA; mining source	0.09	0.03	—	—	Young/nest	NOAEL	[74]	Diet Hg from Suchanek et al. [168]. Unbounded NOAEL below range of effects for all species; limits utility for TRV derivation.
Carolina wren (*Thryothorus ludovicianus*)	South River and North Fork Holston River, Virginia, USA; industrial sources	0.21	0.14	0.3	2.13	Nest success (production of ≥1 fledgling)	LOAEL	[110,128]	No significant difference in productivity among successful nests. Diet Hg from Northam et al. [169], converted from dry weight assuming 65% water content in aerial life stages of insects [76]. MeHg was 41% of total Hg in diet (weighted average) [170]. Egg concentration is the grand mean of average clutch Hg [128]. Blood Hg is the mean for 2010 females. Nest success was affected by both increased predation and nest abandonment. Small sample size. Moderate confidence.
Common loon (*Gavia immer*)	120 lakes in Wisconsin, USA, and New Brunswick and Nova Scotia, Canada; enhanced Hg methylation in low-pH lakes	0.21	0.05	2.6	4.3	Maximum productivity of 5-wk-old to 6-wk-old chicks/pair	Threshold	[13]	Quantile regression measured effects relative to maximum productivity; 50% decrease from maximum approximates a threshold for consistent effects. Egg concentration estimated from blood–egg regression [171]. Loons are potentially affected by a combination of Hg exposure and prey availability, both a function of lake pH [118]. Moderate confidence.
Tree swallow (*Tachycineta bicolor*)	6 sites, Maine and Massachusetts, USA; industrial and non–point sources	0.29	0.4	0.6	3	Hatching and fledging success	NOAEL	[12]	No effects on productivity observed across exposure gradient. Blood concentration estimated from blood–egg regression [172]. High confidence.
Tree swallow (*T. bicolor*)	South River, Virginia, USA; industrial source	0.34	0.5	0.63	3.0	Fledglings/nest	LOAEL ≈ EC20	[11,123]	Approximately 20% reduction in number of fledglings in 2 of 3 yr; parental blood Hg estimated as average of 3 yr; effects associated with adverse weather conditions. Attribution of effect to Hg supported by feather analyses of dead versus surviving nestlings [173]. Diet Hg converted from dry wt assuming 65% water content in aerial life stages of insects [76]. Egg concentration estimated from blood–egg regression [172]. Adult survival not affected [17]. High confidence.
Black-crowned night-heron (*Nycticorax nycticorax*)	Carson River, Nevada, USA; mining source	0.45	0.08	1.8	—	Young/nest	NOAEL	[75,174]	Hypothesized effect threshold of 0.8 mg/kg (egg) was not predictive of effects with egg Hg up to 1.8 mg/kg. Offspring production was lower in study area than reference area, but this was not attributed to Hg because of lack of exposure–response relationship for Hg in eggs. Diet Hg is average of stomach contents; effect of digestion on Hg concentration is uncertain. In stomach contents Hg was 98% MeHg. Moderate confidence.
Snowy egret (*Egretta thula*) (drought years only)	Carson River, Nevada, USA; mining source	0.46	0.09	0.8	—	Young/nest	Diet, dose: LOAEL; egg: threshold	[75,174]	Study tested utility of hypothesized effect threshold in eggs (0.8 mg/kg); sample size deemed too small to derive a study-specific effect threshold. Results consistent with hypothesized threshold primarily during drought years. Dietary exposure is based on 1997 stomach contents; in 1997, offspring production was lower in study area than reference area (reference data not reported for other years). Effect of digestion on Hg concentration is uncertain. In stomach contents Hg was 90% MeHg. Moderate confidence.

(*continued*)

Table 2. (*Continued*)

Species	Site and Hg source	Diet Hg (mg/kg wet wt)	Hg dietary dose (mg/kg-d)	Egg Hg (mg/kg wet wt)	Parental blood Hg (mg/kg wet wt)	Reproductive endpoint	Effect	Reference	Comments[b]
Osprey (*Pandion haliaetus*)	Northern Quebec, Canada; enhanced Hg methylation in reservoirs	1.4	0.29	0.22	—	Fledgelings/nest	NOAEL	[175,176]	Dietary concentration of 1.4 mg/kg represents grand mean of estimated exposures; maximum station-specific average prey Hg was 2.4 mg/kg, also with no observed adverse effect. Egg Hg is mean reported for all reservoir stations. In eggs and nestling stomach contents Hg was 90% to 95% MeHg. Prelaying dietary Hg exposure uncertain.[c] Moderate confidence.
Black skimmer (*Rynchops niger*)	Lavaca Bay, Texas, USA; industrial source	—	—	0.46	—	Young/nest	NOAEL	[177]	Offspring production was lower than in reference area, reflecting differential nest success. However, Hg concentrations were the same between nests where no eggs hatched and those where some or all eggs hatched, indicating no effect from Hg. High confidence.
Bald eagle (*Haliaeetus leucocephalus*)	Aleutian archipelago, Alaska, USA; military and non–point sources	—	—	0.5	—	Young/territory	NOAEL	[161]	Eight sites, no effect on productivity across exposure gradient. Egg Hg converted from dry wt assuming 80% moisture content. High confidence.
Bald eagle (*H. leucocephalus*)	Pinchi Lake, British Columbia, Canada; mining source	—	—	—	6.7	Chicks/territory	NOAEL	[61]	Small sample size. Moderate confidence.
American avocet (*Recurvirostra americana*)	San Francisco Bay, California, USA; mining source, enhanced methylation in saline areas	—	—	0.54	1.47	Hatching success and chick mortality	NOAEL	[14,162]	No difference in egg Hg between unhatched eggs and random eggs from successful nests. Sample size 382 eggs. Egg Hg estimated using feather–egg regression for chick down feathers [178]. Parental blood Hg from Ackerman et al. [179]. High confidence.
Merlin (*Falco columbarius*)	Mainland Britain, agricultural source; Orkney and Shetland Islands; source assumed food web–related	—	—	2/0.6	—	Nest success (production of ≥1 fledgling), brood size	NOAEL (islands)/ Threshold (mainland)	[109]	Mainland effect threshold based on breakpoint in dose–response data set. Nest success was 43% lower for nests with egg Hg above identified threshold; brood size also decreased above Hg threshold. Merlins on islands were unaffected. Basis for geographic difference in responses is uncertain; see text. Egg concentrations converted from dry wt using study-specific moisture content. Limited documentation of methods, $n = 55$ clutches. Moderate confidence.
Black-necked stilts (*Himantopus mexicanus*)	San Francisco Bay, California, USA; mining source, enhanced methylation in saline areas	—	—	0.74/1.2	1.5/2.6	Mortality of newly hatched chicks	NOAEL /LOAEL	[14,162]	Egg Hg estimated using feather–egg regression for chick down feathers [178]. Blood concentrations estimated from egg–blood regression [14].[d] Mean egg Hg was 0.74 mg/kg for newly hatched live chicks ($n = 79$) and 1.2 mg/kg for newly hatched dead chicks ($n = 14$). No effect on chick survival after immediate posthatching period. Hatching success also not affected. High confidence.
White-tailed sea eagle (*Haliaeetus albicilla*)	Baltic coast and Lapland, Sweden; regional non–point sources	—	—	1	—	Nest success (production of ≥1 hatchling)	NOAEL	[42]	Any effect of Hg at concentrations >1 mg/kg confounded by DDE. Does not account for any posthatching effects, $n = 57$ clutches. Moderate confidence.
Common tern (*Sterna hirundo*)	Wabigoon–English River system, northwestern Ontario, Canada; industrial source	—	—	1 / 3.65	—	Abundance of fledged young versus unhatched eggs	NOAEL/ severe effect level	[180]	Semiquantitative description; abundant fledged young at NOAEL ($n = 40$ nests), near complete reproductive failure at LOAEL ($n = 37$ nests). Moderate confidence.

(*continued*)

Table 2. (*Continued*)

Species	Site and Hg source	Diet Hg (mg/kg wet wt)	Hg dietary dose (mg/kg-d)	Egg Hg (mg/kg wet wt)	Parental blood Hg (mg/kg wet wt)	Reproductive endpoint	Effect	Reference	Comments[b]
Forster's tern (*Sterna forsteri*)	San Francisco Bay, California, USA; mining source, enhanced methylation in saline areas	—	—	1.4/1.8	3.1/4.2	Hatching success	NOAEL /LOAEL	[14]	Mean egg Hg was 1.4 mg/kg in random eggs from successful nests and 1.8 mg/kg in unhatched eggs (egg Hg adjusted to fresh wet wt basis). Does not account for effects on chick survival (if any). No effects observed on postfledging survival [18]. Blood concentrations estimated from egg–blood regression [14], $n = 298$ eggs. High confidence.
Forster's tern (*S. forsteri*)	Lavaca Bay, Texas, USA; industrial source	—	—	0.4	0.7	Young/nest	NOAEL	[177]	Offspring production was 70% higher than at reference location. High confidence.

[a]Tabulated concentrations represent total Hg exposures. The percentage of Hg as methylmercury (MeHg) is noted in the comments where available.
[b]Doses are calculated in the present study; all other results are as reported by authors. Dose–response information and sample sizes are given in Supplemental Data, Table S7, except as noted herein.
[c]Authors attribute low egg Hg to limited prelaying foraging in reservoirs as a result of partial ice cover. However, similarly low diet-to-egg Hg bioaccumulation in osprey has also been observed elsewhere [40].
[d]Application of sequential regression equations is justified because of the very high r^2 (96%) of the down feather–egg regression.
DDE = dichlorodiphenyldichloroethylene; EC20 = 20% effect concentration; LOAEL = lowest-observed-adverse-effect level; NOAEL: no-observed-adverse-effect level; TRV = toxicity reference value.

otherwise generally identified as averages based on data from the Cornell Lab of Ornithology [81]. The body weights and food ingestion rates used in analyses and their basis are detailed in Supplemental Data, Table S1.

We characterized exposure–response relationships using 2 complementary approaches: dose–response model analysis and bounding or estimation of effect thresholds. We conducted dose–response regression analyses for studies that reported sufficient data representing a range of effect levels. Although we preferred at least 5 dose groups, including a control, we also deemed a pheasant data set with 4 dose groups [25] suitable for regression analysis, based on the range of effect levels and availability of replicate results. Of the available data, only laboratory studies reported the requisite number of exposure groups with paired effects data. Reproductive results were not normalized to control performance, because this adjustment has been shown to produce biased results [82]. This restriction precluded combined regression analysis of results for the same species from multiple studies, in cases where control results differed markedly among studies. It was possible to combine results from multigeneration studies, however, because these studies exhibited similar control performance across generations. Regression analyses were performed with R software using a Poisson model for count variables (i.e., number of offspring) and logistic models for proportion variables (i.e., surviving chicks per egg laid) [83,84]. A 4-parameter logistic model was used to accommodate data sets that indicated an upper asymptote associated with no-effect exposures. For mallards, the 4-parameter model yielded a poor fit, and a simpler 2-parameter model was used. Regression equations (given in Supplemental Data, Tables S2–S6) were used to calculate 20% and 50% effect concentrations (EC20s and EC50s).

We compared dose–response relationships among studies and species by compiling and graphing results for all studies that provided paired exposure and response data for treatment groups (i.e., laboratory dose groups or field study areas). To allow comparisons across species, data were normalized to control or reference performance; this adjustment is appropriate for visualization purposes, as no multispecies regression analysis was performed. The dose–response compilation included studies with fewer than 4 treatments, as well as those studies for which we performed species-specific regression analyses.

Effect thresholds were characterized as EC20s if available. Otherwise, the bounds around presumed toxicity thresholds were identified as no-observed–adverse-effect levels (NOAELs) or lowest-observed–adverse-effect levels (LOAELs). Results that support only a NOAEL or a LOAEL are considered "unbounded." In a few cases, researchers identified specific thresholds below which adverse effects were not observed and above which adverse effects were frequent, and these results were simply identified as "thresholds." The designation of NOAELs, LOAELs, and thresholds generally defers to the original authors' interpretation; the rationale for specific exceptions is discussed in the section *Literature Review Results*. The compilation of effect thresholds includes several field studies that could not be incorporated in the dose–response evaluation because of limited documentation or because results were organized by reproductive outcome (e.g., Hg concentrations in unhatched eggs versus randomly sampled eggs) rather than by treatment (e.g., proportion of individuals affected in different areas).

We assigned each result a confidence level to reflect the fact that the criteria for data quality and demonstration of causality

are applied to a continuum of study characteristics. Characteristics required for a high confidence rating are evaluation of effects from nest establishment through fledging, adequate sample size, potential confounding factors assessed (field studies), Hg exposures measured using modern analytical methods, no other obvious sources of potential inaccuracy or bias noted, and study methods and results well documented. If at least 1 of these criteria was not met but the data were deemed usable for quantitative analysis, the result was assigned a moderate level of confidence. Uncertainties associated with results assigned a moderate level of confidence are further considered as part of the identification and discussion of TRV ranges. Studies interpretable with low confidence were excluded from quantitative analysis based on the data quality criterion but are discussed qualitatively in the Supplemental Data.

LITERATURE REVIEW RESULTS

The studies compiled and evaluated for the present review are described separately for controlled experiments and field studies. For controlled experiments (Table 1), a key focus is the applicability of each study's results to avian exposures in the natural environment. For field studies (Table 2), a key focus is whether any observed adverse effects can be confidently attributed to Hg exposures. Dose–response data for both laboratory and field studies are compiled in Supplemental Data, Table S7.

Controlled experiments

Table 1 summarizes toxicity test results for 7 bird species exposed to MeHg in controlled experiments. Species represented by more than 1 study include ring-necked pheasant (*Phasianus colchicus*), Japanese quail (*Coturnix japonica*), and mallard (*Anas platyrhynchos*). Three or more exposure groups were tested for 5 of the species, including American kestrels (*Falco sparverius*) [24], zebra finches (*Taeniopygia guttata*) [85], ring-necked pheasants [25], Japanese quail [86,87], and mallards [10,77,88–92]. Dose–response relationships are shown on a dietary Hg basis in Figures 1 and 2. Dose–response relationships based on egg and/or blood Hg concentrations, where available, are similar to the diet-based relationships and are provided as Supplemental Data, Figures S1 through S4; underlying data are documented in Supplemental Data, Tables S2 through S6. For the remaining 2 species—black ducks (*Anas rubripes*) and chickens (*Gallus gallus domesticus*)—toxicity thresholds are poorly defined because testing was limited to greater exposures that induced severe effects. The latter studies are informative with respect to dose–response relationships and the relative sensitivity of the test species, although they are not directly usable to estimate toxicity thresholds.

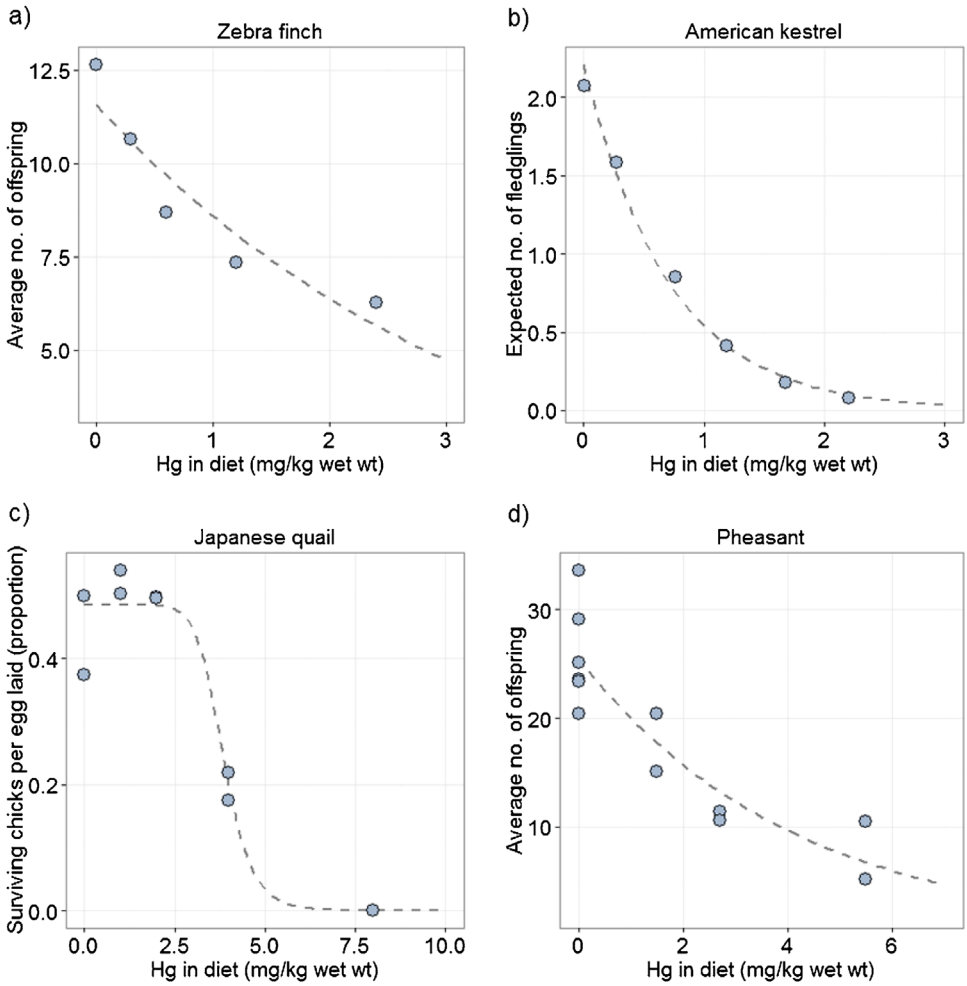

Figure 1. Dose–response relationships for 4 species exposed to methylmercury. Dashed lines represent fitted regressions. (**a**) Zebra finch data [85] represent model averages from generalized linear mixed models, including first- and second-generation pairs. (**b**) For American kestrels, expected number of fledglings accounts for removal of eggs for analysis [24]. (**c**) Japanese quail reproductive success was calculated as % fertility × % hatch × % chick survival (data from Eskeland and Nafstad [86]). (**d**) Pheasant productivity calculated as chicks hatched per hen × % chick survival (data from Fimreite [25]).

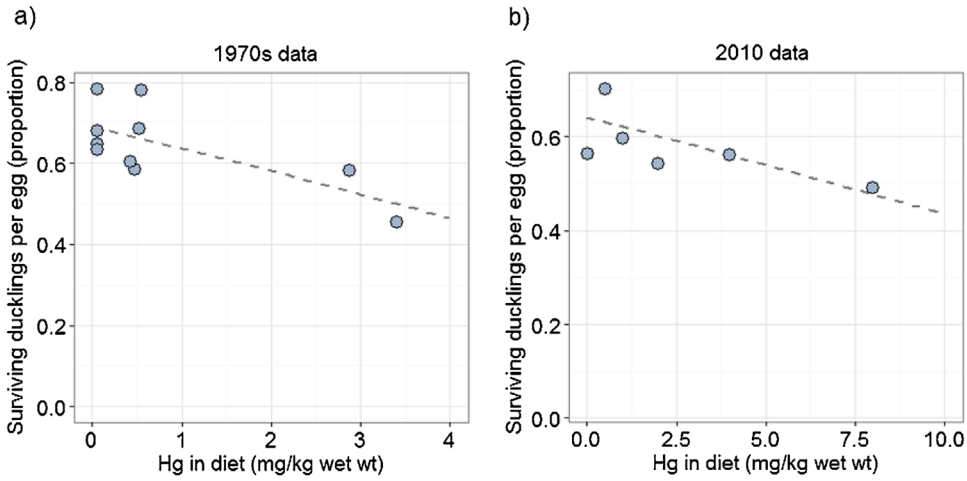

Figure 2. Dose–response relationships for mallards exposed to methylmercury dicyandiamide (1970s) or methylmercury chloride (2010). Dashed lines represent fitted regressions. Response variable calculated as % egg fertility × % hatchability × % duckling survival. Data from Heinz [77,88–90] and Heinz et al. [10,92].

The zebra finch study by Varian-Ramos et al. [85] is viewed with high confidence, as are the results of the mallard study by Heinz et al. [10] once laboratory artifacts related to egg production are factored out (see the section *Mallard studies*). The remaining studies are assigned a moderate confidence rating, in most cases because of study age and historical analytical limitations (or reliance on nominal Hg concentrations). The kestrel study of Albers et al. [24] is assigned a moderate confidence rating because chicks were exposed only via maternal transfer and not via diet. However, even the laboratory studies given a high confidence rating are not without uncertainty. Bioaccessibility of MeHg in laboratory-spiked feed is likely to be greater than that of MeHg that has been biologically incorporated in prey [93]. Also, the ratio of Hg to selenium (Se) in diet is very important because Se protects against Hg toxicity [94], but Hg-to-Se ratios were not reported in spiked feed and may or may not have been realistic (see the section *Extrapolation issues* for further discussion). We also note that the frequently employed practice of artificially incubating eggs eliminates the potential to observe adverse effects on productivity related to parental incubation behavior (nest attentiveness). Adverse effects on hatching success as a result of impaired incubation behavior have been demonstrated for polychlorinated biphenyls [95] and have also been hypothesized as a mechanism by which Hg may cause embryo malposition and subsequent hatching failure in Forster's terns (*Sterna forsteri*) [58]. Lastly, food ingestion rates for laboratory feed may differ from ingestion rates under natural conditions as a result of differing caloric and nutrient contents of dietary items and differing energetic requirements of captive versus free-ranging birds.

Additional discussion is warranted for certain other aspects of the controlled experimental studies, namely, comparison of effects across generations for zebra finches and Japanese quail, comparisons across multiple studies using mallards, and a study using white ibis that is suggestive of possible effects but is not sufficiently conclusive to support TRV derivation. Each of these matters is discussed in the following sections.

Effects on multiple generations. Varian-Ramos et al. [85] observed greater sensitivity in zebra finches that were exposed to Hg throughout their lifetime (i.e., second generation of exposure) compared with finches exposed only as adults (i.e., first generation). The authors posited that combining the results for both generations (Figure 1) is representative of wild populations, which include both immigrants and individuals exposed from conception. Eskeland and Nafstad's [86] study using Japanese quail is noteworthy because it demonstrated selection for Hg tolerance through exposures over 6 generations. The Hg dosage was not consistent across generations, limiting the utility of later generations for TRV development purpose. Doses that were lethal to quail chicks from unexposed parents induced only partial mortality in the chicks descended from quail that had been exposed to moderately toxic Hg doses over several generations. These results illustrate the potential for development of Hg tolerance in bird populations within contaminated areas. For purposes of dose–response analysis, we used data from the first 2 generations. Second-generation chicks consisted of the pooled offspring from the NOAEL and LOAEL dose groups of the first-generation test, which differs from the more typical approach in multiple-generation studies of administering a consistent dosage across generations. However, reproductive responses were generally similar between the first and second generations, and we judged that the uncertainty of including the second-generation results was less than the uncertainty of conducting the regression analysis with 50% fewer data points. An additional Japanese quail study [96] provides results that are generally consistent with those of Eskeland and Nafstad [86], but it could not be included in the regression analysis because the control results were not sufficiently comparable.

Mallard studies. Mallards are the most extensively investigated bird species in experimental studies of MeHg effects on reproduction. Heinz [77,88–90] evaluated effects of a diet containing 0.5 mg/kg Hg as MeHg dicyandiamide on mallard reproduction over 3 generations. A 3 mg/kg exposure was also tested over 2 yr using first-generation birds only [88,89]. The lower dosage has often been identified as a LOAEL [97–100] because production of 1-wk-old ducklings was reduced by 29% ($p < 0.05$) in the second generation only [77]. In the third generation, egg production was 18% lower than the control ($p < 0.05$), but overall duckling production did not differ significantly from control [77]. More recent studies conducted by Heinz et al. [10,92] cast doubt on the identification of 0.5 mg/kg in diet as a reproducible LOAEL for this species.

Heinz et al. [10,92] identified increased productivity (hormesis) in mallards fed a diet containing 0.5 mg/kg Hg in the form of MeHg chloride and observed limited adverse effects even at much greater doses. Hormesis at low Hg exposures was confirmed in a subsequent egg injection study [101].

A limitation common to all the mallard productivity studies cited above is that the authors removed all eggs from the nest for artificial incubation, which stimulated excessive egg production relative to wild populations. Wild ducks typically lay eggs daily until the clutch is complete, whereupon they begin incubating all eggs at the same time. If eggs are removed, the duck will continue to lay; indeed, the total egg production observed by Heinz [77,90] was greatly in excess of the natural production rate [10,92]. Thus, although effects related to egg production rates in the mallard studies could be considered relevant in a livestock production context, with respect to wild birds they are a laboratory artifact.

To further evaluate the implications of artificial incubation on interpretation of the mallard studies, we recalculated the mallard productivity results excluding the egg production endpoint. Specifically, duckling production per egg was identified as the product of egg fertility, hatchability of fertile eggs, and survival of hatchlings. Details are provided in Supplemental Data, Table S6. For exposures up to 1 mg/kg in diet, duckling production per egg was within the range observed for control mallards across studies, even excluding an anomalously low control result from Heinz and Hoffman [91]. At greater exposures, the mallards exposed to MeHg dicyandiamide in the 1970s were more sensitive than those exposed in later studies to MeHg chloride, although without a controlled comparison it is uncertain whether the difference in chemical form was responsible for the difference in toxicological responses. Intraspecies variation is another plausible explanation because the studies used mallards from different sources that may have represented different strains [10,102]. Additionally, analytical methods for quantifying Hg improved considerably after the 1970s [103], such that there is unavoidable uncertainty in Hg concentrations reported from early studies. Animal husbandry practices also may have improved since the 1970s.

We conducted separate analyses of the 2 sets of mallard studies from the 1970s and from 2010. In the 1970s study, the dietary Hg concentration of 2.9 mg/kg caused a statistically significant but small (10%) reduction in duckling survival, an effect accompanied by neurological signs of Hg poisoning and brain lesions [77,89,104]. Greater mortality was associated with exposure to 3.4 mg/kg in diet [88], although Heinz [88] noted uncertainty because of pseudoreplication during that study phase. Based on surviving duckling production per egg, we identified a dietary EC20 of 2.5 mg/kg from that study. In the later MeHg chloride exposures, duckling production per egg was greater than or approximately equal to the control for exposures up to 4 mg/kg in diet, with hormesis observed at a dietary concentration of 0.5 mg/kg [10,92]. We addressed the hormetic results in our regression analysis using methods consistent with those of Folland et al. [105]. Specifically, control results were excluded from the fitted regression but used to define the response level of the EC20 (i.e., 20% lower than the control). This approach yielded an EC20 of 9.3 mg/kg. Results from Heinz and Hoffman [91], an earlier study also using MeHg chloride, could not be included in the regression analysis because of substantially lower control performance. The latter study indicated a severe reduction in reproductive success of mallards exposed to a dietary MeHg concentration of 9.2 mg/kg [91], essentially equal to the EC20 from the later experiment [10,92]. Although the control results from Heinz and Hoffman [91] suggest suboptimal test conditions compared with the other mallard studies, the control-normalized data are included in Supplemental Data, Table S7, for completeness.

Consistent with the marked insensitivity of mallards observed by Heinz et al. [10,92], mallards were among the least sensitive species in a 26-species egg injection study with MeHg [55]. Although egg injection with MeHg produces lower embryotoxicity thresholds than more natural routes of exposure (i.e., diet and maternal transfer) and thus is a weak basis for TRV development, the method may elucidate the relative sensitivity of different species [55]. Also consistent with these findings is a field-based study of duck reproduction at several US National Wildlife Refuges, including a Hg-contaminated area (Lahontan Valley of the Carson River basin, NV, USA) [106]. The authors postulated an egg-based effect threshold for Hg of 0.8 mg/kg wet weight, based on the egg Hg concentration in mallards exposed to 0.5 mg/kg Hg in diet, which the authors identified from Heinz [77] as an unbounded LOAEL. However, Henny et al. [106] observed no difference in hatching success between eggs of multiple duck species containing 3 mg/kg to 9.5 mg/kg dry weight (approximately 0.8–2.4 mg/kg wet wt) compared with eggs with lower Hg concentrations, although the number of samples in the greater concentration range was small [106]. As an additional line of evidence, Heinz and Hoffman [107] evaluated effects of Hg based on concentrations in individual mallard eggs. The lowest egg Hg concentration associated with neurological signs of Hg toxicity in any individual duckling was 2.3 mg/kg, while other ducklings were unharmed despite egg Hg concentrations up to 30 mg/kg. Heinz and Hoffman [107] also evaluated deformities and failure to hatch; but because these conditions also appeared in some control eggs, their cause in individual eggs from Hg-treated mallards could not be definitively determined. In summary, the available data indicate that mallards are relatively insensitive to Hg, with dietary toxicity thresholds of approximately 3 mg/kg to 9 mg/kg.

White ibis study. In addition to the studies summarized in Table 1, a white ibis toxicity study conducted by Frederick and Jayasena [108] would meet the criteria for study inclusion based on study design and documentation; but conclusive interpretation of the study results for TRV development purposes is not possible because of the lack of a clear dose–response relationship and the occurrence of testing artifacts. The study evaluated effects of 3 MeHg chloride treatments on ibis courtship and mating behavior, number of nestlings, and number of fledglings. From the perspective of potential effects on ibis populations, the most relevant of these endpoints is the number of fledglings per female. Although the number of fledglings per female in the low-dose and high-dose groups was nominally lower than the control over 3 breeding yr, the difference was not statistically significant, and the number of offspring fledged per female in the medium-dose group was greater than that of the control. Frederick and Jayasena [108] observed dose-related behavioral effects, most notably male–male pairing. However, male–male pairing also was observed in the control group, even though this behavior has not been reported in wild white ibis at low Hg exposures. Thus, the study reveals an interaction between Hg exposure and captivity, but it is unclear whether the resulting effects on behavior are actually expressed in wild Hg-exposed ibis populations and, if so, whether they occur at a level that would affect overall reproductive success. Frederick and Jayasena [108] also reported that nestling production per female was not

significantly different from that of the control, whereas nestling production per heterosexual male showed a significant difference. The different findings for maternal versus paternal reproductive success are not intuitive but may reflect the occurrence of multiple mating attempts, whereby multiple females eventually mated with the more successful males. In that case, reproductive success would be similar among individual females, but some individual males would register as failing to reproduce. Ultimately it is maternal reproductive success that determines overall productivity and is most critical to population-level effects.

Although Zhang et al. [22] identified the low-dose group in the white ibis study as a reproductive LOAEL, that interpretation is not well supported given that the medium-dose group produced more fledglings per female than the control. On the other hand, we stopped short of identifying the medium-dose or high-dose groups from that study as NOAELs because of the inconsistent results for other reproductive endpoints. Additional investigation is needed to determine the level of Hg exposure that would adversely affect white ibis reproductive success under natural conditions.

Field studies

Table 2 summarizes the results of field studies evaluating Hg effects on reproduction in 16 bird species. Most of the field studies evaluated avian responses to Hg point sources from past industrial, mining, or military operations. Study species included songbirds, raptors, seabirds, shorebirds, wading birds, and other water birds. Species represented by more than 1 field study include tree swallows (*Tachycineta bicolor*), bald eagles (*Haliaeetus leucocephalus*), and Forster's terns. Also, merlin (*Falco columbarius*) results are presented separately for 2 populations that apparently responded very differently to Hg [109], with merlins in mainland Britain exhibiting much greater Hg sensitivity than merlins on the Orkney Islands and Shetland Islands. Merlin brood size on the mainland was not significantly correlated with either DDE or dieldrin metabolite exposures. The authors hypothesized a difference in Hg form, with Hg exposure on the mainland originating primarily from agricultural uses (e.g., MeHg dicyandiamide) and island exposures originating from aquatic food webs. Another possible explanation for the different responses of these merlin populations could have been a difference in Se status (see the section *Extrapolation issues* for further discussion). A third possibility is that the mainland merlins were actually responding not to Hg but rather to differences in available types of prey that happened to contain different Hg levels, as documented recently for Bonelli's eagles [43]. Although we are unable to distinguish these potential causes based on the available data, we provisionally included results for both the mainland and island merlins, recognizing that Hg causality is a significant uncertainty in the mainland data set. In the following sections, we discuss the extensive data available for common loons (*Gavia immer*) and tree swallows, followed by the Carolina wren (*Thryothorus ludovicianus*) study by Jackson et al. [110] (which we interpret differently from the study authors), as well as other field studies that provide supporting information but not stand-alone NOAELs or LOAELs.

Common loon studies. Depew et al. [111] recently reviewed the effects of dietary MeHg on the common loon. The authors proposed an MeHg concentration in prey fish of 0.18 mg/kg as a threshold for significant reproductive impairment in loons, while 0.4 mg/kg was identified as the concentration in fish associated with reproductive failure in wild adult loons. The first of these screening values was derived as the geometric mean of 4 toxicity thresholds [13,112–114]. The inclusion of 1 of these studies [114] relied on extrapolation of egg injection data to a hypothetical dietary concentration and thus did not meet the criteria for inclusion in the present review. Because of the use of quantile regression to address known confounding factors, we consider the analysis by Burgess and Meyer [13] to be the strongest of the available common loon studies, and we have opted to use it to represent common loon sensitivity to MeHg in Table 2. Regardless, both this approach and the Depew et al. [111] synthesis indicate a threshold concentration of approximately 0.2 mg/kg in loon prey.

Although Hg effects on loons have been extensively studied, the exposure–response relationship for this species has not been definitively characterized. Controlled reproductive studies have not been conducted because adult loons fare poorly in captivity. The majority of field studies have focused on loon productivity across regional gradients of Hg exposure, where the observed exposure gradients reflect differential bioaccumulation of atmospherically deposited Hg because of differences in lake pH and other geochemical and landscape factors. However, lake pH and Hg concentrations in fish are also correlated with lake productivity and thus prey availability [115], which in turn influence chick production and survival. Thus, low chick production could be the result of either Hg exposure or low prey availability, and conclusive demonstration of causality is a common challenge to these field studies. Merrill et al. [116] observed loon foraging behavior and the type and size of captured prey across a Hg exposure gradient and concluded that prey availability, rather than Hg exposure, was the factor most likely affecting loon productivity in northern Wisconsin lakes. Indeed, Stafford and Haines [117] and Driscoll et al. [115] identified low lake productivity as a cause of elevated Hg bioaccumulation in fish as a result of low biodilution (i.e., lower growth dilution and/or distribution of the pool of bioavailable MeHg across a smaller total biomass). Kenow et al. [118] identified parental fitness as an additional factor contributing to differences in loon productivity among lakes, with the largest males occupying more desirable (i.e., productive) territories, which also have lower prey Hg levels attributable at least in part to biodilution. Thus, observed correlations do not provide strong evidence of causality and may be specious. The LOAEL identified by Evers et al. [112] for loons in Maine and New Hampshire (0.16 mg/kg in prey) does not account for the characteristic intercorrelation of Hg exposures and prey availability (both a function of lake pH). A recent study of loon reproduction in the Adirondack Mountains (NY, USA) [119] shares the same limitation.

In an evaluation of loon productivity (viable offspring per pair) in Wisconsin and the Canadian Maritimes, Burgess and Meyer [13] addressed confounding factors using quantile regression. This method aims to assess Hg as a limiting factor by quantifying the relationship between maximum productivity and Hg exposure; instances of lower productivity associated with lower Hg exposure are assumed to be caused by other factors. Using quantile regression, Burgess and Meyer [13] calculated an EC50 of 0.21 mg/kg Hg in prey. Although quantile regression is an appropriate tool as applied by Burgess and Meyer [13], even this approach could be confounded if covariance among stressors (e.g., prey productivity and fish Hg concentrations) is sufficiently strong. Also, the term "EC50" as applied to quantile regression results must be interpreted carefully because it represents a 50% decrease compared with the most productive of all loons, not compared with the average

productivity of loons with low Hg exposure. There is a great deal of overlap in productivity distributions between loons exposed to low versus moderate Hg levels in prey, with obvious effects only at exposures exceeding the EC50. This variability is less pronounced when the analysis is carried out using loon blood Hg as the measure of exposure, likely because fish samples are an inexact representation of the species and sizes of prey actually consumed by loons, whereas blood analyses represent loon exposures more directly. Because of the high variability in the exposure–response relationship based on prey Hg concentrations and given Burgess and Meyer's definition of the EC50, Depew et al.'s [111] inclusion of the EC50 from that study for prey-based TRV derivation purposes (rather than the EC20, for example) was appropriate. In Table 2, we identify Burgess and Meyer's [13] EC50 as a "threshold," to avoid confusion with the more typical usage of the term "EC50," namely, an exposure level associated with a 50% reduction in reproductive success compared with average control or reference conditions.

In contrast to the regional studies described, Barr [113] evaluated loon productivity in the vicinity of a point source of Hg (a pulp and paper mill with a chlor-alkali plant) in the Wabigoon–English River system (Ontario), where lake pH was not a confounding factor. However, sudden and frequent dam-related water fluctuations rendered much of the study area essentially unusable for loon nesting regardless of Hg exposure [113], and loons might also have been exposed to other, unmeasured stressors related to pulp and paper mill operations in the vicinity of the Hg source. An association between Hg exposure and reduced productivity remained when water fluctuation–affected nests were removed from the analysis, although the resulting sample size was small ($n = 5$ loon pairs in the LOAEL exposure group). Depew et al. [111] identified a LOAEL of 0.17 mg/kg Hg in prey from that study, based on reported average concentrations in yellow perch (*Perca flavescens*). However, Barr [113] analyzed Hg concentrations in multiple prey species. Although yellow perch are a frequent prey of common loons, they are by no means the only prey [120]. Considering all sampled prey, Barr [113] identified a LOAEL from that study of 0.3 mg/kg to 0.4 mg/kg in prey. Either interpretation is approximately consistent with the toxicity threshold identified from Burgess and Meyer [13].

Depew et al. [111] also evaluated a study of loon productivity in Quebec [121], which demonstrated no correlation between Hg exposure and loon productivity. Because the average prey fish Hg concentration was reported as 0.15 mg/kg [121], Depew et al. [111] considered the lack of effect in that study to be consistent with the TRV derived from the loon studies discussed. By reporting only a single average fish tissue Hg concentration, however, Champoux et al. [121] obscured an important difference between western and eastern Quebec. In part because of differences in lake pH, average Hg concentrations in loon blood (and thus presumably in prey fish) were nearly 5-fold greater in eastern Quebec than in western Quebec [121]. The lack of any discernible effect of Hg on loon productivity in the Quebec study is thus consistent with the observation that there is a high degree of overlap in loon productivity between low and moderate Hg exposures.

In summary, reduced productivity is associated with common loon exposure to Hg at environmentally relevant prey Hg concentrations, but the available field studies do not provide a fully predictive effect threshold. Controlled experimental approaches would benefit the understanding of exposure–response relationships for this species if effective investigative methods could be developed. The recent suggestion of intraperitoneal injections in wild adult female birds as a means of generating varied egg Hg concentrations within a field site [122] may be a useful application in common loons, though further evaluation would be needed to determine whether that practice would replicate important conditions such as the ameliorative effects of Se that are expected to occur with dietary exposures.

Tree swallow studies. For tree swallows, 2 studies examining the effects of similar Hg exposures yielded somewhat different results. Tree swallows exposed to Hg from the South River (VA, USA) exhibited a 20% reduction in productivity that was observable only during 2 of 3 yr, in part because of the role of adverse weather conditions as a costressor [11,123]. In contrast, nearly identical Hg exposures in a 2-yr study of New England tree swallows yielded no adverse effect on hatching or fledging success [12]. While egg Hg concentrations in both of these studies were approximately 0.6 mg/kg, a further study of tree swallow reproduction adjacent to the Carson River (NV, USA) [124] suggests a slightly greater egg-based Hg threshold. Specifically, Custer et al. [124] reported an average Hg concentration of 1 mg/kg in eggs from clutches with 100% hatchability versus an average concentration of 2 mg/kg for clutches with $<100\%$ hatchability. However, the sample size ($n = 5$ nests for each group) was too small to determine whether these results were significantly different [124], and fledging success was not evaluated; therefore, we did not include the study in Table 2.

Carolina wren study. Jackson et al. [110] evaluated Carolina wren reproduction in the floodplains of 2 Hg-contaminated river systems in Virginia (South River and North Fork Holston River) over a period of 4 yr. Wrens were studied upstream and downstream of the historical Hg sources, by monitoring both nest boxes and natural nests. Exposure to Hg was evaluated primarily based on analyses of adult wren blood, although some egg analyses were also conducted. Considering only successful nests (i.e., nests that produced at least 1 fledgling), Jackson et al. [110] identified no significant difference between the study areas and the upstream reference areas in the number of fledglings produced per nest. However, a significant difference was observed in nest success, in part because of parental abandonment of a larger number of nests in the study areas. Jackson et al. [110] used MCESTIMATE software to derive a dose–response relationship based on the 2010 data, estimating nest success as a function of blood Hg concentrations. The resulting dose–response equation was extrapolated to Hg concentrations in eggs, based on a blood–egg regression equation [110]. Several researchers have adopted the EC10 estimates from this dose–response analysis as a means of interpreting both egg and blood Hg concentrations in a variety of bird species [125–127].

Although it is apparent that nest success in 2010 differed between the reference and downstream areas in the Jackson et al. [110] study, there are important limitations in the dose–response relationship developed from the data set. Specifically, the article does not provide sufficient detail to allow the dose–response modeling exercise to be reproduced, and the limited data presented do not agree with the model as presented. The dose–response model predicts that nest success in the references areas should have been between 75% and 80% based on a blood Hg level of 0.2 mg/kg to 0.5 mg/kg wet weight. However, the actual reference area nest success rate is reported as only 60%. Nest success in the study area appears to be predicted more accurately than in reference areas, at least based on

average blood Hg concentrations. Consequently, the slope of the dose–response curve appears to be exaggerated. It is possible that the failure of the model to accurately reflect the underlying data is the result of high sensitivity of the model to individual results when quantifying the likelihood of low-probability outcomes based on limited data. Only a few results fell within a concentration range of 0.5 mg/kg to 1.0 mg/kg [128]; thus, the shape of the exposure–probability curve is not well defined by data in the vicinity of the EC10. Also, in estimating the percent reduction in nest success associated with various Hg exposures, Jackson et al. [110] defined the baseline blood Hg concentration as 0, rather than consistent with reference conditions. Mean blood Hg concentrations in the reference areas were on the order of 0.2 mg/kg to 0.5 mg/kg. The EC10 of 0.7 mg/kg Hg in wren blood was closer to the concentrations in the reference areas than in the study areas, where mean female blood Hg concentrations ranged from 1.96 mg/kg to 3.38 mg/kg.

Nest success by itself is of limited utility as a test endpoint, because it does not account for the fact that many bird species, including Carolina wrens, normally nest more than once per season [23,129]. In fact, nest success and production of fledglings per season often are not correlated [23]. Jackson et al.'s [110] analysis assumes that the success of each nesting attempt is independent of the outcome of the pair's prior nesting attempt(s), but this assumption is not necessarily valid because more experienced breeders may be more likely to lay multiple successful clutches and less experienced breeders may be more likely to establish a first nest in an area susceptible to depredation. Jackson et al. [110] did not report the overall production of fledglings per mated pair, although Jackson and Evers [128] recorded fledgling production by territory during the final year of the same study. Although the latter results suggest production of approximately 1 fledgling fewer per territory (data not shown), the sample size was low ($n = 11$ study area territories); and unlike Jackson et al.'s [110] analysis of nest success, our calculation of fledglings per territory for the present review did not account for observation biases (e.g., the relationship between nest discovery time and probability of observing nest failure).

In addition, Jackson et al. [110] did not evaluate the potential for causative factors other than Hg potentially contributing to the lower nest success rate observed in the study area. Jackson et al. [110] did not consider habitat characteristics, even though nests were monitored in both forested and developed areas. Habitat quality has the potential to affect reproductive success, given that differences in habitat quality may influence susceptibility to disturbance and availability of food. Also, causes of nest failure were recorded only during the last year of the study, and egg predation rates were found to be greater in the study areas than in the reference areas [128]. The dose–response relationship for nest success published by Jackson et al. [110] did not distinguish effects attributable to depredation from those attributable to nest abandonment. The limited available data indicate greater nest abandonment rates and greater egg depredation in the study areas, but the sample sizes for abandoned nests were relatively small (study area $n = 6$ abandoned nests in 4 territories, reference area $n = 2$ abandoned nests in 2 territories). It is not known whether habitat factors or encounters with predators could have contributed to differences in nest abandonment rates. Further, E. Henry (Anchor QEA, Saratoga Springs, New York, personal communication) obtained and reanalyzed the original data and found that nest success rates did not differ between the study and reference areas in 2007 through 2009 and that nest type (natural versus artificial) was a potential confounding factor in 2010.

In summary, although a difference in Carolina wren nest success rates between reference and study areas was sometimes observed, the quantitative dose–response function presented by Jackson et al. [110] does not accurately represent the relationship between Hg exposures and effects at their study sites. Further, the relative contributions of Hg versus other stressors and confounding factors in affecting nest success rates are uncertain, with differential depredation pressure identified as a cofactor. For these reasons, the dose–response function estimated by Jackson et al. [110] is not recommended as a basis for avian Hg TRVs. However, the unbounded LOAEL from that study is provisionally included in the present data compilation (Table 2), recognizing that small sample size and potential costressors are significant limitations.

Other supporting studies. A study of eastern bluebird (*Sialia sialis*) reproduction near the South River (VA, USA) [59] indicated no relationship between maternal blood Hg levels and any measure of reproductive success. A significant correlation was observed between paternal blood Hg and nestling survival. This effect was attributed not to paternal transfer of Hg (indeed, bluebirds are promiscuous) but rather to effects on the ability of males to provide sufficient food for nestlings. Although the results appear consistent with an effect threshold of approximately 1.5 mg/kg in male blood, the authors did not identify any specific effect threshold; and such caution is appropriate because of the small number of male bluebirds with Hg concentrations above this level. Given that the authors did not identify a threshold from their study, we too are cautious about relying on their study as a basis for TRVs.

For marsh wrens (*Cistothorus palustris*) and white-faced ibises (*Plegadis chihi*) breeding at Great Salt Lake (UT, USA), Ackerman et al. [130] found statistically significant differences in Hg concentrations between opportunistically collected eggs from abandoned nests and randomly collected eggs from successful nests (termed "surrogate eggs"). However, the difference in Hg concentration in the 2 groups was small (<0.15 mg/kg), and the eggs consistently contained more Se than Hg on a molar basis, which may ameliorate potential Hg-related effects [56]. Also, the sample size for marsh wrens was small ($n = 6$ for abandoned and failed-to-hatch eggs combined). For both species, an evaluation of nest abandonment rates based on surrogate egg concentrations indicated no significant relationship between egg Hg concentration and nest success. One possible explanation for the apparent discrepancy is that Hg-related nest abandonment occurred primarily during the first week of incubation, before the collection of surrogate eggs, which occurred between incubation day 6 and day 12. However, additional investigation would be required to verify such a specific behavioral effect. Alternatively, factors other than Hg (e.g., differences between sites with respect to habitat, food, shelter, and/or predators) may have influenced nest abandonment behavior in a manner that covaried with egg Hg concentrations. Such differences were taken into account statistically in the surrogate egg evaluation but not in the opportunistic abandoned egg evaluation. For instance, food web differences can be hypothesized as a possible explanation for the observed results [43]. Thus, while the study results are useful for highlighting areas of potential future research, they are not sufficiently conclusive to support identification of NOAELs or LOAELs for TRV derivation purposes. The Great Salt Lake study also reported no evidence of adverse effects of Hg on American avocets (*Recurvirostra americana*), black-necked

stilts (*Himantopus mexicanus*), or Forster's terns, all of which were subject to lower Hg exposures than those identified for the same species in San Francisco Bay [14] (see Table 2).

Three other studies are worth noting despite their exclusion from the present quantitative analysis because of a lack of data from temporally paired reference areas. Great blue herons (*Ardea herodias*) inhabiting Clear Lake (CA, USA) were exposed to 0.56 mg/kg Hg in prey fish and reproduced normally, based on their production of young per successful nest in comparison to regional monitoring data from prior years [70]. Endangered California clapper rails (*Rallus longirostris obsoletus*) exhibited low reproductive success in San Francisco Bay as a result of predation and egg inviability. An assessment of multiple inorganic and organic contaminants identified Hg as the most widespread contaminant potentially contributing to depressed hatching success, with average fresh wet weight egg Hg concentrations in failed-to-hatch eggs ranging from 0.27 mg/kg to 0.79 mg/kg [66]. Herring gulls (*Larus argentatus*) nesting at Clay Lake (Ontario, Canada) exhibited near-complete hatching success, despite egg Hg concentrations up to 15.8 mg/kg. Fledging success was also considered normal compared with past herring gull studies at other sites [71]. Although the interpretation of these studies is too uncertain to use quantitatively for TRV development, the great blue heron results appear consistent with those observed for black-crowned night-herons, whereas the California clapper rail results may be more consistent with those observed for snowy egrets [75]. The reported herring gull exposures are notably high, but these analytical results are particularly uncertain because only first-laid eggs were sampled, analytical methods at the time of the study were less developed than current methods, and the authors did not report whether results were presented on a dry weight or wet weight basis.

Extrapolation issues

In addition to compiling data on Hg toxicity thresholds from avian reproductive studies, we reviewed information relevant to applying those data in ecological risk assessments. In particular, we reviewed available studies related to interspecies differences in sensitivity, considerations related to body weight and dose calculations, bioaccessibility, Hg–Se interactions, and MeHg form.

Interspecies extrapolation is integral to ecological risk assessment because for any given toxicant, species sensitivity has been characterized for only a subset of wildlife species that warrant protection. We discuss 2 factors of particular interest for TRV development: feeding guild and body weight. Feeding guild is important to Hg TRV derivation for birds because there is some evidence that MeHg tolerance may have evolved to a greater extent in piscivores than some other feeding guilds as a result of natural biomagnification of background Hg. Body weight is important because toxicokinetic and toxicodynamic parameters tend to vary as a function of body size.

Mercury tolerance and feeding guild. As reviewed by Robinson et al. [131] and Eagles-Smith et al. [132], birds can detoxify MeHg through demethylation in the liver, with the resulting inorganic Hg being either eliminated or stored as a nontoxic Hg–Se complex. Both MeHg and inorganic Hg can be secreted in bile for elimination in feces. Birds can also depurate MeHg through deposition in feathers, although this mechanism is effective only during periods of feather growth. All of these mechanisms reduce MeHg concentrations in blood and maternal transfer of MeHg to eggs, which in turn may reduce adverse effects on reproduction. Feeding guilds that naturally experience greater MeHg exposure (e.g., piscivores) might thus have evolved more efficient MeHg detoxification [131].

Hepatic demethylation is a dose-dependent process, with increased demethylation efficiency observed above an exposure threshold; both demethylation rates and thresholds vary among species [132]. Hepatic demethylation is thought to be an active process requiring energy input, and the existence of a threshold that triggers this detoxification mechanism is consistent with that requirement [131]. As such, demethylation should be subject to natural selection, with greater demethylation potentially favored in species with higher MeHg exposure, such as predators of large fish. Indeed, ospreys exhibit efficient MeHg demethylation and low diet-to-egg MeHg bioaccumulation [40]. The connection between maternal diet-to-egg transfer and feeding guild has not been confirmed, however, because detoxification processes have been studied primarily in piscivores to date. However, the studies by Robinson et al. [131] and Eagles-Smith et al. [132] suggest that similarity in feeding guild could be an important consideration when extrapolating across species.

Body weight and dose extrapolation. Species body weight affects several parameters relevant to MeHg exposure in birds and other animals, including food ingestion rates and key toxicokinetic processes (absorption, distribution, metabolism, and elimination) [133–136]. Additionally, as an adaptation to flight, small birds (<300–400 g) have proportionally smaller intestines and higher rates of paracellular absorption of nutrients compared with larger birds, which could potentially enhance uptake of water-soluble toxicants [137] such as protein-bound MeHg [138]. Although many aspects of chemical metabolism and toxic responses are not dependent on body weight [134], there is some evidence that longer-lived bird species tend to have greater resistance to oxidative stress [139,140]. Because larger birds tend to have longer life spans and oxidative stress is a mechanism of MeHg toxicity [94], this represents another mechanism by which MeHg exposure–effect relationships could potentially be related to avian body weight.

In North America, ecological risk-assessment practice typically translates the dietary exposures of the toxicity test species to doses, based on species-specific body weights and food ingestion rates. This linear extrapolation approach takes into account differences in food ingestion rates between toxicity test species and species to which TRVs are applied. However, it does not account for differences in elimination rates, which are also related in part to body size, with smaller animals having faster metabolic rates and contaminant elimination rates [133]. In veterinary medicine, it is recognized that linear extrapolation of drug doses among species tends to overdose large animals and underdose small ones [141]; this is analogous to underestimating the effects of a toxicant in large animals and overestimating the effects in small animals. The European Union's environmental standard for Hg in prey tissue was developed directly from dietary concentrations in toxicity studies [100] and does not account for differences in either ingestion rates or elimination rates. Sample et al. [142] found that dose estimation provided no improvement over dietary concentrations in reducing variation in copper toxicity values among species, for either birds or mammals. Although taxonomic similarities in sensitivity are expected, they were evident only when toxicity values were expressed on a dietary concentration basis and not on a dose basis [142]. These findings suggest that dose extrapolation between species of very different body weights (e.g., from loons to songbirds) introduces considerable uncertainty. Also, size-related factors

such as paracellular absorption and oxidative stress resistance suggest that body weight could affect exposure–response relationships when considered on the basis of dietary or tissue MeHg concentrations, in addition to doses.

Bioaccessibility. Several studies have used in vitro methods to assess MeHg bioaccessibility in freshwater fish and seafood potentially consumed by humans. Although results vary widely, bioaccessibility in raw tissue is frequently less than 60% [93,143–145]. He and Wang [93] found that variation in Hg bioaccessibility among species was related to differences in the subcellular distribution of Hg, with Hg bound to heat-stable proteins such as metallothioneins being less bioaccessible than Hg contained in cellular debris. This observation suggests that biologically incorporated MeHg may be less bioaccessible than MeHg in spiked feed prepared for laboratory toxicity tests. Consistent with these findings, Berntssen et al. [146] found that rats fed contaminated fish exhibited greater fecal excretion and less Hg accumulation than rats fed uncontaminated fish spiked with MeHg chloride to the same concentration. Bioaccessibility of MeHg has not been evaluated using methods designed specifically to address avian digestive uptake, but it is reasonable to expect that results of mammalian bioaccessibility investigations are at least qualitatively applicable to birds. Indeed, Kaufman et al. [147] found in vitro estimates of lead bioaccessibility to be very similar between procedures mimicking avian digestive processes and those mimicking mammalian digestive processes. Bioaccessibility differences could contribute to overprediction of risks when extrapolating from laboratory studies to field conditions.

Mercury–selenium interactions. Another complicating factor in interpreting avian Hg exposures is that Hg toxicity depends in part on Se status because Hg and Se can protect against each other's toxicity (i.e., antagonistic interaction) [148,149]. Selenium is a biologically essential element for nervous system function, although it can be toxic to avian reproduction at high concentrations. For a variety of species, the onset of Hg toxicity roughly corresponds to when the molar concentration of Hg exceeds that of Se in tissue or diet [148,150]. The presence of Se can also reduce Hg bioaccumulation [148,149]. Recent evidence suggests that Hg toxicity is the result of Se deficiency because of the sequestration of Se by Hg [94], and thus the presence of an excess of Se guards against Se deficiency caused by this sequestration. As reviewed by Klimstra et al. [56], several studies in birds confirm the generally antagonistic interaction between Se and Hg toxicity. In mallard eggs injected with embryotoxic and teratogenic doses of both Se and Hg, however, the Hg–Se interaction was antagonistic for embryo mortality but approximately additive for deformities [56]. Additional research is needed to further clarify Hg–Se interactions in birds when Se levels approach a toxicity threshold. Despite this uncertainty, Hg–Se ratios are generally interpretable, and their measurement is recommended for future Hg exposure and effect studies.

Methylmercury form. Potential differences in toxicity among different MeHg forms are a source of uncertainty in applying nearly all of the available controlled experimental studies testing MeHg toxicity to birds. Almost no data exist to assess the effects of MeHg form on toxicity. As previously discussed (see *Mallard studies*), Hg toxicity data for mallards suggest that dietary exposure to MeHg dicyandiamide might cause effects at lower doses than MeHg chloride [10,77,92]; without a controlled comparison, however, other explanations can be advanced, such as decreased sensitivity as a result of improvements in animal husbandry since the 1970s. Although MeHg chloride has been considered applicable to present-day food web Hg exposures, Harris et al. [151] determined that Hg in fish exists as MeHg cysteine. And, MeHg chloride is not an ion pair that can be used to introduce "free" MeHg to toxicity test species; rather, the chloride is covalently bound [151]. On the other hand, it appears that MeHg chloride is metabolized to MeHg cysteine in chickens [152]. Varian-Ramos et al. [85] evaluated the toxicity of MeHg cysteine to zebra finches, but zebra finch reproductive responses to other MeHg forms have not been characterized. In an acute fish toxicity test MeHg chloride was more toxic than MeHg cysteine [151], but we identified no chronic comparison of effects of MeHg forms for any species. A controlled comparison of the metabolism and toxicity to wildlife of the cysteine, chloride, and dicyandiamide forms of MeHg would aid interpretation of the available data for TRV derivation purposes.

APPLICATION TO ECOLOGICAL RISK ASSESSMENT

Ecological risk assessments are typically implemented using a tiered approach, beginning with a conservative screening phase to determine whether additional assessment is warranted, followed by a more definitive phase if needed. Corresponding to this tiered approach, TRVs can be developed as screening values or as predictive risk thresholds. The latter are most appropriate for purposes of weighing cost–benefit and risk–benefit trade-offs, as in the case of environmental remediation decisions. In the present review, we describe typical reproductive effect threshold ranges as well as outlying thresholds and severe effect observations. We focus on predictive risk thresholds, although the data compiled herein could also be used to formulate screening values (e.g., using species sensitivity distribution methods or the low end of effect threshold ranges). For specific ecological risk-assessment applications, TRVs should be tailored as closely as possible to the species and the type and degree of effect most relevant to site conditions and management goals.

To help visualize patterns in the available data, we developed 2 sets of graphs based on dose–response data (Figure 3) and effect thresholds (Figure 4) for each exposure metric (i.e., dietary concentration, dietary dose, egg concentration, and blood concentration). Visual inspection of Figure 3 and the range of EC20 values indicates that dose–response relationships tend to show lower interspecies variability when expressed on the basis of tissue Hg concentrations compared with diet-based or dose-based exposures. For Figure 4, we arrayed the toxicity thresholds and bounding estimates from low to high, in a manner analogous to a species sensitivity distribution (recognizing, however, that the effect types and magnitudes are not consistent in this data set). Thresholds and EC20s are shown as circles, while NOAELs and LOAELs are represented by arrows that point toward the presumed toxicity threshold. (That is, the toxicity threshold is presumed to be an unknown Hg concentration or dose that is greater than the NOAEL and/or lower than the LOAEL for each species.) Exposures that caused reproductive impairment of more than 50% compared with controls are indicated with an X; however, such results are omitted for clarity if an EC20 or LOAEL representing less than 50% effect is also available from the same study (as in the case of several controlled experiments). Based on the factors identified as potentially contributing to interspecies differences in Hg sensitivity, we prepared these figures using colors and shading to distinguish species categories based on body weight

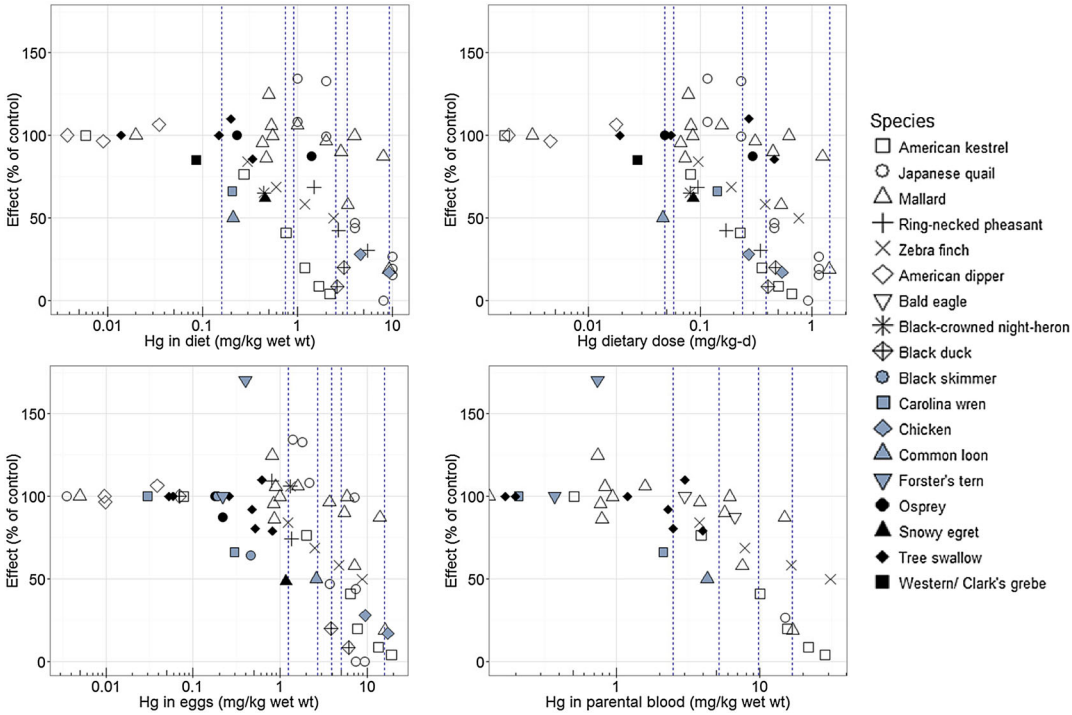

Figure 3. Dose–response data for 18 bird species exposed to methylmercury. Results are measures of reproductive success normalized to control (laboratory) or reference area (field) results for comparability. Vertical lines represent 20% effect concentration values from Table 1.

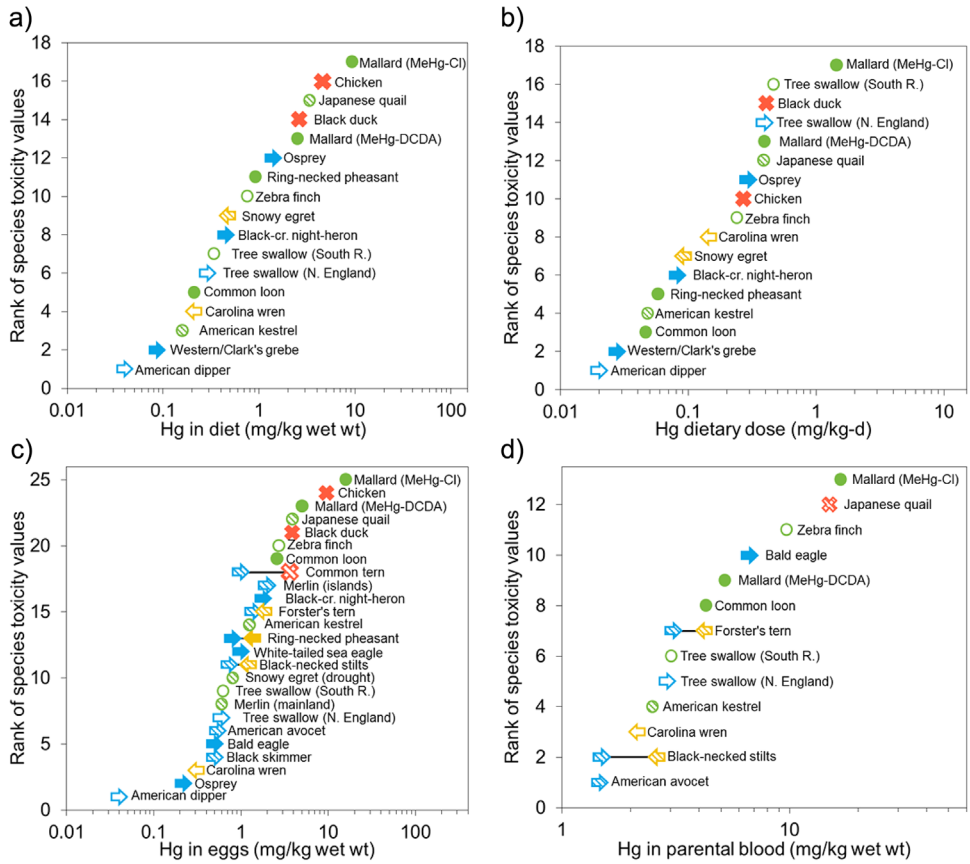

Figure 4. Responses of 23 bird species to methylmercury exposure in laboratory and field studies, based on (**a**) Hg in diet, (**b**) Hg dose, (**c**) Hg in eggs, and (**d**) Hg in parental blood. Blue right-facing arrow indicates no-observed-adverse-effect level; yellow left-facing arrow indicates lowest-observed-adverse-effect level; green circle indicates effect threshold; red X indicates severe effect. Bird size classes are shown as open symbols (small birds, 12–54 g), hatched symbols (medium birds, 120–423 g), and filled symbols (large birds, 794–5500 g).

(Figure 4) and feeding guild (Supplemental Data, Figure S5). Bird size categories were defined as small (12–54 g), medium (120–423 g), and large (794–5500 g), based on natural breaks in the data set as well as the approximate body weight threshold for increased paracellular absorption [137]. Feeding guilds were defined as piscivores, insectivores, omnivores, terrestrial carnivores, and herbivores.

Figure 4 shows that large birds tend to be less sensitive than small or medium-sized birds on the basis of dietary and blood Hg concentrations, with a few exceptions (i.e., common loon and Japanese quail). This difference is somewhat less apparent on an egg Hg basis. Avian body size and taxonomy are not necessarily independent, and thus, it is worth examining whether trends in Hg sensitivity appear more closely related to body size or phylogeny. Although in the present data set the "small" body size category represents only passerine species, the "medium" size category includes 4 different taxonomic orders, and the "large" size category includes 6 orders. It seems unlikely that purely taxonomic differences in sensitivity would coincidentally align with differences in body size, given the large number of orders represented. Conversely, 2 orders are represented by both medium and large species, and these orders present a mixed picture of the relative importance of body size versus taxonomy in affecting MeHg sensitivity. In the Pelecaniformes, the medium-sized species represented in the current data set (snowy egret) exhibits greater sensitivity compared with the large species (black-crowned night-heron). However, in the Galliformes, the medium-sized Japanese quail exhibits sensitivity similar to that observed for larger ring-necked pheasants. It seems likely that both taxonomy and body size may influence sensitivity to MeHg; but overall, the available data support further consideration of body weight in TRV development.

Theoretically, the calculation of dietary doses is supposed to bridge the gap among different size classes of birds by accounting for interspecies differences in food ingestion (and Hg intake) per unit of body weight. Indeed, on a dose basis, the bird size classes are more evenly interspersed with respect to sensitivity. However, if dose calculations accurately reflected differences in Hg intake and elimination, then the sensitivity rankings by dose would resemble those based on tissue Hg because tissue concentrations are a function of Hg intake and elimination rates. In fact, sensitivity rankings based on dose do not resemble those based on egg or blood Hg. For example, tree swallows appear to be moderately sensitive based on their response to Hg on the basis of dietary, egg, and blood Hg concentrations; yet, on a dose basis, they appear highly insensitive. These results suggest that dose-based TRVs for Hg should not be extrapolated among different size classes of birds.

Table 3 summarizes the ranges of effect thresholds and LOAELs by bird size class, as estimated from the available data. Typical ranges and outlying thresholds are identified. Observations of severe effects are also identified and defined for comparison purposes as >50% reproductive impairment relative to controls or reference organisms. The limitations of dose as an exposure metric again are apparent, as dose is the exposure metric for which the observations of severe effects most frequently overlap with the typical range of effect thresholds. Among the effect thresholds identified as extreme values, sensitive outliers include the common loon on a dietary basis and the Carolina wren on an egg basis. The thresholds for both of these species are uncertain because of confounding factors related to prey availability (loons) and predation pressure (wrens). The adverse effect observed in Carolina wrens was related to adult behavior (nest abandonment) rather than embryotoxicity [110]; in fact, on an adult blood basis, the Carolina wren effect threshold does not appear to be an extreme value. Carolina wrens had relatively low egg Hg concentrations relative to blood Hg levels compared with most other species for which both tissue types were evaluated (see Table 2).

At the insensitive end of the spectrum, outlying effect thresholds include the mallard for all exposure metrics, as well as the Japanese quail on a dietary concentration basis and the zebra finch on a blood basis. As previously discussed (see the section *Mallard studies*), multiple lines of evidence indicate that mallards are among the least sensitive species to Hg. Also, the dietary concentrations for both mallards and quail apply to a dry feed mixture, in which both Hg and nutrients may be more concentrated than in a natural diet. Thus, there are substantial uncertainties associated with most of the results identified in Table 3 as extreme values, and these values are not recommended as the basis for predictive risk thresholds to be extrapolated to other species.

Mechanistic studies reviewed by Robinson et al. [131] and Eagles-Smith et al. [132] suggest that feeding guild might affect species sensitivity to Hg. However, sensitivity trends related to feeding guild are not readily apparent on the basis of dietary concentrations, doses, or egg concentrations (Supplemental Data, Figure S5). On the basis of blood concentrations,

Table 3. Summary of estimated reproductive effect thresholds and LOAELs for birds of different size, with severe effect observations shown for comparison

		Hg EC20s, effect thresholds, and LOAELs (mg/kg wet wt)		
Exposure metric	Bird size[a] (*n*)	Typical range	Extreme values	Severe effect observations (mg/kg wet wt)[b]
Diet	Small–medium (6)	0.16–0.75	3.3 (Japanese quail)	0.8–8
	Large (8)	>0.45–>1.4	0.2 (common loon), 2.5–9.3 (mallard)	2.6–9.2
Dose	Small–medium (6)	0.05–0.5	None	0.2–0.9
	Large (8)	0.05–>0.3	0.4–1.2 (mallard)	0.2–0.5
Egg	Small–medium (11)	0.6–2.7	0.3 (Carolina wren), 3.9 (Japanese quail)	1.2–19[c]
	Large (9)	>1–2.6	5.0–16 (mallard)	3.9–17
Blood	Small–medium (7)	2.1–4.2	9.7 (zebra finch)	10–31
	Large (3)	4.3–>6.7	15 (mallard)	17

[a]Bird size ranges are based on average adult female body weight as small = 12–54 g, medium = 120–423 g, and large = 794–5500 g.
[b]Severe effects are defined for comparison purposes as >50% effect compared to control or reference organisms.
[c]Low end of severe effect range is estimated for snowy egret, lower Carson River system, 1997 [75]; data from 2006 in the same system showed no such effect despite higher egg Hg concentrations [174]. Excluding snowy egrets, the severe effect range for egg Hg in small–medium birds is 3.7–19 mg/kg.
EC20 = 20% effect concentration; LOAEL = lowest-observed-adverse-effect level.

piscivores are less sensitive than insectivores; but the number of species in the blood-based analysis is more limited than for other exposure metrics. If similar trends exist on a dietary or egg basis, they may be obscured by differences related to body weight as well as differences in study design and inclusion of unbounded NOAELs and LOAELs in the toxicity data set. Additional research is needed to understand the extent to which feeding guild can be used as a predictor of species sensitivity to Hg.

COMPARISON WITH EXISTING TRVS

Previously published TRVs for protection of birds from the adverse effects of Hg are summarized in Table 4. Most of the previously published TRVs are based on dietary exposures (concentration and/or dose) and derive from seminal TRV development efforts in the 1990s [97,98]. Those original TRVs adopted a conservative interpretation of the mallard studies that were available at the time, and they employed additional uncertainty factors to address data gaps. Two recent publications [3,22] proposed TRVs on the basis of diet and/or tissue based on more current reviews of the avian toxicity literature. Figure 5 compares these previously published TRVs for Hg based on diet, dose, egg, and blood exposures with the reproductive toxicity data set compiled for the present review.

Diet-based and dose-based TRVs

Most of the existing diet-based and dose-based TRVs are lower than the lowest effect thresholds or LOAELs shown in Figure 5, some by more than an order of magnitude. To understand these differences, we review the derivation of the previously published TRVs. Additionally, as a measure of the TRVs' reasonableness, we compare the diet-based TRVs to estimates of preindustrial background Hg concentrations in prey fish. This comparison is appropriate because bird populations have persisted for millennia despite naturally occurring Hg exposures; thus, at least at the population level, Hg exposures at or below levels prevalent over an evolutionary timescale should not be expected to cause adverse effects.

Derivation of existing TRVs. With the exception of the TRVs reported by Zhang et al. [22], all of the diet-based and dose-based TRVs are based on mallard studies by Heinz [77,88–90]. Even though more recent data show that mallards are relatively insensitive to Hg, the mallard-based TRVs derived from Heinz [77,88–90] are lower than necessary for several reasons. First, they are based on identification of the lowest-dose group from the 1970s mallard studies as a LOAEL. This interpretation is not supported by subsequent investigations, and it places undue weight on egg production in studies that used artificial incubation, which induced ducks to lay many more eggs than they would in a natural environment (see the section *Mallard studies*). Second, many of the TRVs incorporate LOAEL to NOAEL and interspecies uncertainty factors to address data gaps, which are no longer applicable given the large amount of avian toxicity data generated since those TRVs were derived. Third, several of the diet-based TRVs entail dose extrapolation from the mallard (a large bird) to much smaller bird species and subsequent back-calculation of diet concentrations for the smaller species. As previously discussed (see the section *Body weight and dose extrapolation*), such dose-based

Table 4. Previously published toxicity reference values (TRVs) for Hg effects on birds

Source (abbreviation)	TRV			Basis per TRV developers[a]
	Hg dose (mg/kg/d)	Hg in diet (mg/kg wet wt)	Hg in avian tissue (mg/kg wet wt)	
Sample et al. [98] (ORNL)	0.0064	0.005	NA	Mallard reproduction LOAEL [77], 10× LOAEL-to-NOAEL uncertainty factor; dose extrapolated to diet of American robin
Zhang et al. [22] (CRAES-SSD)	0.00309	0.00956	NA	SSD, combines multiple end points (biochemical, behavioral, reproductive, mortality); HC5 dose extrapolated to diet of night heron, little egret, and Eurasian spoonbill
Zhang et al. [22] (CRAES-CSA)	0.005	0.01547	0.365 (blood)	White ibis reproduction LOAEL [108], 2× LOAEL-to-NOAEL uncertainty factor; dose extrapolated to 3 species' diet (as above)
USEPA [97,181] (US GLI)	0.013	0.02	NA	Mallard reproduction LOAEL [77], 3× interspecies uncertainty factor, 2× LOAEL-to-NOAEL uncertainty factor; dose extrapolated to diet of belted kingfisher, herring gull, and bald eagle
European Commission [100] (EU)	NA	0.022	NA	Mallard reproduction LOAEL [77], 2× LOAEL-to-NOAEL uncertainty factor, 10× general uncertainty factor
Environment Canada [99] (Canada)	0.031	0.033	NA	Mallard reproduction [77], geometric mean of NOAEL and LOAEL, where NOAEL estimated using 5.6× LOAEL-to-NOAEL uncertainty factor; dose extrapolated to diet of Wilson's storm petrel
Oregon DEQ [9] (Oregon-Ind, Oregon-Pop)	0.013 (Ind), 0.026 (Pop)	0.074 (Ind), 0.15 (Pop)	0.5 (egg, Ind), 2.5 (egg, Pop)	Protection of individual birds based on NOAEL (Ind) and avian populations based on LOAEL (Pop). Doses apparently from USEPA [97]; doses extrapolated to diet of great blue heron. Egg TRV for individuals is bald eagle productivity NOAEL [39]; egg TRV for populations calculated with 5× NOAEL-to-LOAEL uncertainty factor
Ontario Ministry of the Environment [182] (Ontario)	0.064	NA	NA	Mallard reproduction LOAEL as identified by Sample et al. [98]
Shore et al. [3] (Shore-SSD)	NA	NA	0.6 (egg)	Species sensitivity distribution, avian reproduction

[a]The lowest-observed–adverse effect levels and no-observed–adverse effect levels identified by past toxicity reference value (TRV) developers are outdated (mallard), not well supported (ibis), or misidentified (eagle); see text.

ORNL = Oak Ridge National Laboratory; CRAES = Chinese Research Academy of Environmental Sciences; SSD = species sensitivity distribution; CSA = critical study approach; USEPA = US Environmental Protection Agency; GLI = Great Lakes Initiative; DEQ = Department of Environmental Quality; HC5 = hazardous concentration for 5% of species; Ind = individual; Pop = population; LOAEL: lowest-observed-adverse-effect level; NOAEL: no-observed-adverse-effect level; NA = not available.

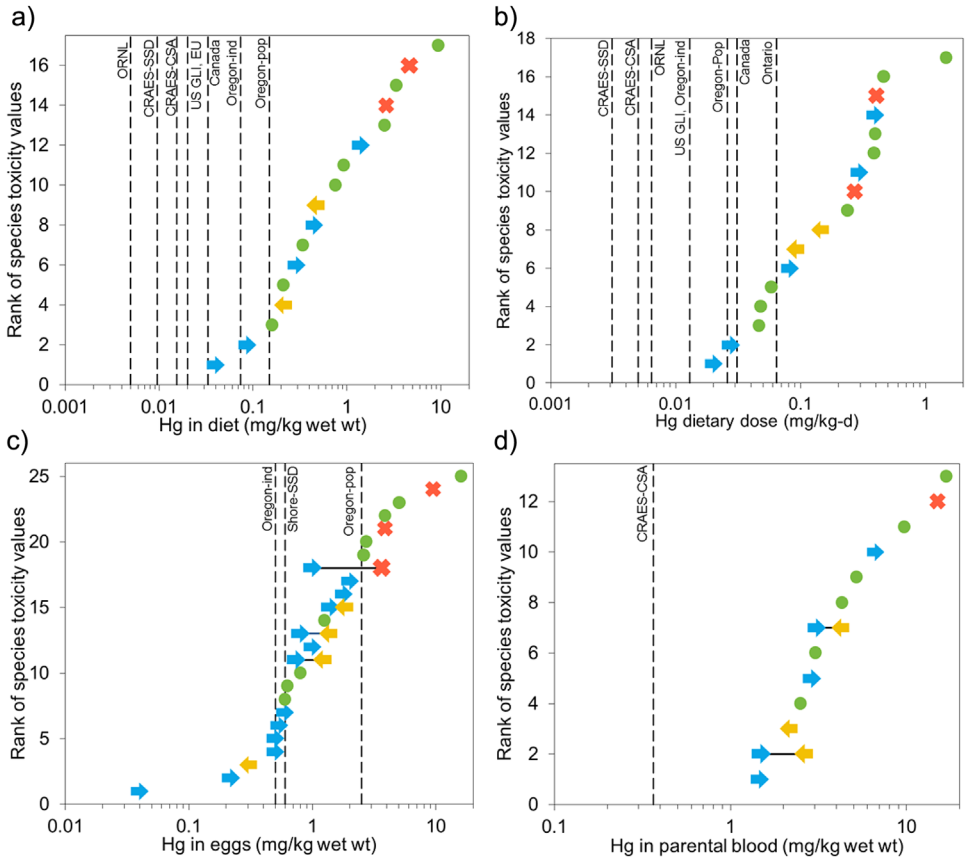

Figure 5. Comparison of previously published toxicity reference values with avian exposure–response data set compiled for the present review, based on (**a**) Hg in diet, (**b**) Hg dose, (**c**) Hg in eggs, and (**d**) Hg in parental blood. Vertical lines indicate toxicity reference values. Blue right-facing arrow indicates no-observed-adverse-effect level; yellow left-facing arrow indicates lowest-observed-adverse-effect level; green circle indicates effect threshold; red X indicates severe effect. TRV sources are shown in Table 4. CRAES = Chinese Research Academy of Environmental Sciences; CSA = critical study approach; EU = European Union; Ind = individual; ORNL = Oak Ridge National Laboratory; Pop = population; SSD = species sensitivity distribution; US GLI = US Great Lakes Initiative.

extrapolations between large and small species tend to distort interspecies sensitivity patterns. Thus, although data limitations meant that the mallard-based TRVs were appropriate at the time they were originally derived, they are now outdated.

Zhang et al. [22] developed avian TRVs for MeHg on behalf of the Chinese Research Academy of Environmental Sciences using 2 approaches: the critical study approach and the species sensitivity distribution approach. The critical study approach is like that used to derive the mallard-based TRVs in that a single toxicity study is identified as being appropriately representative of sensitive species targeted for protection, and the results of that study are adapted using uncertainty factors and interspecies extrapolation methods to develop TRVs. The species sensitivity distribution approach compiles all available and relevant toxicity test results for taxa of interest and then estimates a quantitative species sensitivity distribution function. A target percentile of the distribution function, often the 5th percentile (5% hazard concentration [HC5]), is then selected as the TRV. Both approaches have precedents in existing environmental management arenas. For example, the USEPA uses the critical study approach in the development of toxicity criteria for human health risk assessment and the species sensitivity approach in the derivation of aquatic life criteria for surface water. Although the basic methods are widely accepted, Zhang et al.'s [22] applications of both are problematic.

Using the critical study approach, Zhang et al. [22] identified the white ibis study of Frederick and Jayasena [108] as the most appropriate basis for avian TRVs. As previously discussed (see the section *White ibis study*), that study did not yield a clear dose–response relationship. Although Zhang et al. [22] identified the lowest Hg treatment in that study as a LOAEL, the effect on fledgling production per female was not significant in the lowest treatment group, and it exceeded that of the control in a treatment group receiving greater Hg exposures. Thus, this TRV derivation is inconsistent with the authors' stated methods, which specify that the critical study should demonstrate a clear dose–response relationship for an ecologically relevant endpoint.

For the species sensitivity distribution approach, Zhang et al. [22] compiled NOAELs observed or estimated from controlled experiments for 10 species and used the resultant HC5s to derive dose-based and diet-based TRVs. In principle, the species sensitivity distribution approach provides a useful framework to incorporate a large amount of relevant data. However, the data set compiled by Zhang et al. [22] mixes several different endpoints of varying sensitivity and varying magnitude of effect, ranging from biochemical endpoints to mortality. As a result, the relative sensitivity of the test species to MeHg is not necessarily accurately reflected, and the biological response associated with the HC5 cannot be defined. The inclusion of mortality results is potentially underprotective because reproductive effects tend to be more sensitive than mortality in Hg-exposed birds. Conversely, inclusion of biochemical endpoints adds uncertainty and is potentially overprotective because the magnitude of the response that would correspond to an ecologically relevant effect is unknown.

For this reason, endpoints such as biochemical parameters, immune function, and behavior often are excluded from TRV derivation [153], as they are in the present review. In the case of chicken sensitivity, the magnitude of effect identified by Zhang et al. [22] as a LOAEL (i.e., a 2% decrease in body weight compared with control [154]) is not ecologically relevant. Despite the very small effect reported (i.e., 2%), the chicken LOAEL was divided by a 20-fold uncertainty factor to account for study duration and lack of a NOAEL, causing the chicken to be identified as highly sensitive to MeHg. Such an uncertain datum should have been omitted from the data set. Zhang et al. [22] also included data from a pheasant toxicity test using ethylmercury p-toluene sulfonanilide [52], although the toxicity of this compound relative to MeHg is uncertain. Overall, the most sensitive values in the species sensitivity distribution are questionable for the various reasons presented above, resulting in questionable TRVs.

Comparison with natural background concentrations. Because Hg is naturally occurring (e.g., in volcanic eruptions, natural seeps, geological deposits) and bioaccumulative, there must be a lower limit to the Hg concentrations in prey that could plausibly harm bird populations; that is, TRVs should not be lower than naturally occurring Hg concentrations in the normal prey of the bird species being assessed. However, as reviewed by Fuchsman et al. [155], it is challenging to define naturally occurring Hg concentrations in fish and other avian prey, because Hg released by humans to the environment over centuries has become globally distributed. Fuchsman et al. [155] evaluated 3 lines of evidence relevant to estimating natural background Hg concentrations in prey fish: a modeling exercise by Hope and Louch [156], Hg concentrations in control fish from toxicity experiments [157], and Hg concentrations in fish collected from areas minimally impacted by anthropogenic increases in aerial deposition of Hg and sulfur [158–160]. Sulfur deposition is relevant because it contributes to increases in Hg methylation and subsequent bioaccumulation [115]. These lines of evidence indicated that average naturally occurring Hg concentrations in forage fish are roughly 0.03 mg/kg to 0.1 mg/kg, with greater concentrations (on the order of 0.1–0.3 mg/kg) expected in predatory fish [155]. By this estimate, all of the previously published diet-based avian TRVs for Hg are similar to or lower than naturally occurring Hg concentrations in fish. As such, these TRVs would be expected to overpredict risks to piscivorous birds.

In contrast, the typical diet-based Hg threshold ranges identified in the present review for small to medium-sized birds are slightly greater than estimated naturally occurring Hg concentrations in forage fish, while the typical diet-based threshold ranges for large birds are greater than estimated naturally occurring Hg concentrations in larger fish (Table 3). The data set underlying the typical threshold range for small to medium-sized birds includes few piscivorous species. Thus, it would be more appropriate to compare the diet-based threshold ranges for these bird species to preindustrial background Hg concentrations in invertebrate prey, but no such background estimates are available for comparison. However, most invertebrates and other prey normally contain lower Hg concentrations than are present in fish. In summary, from an evolutionary perspective, the Hg threshold ranges identified in the present review seem more reasonable than previously published diet-based TRVs.

Egg-based TRVs

We identified 3 egg-based TRVs from 2 sources [3,9], all of which fall within the typical threshold range for Hg in eggs. Specifically, Shore et al. [3] identified an HC5 of 0.6 mg/kg. The Oregon Department of Environmental Quality [9] identified egg-based TRVs specifically for protection of ospreys and eagles, with a lower TRV targeting protection of individual birds and a higher TRV targeting protection of populations.

Shore et al. TRV. Shore et al. [3] assembled egg-based NOAELs and LOAELs for Hg effects on reproduction in 19 bird species and applied a species sensitivity distribution approach to the set of LOAELs ($n = 10$). We assembled a substantially different set of egg-based EC20s, NOAELs, and LOAELs for Hg. For example, Shore et al. [3] included a LOAEL of 1 mg/kg in eggs based on older mallard studies, whereas we identified an EC20 from the same studies as 2.5 mg/kg (see the section *Mallard studies*). As another example, Shore et al. [3] included a LOAEL of 1.15 mg/kg for white-tailed sea eagles (*Haliaeetus albicilla*) from Helander et al. [42], but the authors of that study attributed the observed effects to DDE rather than Hg, such that only a NOAEL of 1 mg/kg can be appropriately identified for Hg. Despite differences in the underlying data sets, the Shore et al. [3] TRV is consistent with the exposure–response data compiled in the present review. We identified an effect at an egg concentration lower than 0.6 mg/kg in only 1 of 22 species included in Figure 4, and that LOAEL (for Carolina wrens) is relatively uncertain. The Shore et al. [3] egg TRV is intended to be protective of 95% of species and appears to be consistent with that goal.

Oregon TRVs. Oregon state law requires that TRVs for the protection of bird populations be identified based on LOAEL exposures, whereas TRVs for the protection of individual birds (i.e., for threatened and endangered species) must be identified based on NOAEL exposures. The Oregon Department of Environmental Quality [9] stated that the Hg egg-based TRV for protection of individual birds (0.5 mg/kg) was based on a NOAEL for bald eagle eggs from Wiemeyer et al. [39]. The Oregon Department of Environmental Quality derived the population-level TRV by multiplying the individual-level TRV by a default NOAEL to LOAEL uncertainty factor of 5. In fact, Wiemeyer et al. [39] did not provide a bald eagle NOAEL, although the authors did cite an egg concentration from Wiemeyer et al. [38] for comparison purposes. That comparison value was based on the pheasant toxicity study of Fimreite [25], in which the lowest Hg concentration in pheasant eggs from the LOAEL dose group was 0.5 mg/kg. The identification of this concentration as a NOAEL is thus questionable, and the derivation of a LOAEL from this value using a default uncertainty factor could be underprotective. Nevertheless, the population-based TRV lies within the typical threshold range for Hg in bird eggs. The Oregon Department of Environmental Quality [9] TRV for protection of individual eagles is based on a misinterpretation of historical studies, but it is coincidentally equal to a more recent bald eagle NOAEL [161] and, thus, achieves its target level of protection.

Blood-based TRVs

The present review represents the first broad compilation of avian blood Hg data associated with toxicity studies. As such, only 1 existing blood-based TRV is available for comparison [22], although some researchers have also used the calculated EC10 from Jackson et al. [110] as a basis for comparison (see the section *Carolina wren study*). Zhang et al. [22] identified a blood-based TRV using the critical study approach, based on the white ibis study of Frederick and Jayasena [108]. Analogous to their diet-based TRV, Zhang et al. [22] identified the lowest Hg treatment from that study as a

LOAEL and further modified the corresponding Hg blood concentration with a LOAEL to NOAEL uncertainty factor to identify a TRV (Table 4). As previously discussed (see the section *Diet-based and dose-based TRVs*), this interpretation of the white ibis study is problematic because of the lack of a dose–response relationship or a statistically significant effect on key endpoints. Indeed, the white ibis blood Hg concentration of 0.73 mg/kg would be an outlier compared with the blood Hg results assembled in Figure 4, further supporting our conclusion that this exposure is not a LOAEL. Similarly, the Carolina wren EC10 calculated by Jackson et al. [110] as 0.7 mg/kg is not well supported by the underlying data from that study. The data provisionally support identification of an unbounded LOAEL for Carolina wrens of 2.1 mg/kg Hg in blood, with the recognition that factors other than Hg exposure (e.g., predation pressure, habitat, small sample size) may have affected the results (see the section *Carolina wren study*).

We identified typical ranges of effect thresholds for Hg in avian blood as 2.1 mg/kg to 4.2 mg/kg for small to medium-sized birds and 4.3 mg/kg to >6.7 mg/kg for large birds (Table 3). Studies involving lower Hg exposures found no evidence of adverse effects when parental blood Hg concentrations were 1.5 mg/kg or lower in American avocets and black-necked stilts [14,162]. The bluebird study of McCullagh et al. [59] is also consistent with a lack of adverse effects as a result of adult blood Hg concentrations $\leq$ 1.5 mg/kg, although interpretation of possible effects at greater concentrations in that study was uncertain because of the small number of bluebirds exposed at such levels (see the section *Other supporting studies*). In summary, the data compiled for the present review indicate that Zhang et al.'s [22] blood-based TRV and Jackson et al.'s [110] blood-based EC10 are lower than necessary by factors of approximately 4 and 2, respectively.

CONCLUSIONS

We conducted a comprehensive review of MeHg effects on avian reproduction, using transparent and objective criteria for study inclusion, evaluating uncertainties and biases in each study reviewed and assigning confidence levels to the compiled data. Where multiple studies were available for the same species, we evaluated their consistency and identified possible reasons for inconsistencies where noted. The resulting data set compiles data documenting the occurrence or lack of observed adverse effects attributed to Hg exposure in 23 bird species. We also reviewed information relevant to the extrapolation of these data to other species, including issues related to avian body size and feeding guild as well as Hg bioaccessibility and chemical interactions. Based on the present review, typical ranges of Hg thresholds for adverse effects on avian reproductive success are approximately 0.2 mg/kg to >1.4 mg/kg in diet, 0.05 mg/kg/d to 0.5 mg/kg/d on a dose basis, 0.6 mg/kg to 2.7 mg/kg in eggs, and 2.1 mg/kg to >6.7 mg/kg in parental blood. Within these ranges, the observed thresholds vary for different size classes of birds (Table 3). Severe effects (>50% reduction of reproductive success) are generally limited to exposures greater than the threshold ranges, although this trend is less reliable when exposure is expressed on a dose basis. This analysis is intended to support predictive ecological risk assessments that in turn will support realistic cost–benefit and risk–benefit analyses with respect to environmental decisions such as remediation planning for contaminated sites.

The effect threshold ranges identified in the present review are greater than previously published TRVs on the basis of dietary and blood-based exposures, whereas they are consistent with previously published egg-based TRVs. The discrepancy among diet-based TRVs (including related dose-based TRVs) is primarily the result of past reliance on a conservative interpretation of a mallard toxicity study from the 1970s, which is no longer supportable based on subsequent investigations by the same researchers. Indeed, the continuing widespread reliance on a single, dated mallard study could be viewed as a failure to use available information to advance the science of TRVs and underscores the need for critical review. Certain other TRVs also differ from those proposed in the present review because of specific differences in interpretation of particularly uncertain studies, notably in the identification of a LOAEL for white ibis despite the lack of a dose–response relationship in the subject study. Based on the systematic methodology used and the comparison of TRVs to background Hg concentrations in fish, we contend that the TRVs presented in the present review are more supportable than those previously published by others.

Although MeHg effects on birds have been studied extensively, some important research needs remain. In particular, the interpretation of controlled experimental results would benefit greatly from research to improve the understanding of MeHg bioaccessibility to birds in wild prey versus laboratory-spiked feed. A comparative study of the metabolism and toxicity of MeHg cysteine (the form of MeHg found in fish) versus MeHg chloride and MeHg dicyandiamide is also warranted. Techniques to apply controlled experimental exposures to wild loons are also intriguing because prey availability and Hg exposures are closely intertwined in this key indicator species' habitat, complicating the interpretation of field studies. Further work is needed to improve methods of interspecies extrapolation that limit the distortions introduced by the current practice of applying body weight–normalized doses, which implicitly assumes that body weight–normalized intake governs interspecies differences without regard for differences in elimination rates. Understanding the physiological and genetic bases for differences in sensitivity to MeHg would greatly aid interspecies extrapolation. Research is also needed to clarify interpretation of Hg–Se ratios in birds and their prey, especially when Se concentrations approach a toxicity threshold, although existing data are already sufficient to recommend Se analyses for all Hg exposure and toxicity studies. In the meantime, ecological risk assessors evaluating species not tested for MeHg toxicity should strive to apply toxicity data from species of similar body weight.

Supplemental Data—The Supplemental Data are available on the Wiley Online Library at DOI: 10.1002/etc.3606.

Acknowledgment—Funding was provided by the Sediment Management Work Group. We thank E. Perruchon, A. Kovach, A. Fogg, J. Avantaggio, and M. Cisz for research assistance and L. Leighton for assistance with manuscript preparation. In addition, S. Brown, R. Stahl, W. Gala, and E. Henry provided thoughtful comments on earlier drafts of the manuscript. We also thank P. Frederick, N. Jayasena, and J. Ackerman for clarifications of their research findings and 2 anonymous reviewers for their thoughtful and constructive comments.

Data Availability—Data are provided in the online Supplemental Data and in the cited references.

EXECUTIVE SUMMARY

Introduction

In January 2001, the U.S. Environmental Protection Agency (EPA) developed a new recommended water quality criterion for methylmercury, under section 304(a) of the federal Clean Water Act. The criterion, a tissue residue concentration (TRC) of 0.3 milligrams per kilogram wet weight (mg/kg, ww) of methylmercury in edible portions of fish and shellfish, was designed to protect human health against adverse effects of methylmercury toxicity. The EPA intends to propose this human health criterion in California in order to fulfill consultation obligations under the federal Endangered Species Act (ESA) stemming from promulgation of the California Toxics Rule in 2000. As part of that ESA consultation, the EPA agreed that the human health criterion should be sufficient to protect federally listed aquatic and aquatic-dependent wildlife species in California. In proposing this criterion, the EPA must complete a biological evaluation of the effects of the proposed action on federally listed and proposed threatened and endangered species and critical habitat within California.

To facilitate this biological evaluation, the EPA's Region 9 entered into an Intergovernmental Agreement (IAG) with the U.S. Fish and Wildlife Service's (Service) Sacramento Fish and Wildlife Office, Environmental Contaminants Division (ECD). The primary objective of this IAG was to conduct the analyses necessary to determine whether the TRC may affect any federally listed species in California. This document presents the risk assessment methodology, developed collaboratively by scientists from both the Service and EPA, used to perform these analyses. This document also provides the ECD's interpretation of the results and our conclusions regarding the TRC's effect on the species evaluated. **These conclusions do not represent the results of consultation under Section 7 of the ESA, rather they were based solely on our current understanding of methylmercury's behavior in aquatic ecosystems and the toxicological foundation from which the risk assessment methodology was developed.** The results of these analyses may be used by the EPA in making ESA-related effects determinations for the subsequent biological evaluation. Any such determinations are solely the responsibility of the EPA.

Evaluating Wildlife Protection

The 0.3 mg/kg TRC represents a generic dietary concentration intended to be the maximum allowable concentration of methylmercury in freshwater and estuarine fish and shellfish that would protect human consumers, based on an average consumption of 17.5 grams of fish and shellfish per day. It is possible to develop similar dietary concentrations for wildlife species, provided sufficient life history and toxicity data exist. However, the protection of wildlife cannot be evaluated by simply comparing a protective generic dietary concentration determined for any given species with the generic dietary concentration proposed as the human health criterion.

One of the primary principles in constructing a risk assessment to evaluate wildlife protection is the need to consider the food chains of aquatic ecosystems in terms of trophic levels. Food chains, defined in their most simplistic form, start with trophic level 1 (TL1) plants. These plants are consumed by trophic level 2 (TL2) herbivores, which are consumed by trophic level 3 (TL3) predators, which are then consumed by the top predators in trophic level 4 (TL4). Consideration of trophic levels is necessary because methylmercury is a highly bioaccumulative pollutant which concentrates in biological tissues and biomagnifies as it moves up through successively higher trophic levels of a food chain. Organisms higher on the food chain contain greater methylmercury concentrations than those lower on the food chain. If fish and shellfish from TL2 contain tissue methylmercury concentrations of 0.3 mg/kg, then biota from TL3 and TL4 will have higher tissue concentrations. Conversely, if TL4 biota have tissue concentrations of 0.3 mg/kg, biota from TL2 and TL3 will have lower tissue concentrations.

There are numerous challenges in taking a trophic level approach to evaluating the TRC for its protectiveness of multiple listed fish and wildlife species. Most predators that feed from aquatic food webs are opportunistic and will consume prey from more than one trophic level. These dietary habits vary widely among different species and can change seasonally. Thus, methylmercury concentrations in any trophic level that may be protective of one species may place another consumer from the same water body at increased risk. In addition, different species of wildlife vary in their sensitivity to methylmercury toxicity. Since the toxicological literature contains dosing studies from very few species of wildlife, most ecological risk assessment methodologies, including this one, use uncertainty factors to account for unknown variations in sensitivity among species.

Consideration of these food chain dynamics in a risk assessment for wildlife requires trophic level-specific methylmercury concentrations. The manner in which the TRC is to be implemented for protection of human health will determine the limiting concentrations of methylmercury in the various trophic levels. Under a strict interpretation of the criterion (*i.e.*, no fish tissue exceeding the TRC), and given an understanding of biomagnification relationships between trophic levels, it is possible to set the TRC as the limiting concentration for TL4 biota and then estimate the tissue concentrations expected for biota in TLs 2 and 3. However, if a specific human population consumes only TL2 or TL3 fish from a water body, then the TRC could be applied to just those trophic levels. This would result in methylmercury concentrations in TL4 biota that are higher than the TRC and increase the exposure risks for wildlife.

For this evaluation, two approaches were used to determine trophic level-specific methylmercury concentrations that could be expected from the TRC. The Average Concentration TL Approach estimated these concentrations based on the human consumption rate of 17.5 g per day, with a defined trophic level composition (*i.e.*, a certain percentage from each trophic level). The Highest TL Approach set the TRC as the limiting concentration for TL4 biota, and then estimated the subsequent concentrations for TLs 2 and 3. Both approaches required assumptions about the relationships of bioaccumulation and biomagnification between trophic levels.

Average Concentration Trophic Level Approach

This approach estimated the methylmercury concentrations in each trophic level consumed by humans that, when combined, would correspond to the overall dietary concentration of 0.3 mg/kg. The EPA's human health methylmercury criterion document presented a national average intake rate of 17.5 grams of fish per day based on an assumed percentage from each individual trophic level: TL2 - 21.7% (3.8 g), TL3 - 45.7% (8.0 g), TL4 - 32.6% (5.7 g), for a total of 100% (17.5 g).

Based on national bioaccumulation data, it was determined that methylmercury concentrations in TL4 biota are generally 4.0 times those seen in TL3 biota. Concentrations in TL3 biota are generally 5.7 times those seen in TL2 biota. Using these methylmercury biomagnification factors and the assumed trophic level composition of the average human diet, the concentration of methylmercury in TL2, TL3, and TL4 fish and shellfish that will maintain an overall human dietary concentration of 0.3 mg/kg methylmercury can be calculated. The resulting concentrations are: TL2 - **0.029 mg/kg**; TL3 - **0.165 mg/kg**; and TL4 - **0.660 mg/kg**.

Highest Trophic Level Approach

This approach would set the proposed TRC of 0.3 mg/kg as the limiting concentration in TL4 biota. Concentrations expected in TLs 2 and 3 were then estimated by dividing by the appropriate biomagnification factors (*i.e.*, TL3 = TL4 concentration divided by 4, TL2 = TL3 concentration divided by 5.7). The resulting concentrations are: TL4 - **0.3 mg/kg**, TL3 - **0.075 mg/kg**; and TL2 - **0.013 mg/kg**.

This approach is the most conservative (*i.e.*, protective) method of establishing trophic level concentrations with the TRC. This is because it eliminates the possibility of different human populations exceeding the protective reference dose, assuming the national average consumption rate remains constant. Thus, a diet of 100 percent TL4 fish would maintain the overall dietary concentration of 0.3 mg/kg. Any other combination of trophic level foods in the diet (totaling 17.5 g per day) will maintain a dietary concentration at or below the protective level.

The trophic level methylmercury values for the two approaches were then used, along with dietary intake information for each species of concern, to evaluate the protectiveness of the TRC for aquatic and aquatic-dependent wildlife species at greatest risk from exposure to methylmercury.

Selection of Species

Based on the information available in the scientific literature, and given consideration of methylmercury's capacity to bioaccumulate and biomagnify in the aquatic food chain, this evaluation assumed that upper trophic level wildlife species (*i.e.*, predatory birds and mammals)

have the greatest inherent risk from exposure to methylmercury. In California these species are:

Southern Sea Otter (*Enhydra lutris nereis*)
California Least Tern (*Sterna antillarum brownii*)
California Clapper Rail (*Rallus longirostris obsoletus*)
Light-Footed Clapper Rail (*Rallus longirostris levipe*)
Yuma Clapper Rail (*Rallus longirostris yumaensis*)
Western Snowy Plover (*Charadrius alexandrinus nivosus*)
Bald Eagle (*Haliaeetus leucocephalus*)

The scientific literature was also reviewed to see whether the listed fish, reptile, and amphibian species may be protected under either trophic level approach. For fish species, the risk assessment was based solely on adverse effects associated with tissue methylmercury concentrations. The scientific literature contains little information on methylmercury risk to reptiles and amphibians.

Wildlife Values and Predicted Dietary Concentrations

A Wildlife Value (WV) represents the overall dietary concentration of methylmercury necessary to keep the daily ingested amount at or below a level at which no adverse effects are expected. The WV is analogous to the TRC for the human health criterion. For each species of concern, a WV was determined using body weight, total daily food ingestion rate, and a protective reference dose.

A predicted dietary concentration (DC) also represents an overall concentration in the diet, but is determined using the trophic level methylmercury concentrations expected under each TL approach and the trophic level composition of the species' diet. In effect, the percentage of each trophic level consumed is multiplied by the concentration expected for that trophic level. The resulting products are then summed to provide the total concentration of methylmercury in the diet.

The predicted DC for each species of concern was then compared to the WV determined to be protective for that species. If the predicted DC was at or below the WV then it was assumed that the species is not at risk from dietary exposure to methylmercury under that scenario. If the predicted DC is higher than the WV, it was assumed that the species would likely have a dietary exposure that may place it at risk for adverse effects from methylmercury toxicity.

Results of the Evaluation

Average Concentration Trophic Level Approach

Based on the analyses conducted for this evaluation, applying the TRC with the estimated trophic level methylmercury concentrations under the Average Concentration TL Approach may be

sufficiently protective for only two of the seven species considered: southern sea otter and Western snowy plover. **The five other species examined (California least tern; California, light-footed, and Yuma clapper rails; bald eagle) would likely have dietary exposures under this approach that may place them at risk for adverse effects from methylmercury toxicity**.

Highest Trophic Level Approach

This approach, with its lower estimated trophic level methylmercury concentrations, would provide a greater degree of protection than the Average Concentration TL Approach. Applying the TRC under the Highest TL Approach should be sufficiently protective for four of the seven species considered: southern sea otter, California clapper rail, Western snowy plover, and bald eagle. **Two of the species examined (California least tern and Yuma clapper rail) would likely have dietary exposures under this approach that may place them at risk for adverse effects from methylmercury toxicity**. The least tern may be at an elevated risk for methylmercury toxicity because of its small body size and its diet of exclusively TL3 fish. Although methylmercury concentrations for all three trophic levels are expected to be substantially lower under this approach, the estimated TL3 concentration of 0.075 mg/kg would still not be low enough to remove the potential risk of adverse effects from dietary methylmercury exposure for the least tern. The evaluation for the Yuma clapper rail, regardless of the WV used in the analysis, indicates this subspecies would likely have a dietary exposure under this approach that may place it at risk for adverse effects from methylmercury toxicity.

At this time, no conclusion can be drawn regarding the light-footed clapper rail. If this subspecies' sensitivity to methylmercury is the same as the California clapper rail and the analysis of its dietary composition is correct, the light-footed rail would likely have dietary exposures under this approach that may place them at risk. However, if other biological characteristics (*e.g.*, a greater ability to detoxify ingested methylmercury, lower diet-to-egg transfer efficiency) indicate a lower sensitivity to methylmercury, the evaluation results suggest this TL approach should be sufficiently protective for the light-footed rail. Research should be initiated to answer questions surrounding the relative sensitivity of this subspecies and to determine the appropriate trophic level methylmercury concentrations to provide sufficient protection against toxicity.

Fish

None of the data examined provided definitive answers regarding the level of protection for fish afforded by the TRC. **The methylmercury concentrations expected from applying the TRC under both trophic level approaches appear to be well below observed adverse effects concentrations; however, the trophic level concentrations expected under the Average TL Approach are much closer to these adverse effects concentrations.** Increasing emphasis on examining more subtle methylmercury-induced effects may reveal even lower tissue-based threshold effects concentrations for fish.

Reptiles and Amphibians

Too little is presently known about mercury bioaccumulation in reptiles and amphibians to allow for any comparative risk prediction capability based on bioaccumulation in fish. **The available scientific literature strongly suggests that both reptiles and amphibians can bioaccumulate methylmercury, although possibly less so than piscivorous birds and mammals with a greater daily reliance on aquatic prey. Until the appropriate toxicological data are generated, no definitive conclusions can be drawn about the protectiveness of either trophic level approach for the California red-legged frog, San Francisco garter snake, or giant garter snake.**

Discussion

The Service's Environmental Contaminants Division believes the analyses presented in this document represent the most current state of knowledge regarding the risk to California's listed species from dietary methylmercury. Conclusions about the protectiveness of the TRC for each species evaluated by the two trophic level approaches are summarized in Executive Summary (ES) Table 1. Of the two approaches evaluated, the Highest TL Approach affords a greater degree of protection for California's listed bird and mammal species than the Average TL Approach. The best currently available data on mercury toxicity in fish suggest that the TRC under either approach should be sufficiently protective of all listed fish in California; however, the trophic level concentrations expected under the Average TL Approach would be much closer to observed adverse effects concentrations described in the scientific literature. Although a lack of relevant data precludes any conclusions regarding the potential impact of the TRC on the reptile and amphibian species considered, the lower trophic level concentrations expected under the Highest TL Approach would afford a greater measure of protection than those expected under the Average TL Approach. **We believe that the TRC would not adequately protect all listed species in California; however, applying the TRC under the Highest TL Approach would reduce the number of species at risk.**

These conclusions reflect the interpretation of the evaluation results by the Service's Environmental Contaminants Division only, and are not intended to represent the views of those EPA or Service scientists who helped develop the risk assessment methodology. In addition, these conclusions do not constitute the results of consultation under Section 7 of the ESA.

Finally, it must be noted that the risk assessment methodology presented in this document was not applied to any wildlife species other than the federally listed species. Other non-listed wildlife may be potentially at risk under the TRC, due to their dietary dependence on aquatic ecosystems. **Using the same approach followed in this effort, regulatory agencies should be able to determine whether concentrations of methylmercury in fish tissue under the TRC may also pose a risk to non-listed wildlife species.**

ES Table 1. Protectiveness of EPA's Methylmercury Tissue Residue Criterion for Seven Federally Listed California Species.

Is the TRC Protective for...	Southern Sea Otter	Ca. Least Tern	Ca. Clapper Rail	Light-footed Clapper Rail	Yuma Clapper Rail	Western Snowy Plover	Bald Eagle

I. INTRODUCTION

I.A. Background

In January 2001, the U.S. Environmental Protection Agency (EPA) developed a new recommended water quality criterion for methylmercury, under section 304(a) of the federal Clean Water Act (CWA; 33 U.S.C. 1251 - 1376, as amended). The criterion, a tissue residue concentration (TRC) of 0.3 milligrams per kilogram wet weight (mg/kg, ww) of methylmercury in edible portions of fish and shellfish, was designed to protect human health against adverse effects of methylmercury toxicity. In order to fulfill consultation obligations under the federal Endangered Species Act (ESA; 16 U.S.C. 1531-1544, as amended) stemming from promulgation of the California Toxics Rule in 2000, the EPA intends to propose this criterion in the State of California. While EPA intends to propose this TRC as a human health criterion, the Agency agreed as part of the California Toxics Rule ESA consultation that the human health criterion should be sufficient to protect federally listed aquatic and aquatic-dependent wildlife species. As part of the proposal process, the EPA must complete a biological evaluation of the effects of the proposed action on federally listed and proposed threatened and endangered species (see Appendix) and critical habitat within California.

To facilitate this biological evaluation, the EPA's Region 9 entered into an Intergovernmental Agreement (IAG) with the U.S. Fish and Wildlife Service's (Service) Sacramento Fish and Wildlife Office, Environmental Contaminants Division (ECD). The primary objective of this IAG was to conduct the analyses necessary to determine whether the TRC may affect any federally listed species in California. This document presents the risk assessment methodology, developed collaboratively by scientists from both the Service and EPA, used to perform these analyses. The results of these analyses may be used by the EPA in making ESA-related effects determinations for the subsequent biological evaluation. Any such determinations are solely the responsibility of the EPA. However, this document also provides the ECD's interpretation of the analytical results and our conclusions regarding the TRC's effect on the species evaluated. These conclusions do not represent the results of consultation under Section 7 of the ESA, rather they were based solely on our current understanding of methylmercury's behavior in aquatic ecosystems and the toxicological foundation from which the risk assessment methodology was developed.

I.B. Evaluating Wildlife Protection

When sufficient methylmercury toxicity data exist to determine a dietary dose at which no adverse effects to an organism are expected, then it becomes a relatively simple process to calculate a protective methylmercury concentration in the overall diet, based on information about that organism's body weight and daily food consumption. The 0.3 mg/kg[1] TRC represents just such a generic dietary concentration for humans. The TRC is intended to be the maximum

[1] All concentrations are reported on a wet weight basis unless otherwise noted.

allowable concentration of methylmercury in freshwater and estuarine fish and shellfish that would protect human consumers, based on an average consumption of 17.5 grams of fish and shellfish per day.

However, the protection of wildlife cannot be evaluated by simply comparing a protective generic dietary concentration determined for any given species with the generic dietary concentration proposed by the human health criterion. One of the primary principles in constructing a risk assessment methodology to evaluate wildlife protection was the need to consider aquatic ecosystems in terms of trophic levels. Trophic levels are general classifications applied to the various biotic components of a food chain, and organisms are placed in these classifications depending on what they consume. Stated in its most simplistic form, trophic level 1 plants are consumed by trophic level 2 herbivores, which are consumed by trophic level 3 predators, which are then consumed by the top predators in trophic level 4. Predator-prey relationships in real-world ecosystems are generally more complex than this simple linear model, with a tendency for higher order predators to include prey from more than one trophic level in their diets. However, the risk assessment methodology employed in this evaluation was based on the assumption that the general concepts underlying the simple linear food chain model remain a valid approach for considering the trophic transfer of methylmercury in aquatic biota. Trophic levels used in this evaluation were based on definitions provided in Volume I of *Trophic Level and Exposure Analyses for Selected Piscivorous Birds and Mammals* (U.S. Environmental Protection Agency, 1995a):

Trophic Level 1 - Plants and detritus
Trophic Level 2 - Herbivores and detritivores
Trophic Level 3 - Predators on trophic level 2 organisms
Trophic Level 4 - Predators on trophic level 3 organisms

This consideration of trophic levels was necessary because methylmercury is a highly bioaccumulative pollutant which concentrates in biological tissues and biomagnifies as it moves up through successively higher trophic levels of a food chain. The TRC was not derived by assuming specific methylmercury concentrations in any particular trophic level. Instead, 0.3 mg of methylmercury per kg of fish and shellfish tissue in a daily consumed average of 17.5 g was assumed to be protective for human populations eating from various trophic levels, rather than from any particular trophic level. However, due to the characteristics of methylmercury described above, aquatic food chains do not attain a steady-state condition wherein aquatic biota from all trophic positions exhibit the same tissue concentrations. Instead, organisms higher on the food chain contain greater concentrations than those lower on the food chain. For example, if fish and shellfish from trophic level 2 (*e.g.*, herbivorous fish) contain concentrations of 0.3 mg/kg, then biota from trophic levels 3 and 4 (*e.g.*, predatory fish) will undoubtedly have higher tissue concentrations. Conversely, if aquatic biota from the highest trophic level in the system have tissue methylmercury concentrations of 0.3 mg/kg, examination of lower order biota will show substantially lower tissue concentrations. Consideration of methylmercury's propensity to bioaccumulate and biomagnify as it is passed up the aquatic food chain was critical in this

evaluation as many higher order predators (*e.g.*, piscivorous birds and mammals) eat aquatic biota from a variety of trophic levels.

There are several challenges in evaluating the TRC for its protectiveness of multiple listed fish and wildlife species. The first involves determining the dietary characteristics of the species of concern (*e.g.*, ratio of daily food ingestion rate to body weight; trophic level composition of diet). Most predators that feed from aquatic food webs are opportunistic and will consume prey from more than one trophic level. Furthermore, the distribution of prey types they consume may vary seasonally. While an overall dietary methylmercury concentration can be calculated that will protect any given species, the amount of prey consumed from each trophic level is the driving factor influencing the amount of methylmercury ingested on a daily basis. The methylmercury concentration in the overall diet for any species is dependent on both the trophic level composition of its diet *and* the methylmercury concentrations in each of the trophic levels from which the species feeds. Without an understanding of this dietary composition, it is impossible to determine the limiting concentrations for each trophic level that will result in any calculated overall dietary concentration.

A second challenge is that these dietary characteristics vary widely from species to species. While one species may eat primarily from trophic level 2, another may prey predominantly on higher trophic level organisms. Methylmercury concentrations in any trophic level that may be protective of one species may place another consumer from the same water body at increased risk.

Another challenge is due to the potential for different species of wildlife to vary in their sensitivity to methylmercury toxicity. The toxicological literature contains dosing studies from very few species of wildlife, so most ecological risk assessment methodologies, including this one, use uncertainty factors to account for unknown variations in sensitivity among species. This is discussed in more detail in Section III.D., below.

In addition to the complexities of wildlife diets, another challenge involves how the TRC is to be implemented for protection of human health. Under a strict interpretation of the criterion (*i.e.*, no fish tissue exceeding the TRC), and given an understanding of biomagnification relationships between trophic levels, it may be possible to set the TRC for trophic level 4 biota and then estimate the tissue concentrations expected for biota in trophic levels 2 and 3. If the aforementioned dietary characteristics can be determined, the various trophic level methylmercury concentrations can then be used to evaluate their protectiveness for any given species. However, in implementing the criterion, adjustments may be made to account for site-specific or regional conditions regarding human consumption of fish and shellfish. These adjustments could include apportioning a fish intake rate to the highest trophic level consumed for a specific human population. This suggests that if a specific human population consumes only trophic level 2 or 3 fish from a water body, then the TRC could be applied to those trophic levels. The increased methylmercury concentrations in higher trophic levels resulting from this implementation could then increase the exposure for top wildlife predators.

II. APPROACHES TO EVALUATION

In order to evaluate the protectiveness of any given criterion expressed as a general concentration in the overall diet of a consumer eating from various trophic levels, it is first necessary to establish concentrations specific to each trophic level. As noted above, it is possible to set the human health criterion as the limiting concentration at trophic level 2, 3 or 4, depending on the particular fish consumption habits of the human population to be protected. Alternatively, varying concentrations in each trophic level could be calculated based on different combinations of the human dietary trophic level composition (*e.g.*, 90% trophic level 4 and 10% trophic level 3 vs. 50% trophic level 4, 40% trophic level 3, and 10% trophic level 2). Although a multitude of trophic level approaches are possible, this evaluation is focused on two options, each described below.

II.A. Average Concentration Trophic Level Approach

In the human health criterion development, the TRC was determined using a national average fish consumption rate of 17.5 g/day for the general population. This national average can be broken out by determining the percentage of fish and shellfish consumed from each of the three trophic levels (TL2, TL3, TL4). A trophic level breakout was presented in the human health criterion document, although this was not intended to be used in setting concentration limits for each trophic level. However, using this breakout to estimate individual trophic level concentrations that would maintain the overall dietary concentration of 0.3 mg/kg provides one way to evaluate the protectiveness of the TRC for species of concern. The following methodology describes the steps for conducting this approach.

The first step is to estimate the methylmercury concentrations in each trophic level consumed by humans that, when combined, would correspond to the overall dietary concentration of 0.3 mg/kg. In order to do this, several input parameters must first be identified:

%TL2 - Percent of trophic level 2 biota in diet
%TL3 - Percent of trophic level 3 biota in diet
%TL4 - Percent of trophic level 4 biota in diet
MTL3 - Food chain multiplier from TL2 to TL3 biota
MTL4 - Food chain multiplier from TL3 to TL4 biota

Food chain multipliers are values derived from relationships of bioaccumulation and biomagnification between trophic levels. These can be determined several ways, depending on the information available. For example, bioaccumulation factors (BAFs) are numeric values showing the amount of contaminant uptake into biota, relative to concentrations in the water column. These BAFs can be determined for each trophic level of aquatic biota. The food chain multiplier for any given trophic level is the ratio of the BAF for that trophic level to the BAF for the trophic level directly below.

For example: BAF for water to trophic level 4 = 680,000
BAF for water to trophic level 3 = 160,000

MTL4 = 680,000/160,000 = 4.25

Any methylmercury concentration estimated for trophic level 3 biota can then multiplied by the MTL4 to estimate the expected concentration in trophic level 4 biota.

If sufficient data on existing fish tissue methylmercury concentrations are available, food chain multipliers can also be established using the ratio of these concentrations between trophic levels.

For example: Average tissue concentration in TL4 fish = 0.45 mg/kg
Average tissue concentration in TL3 fish = 0.15 mg/kg

MTL4 = 0.45/0.15 = 3

For this evaluation, food chain multipliers were calculated from draft national BAFs presented in the EPA's methylmercury criterion document. Although these values are draft only, they were empirically derived from national data. If more site-specific BAF data exist for water bodies in California, they may be used in place of the draft values to calculate food chain multipliers.

Draft national BAF for trophic level 4 = 2,700,000
Draft national BAF for trophic level 3 = 680,000
Draft national BAF for trophic level 2 = 120,000

MTL4 = 2,700,000 / 680,000 = 4
MTL3 = 680,000 / 120,000 = 5.7

Having identified the above input parameters, the following additional terms are necessary to then construct the equation for calculating trophic level concentrations necessary to maintain the overall dietary concentration:

FDTL2 - concentration in food (FD) from trophic level 2
FDTL3 - concentration in food from trophic level 3 - (equivalent to FDTL2 × MTL3)
FDTL4 - concentration in food from trophic level 4 - (equivalent to FDTL2 × MTL3 × MTL4)

The overall dietary concentration (DC) of methylmercury can be expressed in the equation:

$$\mathbf{DC = (\%TL2 \times FDTL2) + (\%TL3 \times FDTL3) + (\%TL4 \times FDTL4)} \quad \mathbf{(1)}$$

The equation can then be further arranged, substituting food chain multiplier equivalents, as:

$$\mathbf{DC = (\%TL2 \times FDTL2) + (\%TL3 \times FDTL2 \times MTL3) + (\%TL4 \times FDTL2 \times MTL3 \times MTL4)} \quad \mathbf{(2)}$$

This equation can then be solved for the concentration in the lowest trophic level:

FDTL2 = DC / [(%TL2) + (%TL3 × MTL3) + (%TL4 × MTL3 × MTL4)] **(3)**

Once the concentration in trophic level 2 is calculated, the remaining trophic levels can be determined using the food chain multiplier relationships:

FDTL3 = FDTL2 × MTL3 **(4)**

FDTL4 = FDTL3 × MTL4 **(5)**

As discussed above, the human health methylmercury criterion document presents a national average intake rate of 17.5 grams of fish per day for the general population. This national average was based on an average consumption of individual trophic levels as follows: TL2 = 3.8 g, TL3 = 8 g, TL4 = 5.7 g. These values correspond to: TL2 = 21.7%, TL3 = 45.7%, TL4 = 32.6%. Using these values, and substituting the TRC for the DC term in Equation 3, the concentration in trophic level 2 biota necessary to maintain the overall dietary concentration can then be calculated.

FDTL2 = TRC / [(%TL2) + (%TL3 × MTL3) + (%TL4 × MTL3 × MTL4)]

FDTL2 = 0.3 mg/kg / [(0.217) + (0.457 × 5.7) + (0.326 × 5.7 × 4)]

FDTL2 = 0.3 / 10.247

FDTL2 = 0.029 mg/kg

Then, using the previously calculated food chain multipliers from above:

FDTL2 = 0.029 mg/kg
FDTL3 = 0.029 × 5.7 = **0.165 mg/kg**
FDTL4 = 0.165 × 4.0 = **0.660 mg/kg**

Based on the trophic level breakout for the default human fish consumption rate identified in the criterion document, the above concentrations of methylmercury will result in an overall dietary concentration (DC) of 0.3 mg/kg:

DC = (%TL2 × FDTL2) + (%TL3 × FDTL3) + (%TL4 × FDTL4)

0.3 mg/kg = (.217 × 0.029 mg/kg) + (.457 × 0.165 mg/kg) + (.326 × 0.66 mg/kg)

II.B. Highest Trophic Level Approach

In contrast to the Average Concentration Trophic Level Approach, the Highest Trophic Level Approach sets the proposed human health methylmercury criterion of 0.3 mg/kg as the limiting concentration in edible portions of trophic level 4 fish. Concentrations expected in trophic levels 2 and 3 can then be estimated using a variation of the food chain multiplier approach described above. In effect, these multipliers determined by the ratios of trophic level concentration relationships become food chain dividers: 0.3 mg/kg in trophic level 4 is divided by the MTL4 to estimate the concentration in trophic level 3, which is then divided by the MTL3 to estimate the concentration in trophic level 2.

FDTL4 = 0.3 mg/kg
FDTL3 = 0.3 / 4 = **0.075 mg/kg**
FDTL2 = 0.075 / 5.7 = **0.013 mg/kg**

This approach is the most conservative (*i.e.*, protective) method of establishing trophic level concentrations with the TRC, as it eliminates the possibility of different human populations exceeding the protective reference dose, assuming the national average consumption rate remains constant. A diet of 100 percent trophic level 4 fish would maintain the overall dietary concentration of 0.3 mg/kg.

III. PROTECTIVE WILDLIFE VALUES

III.A. Selection of Species

The next step in this evaluation was to determine an overall dietary concentration of methylmercury that will protect each species of concern. Species considered in this evaluation include representatives from several taxonomic classes: birds, mammals, fish, reptiles, and amphibians (see Appendix). Initially, the taxonomic class or classes with the greatest potential risk from methylmercury concentrations in fish tissue were identified. For fish species, risk assessment was based solely on adverse effects associated with tissue methylmercury concentrations (see Section X). For non-fish species, the risk assessment was based on exposure through ingestion of methylmercury-contaminated aquatic prey.

The scientific literature contains little information on methylmercury risk to reptiles and amphibians, with no studies found that relate effects to dietary doses (see Section X). Throughout the past several decades, however, a great deal of toxicity research has been conducted on various birds, mammals, and fish. While toxicity data for fish indicate adverse effects resulting from a wide range of tissue methylmercury concentrations, the majority of this research has been conducted with tissue concentrations substantially higher than the TRC. Research on birds and mammals, particularly piscivorous species, is also extensive. Much of this work has involved oral dose studies.

Based on the information available in the scientific literature, and given consideration of methylmercury's capacity to bioaccumulate and biomagnify in the food chain, this evaluation assumed that upper trophic level wildlife species (*i.e.*, predatory birds and mammals) have the greatest inherent risk from exposure to methylmercury, compared to other biota. Wildlife Values (WV), which are the total dietary methylmercury concentrations that will protect predatory birds and mammals, were determined for these upper trophic level species. The methodology then allows for an assessment of whether these values would be exceeded based on the various trophic level concentrations estimated by the two approaches described above. After an analysis of the protection afforded to listed birds and mammals, the scientific literature was reviewed to see whether the listed fish, reptile, and amphibian species may be protected by either trophic level approach.

Listed species for which WVs were generated:

Southern Sea Otter (*Enhydra lutris nereis*)
California Least Tern (*Sterna antillarum brownii*)
California Clapper Rail (*Rallus longirostris obsoletus*)
Light-Footed Clapper Rail (*Rallus longirostris levipe*)
Yuma Clapper Rail (*Rallus longirostris yumaensis*)
Western Snowy Plover (*Charadrius alexandrinus nivosus*)
Bald Eagle (*Haliaeetus leucocephalus*)

III.B. Equation to Calculate Wildlife Values

A Wildlife Value represents the overall dietary concentration of methylmercury necessary to keep the daily ingested amount at or below a sufficiently protective reference dose. Reference doses (RfD) may be defined as the daily exposure to a toxicant at which no adverse effects are expected. In effect, the WV converts the protective RfD into an overall dietary concentration (in mg/kg in diet). The WV is analogous to the TRC for the human health criterion. The WV is calculated using the following equation:

$$\mathbf{WV} = \frac{\mathbf{RfD} \times \mathbf{BW}}{\sum \mathbf{FIR_i}} \qquad \mathbf{(6)}$$

WV = Wildlife Value (mg/kg in diet)
RfD = Reference Dose
BW = Body Weight (in kg) for species of concern
FIR_i = Total Food Ingestion Rate (kg food/day), from the i^{th} trophic level, for species of concern

Because the most sensitive endpoints for toxicity of methylmercury in birds and mammals relate to reproduction, the focus of this methodology is to establish reference doses based on preventing adverse impacts from maternally ingested methylmercury, that could potentially affect the reproductive viability of the species. In order to establish RfDs, the scientific literature was first

reviewed to find the most appropriate toxicity test doses for avian and mammalian species. An uncertainty analysis (described below, Section III.D.) was then conducted for each test dose to arrive at the appropriate RfD. Body weights used in this approach were those of adult females for the species of concern. Total food ingestion rates for species of concern, and the trophic level breakout of the diet, were obtained from the scientific literature or estimated using allometric equations.

III.C. Determination of Test Doses

Once the taxonomic class or classes assumed to be at greatest risk were identified (*i.e.*, predatory birds and mammals), the next step in the evaluation was to identify appropriate toxicity test doses to use for determining a protective RfD for each group. As the species of concern for this evaluation are federally listed as threatened or endangered, the goal of this step was to find the lowest test doses associated with endpoints that could adversely affect the continued existence of the species or the loss of individuals from the population. Most often these toxicity endpoints were based on subtle effects concentrations (*e.g.*, reproductive success), rather than more severe effects in individuals (*e.g.*, lethality). However, if the lowest test dose was found to cause impacts that could effectively remove an individual from the population, even without any apparent effect on reproductive success, this test dose was used in the analyses.

The approach used in this methodology assesses toxicity through ingestion of methylmercury in contaminated prey, so the scientific literature was searched for all available oral test doses demonstrating observable effects concentrations. The data preferences used in this analysis were the same as outlined in the Great Lakes Initiative (GLI) *Technical Support Document for Wildlife Criteria* (U.S. Environmental Protection Agency, 1995c):

- Appropriate endpoints (reproductive or developmental success, organismal viability or growth, other parameters influencing population dynamics)
- Chemical-specific dose-response curve
- Chronic or sub-chronic study duration
- Wildlife species preferred over traditional laboratory animals
- Field studies preferred over laboratory studies
- Oral route of exposure, although other routes acceptable if possible to convert to oral dose

Many oral dose toxicity studies report test doses as the amount of contaminant in the diet of the tested species (*e.g.*, mg/kg food). Therefore, it is often necessary to convert these reported levels to a daily ingested dose (mg/kg-bw/day), using body weights and food ingestion rates for the species studied (*i.e.*, mg/kg in food × kg food consumed per kg body weight per day = mg/kg body weight per day).

For this evaluation, the scientific literature was reviewed with particular emphasis on searching for rigorous data reported since the development of water quality wildlife criteria for the GLI in

1995. For the GLI effort, two studies that best fit the data preferences were selected to calculate the mercury wildlife criteria for avian and mammalian species. These are described below, along with relevant findings from the current literature search.

Mammalian Test Dose: In developing water quality criteria for mercury in the GLI, the EPA reviewed numerous mammalian chronic and subchronic toxicity studies. Test animals studied were rats and mink. Toxicity to mink was evaluated in two subchronic studies by Wobeser *et al.* (1976a,b), and these studies formed the basis for EPA's calculation of the mammalian wildlife criterion for mercury. Each study had different exposure durations (93 and 145 days) and dosing levels. The 145 day study dosed mink with two methylmercury concentrations (0.22 and 0.33 mg/kg) in food. These concentrations corresponded to dietary doses of 0.033 and 0.05 mg/kg-bw/day, respectively, using a food ingestion rate of 0.15 kg/day and a body weight of 1 kg for captive mink. The EPA determined that no adverse effects were seen at either dose, and concluded the 0.05 mg/kg-bw/day constituted a No Observable Adverse Effects Level (NOAEL) test dose.

From the 93 day study, the EPA determined both NOAEL and LOAEL (Lowest Observable Adverse Effects Level) test doses. A concentration of 1.1 mg/kg in food caused pathological alterations in the mink nervous system (nerve tissue lesions), while concentrations of 1.8 mg/kg and higher in food resulted in clinical signs of mercury intoxication [anorexia (loss of appetite) and ataxia (loss of coordination)] and subsequent mortality. Using the same food ingestion rate and body weight converts the 1.1 and 1.8 mg/kg concentrations to dietary doses of 0.16 and 0.27 mg/kg-bw/day, respectively. The EPA concluded that the effects seen in the 0.16 mg/kg-bw/day dose group were not associated with any obvious clinical evidence of toxicity, and that this dose constituted the NOAEL test dose, despite Wobeser's conclusion that distinct clinical signs of toxicity would have resulted had the exposure period been longer. The 0.27 mg/kg-bw/day dose was designated the LOAEL.

For several years, the U.S. Department of Energy (DOE) (1993-1996) has published *Toxicological Benchmarks for Wildlife*. These documents have also used toxicity studies of rats and mink to determine the mammalian benchmarks for methylmercury compounds. In determining final NOAEL and LOAEL values for piscivorous mammals, Wobeser *et al.*'s (1976b) 93 day study was used. The DOE's evaluation of this study agreed with the EPA's conclusion that the 1.1 mg/kg concentration constituted a NOAEL; however, using a slightly different value for the mink food ingestion rate (0.137 kg/day), a dietary dose of 0.15 mg/kg-bw/day was calculated.

In 1997, the EPA published the *Mercury Study Report to Congress* (MSRC). Volume VI of this report (U.S. Environmental Protection Agency, 1997a) presented reviews of several methylmercury toxicity tests with mammalian wildlife, including both Wobeser *et al.* (1976a,b) studies. For the MSRC, the EPA concluded that the nerve tissue lesions observed in the 1.1 mg/kg concentration group from the 93 day study were relevant effects endpoints, noting the researcher's opinion that the nerve tissue damage would have become manifested as impaired

motor function had the study continued for a longer period. For this reason, the EPA assigned the 1.1 mg/kg concentration as the LOAEL. As this was the lowest dosing group in the study, a NOAEL could no longer be determined. Instead, the EPA selected the 0.33 mg/kg concentration from the 145 day study as the NOAEL. Using the food ingestion rate found in the DOE analysis (0.137 kg/day) and a body weight of 0.8 kg (as opposed to 1.0 kg used in both the GLI and DOE reports), the EPA converted the 0.33 mg/kg dose in food to a dietary NOAEL test dose of 0.055 mg/kg-bw/day for the MSRC.

The MSRC also presented findings from a long-term feeding study with domestic cats (Charbonneau *et al*., 1974). Cats were fed various doses of methylmercury, either as methylmercuric chloride in food or as methylmercury-contaminated fish, for two years. The dietary test doses of 0.046 and 0.020 mg/kg-bw/day were determined to be the LOAEL and NOAEL, respectively, based on neurological impairment effects. These values were only used for comparative purposes, however, as the intent of the MSRC effort was to derive water quality criteria that would be protective of wildlife. The NOAEL test dose from the 145 day mink study was used in the subsequent MSRC calculations to derive criteria values for mammalian wildlife.

As all the effects seen in the semi-domesticated mink and domestic cat studies involved toxicity to individual animals, an effort was made for this evaluation to find data on effects to reproductive performance. Wren *et al*. (1987) reported no effects on reproduction in mink fed a diet supplemented with 1.0 mg/kg methylmercury every other day for 150 days. In a two generation study (G1, G2) of mink fed organic mercury-contaminated diets, Dansereau *et al*. (1999) analyzed effects on reproductive performance. Dosing groups were 0.1, 0.5, and 1.0 mg/kg total mercury. Whelping percentage for the G1 females was statistically higher in the 0.1 mg/kg group than in the 0.5 or 1.0 groups. Whelping percentages for all other G1 and G2 dosing groups were low relative to reported performance of untreated female mink. The researchers suggested that the observed linear decrease of performance with increasing methylmercury exposure may have been the result of adverse effects of methylmercury on the reproductive process; however, they were unable to show a statistically significant difference. Although the study could not conclude the reproductive process itself was adversely affected, female mink from both generations in the 1.0 mg/kg suffered mortality from methylmercury intoxication. A large percentage of first generation females died at 11 months of age, after 90 days of exposure. Death occurred approximately one month after whelping the G2 offspring. Second generation females died at the same age as their mothers, but after approximately 330 days of exposure. However, the G2 females had been mated at the age of 10 months and death occurred one month later in 6 out of 7 individuals, before giving birth. The remaining individual died shortly after giving birth. The researchers concluded that "...survival and consequently the reproduction of the G2 females fed 1.0 ppm Hg diet were therefore affected."

Although the 1999 Dansereau *et al*. study could not confirm impaired reproductive performance, it is useful for validating that a concentration of 1.0 mg/kg methylmercury in food represents an observable adverse effects level, which could inhibit the overall success of a population by removing reproductively viable individuals. The researchers found no mortality or neurological

signs of toxicity in any mink in the 0.1 and 0.5 mg/kg diet groups; however, the animals were not sacrificed and examined for histopathological effects in either of these groups. A review of the available scientific literature since the GLI revealed no new data that better fits the GLI preferences or that reports lower oral dose observed effects concentrations for mammalian wildlife. Therefore, the NOAEL dose of 0.33 mg/kg in food (0.055 mg/kg-bw/day) from the 145 day study by Wobeser *et al*. (1976a) is the appropriate test dose for determining protection of piscivorous mammalian wildlife in this evaluation.

Avian Test Dose: For the GLI effort, the EPA also reviewed numerous subchronic and chronic mercury toxicity studies using avian species. Species examined in this review included domestic chicken, pheasant, Japanese quail, red-tailed hawk, zebra finch, and game farm mallard ducks. The EPA ultimately selected a study examining reproductive and behavioral effects in three generations of mallard ducks (Heinz, 1979) to determine an appropriate test dose for its avian wildlife criteria calculations.

In these studies, three generations of mallard ducks were exposed to a mercury-free control diet or one containing 0.5 mg/kg methylmercury dicyandiamide. Several measurements of reproductive success were evaluated throughout the course of the study. Statistically significant adverse effects were observed in the percentage of eggs laid outside the nest box (increase) and in the number of one-week-old ducklings produced (decrease), relative to controls. In addition, adverse behavioral effects were seen in the ducklings from the treatment group, relative to controls. The behavioral aberrations observed included a smaller percentage of ducklings approaching tape-recorded maternal calls, and an increased sensitivity to frightening stimuli, as measured by the distance traveled in avoidance.

Based on the methylmercury concentration tested (0.5 mg/kg in food) and the reported average food consumption rate for 2nd and 3rd generation mallards in the treatment group (0.156 kg/kg-bw/day), the EPA determined a dietary dose of 0.078 mg/kg-bw/day. No lower effects concentration test doses were reported in any of the other avian toxicity studies evaluated by the EPA. As there were no lower treatment concentrations in the mallard studies, the EPA assigned this dietary dose as the LOAEL to be used in avian wildlife value calculations. For the GLI, the EPA (1995b) concluded that the mallard studies best fit the data preferences, providing a chemical-specific dose-response curve and demonstrating effects that "...clearly have potential consequences on populations of mallards exposed to methylmercury."

Although mercury toxicity has been studied extensively using avian species, both before and after the GLI effort, Heinz' (1979) multi-generational mallard work has been used almost exclusively in subsequent efforts to derive water quality values for methylmercury that are protective of avian wildlife (U.S. Department of Energy, 1994-1996; U.S. Environmental Protection Agency, 1997a; Nichols *et al*., 1999; Canadian Council of Ministers of the Environment, 2000; Buchanan *et al*., 2001; California Regional Water Quality Control Board - Central Valley Region, 2001; Evers *et al*., 2002). In large part, this is because few other studies have attempted to establish oral dose-response data from long-term feeding studies. There is a

great deal of scientific literature devoted to methylmercury residues in various avian tissues (*e.g.*, muscle, liver, egg); however, these studies were generally not designed to determine chronic dietary doses. The literature search for this evaluation only revealed a few additional studies, described below, that could be used for evaluating dietary concentrations associated with subchronic or chronic effects.

In a broad survey of freshwater lakes in Canada, which were contaminated with mercury and experienced unnatural water level fluctuations and turbidity, Barr (1986) examined the population dynamics of common loons. Loons in these systems preyed on fish containing various concentrations of methylmercury. Based on his observational data, Barr concluded that adverse reproductive effects in loons (*i.e.*, reductions in egg laying, and nest site and territorial fidelity) were associated with mean fish tissue concentrations ranging from 0.3 - 0.4 mg/kg methylmercury. As this study was not designed as a controlled feeding experiment, Barr did not convert these concentrations into daily ingested doses (*i.e.*, mg/kg-bw/day). However, Barr's reported average body weights for male and female loons (~ 4.0 kg) and assumed food consumption rate of 20 percent body weight per day (0.8 kg/day) allowed for comparison with the 0.078 mg/kg-bw/day dietary dose from the Heinz (1979) mallard work. Multiplying the lowest concentration Barr associated with adverse effects (0.3 mg/kg in fish) and the assumed average food ingestion rate (0.2 kg/kg-bw/day) produces a daily dietary dose of 0.06 mg/kg-bw/day. While the limitations of the Barr study (*i.e.*, no controlled oral dose-response data) prevent the use of this daily value as the appropriate test dose for this evaluation, it serves to support the test dose selected by the EPA for the GLI effort.

Effects of controlled methylmercury dosing on captive great egret nestlings were reported in Bouton *et al*. (1999) and Spalding *et al*. (2000a,b). In these studies, 16 great egret nestlings were captured from the wild and separated into various dosing groups (0, 0.5, 5.0 mg/kg methylmercury chloride in diet) for 14 weeks. Methylmercury was administered via gelatin capsules, and doses were maintained based on daily food consumed. Although dietary concentrations were maintained, the daily amount of methylmercury consumed per kilogram of body weight varied from 0.048 to 0.135 mg/kg-bw/day. This was because nestling body weights and food consumption rates are very dynamic during this intense growth phase. The variation in daily dietary doses limited the usefulness of these studies for determining an appropriate avian test dose for this evaluation; however, analysis of effects observed in the 0.5 mg/kg dose group for each of the three studies (described below) allowed for comparison with the LOAEL concentration from the Heinz (1979) effort.

Bouton *et al*. (1999) measured behavioral effects in the captive egrets during the period of the experiment (10-14 weeks) approximate to post-fledging in wild egrets (11 weeks of age). These researchers concluded that adverse effects, including reduced activity, food intake, and willingness to hunt prey, were demonstrated in the 0.5 mg/kg dosing group. They also postulated that these behavioral effects may result in reduced juvenile survival in free-ranging birds.

Spalding *et al*. (2000a) examined the accumulation of methylmercury in tissues of the captive egrets and its effect on growth and appetite. These researchers hypothesized that nestling wading birds would be less at risk from ingested methylmercury than fledgling birds, due to depuration of the methylmercury into the rapidly growing feathers of the younger birds. Reduced appetite, and a subsequent decline in growth, was observed after the ninth week of the experiment in both the 0.5 and 5.0 mg/kg dose group, corresponding to the cessation of feather growth. Although the magnitude of weight loss was small, the study's authors concluded that the abundance of food in the controlled setting may have masked some of the effects that would have resulted had the birds been hunting on their own. The study results supported the conclusion that, relative to pre-fledging nestlings, post-fledging birds are at an elevated risk from methylmercury exposure at even the 0.5 mg/kg dietary concentration, during the period when feathers stop growing. The researchers noted that this period also coincides with the time that young birds face the multiple risk factors of having to forage on their own, leave the natal colony, and become exposed to novel predation and disease factors.

Spalding *et al*. (2000b) examined the same egrets for histologic, neurologic, and immunologic effects. Both dosing groups exhibited effects of varying magnitude. Birds in the 5.0 mg/kg dose group showed severe ataxia, as well as hematologic, neurologic, and histologic changes, with the most severe lesions in immune and nervous system tissues. The 0.5 mg/kg dosed birds also exhibited multiple effects for various endpoints, relative to birds in the control group. In comparing their findings with effects reported in studies of wild birds, the authors concluded that the thresholds for sublethal effects measured in captive birds were lower than those in wild birds. However, these researchers attributed this discrepancy to the increased detectability of effects in controlled experiments, and suggested that LOAELs from captive studies may be a more accurate predictor of effects for field situations than field-derived LOAELs applied to captive studies.

Taken together, these three studies (Bouton *et al*., 1999 and Spalding *et al*., 2000a,b) demonstrated adverse effects in juvenile piscivorous birds exposed to a diet containing 0.5 mg/kg methylmercury. The multitude of effects reported, while not directly associated with reproduction, could have significant implications for population viability. Even if the number of offspring produced is not affected by a diet containing 0.5 mg/kg methylmercury, the number of juvenile birds becoming breeding individuals may be reduced through impaired fitness or increased mortality. These studies provided validation for adverse effects to avian species resulting from a dietary concentration of 0.5 mg/kg methylmercury.

In a similar evaluation of methylmercury impacts to juvenile piscivorous birds, Henny *et al*. (2002) studied three bird species nesting in a mercury-contaminated watershed. Various tissues and endpoints from both adult and juvenile double-crested cormorants, black-crowned night herons, and snowy egrets were measured, including methylmercury concentrations in stomach contents. Based on stomach content analyses, it was determined that young of these species were fed diets averaging 0.36 - 1.18 mg/kg methylmercury through fledging. Although adult birds were exposed to the same prey pool and had higher total mercury concentrations in their livers than fledglings, the younger birds exhibited greater evidence of sublethal toxicity to their

immune, detoxification, and nervous systems. The strongest evidence of these effects was seen in the cormorants, which had the highest average methylmercury concentration reported from stomach content analysis (1.18 mg/kg). However, these effects were also observed in the other species, with average dietary concentrations of 0.36 mg/kg (snowy egrets) and 0.43 mg/kg (black-crowned night herons). No conclusions could be drawn regarding post-fledging survival, as the study concluded at about the time of fledging. However, noting that many of the fledglings remained in the watershed after leaving the nest area, the study authors suggested that the additional period of foraging in the contaminated system, coupled with the completion of feather growth, may have critically increased the body burden of mercury and its potential toxicity.

None of the studies described above (Barr, 1986; Bouton *et al*., 1999; Spalding *et al*., 2000a,b; Henny *et al*., 2002) provided a suitable avian oral test dose for methylmercury that could be used as an alternative to the one generated in the Heinz (1979) work with mallard ducks. They do, however, confirm that a concentration of methylmercury in food around 0.5 mg/kg is sufficient to cause significant adverse effects to avian reproduction and health that could have deleterious impacts at both the individual and population levels. A review of the scientific literature revealed no other dose-response studies that established appropriate oral test doses for avian species, and the Heinz (1979) work remains the most robust benchmark for evaluating impacts to birds from methylmercury in the diet.

The body of work on mercury toxicity to avian species includes a great deal of data on residue concentrations in various tissues (*e.g.*, brain, liver, feather). Often these studies have attempted to establish threshold concentrations in specific tissues correlated with adverse effects. The use of egg concentrations is often cited as a valuable endpoint in evaluating the toxicity of methylmercury, as developing embryos are more sensitive than adults (Wiener *et al*., 2002). Reviews of studies reporting data on mercury concentrations in eggs of both wild and captive birds can be found in Thompson (1996), Burger and Gochfeld (1997), Wolfe *et al*. (1998), and Eisler (2000). However, as important as these studies are for determining concentrations associated with embryotoxic effects, relatively few provide information on the dietary doses of the laying birds that resulted in the observed egg methylmercury concentrations.

The two most commonly cited studies reporting egg methylmercury concentrations and adverse effects resulting from controlled feeding studies examined pheasants (Fimreite, 1971) and mallards (Heinz, 1979). The mallard study is the same as the one discussed above, used in determining the LOAEL dietary test dose for the GLI. From a dietary concentration of 0.5 mg/kg methylmercury, Heinz (1979) reported an average concentration over three generations of 0.83 mg/kg wet weight in eggs. Although mallard embryos were not examined for signs of toxicosis, the egg concentrations reported resulted from a dietary dose causing adverse reproductive effects. Fimreite's (1971) controlled dosing experiment with ring-necked pheasants demonstrated reduced hatchability, expressed as the percentage of eggs incubated, in egg samples containing between 0.5 - 1.5 mg/kg methylmercury. This range is similar in magnitude to the average egg concentration (0.83 mg/kg) reported by Heinz (1979), and the lower end (0.5 mg/kg) is often

cited as a LOAEL for avian eggs (Wolfe *et al*., 1998). Based on the egg concentrations and associated adverse reproductive effects reported in these two studies, it is generally accepted in the scientific literature that eggs of pheasants are more sensitive to methylmercury than mallard eggs. However, the dietary concentrations (~ 2-5 mg/kg) resulting in the range of egg concentrations observed in pheasants by Fimreite (1971) were substantially higher than the 0.5 mg/kg dietary concentration causing the similar egg values reported in mallards by Heinz (1979). This indicates a substantial difference between these species in the transfer efficiency from methylmercury in the maternal diet to methylmercury in the egg.

Recent and ongoing efforts by Heinz (pers. comm., 2003) are focused on more closely examining interspecies differences in sensitivity to egg methylmercury concentrations. Through direct injection into the eggs of various bird species, different concentrations of methylmercury can be evaluated as to their effects on developing embryos. Preliminary results seem to confirm the findings from the feeding studies described above that pheasant eggs are more sensitive than mallard eggs. In addition, there appears to be a broad range of species sensitivity, both more and less sensitive than mallard eggs. While the data from these efforts, when published, will provide important information concerning the relative magnitude of sensitivity exhibited by different species, their utility for evaluating effects from dietary methylmercury is limited by two constraints. First, it requires less methylmercury to cause adverse effects in eggs when it is injected than when naturally deposited by the mother. Therefore, species-specific LOAELs for eggs cannot be determined from injected concentrations until a relationship to maternally-deposited concentrations can be accurately determined. Second, as seen with the pheasant and mallard feeding studies, there may be wide variations among species in diet-to-egg transfer efficiency. Selecting an egg LOAEL based on the most sensitive species examined in injection studies may correspond to a higher dietary concentration, relative to other species with higher egg LOAELs.

As no other toxicity data were found that could provide a more appropriate oral test dose for avian species, the results of the Heinz (1979) study with mallard ducks was used for this evaluation. However, discrepancies were noted in the scientific literature regarding how these results were used to convert the dietary concentration (mg/kg in food) to a daily dose (mg/kg-bw/day). As described above, the EPA used the average food consumption rate for 2nd and 3rd generation mallards in the treatment group (0.156 kg/kg-bw/day) to calculate a dietary dose of 0.078 mg/kg-bw/day for use in the GLI avian wildlife criterion derivation (U.S. Environmental Protection Agency, 1995d). In a departure from this approach, the U.S. Department of Energy (1993-1996) used the average food consumption rate for the study's control group (0.126 kg/kg-bw/day) to calculate a dietary dose of 0.064 mg/kg-bw/day for the derivation of toxicological benchmarks for wildlife. This lower value has been used in Wolfe and Norman (1998) and California Regional Water Quality Control Board - Central Valley Region (2001), while the higher value has been used in Nichols *et al*. (1999), Canadian Council of Ministers of the Environment (2000), Buchanan *et al*. (2001), and Evers *et al*. (2002). Further confounding the matter, the MSRC used the higher value in one volume (Vol. VI) (U.S. Environmental Protection Agency, 1997a) and the lower value in a different volume (Vol. VII) (U.S. Environmental

Protection Agency, 1997b), although the higher value was used in the Report to calculate water quality criteria.

In an effort to understand the rationale for using the control group's food consumption rate to calculate a LOAEL, the author of the 1979 mallard study was contacted (Heinz, pers. comm., 2002). Heinz stated that the difference in his reported ingestion rates for the two study groups was not due to greater wastage on the part of the treatment group, and further, that the reported rates were probably not very accurate for either group. He explained that the ability to distinguish wasted food from the debris at the bottom of test subject cages (fecal matter, undigested food, *etc*.) was insufficient to calculate feeding rates with a great degree of precision. However, based on his understanding of work subsequent to the 1979 study, Heinz believes that true mallard feeding rates are likely even lower than the rates he reported (0.1 kg/kg-bw/day vs. 0.128 and 0.156). While Heinz did not suggest a 0.1 kg/kg-bw/day ingestion rate be used to determine the LOAEL, he did caution against using the 0.156 kg/kg-bw/day rate reported for his 1979 treatment group. This conversation supported the use of the 0.064 mg/kg-bw/day LOAEL calculated with Heinz' control group feeding rate as the appropriate dietary dose for evaluating risk to avian species, with the acknowledgment that true mallard feeding rates may suggest the need for a lower LOAEL.

III.D. Determination of Reference Doses

As noted previously, a reference dose (RfD) may be defined as the daily exposure to a toxicant at which no adverse effects are expected, analogous to NOAEL doses determined from toxicity tests. However, RfDs are intended to protect all species likely to be at risk from exposure to the contaminant, from each taxonomic class for which test doses were determined. Ideally, toxicity tests to determine chronic effects of a contaminant will be of sufficient duration and dose spacing to allow for establishment of a reliable NOAEL. For a variety of reasons, the duration and dose spacing of many toxicity tests are not suitable for this, and NOAELs must be extrapolated from the test information available. In addition, any NOAELs established may only be applicable for the species tested. Extrapolating any given test dose into a RfD at which no adverse effects are expected, for potentially a broad range of species, involves some amount of uncertainty.

In order to determine the RfD for a given taxonomic group, the test dose selected to represent that group may need to be adjusted by uncertainty factors to incorporate variability in toxicological sensitivity among species and to extrapolate for duration (subchronic-to-chronic) or dose spacing (LOAEL-to-NOAEL) issues. The RfD is calculated using the following equation:

$$\mathbf{RfD} = \frac{\mathbf{TD}}{\mathbf{UF_A} \times \mathbf{UF_S} \times \mathbf{UF_L}} \qquad \mathbf{(7)}$$

RfD = Reference Dose (mg/kg-bw/day)
TD = Test Dose (mg/kg-bw/day)
UF_A = Interspecies Uncertainty Factor (unitless)
UF_S = Subchronic-to-Chronic Uncertainty Factor (unitless)
UF_L = LOAEL-to-NOAEL Uncertainty Factor (unitless)

The concept of adjusting test doses to account for these types of uncertainty has been widely used in efforts to develop avian and mammalian reference doses for methylmercury that would be protective of a range of wildlife species (U.S. Department of Energy, 1993-1996; Canadian Council of Ministers of the Environment, 2000; Buchanan *et al*., 2001; California Regional Water Quality Control Board - Central Valley Region, 2001; Evers *et al*., 2002). However, the majority of these efforts have used the same uncertainty factors originally determined in either the GLI effort (U.S. Environmental Protection Agency, 1995d) or the MSRC (U.S. Environmental Protection Agency, 1997a,b). Guidance on determining the appropriate values for each uncertainty factor can be found in two EPA documents: *Technical Basis for Recommended Ranges of Uncertainty Factors used in Deriving Wildlife Criteria for the Great Lakes Water Quality Initiative* (Draft Report) (Abt Associates Inc.,1995) and Great Lakes Water Quality Initiative *Technical Support Document for Wildlife Criteria* (U.S. Environmental Protection Agency,1995a).

Mammalian RfD: As described previously in Section IV,C (Determination of Test Doses), the EPA selected studies by Wobeser *et al*. (1976a,b), in both the GLI and the MSRC, to determine the appropriate mammalian test dose for calculating the RfD. However, the two efforts applied different assumptions and arrived at different test doses. For the GLI, a test dose of 0.16 mg/kg-bw/day was determined to be the NOAEL, while the MSRC concluded the test dose of 0.055 mg/kg-bw/day was the appropriate NOAEL. In addition to this difference, each effort then applied different uncertainty factors to each test dose to determine the RfD.

In the GLI, the UF_A and UF_L were both assigned a value of 1. This was because the experimental animal (mink) and the representative species to be protected (river otter) are closely related and assumed to be similarly sensitive, and because the study identified a NOAEL. The UF_S was set at a value of 10 because the study chosen (Wobeser *et al*., 1976b) was of subchronic duration. Applying these three combined uncertainty factors to the test dose of 0.16 mg/kg-bw/day resulted in a mammalian RfD of 0.016 mg/kg-bw/day.

For the MSRC, the UF_A and UF_L were also both assigned a value of 1, for the same reasons outlined above. However, the UF_S for this effort was set at a value of 3 because the effects observed at the subchronic NOAEL (Wobeser *et al*., 1976a) were not associated with overt signs of toxicity (Nichols *et al*., 1999). Applying these three uncertainty factors to the test dose of 0.055 mg/kg-bw/day resulted in a mammalian RfD of 0.018 mg/kg-bw/day.

So despite the discrepancy regarding the appropriate test dose for mammals, both efforts arrived at roughly the same mammalian RfD. The single mammalian species of concern for this

evaluation is the southern sea otter (*Enhydra lutris nereis*), in the same taxonomic family (*Mustelidae*) as the mink and river otter. Therefore, no further adjustments to the UF_A or UF_L were necessary. The analyses regarding the mammalian test dose and UF_S presented in the MSRC represent the most current comprehensive assessment of these Wobeser *et al*. (1976a,b) studies. As a result, **a mammalian RfD of 0.018 mg/kg-bw/day** was used in this evaluation (Table 1.).

Avian RfD: Similar discrepancies concerning uncertainty factors for the avian RfD were noted between the GLI and the MSRC. Both of these efforts agreed on an avian test dose (0.078 mg/kg-bw/day) from the three generation mallard duck study (Heinz, 1979), and both agreed that the UF_S should be assigned a value of 1 because the study was of sufficient chronic duration. However, varying assumptions regarding LOAEL-to-NOAEL relationships and interspecies sensitivity resulted in each effort assigning different UF_L and UF_A values.

Regarding the UF_L, a value of 2 was assigned for the GLI because the LOAEL identified by the EPA from the mallard study, 0.078 mg/kg-bw/day, "...appeared to be very near the threshold for effects of mercury on mallards." As explained in Nichols *et al*. (1999), a range of 1 - 10 was used to set the UF_L values in the GLI, based on an evaluation of chronic toxicity studies with wildlife species using five chemicals (cadmium, DDT, DDE, dieldrin, and mercury). This conclusion was reached after determining that 97 percent of the LOAEL-to-NOAEL ratios examined were less than or equal to 10 and 50 percent were less than or equal to 3.

In contrast, the authors of the MSRC evaluated toxicity studies with methylmercury only. Twenty LOAEL-to-NOAEL ratios were calculated, with the majority between 1 - 2 or 4 - 5 (Nichols *et al*., 1999). For the final calculations of wildlife criteria values in the MSRC, the UF_L was assigned a value of 3. The MSRC (Vol. VI) concluded that "Given the substantial uncertainties in all the values used to calculate the WC for mercury exposure, neither two nor three can be considered to be the only correct value" (U.S. Environmental Protection Agency, 1997a).

The conceptual basis for use of a UF_A is that toxicokinetic and/or toxicodynamic differences among species may result in variable responses to the same applied dose. Empirical data from acute and chronic toxicity tests with wildlife species support the use of a UF_A ranging from 1 to 100 when extrapolating toxicological effects across species. Values tending toward the lower end of this range may be justified by several factors including: 1) the amount and quality of available testing data, 2) a close taxonomic relationship between the tested species and the species of interest, 3) similarity in size of the tested species and the species of interest, and 4) toxicokinetic and / or toxicodynamic information which would suggest that the tested species is likely to be more sensitive than the species of interest.

For the GLI, a UF_A greater than 1 was recommended because of the need to extrapolate mallard data to species in different taxonomic orders, and because of the possibility that another of the species (pheasant) examined in toxicity studies might prove more sensitive if given a longer

exposure duration. However, because the analysis of suitable avian toxicity values reviewed for the GLI indicated that the mallard was possibly the most sensitive to mercury of the six species examined, the conclusion was drawn that a UF_A of 10 would likely be overly conservative. A UF_A of 3 (half-way between 1 and 10 on a log 10 scale) was therefore applied as a reasonable protection for those species that may be more sensitive than mallards.

The question of interspecies sensitivity was revisited in the MSRC. The three species selected in the GLI to represent avian wildlife (belted kingfisher, herring gull, bald eagle) are piscivorous birds. The authors of the MSRC cited literature suggesting that piscivorous birds possess, in comparison to non-piscivorous birds, a greater capacity to demethylate and thereby detoxify methylmercury. Although piscivorous birds are likely faced with the greatest exposure to methylmercury, the MSRC authors concluded that these birds are unlikely to be more sensitive than mallard ducks (an omnivorous species) to the toxic effects of methylmercury, and that application of a UF_A greater than 1 was unwarranted for piscivorous species. Research conducted since publication of the MSRC has provided additional support for the existence of a protective demethylating capability in piscivorous birds (Henny *et al*., 2002). As the species selected in the MSRC to represent avian wildlife (belted kingfisher, loon, osprey, bald eagle) are also piscivorous, the UF_A for that effort was assigned a value of 1. In summary, the uncertainty factors used in both the GLI and the MSRC to adjust the mallard test dose to an avian RfD were as follows:

	GLI	MSRC
UF_A	3	1
UF_S	1	1
UF_L	2	3

For this evaluation, two of the federally-listed avian species of concern are primarily (bald eagle) or exclusively (California least tern) piscivorous. For these species, the rationale used in the MSRC to assign a UF_A of 1 is therefore applicable. This effort differs, however, from both the GLI and MSRC efforts insofar as it includes consideration of four species (California clapper rail, light-footed clapper rail, Yuma clapper rail, and snowy plover) which feed extensively on invertebrates, including (in the case of the snowy plover) invertebrates of non-aquatic origins.

No information could be found regarding the capability of clapper rails or snowy plovers to detoxify methylmercury. Henny *et al*. (2002) provided some data indicating that adult birds whose diet consists largely of aquatic invertebrates may also possess this detoxifying capacity. In this study, Henny *et al*. examined three bird species nesting in a mercury-contaminated watershed. Examination of stomach contents for two of these species, black-crowned night herons (*Nycticorax nycticorax*) and snowy egrets (*Egretta thula*), revealed diets ranging from 100 percent fish to 100 percent large aquatic insect larvae. The diet of the third species, double-crested cormorant (*Phalacrocorax auritus*), was comprised entirely of fish. Analysis of livers from all three species indicated that hepatic demethylation, possibly in a dose-dependent

relationship, allowed adult birds to tolerate relatively high mercury concentrations without apparent adverse effects. Fledglings did not exhibit the same degree of tolerance to liver mercury concentrations; however, the study ended before it could be determined whether hepatic demethylation would become more pronounced as the fledglings matured. The results of this study lend support to the idea that even birds that are not strictly piscivorous, but still primarily consume aquatic biota, may be less sensitive to methylmercury than the non-piscivorous mallard.

However, as described previously in the section on avian test doses, there has been recent work on interspecies sensitivity to methylmercury using egg injection studies (Heinz, pers. comm., 2003). The clapper rail is one of the species examined thus far whose sensitivity to methylmercury in the egg appears to be greater than the mallard, perhaps closer in sensitivity to the pheasant. These results are preliminary only, and presently it is impossible to translate differences in sensitivity of clapper rail and mallard duck eggs to an injected dose of methylmercury into an ecologically meaningful comparison. No information was available from this work on the amount of methylmercury in food necessary to achieve any observed egg effects concentrations or on the relationship of observed effects concentrations to a maternally-deposited dose. The diet-to-egg transfer efficiency can vary widely between different species, as evidenced by the controlled feeding studies with mallards (Heinz, 1979) and pheasants (Fimreite, 1971). It would be imprudent to assume that similar sensitivities to egg concentrations between the clapper rail and the pheasant would necessarily be caused by the same dietary concentration. However, although no definitive conclusions can presently be drawn as to whether the clapper rail is more or less sensitive to methylmercury in food than the mallard, the need for a greater UF_A for this species in determining a reference dose could not be ruled out.

Based on the information outlined above, the uncertainty factors presented in the MSRC are more generally appropriate than those from the GLI for determining the avian reference dose. However, because several of the bird species considered in this effort are not obligate piscivores, the argument presented in the MSRC for using a UF_A of 1 may not be appropriate for these species. For this reason the derivation and subsequent assessment of WVs was based on a UF_A of 1 for piscivorous avian species (least tern and bald eagle) and UF_As of both 1 and 3 for the snowy plover and clapper rails. The UF_A of 3 was selected using the same rationale from the GLI (*i.e.*, half-way between 1 and 10 on a log scale). The alternative reference doses generated by the two UF_As provided for a comparative analysis of protection afforded by both evaluation approaches.

Based on the avian TD of 0.064 mg/kg-bw/day from the Heinz (1979) mallard duck study, and the uncertainty factors from the MSRC, **an avian RfD of 0.021 mg/kg-bw/day** was used in this evaluation (Table 1.). An **alternative avian RfD of 0.007 mg/kg-bw/day** was also presented for the three clapper rail subspecies and the snowy plover.

Table 1. Test Doses, Uncertainty Factors, and Reference Doses for Birds and Mammals

	Mammals	All Birds	Clapper Rails / Snowy Plover
Test Dose	0.055 mg/kg-bw/day	0.064 mg/kg-bw/day	0.064 mg/kg-bw/day
UF_A	1	1	3
UF_S	3	1	1
UF_L	1	3	3
RfD	0.018 mg/kg-bw/day	0.021 mg/kg-bw/day	0.007 mg/kg-bw/day

IV. CALCULATING WILDLIFE VALUES: BODY WEIGHTS, DIETARY COMPOSITION, FOOD INGESTION RATES

Once the RfDs for each taxonomic group were determined from the appropriate test doses, species-specific WVs were calculated (Equation 6; see page 7). This required information on average adult female body weights (kg) and species-specific daily food ingestion rates (FIR *in* kg food/day). References for body weights are provided in each species account below.

Allometric calculations to determine FIRs for numerous wildlife species have been developed by Nagy (1987 and 2001), based on measurements of free-living metabolic rates (FMR) and the metabolizable energy (ME) in various foods (*e.g.*, fish, birds, mammals). Generic allometric equations from Nagy (1987) to calculate FIRs for broad categories (*e.g.*, all birds, passerines, seabirds) were presented in the *Wildlife Exposure Factors Handbook* (U.S. Environmental Protection Agency, 1993). These equations provide FIR in grams of dry matter per day, which can then be converted to wet weight based on percent moisture in the food. More recent work by Nagy (2001) expanded on the development of generic allometric equations, providing both dry weight and wet weight calculations for a broader range of distinct wildlife categories (*e.g.*, Charadriiformes, Galliformes, Insectivorous Birds, Carnivorous Birds). However, because all the generic allometric equations are based on the compilation of metabolic data from a wide range of species, they may not provide the most accurate estimate of FIRs for specific species of concern. If available, estimates of FMR, dietary composition, and assimilation efficiency (AE) for the species of concern should be considered, as this information will provide a more accurate estimate of daily food requirements.

Dietary composition, the amount of each food type consumed on a daily basis, is a critical component in determining FIR, as different foods provide different amounts of gross energy (*e.g.*, kcal/g food matter) to the consumer. For example, the gross energy (GE) available from aquatic invertebrates is greater than that available from aquatic algae (U.S. Environmental

Protection Agency, 1993). The AE values for different foods may also vary substantially. For example, a bird eating aquatic invertebrates assimilates the available energy at a substantially higher efficiency (77%) than if it were eating aquatic vegetation (23%) (U.S. Environmental Protection Agency, 1993). Therefore, the amount of aquatic invertebrate food necessary to fulfill the energetic requirements of a bird consumer would be substantially less than the amount of aquatic vegetation needed to meet the same requirements.

In addition to providing the percentages of each food type in a wildlife consumer's diet, feeding ecology studies can establish the trophic level composition of the diet. While this information is not necessary for calculating WVs, it is essential for evaluating whether either of the TRC trophic level approaches presented here will result in an exceedance of the WVs. Ideally, dietary information on both food type amounts and trophic level composition can be determined in percent biomass, as this provides the most accurate representation of actual ingestion. However, due to the difficulty inherent in determining the exact daily dietary composition of any free-living animal, dietary studies often rely on frequency of feeding observations or analysis of prey remains or a combination of both. These types of data pose less of a problem if the prey species are the same kind (*e.g.*, all fish) and roughly the same size. As the diversity of the prey base increases, however, the relative contribution from each prey item to the daily ingested biomass can be over- or under-represented if reported on the basis of occurrence frequency. For example, observations of predation may indicate an animal consumes small crabs and clams in equal amounts (*i.e.*, 50% clams:50% crabs). However, clams may provide more biomass per animal consumed than crabs, indicating the need for a different dietary ratio (*e.g.*, 70% clams:30% crabs) in estimating food ingestion rates and determining whether WVs will be exceeded.

The following accounts present the best available information regarding dietary composition and FIRs for the species of concern in this evaluation. When species-specific information regarding metabolic needs and assimilation efficiencies for various food types was not available, FIRs were determined using the most appropriate allometric equations from Nagy (2001). When this information was available, FIRs were determined using equations to estimate FMR (Nagy, 1987) and the methodology described in the *Wildlife Exposure Factors Handbook* (U.S. Environmental Protection Agency, 1993). The reader is directed to the three references mentioned for a complete explanation of the allometric methodology.

As the goal of the evaluation was to consider potential effects to animals living and breeding in California, every attempt was made to find the most rigorous dietary data for resident animals. For some species, few detailed feeding studies have been conducted. As a result, some of the following dietary information is based on only one or two studies, some conducted several decades ago. Until new data are generated, however, these studies remain the best source for dietary information.

IV.A. Southern Sea Otter (*Enhydra lutris nereis*):

Sea otters are the largest member of the Mustelidae family but one of the smallest marine mammals (Riedman and Estes, 1988). Based on length measurements of dead sea otters in California, the predicted average weights of healthy animals are 29.0 kg (males) and 19.8 kg (females) (Riedman and Estes, 1990). Although individual body weights may vary from these values, the predicted **average weight for female otters (19.8 kg)** was used for the calculation of wildlife values in this evaluation.

Information on southern sea otter diet was taken primarily from Riedman and Estes (1988, 1990). The diet of southern sea otters rarely or never includes fish, instead being comprised almost exclusively of benthic macroinvertebrates. Over 60 different invertebrate species have been identified as prey items of southern sea otters. However, sea otter diet is influenced by prey species availability, length of time otters have occupied an area, habitat type, and time of year.

Southern sea otters are primarily associated with subtidal habitats characterized by rocky substrata, although they are also found in areas with soft-sediment substrata. The main prey items in rocky subtidal habitats are abalones (*Haliotis* spp.), rock crabs (*Cancer* spp.), and red sea urchins (*Strongylocentrotus* spp.) (Riedman and Estes, 1988). Abalones and sea urchins are predominantly herbivorous, while rock crabs (*e.g.*, red crab, Dungeness crab) are carnivorous on small crustaceans, clams, and oysters (Morris *et al*., 1980). Sea otters in soft-sediment substrata also rely heavily on bivalve molluscs (*e.g.*, Pismo, Washington, and gaper clams), although the 13 soft-sediment species identified as prey in these habitats include rock crabs and the Lewis's moon snail (*Polinices lewisii*) (Kvitek and Oliver, 1988). The moon snail is primarily a predator on clams (Morris *et al*., 1980).

In addition to the aforementioned invertebrates, southern sea otter diets can include a wide variety of prey: kelp crabs (*Pugettia* spp.), turban snails, mussels (*Mytilus* spp.), octopus (*Octopus* spp.), barnacles (*Balanus* spp.), scallops (*Hinnites* spp.), fat innkeeper worms, sea stars (*Pisaster* spp.), and chitons (*Cryptochiton* spp.) (Riedman and Estes, 1990). Seasonal abundance can also play a role in determining important food items. Squid, spawning during fall and spring in Monterey Bay, constitute a large component of some sea otter diets (Riedman and Estes, 1990). Sea otters also occasionally prey on various seabirds, including western grebes (*Aechmophorous occidentalis*), surf scoters (*Melanitta perspicillata*), cormorants (*Phalacrocorax* spp.), common loons (*Gavia immer*), and gulls (*Larus* spp.). However, observations of this foraging behavior suggest that it is rare and that male otters may be responsible for the majority of seabird predation (Riedman and Estes, 1990).

The diet of southern sea otters may include a number of species considered trophic level 3 organisms (*e.g.*, octopus, squid, rock crab, moon snail, sea stars), although trophic level 2 organisms (*e.g.*, abalones, clams, mussels, urchins) appear to be the predominant prey. However, diet and foraging strategy appear to vary between individual otters, even within the same foraging habitat (Riedman and Estes, 1988). Sea otters appear to specialize on certain available

prey species, and these preferences may be maintained for several years. Observations of tagged female sea otters in Monterey Bay provided examples of this specialization, with one female preferentially eating kelp crabs, turban snails, and purple urchins, while another female foraged on abalones and rock crabs (Riedman and Estes, 1988).

This apparent foraging specialization, coupled with the diverse array of prey known to be consumed by sea otters, makes it difficult to assign a particular dietary trophic level composition. In a study of foraging in soft-sediment habitats, clams (trophic level 2) were captured and eaten on more than 75 percent of successful foraging dives (Kvitek and Oliver, 1988). Crabs considered trophic level 3 organisms (*Cancer* spp.) appeared to account for only a small percentage (~ 4%) of the diet, with other, lower trophic level crabs (*e.g.*, mole crab, kelp crab) and molluscs comprising the remainder. No comparable estimations of dietary composition were found for otters in rocky habitats, although it appears generally accepted that trophic level 2 organisms like abalones and sea urchins account for the majority of food consumed by these otters. However, based on the availability of a variety of trophic level 3 prey and the potential for individual otters to specialize on certain species, the dietary composition used for evaluating the TRC trophic level approaches for sea otters was **20 percent trophic level 3, 80 percent trophic level 2**. These are not static values and further research may indicate the need for an alternate estimation of dietary composition.

It has been estimated that free-ranging adult sea otters may consume food equivalent to 23-33 percent of their body weights per day (Riedman and Estes, 1990). Using the high end of this range (*i.e.*, 33%) as a conservative approach to represent the assumed higher metabolic needs of a breeding female sea otter, and the predicted average female weight of 19.8 kg results in a daily food ingestion rate of 6.5 kg/day. This estimate of FIR is substantially higher than what would be expected using any of the allometric equations described previously. However, this apparent discrepancy may be explained by considering the sea otter's metabolism and energetic requirements. Sea otters are small relative to other marine mammals, and lack the blubber layer which provides insulation and an energy reserve. Sea otters compensate for the thermal stress of a marine existence by maintaining a high level of internal heat production; 2.4 - 3.2 times that expected for a terrestrial mammal of similar size (Riedman and Estes, 1990). Based on the otter's elevated energetic requirements, it has been estimated that a 20 kg adult would need between 4,295 and 5,750 kcal/day (Riedman and Estes, 1990), roughly twice the FMR estimated using Nagy's allometric equation for all placental mammals (U.S. Environmental Protection Agency, 1993).

FIR for southern sea otter = 6.5 kg wet weight/day

IV.B. California Least Tern (*Sterna antillarum browni*):

The least tern is the smallest of the tern species that nest on open beaches and islands free of vegetation (Thompson *et al*., 1997). Adult female body weights presented in this reference range from 36 - 62 g; however, this range includes three geographic subspecies: *S. a. antillarum* (U.S.

Atlantic/Gulf coasts, West Indies); *S. a. athalassos* (interior U.S.); and *S. a. browni* (California coast, west coast of Mexico). The mean weight for *S. a. antillarum* is 49.3 g, while that of *S. a. athalassos* is 42.5 g. The reported weight for *S. a. browni* (39.8 g) was only based on one specimen. Dunning (1993) reported a mean weight of 43.1 g (unknown sex) for breeding birds in Kansas (most likely *S. a. athalassos*). Using the mean weights reported in Thompson *et al.* (1997) for the two coastal subspecies results in an **average adult female body weight of 45 g**.

Although other subspecies' diets include small crustaceans and insects (Thompson *et al.*, 1997), the California least tern appears to be strictly piscivorous (Massey, 1974). Breeding colonies may form on beach sites along the coast or on suitable alternative substrates set back from the ocean (U.S. Fish and Wildlife Service, 1985a). Colonies are generally located either near the coast, or near lagoons, estuaries, or rivers (Thompson *et al.*, 1997).

Individuals from three breeding colonies near the coast, that had little or no freshwater or estuarine habitats nearby, were found to forage almost exclusively in relatively shallow, nearshore ocean waters in the vicinity of major river mouths (Atwood and Minsky, 1983). Terns were observed to feed on three primary forage fish species: northern anchovy (*Engraulis mordax*) and two species in the silversides family - topsmelt (*Atherinops affinis*) and jacksmelt (*Atherinopsis californiensis*). Prey size at two coastal colonies varied for each tern age class, with chicks consuming smaller fish than adults or juveniles. However, 73 percent of the three primary forage fish species eaten by all age classes were less than 5 cm in length (Atwood and Kelly, 1984).

In contrast to tern colonies which foraged mainly in nearshore ocean waters, terns from breeding colonies located near estuarine habitats fed primarily in shallow saltmarsh channels and tidal estuaries (Atwood and Minsky, 1983; Atwood and Kelly, 1984). The dominant forage fish species in these waters, and the majority (82%) of fish dropped at a colony in Anaheim Bay, were the topsmelt and California killifish (*Fundulus parvipinnis*). Atwood and Kelly (1984) found that fish dropped at breeding tern colonies, either accidentally or from lack of hunger, were generally valid indicators of the principal prey species consumed. Two other forage fish, deepbody anchovies (*Anchoa compressa*) and slough anchovies (*Anchoa delicatissima*), were the most abundant prey dropped at two southerly colonies, although no distinction was made as to where terns from these colonies foraged (Atwood and Kelly, 1984). Although a total of 49 forage fish species, all represented by individuals less than 1 year old, were found at 10 breeding tern colonies, Atwood and Kelly (1984) concluded that five fish (northern anchovy, topsmelt, jacksmelt, deepbody anchovy, slough anchovy) represented the main food items at least tern breeding colonies in California.

Foraging ecology for a tern breeding colony located near San Francisco Bay has been monitored for numerous years, providing a long-term assessment of the colony's dietary preferences (Elliott and Sydeman, 2002). Prey fish dropped at the colony by foraging birds were collected and identified from 1981-1982, 1984-1995, and 2000-2001. Although minor variations in forage fish species abundance were reported between years, the combined data from all years revealed that

three fish (topsmelt, jacksmelt, northern anchovy) accounted for more than 86 percent of all samples collected. The next most abundant prey (> 7% of total) were various surfperch species (*Embiotocidae*).

Based on the above information, the diet of adult female California least terns is comprised solely of small fish from various species. Several of these species (northern anchovy, topsmelt, jacksmelt, California killifish) appear to account for the majority of prey items taken by both courting and nesting terns, including those birds that forage in estuarine and tidal waters. In addition, data indicate that the majority of fish captured by breeding terns are small (5 cm or less) and all are young-of-year (Atwood and Kelly, 1984). According to the *Trophic Level and Exposure Analyses for Selected Piscivorous Birds and Mammals* (Vol. III) (U.S. Environmental Protection Agency, 1995b), these prey species are generally considered trophic level 3. Even juvenile fishes from this group (*e.g.*, topsmelt, northern anchovy) are listed as trophic level 3 by this reference.

It is important to note that all of these forage fish species exhibit some amount of omnivory, feeding to varying degrees on primary producers and detritus. Juvenile northern anchovies generally consume small crustaceans and other zooplankton, although algae and other phytoplankton may constitute a substantial portion of their diet (Wang,1986). Anchovies can be filter-feeding or biting planktivores, indicating the ability to selectively prey on individual organisms (California Department of Fish and Game, 2001). Similarly, the diet of the California killifish consists primarily of benthic and planktonic invertebrates, with juveniles more likely than adults to feed on terrestrial insects and zooplankton (Moyle, 2002). West and Zedler (2000) examined gut contents of adult killifish and reported algae and detritus as minor dietary items. Nonetheless, both anchovy and killifish appear to feed primarily on trophic level 2 organisms.

In contrast to the anchovy and killifish, the feeding habits of the other two primary tern prey fish (topsmelt and jacksmelt) indicate a greater dietary dependence on trophic level 1 food. Wang (1986) listed the major food items for juvenile jacksmelt as algae, detritus, and small crustaceans. In addition, amphipods were described as a common food item. The same reference (Wang, 1986) states that juvenile topsmelt feed on crustaceans, diatoms, algae, detritus, chironomids, and amphipods. The California Department of Fish and Game (2001) states that topsmelt inhabiting intertidal areas consume algae and fly larvae, as well as crustaceans. Moyle (2002) points out that the diet of small topsmelt (4.9 - 5.6 cm) in one estuary consisted primarily of diatoms and filamentous algae (50% by volume), and detritus (29%), with chironomid midge larvae and amphipods comprising an additional 20 percent.

While all of these forage fish may incorporate some amount of primary producers and detritus in their diets, none can be considered exclusively trophic level 2 consumers. California least terns are not species-specific predators; therefore, their overall dietary composition will vary depending on the relative abundance of suitable prey species. At any given time or location, it is impossible to predict whether prey fish are primarily consuming plant material or the trophic level 2 organisms that feed on plant material. In order to adequately evaluate the full potential

impact of the methylmercury TRC on the endangered California least tern, a diet of **100 percent trophic level 3 fish** is assumed.

The FMR for least terns was estimated using Nagy's allometric equation for all birds (*in* U.S. Environmental Protection Agency, 1993):

FMR (kcal/day) = 2.601 × (body weight in g)$^{0.640}$
FMR = 2.601 × 45 $^{0.640}$
FMR = 29.7 kcal/day

The FIR was then calculated using the equation:

FIR = FMR ÷ metabolizable energy from food (ME)

where ME equals the gross energy (GE) from the food type times the assimilation efficiency (AE) of the animal consuming that food. The GE of bony fishes is 1.2 kcal/g wet weight. The AE for birds consuming fish is 79%. Therefore, the ME for the least tern is 0.948 kcal/g fish.

FIR = 29.7 kcal/day ÷ 0.948 kcal/g fish

FIR for California least tern = 0.031 kg wet weight/day

IV.C. California Clapper Rail (*Rallus longirostris obsoletus*):

The California clapper rail (*R. l. obsoletus*) is the largest of the three rail subspecies considered in this evaluation, followed in descending order by the light-footed and Yuma clapper rails (U.S. Fish and Wildlife Service, 1976). In the only literature found for this particular subspecies that provided body weights, nineteen female California clapper rails from south San Francisco Bay were examined as part of a Master's Degree thesis (Albertson, 1995). Weights ranged from 300 to 400 g, with a **mean weight of 346.1 g**. This mean value was used for the calculation of a wildlife value for this subspecies.

The most comprehensive assessment of the California clapper rail diet is presented by Moffitt (1941). Stomach contents from 18 birds were examined and the food items identified and measured as a volumetric percentage. On average, animal matter accounted for approximately 85 percent of the diet, with the remainder composed of seed and hull fragments of marsh cordgrass. Over half (56.5%) of the overall diet was comprised of plaited horse mussels (*Modiolus demissus*). Spiders of the family Lycosidae (wolf spiders) accounted for 15 percent of the diet, while little macoma clams (*Macoma balthica*) (7.6%), yellow shore crabs (*Hemigrapsis oregonensis*) (3.2%), and worn-out nassa snails (*Ilyanassa obsoletus*) (2.0%) were the remaining important dietary items. Worms, insects, and carrion combined accounted for a total of 1.1 percent of the remaining diet found by Moffitt (1941) in the 18 clapper rail stomachs. The importance of crabs in the clapper rail diet was confirmed by Varoujean (1972), who observed

rails eating striped shore crabs (*Pachygrapsus crassipes*).

Although Moffitt (1941) reported that plant matter accounted for approximately 15 percent on average of the clapper rail diets, the author stated that this percentage probably represented the maximum of a vegetable diet. This conclusion was based on the fact that the birds were collected in early February, a time when animal food items would typically be at lowest abundance. However, it is important to note that this reported average for plant food (~15%) was calculated from a wide range of percentages in the 18 birds examined (0% - 58% plant food). As with other omnivorous species, the amount of any particular food item consumed at any given time may vary substantially depending on a number of factors. While clapper rails most likely do not eat a set amount of plant matter daily, it is clear from Moffitt (1941) that vegetation generally constitutes a substantial dietary item over time.

Based on Moffitt's (1941) assumption that his mid-winter gut analyses represented a maximum for vegetation in the clapper rail diet, and the knowledge that clapper rails nest during a time when animal foods would be in greater abundance (mid-March - July) (U.S. Fish and Wildlife Service, 1984), the overall rail diet for this effort is assumed to be 10 percent vegetation and 90 percent animal matter. For the purposes of this evaluation, the vegetation portion of the diet will be considered as food not contributing to the daily ingested dose of methylmercury. Although mercury is known to accumulate in aquatic plants (Gupta and Chandra, 1998; Ellis and Eslick, 1997; Breteler *et al*., 1981), the scientific literature indicates that accumulation is primarily in the roots rather than in the rhizomes or above-ground tissues (Boening, 2000; Breteler *et al*., 1981).

The primary animal foods of clapper rails according to Moffitt (1941) appear to be mussels, wolf spiders, clams, shore crabs, and snails. Mussels and clams are mainly filter-feeders on plankton, which may include zooplankton, and both are designated as trophic level 2.2 (U.S. Environmental Protection Agency, 1995b). However, phytoplankton and detritus make up the bulk of these organism's diets; therefore, mussels and clams are considered trophic level 2 for this evaluation. Although the EPA classifies snails as trophic level 2 organisms (U.S. Environmental Protection Agency, 1995b), the EPA notes that some marine forms are carnivorous. According to Morris *et al*. (1980), the species of nassa snails consumed by clapper rails are primarily herbivorous deposit feeders; however, Morris *et al*. note that at least one San Francisco Bay population is also carnivorous, preying on polychaete worms. This feeding behavior warrants the classification of trophic level 3 for nassa snails consumed by California clapper rails. The EPA views crabs as trophic level 3.3 organisms; however, this assumption was based on larger, more predatory crabs (*e.g.*, blue crabs) consuming small fish, other crabs, molluscs, and other invertebrates (U.S. Environmental Protection Agency, 1995b). The two crab species identified as food for the California clapper rail, *Hemigrapsis oregonensis* and *Pachygrapsus crassipes*, are primarily herbivorous, feeding on algae and diatoms (Morris *et al*., 1980; Roth and Brown, 1980). Therefore, it is more appropriate to classify these crab species as trophic level 2 organisms for this evaluation.

Evaluating the importance of wolf spiders in the clapper rail diet presents a unique challenge.

Spiders are generally classified as trophic level 3 organisms due to their predatory nature (U.S. Environmental Protection Agency, 1995b). Spiders are also generally regarded as terrestrial species, with limited involvement with aquatic food webs. However, wolf spiders are active hunters and those inhabiting the wetland habitats of clapper rails may be preying on trophic level 2 aquatic invertebrates. At least one species in this family, *Arctosa serii*, inhabits the sandy intertidal zone in the Gulf of California and actively preys on amphipods and ground beetles (Roth and Brown, 1980). If the wolf spiders consumed by California clapper rails exhibit the same feeding behavior, this would suggest a direct accumulation pathway, similar to the consumption of a trophic level 3 fish. However, it is unknown what effect the physiological processes involved with the capture and ingestion of spider prey (*e.g.*, venom immobilization, digestion) would have on the bioavailability of any methylmercury in that prey. In addition, although Moffitt (1941) reported wolf spiders comprising up to 73 percent of the animal matter in clapper rail stomachs, the relative importance in the overall diet may be minor. Moffitt's (1941) analyses were based on volumetric percentages, not on mass. The small amount of digestible body mass in spiders, relative to mussels, clams, crabs, and snails, suggests spiders may be an insignificant component of the overall diet and of the daily ingested dose of methylmercury.

For this evaluation, 90 percent of the California clapper rail diet is assumed to be from aquatic animal matter and 10 percent from vegetation. Based on the trophic level analyses presented above, **5 percent of the overall diet is assumed to be from trophic level 3 organisms (*i.e.*, nassa snails) and the remaining 85 percent from trophic level 2 organisms (*i.e.*, mussels, clams, and crabs)**. While these values are not static, and individual birds may consume varying percentages of each food type or additional prey items, this trophic level breakdown represents a reasonable dietary composition for California clapper rails based on the best available information.

Clapper rails may consume a wide variety of foods. Values for the gross energy content for some of these foods (*e.g.*, shell-less bivalves, shelled crabs) and the efficiency at which rails assimilate them can be found in the *Wildlife Exposure Factors Handbook* (U.S. Environmental Protection Agency, 1993). However, because rails do not consume set amounts of these food types, FIR must be estimated using one of the generic allometric equations from Nagy (2001). Out of the 17 avian categories for predicting FIRs presented by Nagy (2001), Charadriiformes is the taxonomic order most closely related to rails (Gill, 1995). In addition, the rail's feeding ecology most closely resembles that of birds in the Charadriiformes category (*i.e.*, shore birds, gulls, auks). Therefore, the FIR for California clapper rails was calculated using the following equation:

FIR (wet weight) = $1.914 \times (\text{body weight in g})^{0.769}$
FIR = $1.914 \times 346.1^{0.769}$
FIR = 171.63 g/day wet weight

FIR for California clapper rail = 0.172 kg wet weight/day

IV.D. Light-footed Clapper Rail (*Rallus longirostris levipe*):

As the light-footed clapper rail is smaller than the California clapper rail (U.S. Fish and Wildlife Service, 1976), the body weight for the California rail was not considered appropriate for this subspecies. No subspecies-specific information on body weights was found in the scientific literature. Dunning (1993) reported an average weight of 271 g for seven female clapper rails (*R. longirostris*, unidentified subspecies) from South Carolina. While an average body weight for the light-footed subspecies may be slightly more or less than the average reported by Dunning (1993), this value (**271 g**) was used in the calculation of a wildlife value in this effort.

Light-footed clapper rails occupy coastal marsh habitats, similar to the California clapper rail. The most robust documentation of the light-footed clapper rail's diet is presented by Zembal and Fancher (1988). Through direct observations of foraging and from analyses of food materials regurgitated by light-footed clapper rails, a list of prey items were identified. Observations of foraging revealed that clapper rails hunted in marsh vegetation over 90 percent of the time. During these foraging bouts, rails focused on invertebrates at the base of plants or under dried pieces of vegetation and debris. According to the observations of successful capture and swallowing, rails consumed hundreds of these invertebrates per hour. These small organisms could not be identified but appeared to be very mobile, as they would scatter rapidly when discovered by the rails. Due to the amount of time rails foraged on these organisms and the large numbers swallowed during foraging bouts, the researchers concluded that these invertebrates were important dietary items.

When not foraging in vegetation, rails would switch strategies and hunt tidal creek banks, mudflats, and open water. Rails were observed catching and swallowing various shore crabs (*i.e.*, *Pachygrapsus crassipes*, *Hemigrapsus oregonensis*) and fiddler crabs (*Uca crenulata*) from the creek banks. Both fish (*i.e.*, longjaw mudsucker - *Gillicthys mirabilis*) and ribbed horse mussels (*Ischadium demissum*) were taken from the mudflat habitats. However, observations of foraging on the mussels suggests that only portions of the animals were consumed, as the mussels would close upon first attack and rails appeared unable to reopen them. Other rails in open water were seen capturing California killifish (*Fundulus parvipinnis*) and tadpoles of the Pacific treefrog (*Hyla regila*). Scavenging on fish carcasses was also observed, although the rails may have been eating insect larvae on the carcasses.

Examination of regurgitated pellets provided additional information on clapper rail diets. The most abundant items were the remains of the shore crab species mentioned above. The next most abundant items were the remains of California horn snails (*Cerithidea californica*) and salt marsh snails (*Melampus olivaceous*). Other animal remains identified in regurgitated pellets included crayfish, beetles, isopods, and decapods. These additional items were not ranked according to abundance, although regurgitated pellets collected along a freshwater ditch were composed primarily of crayfish exoskeletons. Plant remains were rare in the regurgitated pellets, with the exception of two pellets that contained 75 elderberry seeds (representing about 25 fruits). The only other plant remains were three small unidentified seeds and several cordgrass seeds. The

researchers noted that only three clapper rails were ever observed feeding on plants, two consuming tips of pickleweed stems and one extracting and swallowing pith from broken cordgrass stems.

Light-footed clapper rails appear similar to other omnivorous birds in that a wide range of both plant and animal foods may be included in the diet, the composition of which may vary depending on any number of environmental or physiological factors. No information was provided by Zembal and Fancher (1988) regarding the percentage of specific food items in the rail diet; however, the authors offered some conclusions about the relative importance of certain organisms. Crabs and snails were considered important prey because of their large size and abundance in rail habitats. The two shore crabs and two snails identified above as prey for clapper rails are all trophic level 2 organisms, feeding on plants or detritus (Morris *et al*., 1980). Fiddler crabs feed primarily on detritus (Barnes, 1980; Kozloff, 1990); therefore, they are also considered trophic level 2 organisms. The small invertebrates consumed by clapper rails were also considered important in the diet because of the large numbers eaten and the amount of time rails spent foraging on them. Although these invertebrates could not be identified by the researchers, the small size of the animals and their tendency to cluster in large concentrations indicates that they should be classified as trophic level 2 organisms.

Zembal and Fancher (1988) did not offer any conclusions regarding the importance of other dietary items such as fish, mussels, tadpoles, and crayfish. However, they observed rails capturing fish numerous times and suggested that fish consumption may be more common than their results would indicate. The two fish species identified as prey, California killifish and longjaw mudsucker, are trophic level 3 predators (Moyle, 2002). In addition to trophic level 3 fish, crayfish were identified in pellets regurgitated by clapper rails. The EPA classifies crayfish at an intermediate trophic level (2.4), noting that crayfish are primarily herbivorous and that animal food is a minor part of the diet if vegetation is available (U.S. Environmental Protection Agency, 1995b). However, Slotton *et al*. (2000) found that signal crayfish (*Pacificasticus leniusculus*) in California can accumulate mercury to high concentrations, similar to predatory fish. While *P. leniusculus* is in a different genus than those identified in the pellets regurgitated by light-footed clapper rails, the omnivorous nature of all crayfish indicates the potential for a greater reliance on animal food than on plant material. For this evaluation, a higher intermediate trophic level (*i.e.*, 2.8) was assigned to crayfish consumed by light-footed clapper rails. Assuming 10 percent of the overall diet is crayfish, 8 percent of this contribution was assigned to trophic level 3 and 2 percent to trophic level 2 (*i.e.*, TL2.8 = 80% TL3, 20% TL2). Further assuming the trophic level 3 fish prey contributes 10 percent of the diet, a total of 18 percent of the overall diet was assigned to trophic level 3 (*i.e.*, 8% from crayfish, 10% from fish).

As noted above, plants appeared to play a minor role in the light-footed clapper rail diet, with the exception of elderberry fruits near a freshwater ditch (Zembal and Fancher, 1988). The fact that rails were only seen eating vegetation by the researchers on three occasions, despite approximately 180 hours of visual contact between March 1979 and August 1987, indicates that vegetation may be an insignificant food source, relative to the overall diet. For this reason, the

breakdown of dietary trophic level composition is based on an assumption of 100 percent animal foods.

The predominant foods of the light-footed clapper rail appear to be trophic level 2 crabs, snails, and small invertebrates. Other important foods, from a bioenergetic standpoint, include trophic level 3 fish and crayfish. Although no specific information was found regarding the percentage of each trophic level contributing to the overall diet, a reasonable assumption of **82 percent trophic level 2 and 18 percent trophic level 3** was used in the calculation of wildlife values for the light-footed clapper rail.

Although differing from the California clapper rail, in that fish and crayfish are important dietary items and vegetation appears insignificant, the similarly indefinite composition of the light-footed clapper rail's diet requires that FIR be estimated using the same allometric equation (Charadriiformes group) from Nagy (2001). For this effort, the body weight for the light-footed rail was estimated to be 271 g.

FIR (wet weight) = $1.914 \times (\text{body weight in g})^{0.769}$
FIR = $1.914 \times 271^{0.769}$
FIR = 142.2 g/day wet weight

FIR for light-footed clapper rail = 0.142 kg wet weight/day

IV.E. Yuma Clapper Rail (*Rallus longirostris yumaensis*):

The Yuma clapper rail is considered smaller than the both the California and light-footed clapper rails (U.S. Fish and Wildlife Service, 1976). However, there was no defensible way to determine a lower body weight for the Yuma rail than the one used for the light-footed rail. No subspecies-specific information on body weights was found in the scientific literature. Subsequently, the **average body weight of 271 g** reported by Dunning (1993) was used in the calculation of a wildlife value in this effort.

The Yuma clapper rail is unique from other clapper rail subspecies in that it resides and breeds in freshwater marshes (Anderson and Ohmart, 1985). Early literature on Yuma clapper rails suggested that the majority of the birds wintered in brackish marshes along the western coast of Mexico and then returned to their freshwater breeding grounds in the U.S. along the Colorado River and the Salton Sea for the spring and summer nesting period (U.S. Fish and Wildlife Service, 1976; Anderson and Ohmart, 1985). Both the California and light-footed clapper rails are considered non-migratory, although the California clapper rail is known to "wander" from its breeding grounds in fall and early winter (U.S. Fish and Wildlife Service, 1976). The Yuma clapper rails that did overwinter in freshwater habitats in the U.S. were considered a small part of the overall population (U.S. Fish and Wildlife Service, 1976; 1983). One possible explanation given for this migratory behavior was that it was in response to reduced food resources in the winter months (Anderson and Ohmart, 1985). However, radio telemetry work conducted

between February 1985 and December 1987 revealed that at least 70 percent of the population along the lower Colorado River remains resident (Eddleman, 1989). Therefore, the dietary information for birds residing in freshwater marshes is assumed on a year-round basis.

Comprehensive dietary information was presented by Ohmart and Tomlinson (1977), who examined stomach contents from 11 Yuma clapper rails collected from California and Arizona. Four birds from the Colorado River Delta in Mexico were also examined. Crayfish (*Procambarus* spp. and *Oropectes* spp.) were by far the most dominant prey items in the nine birds collected from along the Colorado River, averaging 95 percent by volume (range: 80-100%) of the stomach contents. Other food items included various insects, spiders, and molluscs. A small mammal bone was found in one stomach and plant seeds in another. Of the two birds collected from the confluence of the Gila and Colorado Rivers, one stomach contained an introduced freshwater clam (*Corbicula* sp.) (98%) and the other contained isopods (97%). The remaining food items in these two stomachs were unidentified insect parts. The birds collected in Mexico showed a more diverse food assemblage, with the predominant foods being water beetles (56%) and unidentified fish (32%). Fish do not appear to be important dietary items outside of the river delta habitats. A small amount of vegetative matter was also found in these birds, although plant matter appears to play an insubstantial role in the diet for all birds.

The trophic level dietary composition for Yuma clapper rails is based on 100 percent animal foods. It is clear that Yuma clapper rails residing along the Colorado River rely heavily on various freshwater crayfish. While it was once thought that these crayfish became dormant during the winter months, precipitating migratory behavior in the rails, evidence indicates that crayfish are present year-round in at least some locations and reproduce in autumn and early winter (Eddleman, 1989). As noted above in the analysis for light-footed clapper rails, crayfish are considered trophic level 2.8 organisms for determining the dietary composition. However, it is unlikely that Yuma clapper rails feed exclusively on crayfish, based on evidence that the birds supplement their diets with other foods ranging from terrestrial and aquatic insects to molluscs, depending on location and availability. Some of these supplemental food items may be aquatic (*e.g.*, isopods, damselfly nymphs, molluscs) or removed from the aquatic ecosystem (*e.g.*, grasshoppers, weevils, ground beetles). Assuming a reasonable high volume diet of 90 percent crayfish, 72 percent of this contribution can be assigned to trophic level 3 and 18 percent to trophic level 2 (*i.e.*, TL2.8 = 80% TL3, 20% TL2). Based on the dietary assessment provided by Ohmart and Tomlinson (1977), the diet for the Yuma clapper rail can therefore be assumed as **72 percent trophic level 3 organisms (from crayfish), 23 percent trophic level 2 organisms (from crayfish and other TL2 foods), and 5 percent non-aquatic organisms**.

The FIR for Yuma clapper rails was estimated using the same allometric equation (Charadriiformes group) from Nagy (2001). For this effort, the body weights for all three clapper rail subspecies were estimated to be equal (271 g). Therefore, the FIR calculation for the Yuma clapper rail will be identical to the one for the California and light-footed clapper rails.

FIR (wet weight) = 1.914 × (body weight in g)$^{0.769}$
FIR = 1.914 × 271$^{0.769}$
FIR = 142.2 g/day wet weight

FIR for Yuma clapper rail = 0.142 kg wet weight/day

IV.F. Western Snowy Plover (*Charadrius alexandrinus nivosus*):

Snowy plovers are small shorebirds weighing from 34 - 58 g, ranging in length from 15 - 17 cm (U.S. Fish and Wildlife Service, 2001). Dunning (1993) reports a mean weight of 41.4 g from 38 specimens of *Charadrius alexandrinus* (unknown gender) from California, with a range from 37 - 49 g. No information was found indicating gender-specific differences in weight. Therefore, **a weight of 41 g** was used in the calculation of wildlife values for western snowy plovers.

The snowy plover diet consists primarily of aquatic and terrestrial invertebrates (Page *et al*., 1995), with little quantitative information about specific food habits (U.S. Fish and Wildlife Service, 2001). A wide variety of food items are reported for coastal birds: mole crabs, crabs, polychaetes, amphipods, tanaidaceans, flies, beetles, clams, and ostracods (Page *et al*., 1995). Plovers on beaches forage above and below the mean high-tide line, gathering invertebrates from the sand surface, kelp, foredune vegetation, and marine mammal carcasses (Page *et al*., 1995). Flies, beetles, moths, and lepidopteran caterpillars were taken by birds at San Francisco Bay salt-evaporation ponds (Page *et al*., 1995). Plovers in California have been observed pecking small flying insects from mid-air (U.S. Fish and Wildlife Service, 2001), and are known to charge with open mouth into aggregations of adult flies (Page *et al*., 1995).

Tucker and Powell (1999) examined snowy plover fecal samples from a southern California coastal breeding site. Results indicated that the primary prey were terrestrial insect families (*i.e.*, various flies and beetles), although mole crab and nassa snail parts were also identified. Insect larvae were found in 25 percent of the fecal samples. The authors concluded that their results were consistent with findings from other snowy plover diet studies in that the major prey items are flies and beetles. However, the authors noted that polychaete worms are digested too completely to be identified by their technique, and stated that these worms may be important prey items.

Although it appears that snowy plovers mainly feed on non-aquatic insects, of both larval and adult forms, at least some aquatic organisms are included in the diet. These aquatic prey (mole crabs, nassa snails, polychaete worms, amphipods, ostracods, clams, tanaidaceans) can all be classified as trophic level 2 organisms based on their diets (U.S. Environmental Protection Agency, 1995b; Morris *et al*., 1980). For this evaluation, an assumption was made that **trophic level 2 organisms constituted 25 percent** of the overall snowy plover diet. The remaining portion of the diet **(75%) was assumed not to be significantly contributing to the daily ingested dose of methylmercury**. Additional research into the possible relationship between methylmercury in an aquatic system and its bioavailability to terrestrial insects may remove some

of the uncertainty in this assumption.

Due to the wide variety of potential prey items and the subsequent variability in gross energy content and assimilation efficiencies, the FIR for snowy plovers was determined using Nagy's (2001) allometric equation for Charadriiformes (shore birds, gulls, auks):

FIR (wet weight) = $1.914 \times (\text{body weight in g})^{0.769}$
FIR = $1.914 \times 41^{0.769}$
FIR = 33.3 g/day wet weight

FIR for western snowy plover = 0.033 kg wet weight/day

IV.G. Bald Eagle (*Haliaeetus leucocephalus*):

The bald eagle was a representative species used for the derivation of wildlife criteria in the aforementioned GLI (U.S. Environmental Protection Agency, 1995c). For that effort, the bald eagle body weight used in criteria calculations (4.6 kg) was based on the mean of average male and female eagle body weights, although it was noted that female eagles are approximately 20 percent heavier than males. As the avian reference dose for methylmercury is based on adverse reproductive effects manifested by laying females, it is more appropriate to use average female body weights in the calculation of wildlife values.

In the GLI, the EPA presented an average body weight of 5.2 kg for female bald eagles. This value was based on the weights of 37 birds, taken from Snyder and Wiley (1976). Dunning (1993) presented an average female body weight of 5.35 kg, also based on the weights of 37 birds, taken from Palmer (1988). Taking both values into consideration, a **body weight of 5.25 kg** was used in the calculation of wildlife values for this evaluation.

The bald eagle diet has been extensively studied throughout the country. Although generally known as a piscivorous species, bald eagles are opportunistic predators and carrion scavengers (Buehler, 2000). Various birds, mammals, reptiles, amphibians, and crustaceans may serve as additional bald eagle prey (Buehler, 2000). As explained in the introduction to this section, FIRs can be most accurately estimated for an animal consuming different food types (*e.g.*, fish and birds) when there is information about the metabolic energy available from these foods and a reliable estimate of the amount of each food type consumed daily (*e.g.*, 75% fish, 25% birds). Information presented in the Wildlife Exposure Factors Handbook (U.S. Environmental Protection Agency, 1993) regarding the metabolizable energy available from various prey types and the ability of bald eagles to assimilate this energy allows for the use of this method to estimate daily food requirements. However, attempting to quantify a specific dietary composition for bald eagles is more difficult than for other species with a narrower range of prey types, and is further confounded by the fact that food preferences may vary both geographically and temporally.

An additional difficulty in calculating a general FIR for deriving the WV for bald eagles arises because the trophic level composition of the diet can also vary substantially between seasons, locations, or individuals. Calculating the FIR based solely on the percentage of various food types in the diet may not result in a WV representative of the greatest risk from methylmercury in the diet. For example, the daily FIR for an eagle with a diet of 95 percent fish / 5 percent birds will be greater than the FIR for an eagle with a diet of 80 percent fish / 20 percent birds (*i.e.*, less energy available from fish prey requires a greater amount consumed to satisfy bald eagle's free-living metabolic rate). The higher FIR, in turn, results in a lower WV, which may seem the most desirable outcome of this methodology. However, if the bulk of the 95/5 diet consists of trophic level 2 fish and terrestrial birds, the methylmercury concentration in the eagle's overall diet will remain substantially below the WV, regardless of the trophic level approach used. By contrast, the higher WV calculated from the 80/20 diet may be substantially exceeded by either trophic level approach if the diet consists primarily of trophic level 4 fish and piscivorous birds.

In this example, using the dietary composition resulting in the lowest WV as a surrogate for all eagles would give the misleading impression that all eagles may be protected (false negative) by the TRC, while using the higher WV would indicate that all eagles may be at risk from the TRC (false positive). However, the goal of this analysis is to evaluate the protectiveness of the two trophic level approaches, using data for birds with the greatest potential for methylmercury exposure through their diet. Therefore, the FIR used to calculate the WV must be based on the most reliable bald eagle diet with the highest combined percentage of trophic level 4 fish and aquatic-dependent avian prey, and the lowest percentage of terrestrial prey (*i.e.*, no connection to methylmercury in the aquatic environment).

The feeding ecology of avian prey of bald eagles is critical for this analysis because prey birds that consume aquatic biota represent an additional exposure pathway for bald eagles, as methylmercury in fish and aquatic invertebrates is biomagnified as it moves through successively higher trophic level organisms. The biomagnification of methylmercury through piscivorous avian prey was factored into the GLI effort, as data showed piscivorous herring gulls (*Larus argentatus*) were an important dietary component (5.6% of the dietary biomass on average) of Lake Superior bald eagles (U.S. Environmental Protection Agency, 1995d). The study used to determine the bald eagle diet for the GLI effort (Kozie and Anderson, 1991) also found various waterfowl in eagle prey remains. These waterfowl species were not considered piscivorous, yet for some, trophic level 2 aquatic biota can constitute a substantial part of their diet. These waterfowl were not included in the GLI estimate of methylmercury exposure, as the bulk of the bird prey component was comprised of herring gulls. However, in areas where bald eagles consume large numbers of these aquatic-dependent birds, the biomagnification of methylmercury from trophic level 2 organisms into waterfowl tissues may contribute substantially to the bald eagle's daily ingestion of methylmercury.

Several efforts to develop protective mercury criteria (*e.g.*, U.S. Environmental Protection Agency, 1997a; Buchanan *et al*., 2001; California Regional Water Quality Control Board - Central Valley Region, 2001) have used the dietary composition developed in the GLI (U.S.

Environmental Protection Agency, 1995c). Using information on bald eagles nesting on islands and along the shore of Lake Superior in Wisconsin (*from* Kozie and Anderson, 1991), and adjustment factors to estimate the relative number of birds and fish delivered to a nest based on the prey remains found under the nest, the EPA determined that 92 percent of the dietary biomass was comprised of fish and 8 percent comprised of birds or mammals. The adjustment factor was developed to account for the inherent error in estimating a dietary composition based solely on the analysis of prey remains. The Kozie and Anderson (1991) study used to determine bald eagle diets reported that fish comprised 50 percent and birds comprised 48.4 percent of the nest site prey remains. However, direct observations of three nests during part of the study period revealed that fish constituted 97 percent of the captured prey. To address this discrepancy, the EPA's adjustment factors (*i.e.*, - the ratios between the number of each prey type found in nest remains and the number of each prey type observed in nest deliveries during the same period) were applied to the prey remain data for all nest sites in the study. This allowed for an estimate of the total number of birds and fish consumed by bald eagles. Then, using standard body weights for the bird and fish species identified, the percentage of biomass for each food type was calculated.

Using this dietary composition of 92 percent fish and 8 percent birds, along with information about the energetic needs of adult eagles and their ability to assimilate the caloric content of these food types, the GLI presented estimates of the amount of each food type ingested daily: 0.464 kg fish and 0.040 kg birds/mammals (U.S. Environmental Protection Agency, 1995c). The fish component of the overall diet was further broken down as 74 percent trophic level 3 (0.371 kg) and 18 percent trophic level 4 (0.0928 kg), based on data indicating the average trophic level for the fish component of Lake Superior bald eagles is 3.2 (*i.e.*, 80% TL3, 20% TL4). The remaining bird/mammal component of the overall diet was delineated as 5.6 percent piscivorous herring gulls (0.0283 kg) and 2.4 percent non-piscivorous other food (0.0121 kg). Although the GLI breakdown of the bald eagle diet has been used as a default composition in subsequent wildlife criteria efforts, studies of bald eagle diets from other parts of the country reveal a wide range of possible composition preferences. Several of these studies are summarized below.

A study of bald eagles in a desert riparian habitat in central Arizona found that fish comprised 77 percent of the total prey remains found under nests (Haywood and Ohmart, 1986). Mammals accounted for an additional 12 percent, birds 11 percent, and reptiles or amphibians 0.6 percent. The same study compared the findings from prey remains with direct observations of prey capture (73% fish, 5% mammals, 1% birds, 4% reptiles or amphibians, and 17% unidentifiable) and found only a minimal difference in percent composition.

By contrast, bald eagles nesting at various sites along the coast of Washington displayed a stronger dietary preference for birds, which accounted for 53 percent of the total prey remains (N = 1198) found under nests in three different regions (Knight *et al.*, 1990). Fish comprised 34 percent of the total remains, with mammals (9%) and invertebrates (4%) making up the rest. There were composition differences between the three sites evaluated, but in each case, birds accounted for the majority of food. Birds comprised 78 percent of all prey remains at Olympic

Peninsula nest sites, but down to 48 percent at San Juan Island sites. The researchers also compared their findings from collected prey remains with direct observations of prey delivery (*N* = 47) and concluded that birds were over-represented in prey collections beneath nests and fish were over-represented in observations of prey carried to nests. The high incidence of bird prey remains (53%) during the observation period is in contrast to the frequency of observations in which birds were delivered to the nest (8%). The frequency of observed fish deliveries was high (92%), but was much lower in prey remain collections (44%) during the observation period. Birds may be over-represented in nest collections due to a greater persistence than fish remains in the environment, while over-representation of fish in observations may be due to the relative ease of identification (Mersmann *et al*., 1992; Knight *et al*., 1990). However, this study indicates that birds are important prey for coastal bald eagles.

Dietary habits of resident bald eagles from three nesting areas in southcentral Oregon were studied between 1979 and 1983 (Frenzel, 1984). Nest site prey remain collections and direct observations of 16 eagles fitted with radio transmitters were the methods used. The three study areas were Upper Klamath Lake, outer Klamath Basin, and the Cascade Lakes region. Discrepancies between prey remain collections and observations of predation were also found in this study. At the Upper Klamath Lake site, fish comprised only 25 percent of the prey remains but accounted for 62 percent of the observed prey taken during the breeding season. The amount of fish observed taken at this site increased to 69 percent during the post-breeding season, but then dropped to less than 20 percent in fall and winter. Birds became the dominant food during these seasons, accounting for over 82 percent of the observed prey taken. Mammals were observed taken throughout the breeding and post-breeding seasons, but were not observed during the fall and winter. At Wickiup Reservoir in the Cascade Lakes study area, fish accounted for 100 percent of the observed prey taken during the breeding and post-breeding seasons. The same study looked at the diets of wintering-only bald eagles in the Klamath Basin. For these eagles, wintering and staging waterfowl were the primary food source, supplemented with some mammal prey. No fish remains were found in bald eagle castings from communal roosts, and no foraging attempts on fish were observed through the study.

In addition to the above studies, Volume III of *Trophic Level and Exposure Analyses for Selected Piscivorous Birds and Mammals* (U.S. Environmental Protection Agency, 1995b), presented summaries of bald eagle dietary habit studies throughout the U.S. and British Columbia, along with estimated prey trophic levels. The diets presented in these summaries confirm the wide variability of prey types inherent with an opportunistic forager like the bald eagle. While none of the studies described provided one definitive diet composition preferred by bald eagles, they show that fish are generally the predominant food item during the spring and summer breeding seasons. Birds are second in importance, followed by mammals.

As mentioned previously, the dietary composition developed for the bald eagle in the GLI has been used in various places for the derivation of avian wildlife criteria. However, this dietary composition was specifically determined for the aquatic ecosystem of the Great Lakes and may not be an appropriate default for other parts of the country. Califomia supports both wintering

and resident bald eagles, with a broad array of suitable foraging habitats. Because of this variety, eagle diets in California likely span a wide range of possible food types and trophic level combinations. It is not possible in the scope of this analysis to determine all the potential bald eagle diets in California and evaluate them with regard to the trophic level approaches for the methylmercury criterion.

Instead, a weighted risk approach was taken to determine the appropriate eagle diet for calculation of wildlife values. The goal of this approach was to establish a diet based on the highest trophic level composition reasonably likely to occur, from the predominant habitat type characteristic of California's breeding bald eagles. The primary breeding habitats are mountain and foothill forests and woodlands close to reservoirs, lakes, and rivers (California Department of Fish and Game, 2000). Wintering bald eagles can be found in these same habitats throughout the State, but also forage in a variety of different habitats, such as rangelands and coastal wetlands. Basing the diet on the main habitat of resident breeding birds rather than on some other localized habitat used by non-resident birds is a more appropriate method for evaluating potential adverse reproductive effects from the methylmercury criterion, as it is impossible to predict maternal body burdens of methylmercury once wintering eagles reach their breeding grounds outside of California.

Bald eagles are known to nest in several locations and habitat types dispersed throughout California, including in the central and southern Sierra Nevada range, the central coast range, inland southern California, and on Santa Catalina Island. However, most breeding territories are in the northern part of the State (California Department of Fish and Game, 2000). The results of a 1977-1978 study of 95 bald eagle nest sites revealed that 91 percent of the nesting territories were located in five northern counties (Lehman, 1979). A large majority of these nests (87%) were within one mile of a waterbody, and 70 percent of the nests were associated with reservoirs. Two studies of foraging ecology in these characteristic northern California breeding habitats provided detailed assessments of the trophic level composition of bald eagle diets.

Through collection of nest site prey remains, direct observations of foraging eagles, and time-lapse photography of nest activity, the dietary composition was estimated for bald eagles nesting along a hydrologically-regulated section of northern California's Pit River (Hunt *et al*., 1992). The study area encompassed 24.5 km of reservoirs and 45.8 km of flowing, regulated river. The study took place over a period of two years, with results indicating that fish comprised approximately 87 percent of the total prey items, while birds (9%) and mammals (4%) comprised the remainder. Based on estimates of edible biomass determined from the prey remains around eight nests, the biomass comprised of fish ranged from 43.8 to 92.6 percent. For all nesting eagle pairs, one fish species (Sacramento sucker - *Catostomus occidentalis*) was the dominant prey; however, eagles at one reservoir (Lower Britton) foraged on a greater percentage of cyprinid fish (*e.g.*, hardhead, tui chub, Sacramento pikeminnow) than the other study regions. While trophic levels for various species of *Catostomus* range from 2 to 3 (U.S. Environmental Protection Agency, 1995b), the food of Sacramento suckers can be dominated by algae, detritus, or invertebrates, depending on the size of the fish, location, or time of year (Moyle, 2002). The next

two most important fish species in all study areas were the hardhead (*Mylopharodon conocephalus*) and Sacramento pikeminnow (*Ptychocheilus grandis*). These fish should be classified as trophic level 3 and 4, respectively, based on their diets (Moyle, 2002).

A variety of avian species were identified in the prey remains collected in this study, amounting to 102 individual birds. In terms of edible biomass, the percentage of the diet comprised of birds ranged from 4.9 to 46.3 percent among the eight nests sampled. While the bird species composition or estimated biomass of birds consumed were not presented for each individual study nest, 18 (17.6%) of the total 102 birds identified were piscivorous species. Based on the overall percentage of all birds in the eagle diets (9%), piscivorous birds accounted for roughly 1.6 percent of the total eagle diet (*i.e.*, - 0.09 × 0.176 × 100 = 1.58%).

While this study (Hunt *et al*., 1992) presents estimates of the percent biomass for each food type at each study site, including a breakdown for individual fish species, the estimates were based solely on an analysis of prey remains. The prey remains analysis conducted in this study was quite rigorous, in that individual fish scales were included in the collections and used to determine total numbers of fish prey. Other studies of bald eagle diets (*e.g.*, Kozie and Anderson, 1991) relied solely on samples of bones and feathers collected from nest sites. However, in a subset of the entire Hunt *et al*. (1992) study, diets were analyzed for three nests using a comparison of prey remains with time-lapse photographic observations of prey delivered to the nests. The number of fish delivered to the nests during this period ($N = 117$) was almost twice the number estimated from prey remains during the same period ($N = 64$). The biomass estimated from photographic observations of fish prey (55.1 kg) was also substantially greater than the estimate from prey remains (37.6 kg). The authors suggested that some remains may have been dropped or taken from the nests and that other prey items may have been entirely consumed. Further confounding the analysis, the authors reported that a total of 236 prey deliveries were recorded by the time-lapse cameras, yet only the 117 fish deliveries were presented in the journal article. If the 119 unidentified prey deliveries were birds or mammals, this suggests that fish only accounted for 49.5 percent of the diet during the observation period. Although these discrepancies make it difficult to assign a general dietary composition from this study, the author's comparison of prey remains data and photographic observations indicated that larger fish species were not over-represented in prey remains because of larger and more persistent bones, and smaller fish were not under-represented in prey remains because of softer, less persistent bones.

In an expansion of the previous work, prey remains from 56 eagle nesting territories in three major drainage basins (Sacramento-San Joaquin, Lahontan, Klamath) were collected between 1983 and 1992 (Jackman *et al*., 1999). The total study area comprised numerous rivers, lakes, and reservoirs. Over 80 percent of studied nesting territories were near reservoirs, with the remainder on natural lakes. Riverine habitats were also available as foraging sites for all nesting eagles. Prey remains were collected from in and below nests, sometimes during the late nestling stage but primarily after the young had fledged. Sample collections included bones, fur, feathers, and fine nest lining, the latter containing fish scales and fine bones. The authors acknowledged

that the dietary analysis was biased in that it was based exclusively on prey remains (*i.e.*, no comparison of remains with prey deliveries). However, as demonstrated in the earlier Pit River study, the authors noted that their inclusion of fish scale analysis from the nest lining samples helped to mitigate the potential over- or under-representation of certain fish types. In addition, fish scales may have a greater environmental persistence at nest sites than fish bones, which are typically used in prey remain analyses. Although it is commonly suggested that birds and mammals may be over-represented in dietary studies due to a greater environmental persistence of their prey remains compared with fish remains (*i.e.*, feathers vs. bones), the inclusion of fish scales in the dietary analysis may also help to mitigate this potential bias.

From the 56 nesting territories sampled in this study, 2,351 individual prey items were identified. Fish accounted for over 70 percent of both overall prey numbers and total estimated biomass (1,637 kg). The mean standard lengths of the most commonly taken fish were over 30 cm, with the exception of tui chub (28 cm) and brown bullhead (24 cm). Birds contributed approximately 22 percent and mammals less than 6 percent to total prey numbers and biomass. Western pond turtles and crayfish were the only other prey items identified, and contributed insignificant amounts to the overall diet (<1%). The prey composition varied substantially between 19 waterway study groups, with fish accounting for greater than 50 percent of prey numbers and biomass at most locations. However, birds and mammals were the predominant prey at several individual locations isolated from large rivers. Overall, 20 species of fishes, 41 species of birds, and 15 species of mammals were identified from prey remains.

Of the 20 fish species identified (71.2% of total biomass in overall bald eagle diet), the four primary prey species were brown bullhead (*Ameiurus nebulosus*), Sacramento sucker (*Catostomus occidentalis*), common carp (*Cyprinus carpio*), and tui chub (*Gila bicolor*). The majority of the 20 fish species identified should be classified as trophic level 3 consumers based on their diets of trophic level 2 organisms (Moyle, 2002). However, at the body sizes estimated from the prey remain analysis and the dietary habits presented in Moyle (2002), several fish species identified should be classified as trophic level 4 piscivores: Sacramento pikeminnow (*Ptychocheilus grandis*), rainbow trout (*Onchorhyncus mykiss*), largemouth bass (*Micropterus salmoides*), and Sacramento perch (*Archoplites interruptus*). In addition to the identified fish species, numerous other fish remains could only be identified to family: Centrarchidae, Ictaluridae, Cyprinidae, Salmonidae, and Catostomidae. Of these, it can be assumed that the fish prey identified as Salmonidae should be classified as trophic level 4 organisms.

With the exception of largemouth bass, the majority of the Centrarchid prey remains could not be identified to species, although bass (*Micropterus* spp.), smallmouth bass (*Micropterus dolomieui*), sunfish (*Lepomis* spp.), and bluegill (*Lepomis macrochirus*) were noted in the general Centrarchid grouping. It was impossible to assign a single trophic level to the general Centrarchidae dietary contribution, as large bass should be considered trophic level 4 fish and smaller sunfish and bluegills should be considered trophic level 3 fish (Moyle, 2002). Therefore, an intermediate trophic level (*i.e.*, 3.5) was assigned to the non-specific Centrarchidae contribution to the bald eagle diet. This resulted in 50 percent of the "Other sunfish

(Centrarchidae)" grouping assigned to each of trophic level 3 and 4 (*i.e.*, TL3.5 = 50% TL3, 50% TL4).

The two Ictalurids identified in the study [brown bullhead and channel catfish (*Ictalurus punctatus*)] are opportunistic omnivores, consuming whatever prey they can locate. Benthic invertebrates often constitute the majority of the diet for smaller Ictalurids; however, as bullheads and catfish increase in size, small trophic level 3 fish can become the predominant prey item (Moyle, 2002; U.S. Environmental Protection Agency, 1995b). The fish lengths determined from Ictalurid prey remains in this study ranged from 12.9 - 35.6 cm for brown bullhead and 25.1 - 55.1 cm for channel catfish, suggesting that an intermediate trophic level of 3.5 be assigned to all Ictalurids eaten by bald eagles. As with the non-specific Centrarchids, 50 percent of the Ictalurid biomass contribution to the bald eagle diet, whether identified to species or family, was assigned to each of trophic levels 3 and 4.

With the exception of the Sacramento pikeminnow, Cyprinid minnows in California should be considered trophic level 3 (Moyle, 2002). Therefore, the dietary contribution from fish prey grouped under "Unidentified minnows (Cyprinidae)" was assigned as trophic level 3 for this effort. All fish prey under the "Unidentified suckers (Catostomidae)" grouping were assigned as trophic level 3.

Using the intermediate trophic level breakdown for Centrarchids and Ictalurids, together with the other trophic level 4 fish identified from the prey remains, indicates that 12.7 percent of the overall estimated biomass in the entire study area was comprised of trophic level 4 fish. The remainder of the overall fish component to the biomass (58.5%) is classified as trophic level 3.

Of the 41 bird species identified (22.8% of total biomass in overall bald eagle diet), the two most commonly seen in prey remains were American coot (*Fulica americana*) and mallard (*Anas platyrhynchos*), representing 4.2 and 3.2 percent, respectively, of the total estimated biomass. Several of the species identified are exclusively terrestrial (*e.g.*, mountain quail); however, the majority are dependent on the aquatic ecosystem. Several of these aquatic-dependent species are primarily piscivorous: western grebe (*Aechmophorus occidentalis*), gull (*Larus* spp.), pied-billed grebe (*Podilymbus podiceps*), and common merganser (*Mergus merganser*). These piscivorous birds accounted for approximately 5 percent of the total estimated biomass of the bald eagle diet. Eagles also consumed waterfowl (*e.g.*, *Anas* spp., diving ducks, coots) that depend to varying degrees on prey that are considered trophic level 2 organisms (*e.g.*, aquatic invertebrates and zooplankton). These birds contributed approximately 13 percent (including the 4.2% and 3.2% represented by American coots and mallards) to the total estimated biomass in the overall bald eagle diet.

Based on the dietary analysis presented by Jackman *et al*. (1999), and the trophic level assessment provided above, a generic composition for the bald eagle diet can be estimated as 6 percent mammals, 71.2 percent fish (58.5% TL3, 12.7% TL4) and 22.8 percent birds (13.2% TL2 consumers, 4.8% TL3 consumers, 4.8% non-aquatic consumers). These figures represent an

average dietary composition for all bald eagles in the study area. However, the study also presented dietary composition results from 19 separate sub-areas, described as waterway territory groups. The data from these sub-areas do not provide the level of taxonomic detail regarding prey species as was presented for the entire study area, but they do reveal that substantial differences exist between nesting territories in the relative contribution of birds, mammals, and trophic level 4 fish to the bald eagle diet. Trophic level 4 fish constituted over 35 percent of the dietary biomass in several of the sub-areas, while at three different sub-areas, birds contributed over 60 percent of the dietary biomass. At one sub-area, birds and mammals accounted for 70.6 and 24.7 percent, respectively, of the dietary biomass.

The dietary compositions for each sub-area were presented in percent biomass of major prey groups (*i.e.*, fish, birds, mammals), with the fish group further divided into seven categories (*e.g.*, trout, suckers, sunfish). This sub-area breakdown illustrates the broad range of dietary compositions possible in these characteristic bald eagle habitats, and allowed for an estimation of a bald eagle diet with the greatest potential for methylmercury exposure (*i.e.*, the highest percentage of TL4 fish and aquatic-dependent birds, with the lowest percentage of terrestrial prey). Because the data were only presented in terms of major prey groups and broad fish categories, the degree of certainty in estimating specific trophic level diets varied with each sub-area. For example, fish represented by the "Minnow" category could be considered trophic level 3 (*e.g.*, Sacramento blackfish) or trophic level 4 (*e.g.*, Sacramento pikeminnow). Similarly, the general "Bird" category could include any combination of aquatic-dependent and/or terrestrial species. Jackman *et al*. (1999) provided a level of species-specific detail for each sub-area that allowed for a reasonable determination of the trophic composition of each fish category; however, sub-area specific detail for bird prey was lacking. By evaluating the estimated biomass contribution of each bird species for the entire study area, a general percentage breakdown of the three bird types (*i.e.*, TL2 consumers, TL3 consumers, non-aquatic consumers) could be determined and applied to the overall bird contribution to each sub-area. For the entire study area, birds that consume aquatic invertebrates (TL2 consumers) accounted for approximately 58 percent, piscivorous birds (TL3 consumers) accounted for approximately 21 percent, and terrestrial birds (non-aquatic consumers) accounted for 21 percent of the total avian prey biomass. Using this breakdown, the relative contribution of birds in the diet for each sub-area could be delineated. For example, if the percentage biomass of birds for a particular sub-area was reported as 25 percent, the relative contribution of each bird type was delineated as 14.5 percent TL2 consumers (25 × 0.58), 5.25 percent TL3 consumers (25 × 0.21), and 5.25 percent non-aquatic consumers (25 × 0.21).

The data for all 19 sub-areas were analyzed to identify the bald eagle diet with the greatest potential exposure to methylmercury. Prey remains from one eagle pair foraging at the inflow of the North Fork Feather River to the Oroville Reservoir indicated that fish and birds comprised 83 and 17 percent, respectively, of the total dietary biomass. **The fish component of this total was comprised of both trophic level 4 (39%) and trophic level 3 (44%) species. The avian component of this total was comprised of TL2-consuming birds (10%), TL3-consuming birds (3.5%), and non-aquatic consuming birds (3.5%)**. This diet represented the highest

combined percentage of trophic level 4 fish and aquatic-dependent birds from the entire study area.

The bald eagle FIR based on this diet (83% fish / 17% birds) was calculated using the methodology in the aforementioned *Technical Support Document for Wildlife Criteria* (U.S. Environmental Protection Agency, 1995c), wherein the animal's free-living metabolic rate (FMR) is divided by the metabolizable energy (ME) from the animal's prey. The FMR was determined by Nagy's (1987) allometric equation relating FMR for birds to body weight:

FMR (kcal/day) = 2.601 × body weight (g)$^{0.640}$
FMR = 2.601 × 5250$^{0.640}$
FMR = 625 kcal/day

According to the *Wildlife Exposure Factors Handbook* (U.S. Environmental Protection Agency, 1993), metabolizable energy equals the gross energy (GE) of the food in kcal/g wet weight times the assimilation efficiency (AE) of the consumer. The Handbook gives a GE value of 1.2 kcal/g for bony fishes, while bird GEs are given as either 1.9 (passerines, gulls, terns) or 2.0 (mallard). Although the majority of avian prey species identified in the Jackman *et al*. (1999) study are more closely related to mallards than to the other bird types, the lower value was used in this analysis because the GE for mallards was for consumption of flesh only. The AEs for eagles consuming birds and fish are given as 78 and 79 percent, respectively.

ME_{fish} = 1.2 kcal/g × 0.79 = **0.948 kcal/g fish**

ME_{birds} = 1.9 kcal/g × 0.78 = **1.482 kcal/g birds**

Following the process in the TSD, if:

Y = grams of birds consumed, and
4.88Y = grams of fish consumed (*i.e.*, 83% fish ÷ 17% birds = 4.88)

then the FIR for each food can be determined by the equation:

FMR = [Y(g) × 1.482(kcal/g birds] + [4.88Y(g) × 0.948 kcal/g fish]

625 kcal/day = 1.482Y + 4.626Y

625 kcal/day = 6.108Y

Y = 102 g birds consumed/day

4.88Y = 498 g fish consumed/day

The total FIR for bald eagles becomes:

FIR = [102 g birds + 498 g fish]/day
FIR = 600 g wet weight/day

FIR for bald eagle = 0.600 kg wet weight/day

V. SPECIES-SPECIFIC WILDLIFE VALUES

Species-specific input parameters, using the RfD generated with a UF_A of 1, and the resulting WVs are presented in Table 2. Table 3 provides WVs using the RfD generated with a UF_A of 3. Wildlife Values were calculated using Equation 6, described previously:

$$\mathbf{WV} = \frac{\mathbf{RfD} \times \mathbf{BW}}{\sum \mathbf{FIR_i}}$$

Table 2. Wildlife Values for Methylmercury Calculated Using Reference Dose Generated with an Interspecies Uncertainty Factor (UF_A) of 1

Species	RfD (mg/kg/day)	Body Weight (kg)	FIR (kg/day)	WV (mg/kg diet)
Southern sea otter	0.018	19.8	6.5	0.055
California least tern	0.021	0.045	0.031	0.030
California clapper rail	0.021	0.346	0.172	0.042
Light-footed clapper rail	0.021	0.271	0.142	0.040
Yuma clapper rail	0.021	0.271	0.142	0.040
Western snowy plover	0.021	0.041	0.033	0.026
Bald eagle	0.021	5.25	0.600	0.184

Table 3. Wildlife Values for Methylmercury Calculated Using Reference Dose Generated with an Interspecies Uncertainty Factor (UF_A) of 3

Species	Alternate RfD (mg/kg/day)	Body Weight (kg)	FIR (kg/day)	WV (mg/kg diet)
California clapper rail	0.007	0.346	0.172	0.014
Light-footed clapper rail	0.007	0.271	0.142	0.013
Yuma clapper rail	0.007	0.271	0.142	0.013
Western snowy plover	0.007	0.041	0.033	0.009

VI. BIOMAGNIFICATION INTO AVIAN PREY OF BALD EAGLES

The next step in the approach was to evaluate the protectiveness of the TRC under each trophic level approach. To do this required the trophic level breakouts (*i.e.*, %TL2, %TL3, %TL4) for the diet of each species of concern, the trophic level concentrations determined in each TRC evaluation approach, and Equation 1:

DC = (%TL2 × FDTL2) + (%TL3 × FDTL3) + (%TL4 × FDTL4)

However, additional information was required to perform this evaluation for the bald eagle. As mentioned previously, bald eagles may consume substantial numbers of birds that feed from the aquatic environment. These aquatic-dependent species may be omnivorous (*i.e.*, - feed to varying degrees on plant matter and trophic level 2 biota) or primarily piscivorous. The biomagnification of methylmercury into these prey birds represents a potentially important additional exposure for bald eagles that must be factored into the estimate of a daily ingested dose. For the GLI effort (U.S. Environmental Protection Agency, 1995d), bald eagle consumption of piscivorous herring gulls (*Larus argentatus*) was included in the criteria derivation because herring gulls in the Great Lakes feed primarily on trophic level 3 fish. The EPA applied a biomagnification factor (BMF) of 10 in the calculation of wildlife criteria to account for the biomagnification from these trophic level 3 fish into herring gull tissues. In effect, the BMF is analogous to a food chain multiplier (FCM) because it represents the amount of methylmercury transfer between a prey organism (TL3 fish) and its predator (piscivorous bird). Although the GLI effort did not consider biomagnification into omnivorous waterfowl, the contribution of methylmercury from this pathway should also be included in the risk assessment

for bald eagles. In order to include the consumption of piscivorous and omnivorous birds in the evaluation for bald eagles, additional terms must be incorporated into Equation 1:

$$DC = (\%TL2 \times FDTL2) + (\%TL3 \times FDTL3) + (\%TL4 \times FDTL4) + (\%OB \times FDOB) + (\%PB \times FDPB)$$

%OB - percent of omnivorous birds (TL2-consumers) in diet
FDOB - methylmercury concentration in omnivorous bird prey
%PB - percent of piscivorous birds in diet
FDPB - methylmercury concentration in piscivorous bird prey

As the two trophic level approaches presented in this evaluation are based only on estimated methylmercury concentrations in aquatic organisms, the terms FDOB and FDPB need to incorporate the biomagnification of methylmercury from the aquatic trophic levels into the tissues of birds consumed by bald eagles. In effect:

FDOB = FDTL2 (concentration in TL2 organisms) × **MOB** (*i.e.*, some BMF value representing biomagnification into omnivorous bird prey)

FDPB = FDTL3 (concentration in TL3 organisms) × **MPB** (*i.e.*, some BMF value representing biomagnification into piscivorous bird prey)

VI.A. Biomagnification Factor for Trophic Level 3 Fish to Piscivorous Bird Prey: **MPB**

The BMF of 10 used in the GLI to represent the biomagnification from trophic level 3 fish into herring gulls was arrived at from data indicating that tissue mercury concentrations in piscivorous birds tends to be from 3 to 12 times higher than the tissue mercury concentrations in the fish that the birds feed on (U.S. Environmental Protection Agency, 1995d). An analysis of the three studies used for the EPA's determination (Vermeer *et al*., 1973; Norheim and Froslie, 1978; and Wren *et al*, 1983) is provided below.

Vermeer *et al*. (1973) examined total mercury residues in herring gull eggs and in breast muscle from 83 ducks (six species) from Clay Lake in western Ontario. Only four of the 83 ducks were adults, the rest being flightless ducklings or immature birds. Many of the immature birds were also flightless. Breast muscle samples from five of the collected birds were also analyzed for methylmercury content. The authors concluded that elevated total mercury residues in herring gull eggs did not affect reproductive success, but no information was provided about methylmercury in herring gull tissues or the gull's prey. No conclusions about BMF values can be drawn from the herring gull portion of this study.

In addition to the duck breast muscle samples, food items were collected from the esophagi and stomachs of three of the duck species and analyzed for total mercury concentrations. These food items included yellow perch (*Perca flavescens*) and shiners (*Notropis* sp.) consumed by common mergansers (*Mergus merganser*), and a variety of aquatic invertebrates consumed by common goldeneyes (*Bucephala clangula*) and hooded mergansers (*Lophodytes cucullatus*). Breast

muscle sampled from the five individual ducks was analyzed for methylmercury, which accounted for 69-99 percent of total mercury concentrations. However, the food items from the three mentioned duck species were analyzed for total mercury, making direct assessments of methylmercury biomagnification difficult. While it is commonly accepted that the majority of mercury in fish muscle is methylmercury, it is unclear whether the same holds true for the various molluscs, crayfish, insects, and annelids found as food items in these ducks. In addition, the information regarding biomagnification from these non-fish prey items into duck tissues would have had limited value for the estimation of a BMF to herring gulls for the GLI.

Ten yellow perch collected from esophagi and stomachs of common mergansers during this study averaged 2.7 mg/kg (range 1.6 - 3.6) total mercury. Common merganser breast muscle was not analyzed for methylmercury, but a mean concentration of 6.79 mg/kg (range 4.4 - 13.1) total mercury was reported from 17 analyzed birds. Assuming the relative proportion of mercury to methylmercury is similar in fish tissue and duck breast muscle, an average methylmercury BMF for these birds would be 2.5. An important consideration in evaluating this BMF, however, is that the birds sampled were either ducklings or sub-adults. If the birds were in a stage of substantial feather growth, much of the ingested methylmercury could have been shunted into the feathers instead of muscle tissue (Elbert, 1996; Wiener *et al*., 2002). Body burdens of methylmercury in adult female muscle tissue prior to egg laying may have been substantially greater than the values reported for ducklings and sub-adults.

In the work of Norheim and Froslie (1978), the degree of methylation and organ mercury distribution in several raptorial species in Norway was examined. While this study provided data on methylmercury concentrations in various raptor tissues and evidence of demethylation in raptor organs, prey items were not evaluated. Because of this data gap, no conclusions can be drawn regarding the biomagnification of methylmercury from the diet into tissues of the raptors examined.

Wren *et al*. (1983) examined the bioaccumulation and biomagnification of 21 naturally occurring elements into abiotic and biotic components in an undisturbed Precambrian Shield lake in Ontario. Among the biotic samples were 5 herring gulls, 20 rainbow smelt (*Osmerus mordax*), and 20 bluntnose minnows (*Pimephales notatus*), although it is not clear from the report whether all 20 of the minnows were analyzed. Breast muscle samples from the herring gulls and dorso-lateral muscle samples from the fish were analyzed for mercury. It appears from the report that analysis was for total mercury; however, as has been discussed previously, mercury in fish and avian muscle tissues is primarily methylmercury. This allows for a reasonable estimation of a methylmercury BMF. Average mercury concentration in herring gull breast muscle was 1.7 mg/kg (range 0.66 - 4.0). Average concentration in bluntnose minnow muscle was 0.12 mg/kg (range 0.05 - 0.26), and in rainbow smelt the average concentration was 0.32 mg/kg (range 0.15 - 0.67). The mean length of collected rainbow smelt and bluntnose minnows was 17.3 and 7.4 cm, respectively.

The authors of this study (Wren *et al*., 1983) offered no indication of what the sampled herring gulls preyed upon, except to say that the gulls would "...generally feed on small fish which contain relatively low Hg levels." Herring gulls in the lower Great Lakes were reported to feed primarily on alewife and smelt, with females feeding more on the smaller smelt (mean length: 9 cm) and males feeding more on alewife (mean length: 16 cm) (U.S. Environmental Protection Agency, 1995c). If female herring gulls on the Wren *et al*. (1983) study lake preyed primarily on the smaller bluntnose minnows, a BMF of 14.2 can be calculated (*i.e.*, 1.7 mg/kg in gull breast muscle divided by 0.12 mg/kg in minnow muscle). However, if rainbow smelt are the primary prey, a BMF of 5.3 is calculated (*i.e.*, 1.7 mg/kg divided by 0.32 mg/kg). Taking the average of these two values results in a BMF just under 10, the BMF used by the EPA in the GLI effort.

There has been a great deal of research over the past several decades examining the relationship between dietary mercury concentrations and the resultant concentrations in avian tissues. Controlled laboratory feeding studies, as well as field studies examining mercury concentrations in bird tissues and in the organisms the birds generally feed on, can provide data with which BMFs can be calculated. However, these studies typically are designed to evaluate mercury concentrations in individual tissues such as the liver, kidney, feathers, blood, or brain. While these types of data, and the information they generate regarding biomagnification, are extremely valuable in understanding the toxicokinetics and toxicodynamics of mercury in the exposed bird, they are of limited value for determining BMFs from food into a "whole body" concentration. Whole body concentrations are needed when evaluating the consumption of exposed birds by a predator such as the bald eagle. Ideally, all edible tissues of a dosed bird would be analyzed to provide the averaged methylmercury concentration for the entire bird. Then, knowing the methylmercury concentration in the food, the most accurate BMF for the consumer can be calculated.

Lacking studies where all edible tissues of an exposed bird are analyzed, the most appropriate BMF when considering consumption of the exposed bird by a bald eagle should be based on the relationship between concentrations in the muscle of the test bird and the concentrations in its food. Muscle tissue represents the majority of edible matter in a consumed bird; the pectoralis major and supracoracoideus muscles of the breast by themselves account for between one-fifth and one-third of body weight in flying birds (Proctor and Lynch, 1993). Therefore, methylmercury concentrations in muscle should serve as the best surrogate for whole body concentrations. Muscle tissue concentrations may underestimate the actual whole body concentration, as methylmercury levels in other tissues may be substantially higher; however, the relatively small contribution of these other tissues to the overall edible mass should help to minimize these differences.

As described, two of the studies used to determine a BMF in the GLI effort for trophic level 3 fish to piscivorous birds examined muscle tissues in the target birds. While these studies provide some information regarding mercury biomagnification into piscivorous birds that could be consumed by bald eagles, there was sufficient uncertainty in their extrapolation of BMFs to warrant further analysis for this current effort. An attempt was made to find data directly

connecting methylmercury concentrations in documented food items to methylmercury concentrations in the muscle tissue of adult piscivorous birds.

The work done by Henny *et al*. (2002), previously discussed in Section IV.C (Determination of Test Doses), provided an assessment of mercury in the food and tissues of three piscivorous birds nesting along the lower Carson River in Nevada. Various tissues from both adult and juvenile double-crested cormorants (DCC), black-crowned night-herons (BCNH), and snowy egrets (SE) were analyzed, including methylmercury concentrations in stomach contents. Based on stomach content analyses, it was determined that mean total mercury concentrations in the diets of the three species in 1998 were 0.515 mg/kg (BCNH), 0.905 mg/kg (SE), and 1.44 mg/kg (DCC). Methylmercury accounted for most of the mercury detected, with mean concentrations of 0.48 mg/kg (BCNH), 0.775 mg/kg (SE), and 1.18 mg/kg (DCC).

In 1998, total mercury was measured in liver, kidney, brain, blood, and feathers of all three species examined. Using these concentrations and the data for total mercury in stomach contents, it is possible to calculate total mercury BMFs for each of these specific tissues. However, these values do not allow for an estimate of whole body methylmercury concentrations for two reasons: 1) mercury found in the liver and kidney samples was predominantly inorganic due to postabsorptive demethylation, and 2) the relative contribution of the analyzed tissues to the total edible biomass of each bird is small compared to the contribution of muscle tissue. Although no muscle tissue from any of the bird species was analyzed in this study, it was possible to estimate muscle methylmercury concentrations based on an assumed relationship in piscivorous birds between muscle and brain tissue concentrations. Once muscle methylmercury concentrations were estimated for the birds in the Henny *et al*. (2002) study, a methylmercury BMF from food into a whole body concentration could be calculated.

Additional analyses in the Henny *et al*. (2002) study on a small number of BCNH egg, feather, blood, and brain samples confirmed that mercury residues in these types of avian tissues are essentially 100 percent methylmercury. Brain tissue concentrations were selected to establish the relationship with muscle tissue for several reasons: 1.) no egg concentration values were reported, 2.) feathers were only collected from nestling/fledgling birds, 3.) no studies were found in the scientific literature in which both avian blood and muscle tissue were analyzed for mercury, and 4.) scientific studies examining mercury in avian muscle tissues most commonly include liver, kidney, and brain samples in the analyses.

In reviewing the scientific literature for studies reporting tissue mercury concentrations in piscivorous birds, work done by Elbert (1996) and Elbert and Anderson (1998) with western and Clarke's grebes (*Aechomorphorus occidentalis* and *Aechomorphorus clarkii*) in California provided the most useful data for establishing a brain / muscle relationship. Twenty-three adult birds were collected from three California lakes in 1992, with liver, kidney, breast muscle, and brain tissues analyzed for total mercury. All three lakes are representative of the characteristic habitat used for determining the bald eagle diet used in this analysis; however, one of the three (Clear Lake) is known to be impaired by mercury contamination. Of the other two study sites,

Eagle Lake is relatively pristine, while Tule Lake has previously had problems with organochlorine compounds in the eggs of nesting western grebes (Elbert and Anderson, 1998). Neither of these two lakes are known to have elevated mercury concentrations.

For all birds sampled from the three Elbert and Anderson (1998) study lakes, mean muscle and brain mercury concentrations were 0.79 and 0.22 mg/kg, respectively. These results suggest breast muscle mercury concentrations in piscivorous birds are approximately 3.6 times the concentrations found in brain tissues. Examining the data from each lake, however, reveals variations in this ratio. Mean muscle and brain mercury concentrations in birds at Tule Lake were 0.46 and 0.16 mg/kg, respectively, resulting in a ratio of approximately 2.9. At Eagle Lake, the values for muscle and brain were 0.43 and 0.13 mg/kg, resulting in a ratio of 3.3. Mercury concentrations in birds at Clear Lake were substantially higher, with 1.06 and 0.28 mg/kg in muscle and brain tissue, respectively. These data suggest breast muscle mercury concentrations in piscivorous birds at a mercury contaminated site are approximately 3.8 times the concentrations found in brain tissue.

Because the birds examined in the study by Henny *et al*. (2002) were also sampled from mercury contaminated sites, the mean mercury concentrations reported for brain tissues were multiplied by 3.8 to estimate the concentrations expected in breast muscle. Estimated muscle concentrations for the three species are: BCNH - 6.61 mg/kg (brain = 1.74), SE - 8.74 mg/kg (brain = 2.30), DCC - 42.79 mg/kg (brain = 11.26). Taking the estimated muscle concentrations and dividing by mean methylmercury concentrations in the stomach contents for each species provides BMF values.

BCNH:	6.61 mg/kg in muscle ÷ 0.48 mg/kg in food = **13.77**
SE:	8.74 mg/kg in muscle ÷ 0.775 in food = **11.27**
DCC:	42.79 mg/kg in muscle ÷ 1.18 mg/kg in food = **36.26**

The BMFs estimated for night-herons and egrets are similar in magnitude to the value used for the EPA's GLI effort, while the estimated BMF for the double crested cormorant is more than three times the GLI value. One possible reason for this disparity may be the degree of piscivory exhibited by cormorants compared with the other two species. Henny *et al*. (2002) reported that the stomachs of all the cormorants sampled contained only fish, whereas the contents of the night-heron and egret stomachs varied from 100 percent fish to 100 percent aquatic insects. Based on the percentage volume of stomach items for these two species, the average diet for night-herons and egrets was approximately 34 and 49 percent fish, respectively. It is possible that methylmercury biomagnification from fish into avian muscle tissue is substantially greater for those bird species that are almost exclusively piscivorous, such as the double-crested cormorant and belted kingfisher (*Ceryle alcyon*).

While the remains of both double-crested cormorants and belted kingfishers were found at the nest sites examined in the study used to develop the bald eagle diet for this effort (Jackman *et al*., 1999), their contribution to the overall prey biomass was minimal. Therefore, the BMFs

estimated for black-crowned night-herons and snowy egrets served as the more appropriate surrogates for developing the MPB value for this evaluation.

Averaging the estimated BMFs for the black-crowned night-heron and snowy egrets results in an **MPB** value of **12.5**, used in this evaluation for the bald eagle.

VI.B. Biomagnification for Trophic Level 2 Organisms to Omnivorous Bird Prey: **MOB**

The majority of research on methylmercury and its biomagnification through the aquatic food chain into avian species has focused on piscivorous birds, as the consumption of fish (*i.e.*, higher trophic level biota) represents a pathway with the greatest potential exposure. A review of the scientific literature revealed little that was useful in developing a standardized biomagnification factor for omnivorous waterfowl. However, some data were examined that allowed estimation of a reasonable BMF for this effort.

The Vermeer *et al*. (1973) study discussed in the previous section examined mercury levels in the breast muscle of several species of piscivorous and omnivorous waterfowl, as well as in the stomach contents from individuals of three of these species. Breast muscle samples from 21 common goldeneyes (*Bucephala clangula*), an omnivorous species, showed a mean total mercury concentration of 7.80 mg/kg (range: 0.9 - 19.4). Two individual goldeneyes were further sampled to compare total mercury to methylmercury levels. In these two samples, methylmercury accounted for 73 and 77 percent of the total mercury values. Applying a value of 75 percent methylmercury to the mean total concentration of 7.80 mg/kg results in a mean methylmercury value of 5.85 mg/kg.

Food items from the esophagi and stomachs from seven of the collected goldeneyes confirmed the predominantly invertebrate diet of this species. These food items were analyzed for total mercury; however, the results were reported in a manner that prevents calculation of a precise average concentration. Average total mercury concentrations in the various food items (*e.g.*, bivalves, aquatic insect nymphs, crayfish) ranged from 0.30 to 7.1 mg/kg. Based on the reported values, the average total mercury concentration in the goldeneye diet is approximately 2 mg/kg. As previously noted, making direct assessments of methylmercury biomagnification from this concentration is difficult because it is unknown what percentage of the total mercury in the various invertebrates is methylmercury. In a recent review of mercury ecotoxicology (Wiener *et al*., 2002), the authors point out that the percentage of total mercury present as methylmercury in aquatic invertebrates can vary substantially. Examples of this variation include methylmercury ranging from 9 to 82 percent of total in aquatic insects from northern Wisconsin lakes, and from 20 to 95 percent of total in benthic aquatic insects (detritivores and predatory dragonflies, respectively) from hydroelectric reservoirs in northern Quebec.

With these wide variations possible, the approximate total mercury concentration of 2.0 mg/kg in the goldeneye diet from the Vermeer *et al*. (1973) study could translate into methylmercury

concentrations of 0.18 mg/kg (9% of total) to 1.9 mg/kg (95% of total). Biomagnification factors for the transfer from prey items into goldeneye breast muscle could therefore range from 32.5 (5.85 mg/kg ÷ 0.18 mg/kg) to 3.08 (5.85 mg/kg ÷ 1.9 mg/kg). The true value is likely toward the lower end of the range, as many of the invertebrate prey identified were themselves predatory, possibly resulting in a higher percentage of mercury in the methylated form. However, as discussed previously, an important consideration in evaluating biomagnification from these data is that the birds sampled were either ducklings or sub-adults. If the birds were in a stage of intense feather growth, much of the ingested methylmercury could have been shunted into the feathers instead of muscle tissue (Elbert, 1996; Wiener *et al*., 2002). In addition, body burdens of methylmercury in adult female muscle tissue prior to egg laying may have been substantially greater than the values reported for ducklings and sub-adults.

In an expansion on the previous study, Fimreite (1974) examined 184 piscivorous and omnivorous waterfowl specimens from five different lakes in the same locale of northwestern Ontario. Liver, breast muscle, and stomach contents from twelve of these birds, including three common goldeneyes representing predominantly invertebrate feeders, were analyzed for total and methylmercury. Invertebrates from the three goldeneye stomachs were not identified; however, the contents of each bird were analyzed separately. Methylmercury concentrations in these stomach contents were reported as 0.09, 0.19, and 0.36 mg/kg. These values represented 100, 56, and 47 percent, respectively, of total mercury concentrations. The corresponding breast muscle samples contained 0.11, 0.23, and 0.51 mg/kg methylmercury. For each bird, the reported values indicate biomagnification from diet into breast muscle is only slightly greater than 1 (~ 1.2 - 1.4).

Although life stage was not reported, the three birds sampled were most likely adults. In a separate component of this study, breast muscle and liver from 12 adult and 3 duckling goldeneyes were analyzed for methylmercury. Results showed that mean methylmercury concentrations in duckling breast muscle (7.10 mg/kg) were substantially higher than in adult breast muscle (0.76 mg/kg). While the data suggest biomagnification from food into adult goldeneye breast muscle is low, the timing of sample collection may have masked a greater level of biomagnification prior to the study than indicated from the results. Birds for this study were collected during the periods 20 July - 5 August 1970 and 20 June - 28 July 1971. These periods coincide with the periods of greatest postnuptial molt of goldeneyes in central Ontario, as well as the late stages of duckling growth (Eadie *et al*., 1995). It is possible that adult body burdens of methylmercury were being depurated into replacement feathers, while the young may have finished producing their adult plumage and were no longer eliminating ingested methylmercury through this pathway. Biomagnification into muscle tissue during non-molt periods or after cessation of juvenile feather growth may be substantially greater. If these late stage ducklings were consuming invertebrates with the same methylmercury concentrations as observed in adult stomach contents, biomagnification factors from food into breast muscle could range from approximately 20 to 80 (*e.g.*, 7.10 mg/kg ÷ 0.9 mg/kg = 78.8).

Depuration of methylmercury into growing feathers, excretion in the feces, and deposition into eggs are the principal means of mercury elimination in adult female birds (Wiener *et al*., 2002).

For many of the omnivorous waterfowl species that would be consumed by California bald eagles, molting and egg laying would occur in the spring and summer on northern breeding grounds outside of California. Such was the case with the common goldeneyes in both of the above studies (Vermeer *et al*., 1973; Fimreite, 1974). Although neither study was designed to determine biomagnification factors, the data they generated could considerably underestimate the extent of biomagnification in California birds.

In order to minimize this potential underestimation, an attempt was made to find data for omnivorous birds in California waters. Eared grebes (*Podiceps nigricollis*) and samples of their invertebrate prey were collected from Eagle Lake, California (Eagles-Smith *et al*., in prep.). Eagle Lake, a relatively pristine body not known to have substantial mercury contamination, is the same location where Elbert and Anderson (1998) examined western and Clarke's grebes. This is a breeding area for eared grebes, while their wintering habitats are Pacific coastal regions, southwestern United States, Baja California, and Mexico (Cullen *et al*., 1999).

In the Eagle Lake work, six adult (3 male, 3 female) and three juvenile birds were collected between August and September of 2000. All adults had completed breeding, and were flightless at the time of collection (*i.e.*, both primary and body feather molt). As with the previous two studies discussed, feather replacement during this molt cycle could be an important elimination pathway for the bird's methylmercury body burden. Breast muscle from each bird was sampled and analyzed for total mercury. Concentrations ranged from 0.031 to 0.104 mg/kg (converted from dry weight using 71.5% moisture), with an average of 0.069 mg/kg.

Eared grebes are known to feed predominantly on brine shrimp and brine flies at fall staging areas prior to their winter migration (Cullen *et al*., 1999). However, their diet at freshwater breeding lakes consists mainly of caddisfly and mayfly larvae (~50%), amphipods (~20%), water beetles (~20%), aquatic snails (~10%), and an occasional fish (Eagles-Smith *et al*., in prep.). Approximately 50 invertebrate samples were collected from Eagle Lake, from locations where grebes were taken, and analyzed for total mercury after being sorted into general taxonomic groups. Based on the general dietary composition presented above, the analytical results were combined in a weighted average approach to provide an overall mercury concentration for the integrated eared grebe diet. The average total mercury concentration for this integrated diet was 0.02 mg/kg dry weight. Using a general value of 75 percent moisture for these aquatic invertebrates results in a wet weight concentration of 0.005 mg/kg total mercury.

Neither the grebe muscle nor invertebrate samples were analyzed for methylmercury. Applying the same value of 75 percent observed in common goldeneyes from the Vermeer *et al*. (1973) study to represent the ratio of total mercury to methylmercury, the average methylmercury concentration in the eared grebe breast muscle was 0.052 mg/kg. As discussed previously, the methylmercury percentage in aquatic invertebrates can vary considerably, depending on factors such as the organism's trophic position. For the invertebrates sampled in the Eagle Lake study, it was estimated that methylmercury accounted for approximately 60 - 70 percent of total mercury (Eagles-Smith *et al*., in prep). Of the two primary grebe prey items, only the caddisfly larvae are

considered omnivorous, occupying a higher trophic position, while mayfly larvae are strictly herbivorous (Kozloff, 1990). The amphipods and naucorids consumed by grebes may also exhibit varying degrees of omnivory. These higher trophic level prey, combined with the occasional fish, allow for a reasonable justification for using the higher value of 70 percent methylmercury in invertebrates. This results in an average methylmercury concentration in the grebe's invertebrate diet of 0.0035 mg/kg.

Dividing the average grebe breast muscle concentration (0.052 mg/kg) by the average integrated invertebrate diet concentration (0.0035 mg/kg) results in a biomagnification factor for methylmercury of slightly less than 15 (14.86). Considering these data were generated from a time when a substantial amount of the grebe's methylmercury body burden may have been shunted into replacement feathers, non-molt biomagnification may be substantially greater. These data demonstrate that methylmercury biomagnification in omnivorous waterfowl can be substantially higher than previous studies would indicate.

Assigning an omnivorous waterfowl biomagnification factor for this effort was complicated by numerous factors, including the fact that the various species consumed by bald eagles can exhibit widely varying degrees of omnivory. The eared grebe feeds exclusively on animal matter while other species, such as the American coot (*Fulica americana*), Northern pintail (*Anas acuta*), or American wigeon (*Anas americana*), rely on animal foods to a much lesser extent (Brisbin and Mowbray, 2002; Mowbray, 1999; Austin and Miller, 1995). For every eagle prey bird like the eared grebe having a biomagnification factor of 15 or greater, there may be another exhibiting biomagnification at less than a factor of five. The processes of molting and egg production also contribute to the difficulty in estimating muscle concentrations at any given time of year. It would be virtually impossible to determine true field biomagnification for all omnivorous waterfowl consumed by bald eagles; however, given the information presented above, it is reasonable to assign a general biomagnification factor of 10 for that portion of the bald eagle diet consisting of omnivorous waterfowl.

An **MOB** value of **10** was used in the evaluation for the bald eagle.

VII. EVALUATION OF THE HUMAN HEALTH METHYLMERCURY CRITERION

Once these additional terms for the bald eagle were defined, the modified Equation 1 was used to evaluate the human health criterion for all species of concern.

$$DC = (\%TL2 \times FDTL2) + (\%TL3 \times FDTL3) + (\%TL4 \times FDTL4) + (\%OB \times FDOB) + (\%PB \times FDPB)$$

Inclusion of the additional terms for bald eagles did not affect the calculations for the other species evaluated in this effort, as they only resulted in zero values for those components of the equation (*i.e.*, if %OB = 0, then [%OB × FDOB] = 0). The modified Equation 1 yields the expected overall dietary concentration (DC) resulting from the amount of food eaten from each trophic level, in conjunction with the trophic level methylmercury concentrations estimated from

each of the two TRC trophic level approaches. The DC values calculated for each species could then be compared to the species-specific WV concentrations generated using reference doses, body weights, and food ingestion rates. This simple comparison showed whether either trophic level approach will result in dietary concentrations higher or lower than the protective WV. If lower, then it may be assumed that the species should not be at risk from dietary exposure to methylmercury. If higher, it could be assumed that the species would likely have a dietary exposure that may place it at risk for adverse effects from methylmercury toxicity. In these latter instances, the methodology outlined in the Average Concentration Trophic Level approach can be used to calculate the trophic level-specific methylmercury concentrations necessary to maintain the DC at or below that species' WV.

VII.A. Average Concentration Trophic Level Approach

As explained previously (see Section II.A.), applying the Average Concentration Trophic Level Approach to the TRC of 0.3 mg/kg yields the following trophic level-specific concentrations in aquatic biota:

FDTL2 = 0.029 mg/kg
FDTL3 = 0.165 mg/kg
FDTL4 = 0.66 mg/kg

For the bald eagle, the two biomagnification factors determined previously were used to estimate methylmercury concentrations in the eagle's avian prey:

FDOB = FDTL2 × MOB
FDOB = 0.029 mg/kg × 10
FDOB = 0.29 mg/kg

FDPB = FDTL3 × MPB
FDPB = 0.165 mg/kg × 12.5
FDPB = 2.06 mg/kg

Then, applying these predicted methylmercury concentrations and the trophic level dietary breakouts determined for each species of concern to the modified Equation 1 yielded the total dietary concentrations (DC) presented in Table 4.

Table 4. Predicted Dietary Concentrations (DC) of Methylmercury Under Average Concentration TL Approach

Modified Equation 1:

$$DC = (\%TL2 \times FDTL2) + (\%TL3 \times FDTL3) + (\%TL4 \times FDTL4) + (\%OB \times FDOB) + (\%PB \times FDPB)$$

Species	%TL2	%TL3	%TL4	%OB	%PB	%OF*	DC (mg/kg)
Southern sea otter	0.80	0.20	na	na	na	na	0.056
California least tern	na	1.00	na	na	na	na	0.165
California clapper rail	0.85	0.05	na	na	na	0.10	0.033
Light-footed clapper rail	0.82	0.18	na	na	na	na	0.053
Yuma clapper rail	0.23	0.72	na	na	na	0.05	0.125
Western snowy plover	0.25	na	na	na	na	0.75	0.007
Bald eagle	na	0.44	0.39	0.10	0.035	0.035	0.431

* - The term '%OF' (*i.e.*, other foods) represents dietary items not expected to significantly contribute dietary methylmercury, and is presented in the table only to provide the full dietary composition assessment for each species. These %OF items include plants, terrestrial insects, or avian prey not dependent on aquatic biota. The term was not included in the equation to determine DC values because the assumed absence of significant methylmercury in these food items would only result in a zero value for that component of the equation, thus having no effect on the final DC value:

[%OF × FDOF (methylmercury concentration in other foods)]
[%OF × 0] = 0

The DC values from Table 4., representing the methylmercury concentration in the overall diet of the species resulting from the trophic level-specific concentrations generated by the Average Concentration Trophic Level Approach, were directly compared with the species-specific WVs (Table 5). These comparisons allowed for the presentation of the DC value as a percentage of the corresponding WV, which provided a measure of the protectiveness afforded by the TRC under this approach.

Table 5. Ratio of DC Values to WVs Under Average Concentration TL Approach

Species	DC Values	WVs*	Ratio (DC/WV)
Southern sea otter	0.056	0.055	102%
California least tern	0.165	0.030	550%
California clapper rail	0.033	0.042 (0.014)	79% (236%)
Light-footed clapper rail	0.053	0.040 (0.013)	133% (408%)
Yuma clapper rail	0.125	0.040 (0.013)	313% (962%)
Western snowy plover	0.007	0.026 (0.009)	27% (77%)
Bald eagle	0.431	0.184	234%

* - Values in parentheses represent the WVs generated from the alternative RfD for clapper rails and snowy plover generated using the UF_A of 3, and the subsequent relationships to the DC values.

Wildlife values for the California least tern, light-footed clapper rail, Yuma clapper rail, and bald eagle would be significantly exceeded if their prey contained methylmercury concentrations allowed under the Average Concentration Trophic Level Approach. Wildlife values determined for all three clapper rail subspecies using the alternative RfD would be exceeded under this approach. The WV for the southern sea otter appears as though it would not be significantly exceeded under this approach, while the DC for the western snowy plover would remain well below the WV regardless of the RfD used.

VII.B. Highest Trophic Level Approach

As explained previously (see Section II.B.), applying the Highest Trophic Level Approach to the TRC of 0.3 mg/kg yields the following trophic level-specific concentrations:

FDTL2 = 0.013 mg/kg
FDTL3 = 0.075 mg/kg
FDTL4 = 0.3 mg/kg

For the bald eagle, the two biomagnification factors determined previously were used to estimate methylmercury concentrations in the eagle's avian prey:

FDOB = FDTL2 × MOB
FDOB = 0.013 mg/kg × 10
FDOB = 0.13 mg/kg

FDPB = FDTL3 × MPB
FDPB = 0.075 mg/kg × 12.5
FDPB = 0.94 mg/kg

Then, applying these predicted methylmercury concentrations and the trophic level dietary breakouts determined for each species of concern to the modified Equation 1 yielded the total dietary concentrations (DC) presented in Table 6.

Table 6. Predicted Dietary Concentrations (DC) of Methylmercury Under Highest TL Approach

Modified Equation 1:

$$DC = (\%TL2 \times FDTL2) + (\%TL3 \times FDTL3) + (\%TL4 \times FDTL4) + (\%OB \times FDOB) + (\%PB \times FDPB)$$

Species	%TL2	%TL3	%TL4	%OB	%PB	%OF*	DC (mg/kg)
Southern sea otter	0.80	0.20	na	na	na	na	0.025
California least tern	na	1.00	na	na	na	na	0.075
California clapper rail	0.85	0.05	na	na	na	0.10	0.015
Light-footed clapper rail	0.82	0.18	na	na	na	na	0.024
Yuma clapper rail	0.23	0.72	na	na	na	0.05	0.057
Western snowy plover	0.25	na	na	na	na	0.75	0.003
Bald eagle	na	0.44	0.39	0.10	0.035	0.035	0.196

* - The term '%OF' (*i.e.*, other foods) represents dietary items not expected to significantly contribute dietary methylmercury, and is presented in the table only to provide the full dietary composition assessment for each species. These %OF items include plants, terrestrial insects, or avian prey not dependent on aquatic biota. The term was not included in the equation to determine DC values because the assumed absence of significant methylmercury in these food items would only result in a zero value for that component of the equation, thus having no effect on the final DC value:

[%OF × FDOF (methylmercury concentration in other foods)]
[%OF × 0] = 0

The DC values from Table 6., representing the methylmercury concentration in the overall diet of the species resulting from the trophic level-specific concentrations generated by the Highest Trophic Level Approach, were directly compared with the species-specific WVs (Table 7). These comparisons allowed for the presentation of the DC value as a percentage of the corresponding WV, which provided a measure of the protectiveness afforded by the TRC under this approach.

Table 7. Ratio of DC Values to WVs Under Highest TL Approach

Species	DC Values	WV Values*	Ratio (DC/WV)
Southern sea otter	0.025	0.055	45%
California least tern	0.075	0.030	250%
California clapper rail	0.015	0.042 (0.014)	36% (107%)
Light-footed clapper rail	0.024	0.040 (0.013)	60% (185%)
Yuma clapper rail	0.057	0.040 (0.013)	143% (438%)
Western snowy plover	0.003	0.026 (0.009)	12% (33%)
Bald eagle	0.196	0.184	107%

* - Values in parentheses represent the WVs generated from using the alternative RfD for clapper rails and snowy plover generated using the UF_A of 3, and the subsequent relationships to the DC values.

Wildlife values for the California least tern and Yuma clapper rail would be substantially exceeded if their prey contained methylmercury concentrations allowed under the Highest Trophic Level Approach. The bald eagle WV would only be slightly exceeded by this approach. Using the alternative RfD, the WV for the light-footed and Yuma clapper rails would be substantially exceeded under this approach, while the WV for the California clapper rail would only be slightly exceeded. The DC for the western snowy plover would remain substantially below the WV regardless of the RfD used.

VIII. EVALUATION RESULTS

VIII.A. Southern Sea Otter

The southern sea otter was federally listed as threatened in 1977 (42 Federal Register 2965). Critical habitat for the species has not been designated. A revised recovery plan was published in 2003 (U.S. Fish and Wildlife Service, 2003).

Life History: Generally, the home ranges of southern sea otters consist of several heavily used areas with travel corridors between them. Animals often remain in an area for a long period of time and then suddenly move long distances; these movements can occur at any time of the year. Male southern sea otters have larger home ranges and are less sedentary than females. Juvenile males move further from natal groups than do juvenile females, likely due to territorial and aggressive behavior exhibited toward juvenile males by older males. Most male southern sea otters leave the central portion of the range and travel to its ends during the pupping season, which occurs primarily in the winter and spring (Riedman and Estes, 1990). Southern sea otters mate and pup throughout the year. A peak period of pupping occurs from January to March, and a secondary pupping season occurs in late summer and early fall. Parental care is provided solely by the female. Because of their ability to eat large quantities of marine invertebrates, sea otters play an extremely important role in the nearshore marine community.

Historic and Current Range: Southern sea otters once ranged from the central coast of Baja California north to at least northern California, although they may have ranged as far north as Prince William Sound in Alaska (Riedman and Estes, 1990; Wilson *et al*., 1991). Prior to being protected from hunting for their pelts in 1911, southern sea otters were reduced to only a remnant colony near Bixby Creek along the Big Sur coast in California. Since 1911, the species has expanded north and south from the Bixby Creek colony. Currently, the range of the southern sea otter extends from about Half Moon Bay to Point Conception, with a small translocated colony at San Nicolas Island in southern California.

Rangewide Trends and Current Threats: Historically, the number of southern sea otters was probably between 16,000 and 20,000 (California Department of Fish and Game, 1976). By the end of the 19th century, the sea otter had been hunted nearly to extinction throughout its range. Southern sea otters along the central coast of California experienced a general recovering trend, increasing from as few as 50 animals in 1911 to an estimated 1,789 in 1976. Limitations on set-net fisheries imposed by the California Department of Fish and Game contributed to population increases in the late 1970s and early 1980s (Estes, 1990). Population counts declined from 1995 through 1999 but have since stabilized or increased. During the spring of 2003, a total of 2,505 sea otters were counted.

Current threats to the southern sea otter include disease, exposure to environmental contaminants, intentional take (shooting), and entanglement in fishing gear. Oil spills, which could occur at any time, threaten the southern sea otter with catastrophic decimation or localized

extinction (U.S. Fish and Wildlife Service, 2003).

Evaluation Results: Although the southern sea otter is at risk of exposure to methylmercury from the aquatic organisms in its diet, the analyses performed under each Trophic Level Approach indicate that the EPA's human health TRC (0.3 mg/kg) is not likely to result in a dietary exposure that would place sea otters at risk from methylmercury toxicity (see Tables 5 & 7). Due to the preponderance of trophic level 2 organisms in the otter's diet, neither the Average Concentration nor Highest Trophic Level Approach would result in dietary concentration (DC) values significantly above the calculated Wildlife Value (WV). The DC value generated from the otter's dietary composition and the trophic level methylmercury concentrations determined in the Average Concentration TL Approach is essentially the same as the calculated WV (DC - 0.056 mg/kg, WV - 0.055 mg/kg). The DC value generated in the Highest TL Approach is substantially below the WV (DC - 0.025 mg/kg, WV - 0.055 mg/kg).

VIII.B. California Least Tern

The California least tern was federally listed as endangered in 1970 (35 Federal Register 16047). A detailed account of the taxonomy, ecology, and biology of the California least tern is presented in the approved Recovery Plan for this species (U.S. Fish and Wildlife Service, 1985a).

Life History: California least terns are migratory. They arrive in California in April to breed and depart to wintering areas in Central and South America by the end of September. Little is known about least tern wintering areas. While in California, least tern adults court, mate, and select nest sites; lay, incubate, and hatch eggs; and raise young to fledging prior to departing from the breeding site.

After their eggs hatch, breeding adults catch and deliver small fish to the flightless young. The adults shift their foraging strategy when chicks hatch in order to obtain the very small sized fish suitable for nestlings (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000). The young begin to fly at about 20 days of age, but continue to be fed and are taught how to feed by their parents for some time after fledging. Most foraging activity is conducted within a couple miles of the colony (Atwood and Minsky, 1983). After fledging, the young terns do not become fully proficient at capturing fish until after they migrate from the breeding grounds.

Historic and Current Range: The California least tern continues to occupy nesting sites distributed throughout its historic range. The historic breeding range extended along the Pacific Coast from Moss Landing, Monterey County, California, to San Jose del Cabo, southern Baja California, Mexico (American Ornithologists Union, 1957; Dawson, 1924; Grinnell, 1928; Grinnell and Miller, 1944). However, least terns were nesting several miles north of Moss Landing at the mouth of the Pajaro River, Santa Cruz County, California, at least from 1939 (W.E. Unglish, Western Foundation of Vertebrate Zoology egg collection) to 1954 (Pray, 1954); and although nesting at San Francisco Bay was not confirmed until 1967 (Chandik and Baldridge, 1967), numerous spring and summer records for the area suggest nesting may have

occurred previously (Allen, 1934; Chase and Paxton, 1965; Grinnell and Wythe, 1927; Sibley, 1952). Since 1970, nesting sites have been documented in California from San Francisco Bay to the Tijuana River at the Mexican Border; and in Baja California from Ensenada to San Jose del Cabo at the tip of the peninsula.

Rangewide Trends and Current Threats: There are no reliable estimates describing the historic numbers of California least terns along the Pacific Coast (U.S. Fish and Wildlife Service, 1985a). Early accounts describe the existence of substantial colonies along the southern and central California coast (Bent, 1921), including a colony of about 600 breeding pairs along a 3-mile stretch of beach in San Diego County (Shepardson, 1909). At the time of its Federal listing as endangered in 1970, the total U.S. population of the California least tern was estimated to be 600 breeding pairs (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000). The dramatic decline in breeding least terns has been attributed to the degradation or loss of breeding sites, colonies, and foraging areas, which resulted from human development and disturbance, and pollution (U.S. Fish and Wildlife Service, 1985a).

The current U.S. population of the California least tern is grouped into 5 geographically discrete clusters, which support multiple active and historic breeding sites. These clusters include: (1) San Diego County, (2) Los Angeles/Orange Counties, (3) Ventura County, (4) San Luis Obispo/Santa Barbara Counties, and (5) San Francisco Bay area. Since its listing, the statewide population of the least tern has reached an estimated 4,009 breeding pairs in 1997 (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000). Despite this dramatic increase in breeding pairs, statewide monitoring has revealed threats to the least tern which emphasize the importance of demography to the least tern's survival and recovery.

California least terns were once common along the central and southern California coast. The decline of the California least tern is attributed to prolonged and widespread destruction and degradation of nesting and foraging habitats, and increasing human disturbance to breeding colonies. Conflicting uses of southern and central California beaches during the California least tern nesting season have led to isolated colony sites that are extremely vulnerable to predation from native, feral, and exotic species, overwash by high tides, and vandalism and harassment by beach users. Control of predators constitutes one of the most crucial needs at California least tern nesting sites.

Evaluation Results: In contrast to the evaluation results for the southern sea otter, applying the TRC under either of the trophic level approaches examined here is likely to result in a dietary exposure that may place California least terns at risk for adverse effects from methylmercury toxicity. Due to the tern's relatively small body size and its exclusively piscivorous diet, the WV (0.030 mg/kg) would be significantly exceeded by the DC values generated from the trophic level concentrations under each TL approach. In the case of the Highest TL Approach, the trophic level concentrations would result in a DC value (0.075 mg/kg) 250 percent of the tern's WV (see Table 7). The trophic level concentrations under the Average Concentration TL Approach would result in an even greater DC value (0.165 mg/kg), 550 percent of the WV (see Table 5). While

the extent of any potential adverse effects from either DC value cannot be quantified, the degree of WV exceedance under each TL approach suggests a high probability that dietary methylmercury exposure from the TRC could reach a level at which adverse effects to least terns may be expected. Based on the analyses performed in this effort, methylmercury concentrations in TL3 fish, the tern's sole prey base, would have to be substantially lower than the TL3 concentrations expected under each TL approach in order to maintain dietary exposure at the protective WV for California least terns.

VIII.C. California Clapper Rail

The clapper rail was federally listed as endangered in 1970 (35 Federal Register 16047). A detailed account of the taxonomy, ecology, and biology of the clapper rail can be found in the approved Recovery Plan for this species (U.S. Fish and Wildlife Service, 1984).

Life History: Clapper rails are non-migratory residents of San Francisco Bay tidal marshes. Research in a north San Francisco Bay marsh concluded that the clapper rail breeding season, including pair bonding and nest construction, may begin as early as February (Evens and Page, 1983). Field observations in south San Francisco Bay marshes suggest that pair formation also occurs in February in some areas (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000). The clapper rail breeding season has two nesting peaks, one between mid-April and early-May and another between late-June and early-July. Harvey (1988) and Foerster *et al.* (1990) reported mean clutch sizes of 7.27 and 7.47 for clapper rails, respectively. The end of the breeding season is typically defined as the end of August, which corresponds with the time when eggs laid during renesting attempts have hatched and young are mobile.

Historic and Current Range: Of the 193,800 acres of tidal marsh that bordered San Francisco Bay in 1850, about 30,100 acres currently remain (Dedrick, 1993). This represents an 84 percent reduction from historical conditions. Furthermore, a number of factors influencing remaining tidal marshes limit their habitat values for clapper rails. Much of the east San Francisco Bay shoreline from San Leandro to Calaveras Point has undergone erosion, resulting in a potential loss of local clapper rail populations. In addition, an estimated 600 acres of former salt marsh along Coyote Creek, Alviso Slough, and Guadalupe Slough, had been converted to fresh- and brackish-water vegetation marshes due to freshwater discharge from south San Francisco Bay wastewater facilities. Converted marshes are of lower quality for clapper rails.

The suitability of many marshes for clapper rails is further limited, and in some cases precluded, by their small size, fragmentation, and lack of tidal channel systems and other micro-habitat features. These limitations render much of the remaining tidal marsh acreage unsuitable or of low value for the species. In addition, tidal amplitudes are much greater in the south Bay than in San Pablo or Suisun bays (Atwater *et al.*, 1979). Consequently, many tidal marshes are completely submerged during high tides and lack sufficient escape habitat, likely resulting in nesting failures and high rates of predation. The reductions in carrying capacity in existing marshes necessitate the restoration of larger tracts of habitat to maintain stable populations.

Several years ago, the clapper rail population was estimated to be approximately 500 to 600 individuals in the southern portion of San Francisco Bay, while a conservative estimate of the north San Francisco Bay population, including Suisun Bay, was 195 to 282 pairs (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000). Historic populations at Humboldt Bay, Elkhorn Slough, and Morro Bay are now extinct; therefore, the 30,100 acres of tidal marsh remaining in San Francisco Bay represent the current distribution of this subspecies.

Rangewide Trends and Current Threats: As described above, the clapper rail's initial decline resulted from habitat loss and degradation, and reduction in range. Throughout San Francisco Bay, the remaining clapper rail population is besieged by a suite of mammalian and avian predators. At least 12 native and 3 non-native predator species are known to prey on various life stages of the clapper rail (Albertson, 1995). Artificially high local populations of native predators, especially raccoons, result as development occurs in the habitat of these predators around the Bay margins (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000). Encroaching development not only displaces lower order predators from their natural habitat, but also adversely affects higher order predators, such as coyotes, which would normally limit population levels of lower order native and non-native predators, especially red foxes (Albertson, 1995).

Hunting intensity and efficiency by raptors on clapper rails also is increased by electric power transmission lines, which criss-cross tidal marshes and provide otherwise-limited hunting perches (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000). Non-native Norway rats (*Rattus norvegicus*) long have been known to be effective predators of clapper rail nests (DeGroot, 1927; Harvey, 1988; Foerster *et al.*, 1990). Placement of shoreline riprap favors rat populations, which results in greater predation pressure on clapper rails in certain marshes. These predation impacts are exacerbated by a reduction in high marsh and natural high tide cover in marshes.

The proliferation of non-native red foxes into tidal marshes of the south San Francisco Bay since 1986 has had a profound effect on clapper rail populations. As a result of the rapid decline and almost complete elimination of rail populations in certain marshes, the San Francisco Bay National Wildlife Refuge implemented a predator management plan in 1991 (Foerster and Takekawa, 1991) with an ultimate goal of increasing rail population levels and nesting success through management of red fox predation. This program has proven successful in increasing the overall south San Francisco Bay populations from an all-time low; however, it has been difficult to effectively conduct predator management over such a large area as the south San Francisco Bay, especially with the many constraints associated with conducting the work in urban environments (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000).

Predator management for clapper rails is not being regularly practiced in the north San Francisco Bay, and rail populations in this area remain susceptible to red fox predation. Red fox activity has been documented west of the Petaluma River and along Dutchman Slough at Cullinan Ranch. Along Wildcat Creek near Richmond, where recent red fox activity has been observed,

the rail population level in one tidal marsh area has declined considerably since 1987, even though limited red fox management was performed in 1992 and 1993 (U.S. Fish and Wildlife Service and National Marine Fisheries Service, 2000).

In addition to habitat loss and predation pressures, pollutants in the aquatic environment appear to be a continuing threat to California clapper rail populations. Schwarzbach *et al*. (in press) examined factors affecting clapper rail reproductive success in San Francisco Bay, including predation, flooding, and contaminant exposure. Both predation and contaminants appeared to contribute to observations of low hatching success and overall fecundity for clapper rail nests in six intertidal salt marshes in the Bay. Egg hatchability was depressed in all marshes, with observations of deformities, embryo hemorrhaging, and embryo malpositions. Failed-to-hatch eggs contained various levels of trace element and organochlorine contaminants, with mercury at elevated concentrations in at least some eggs from all six marshes. The researchers stated that mercury appeared to consistently be the contaminant most likely to produce the low hatchability observed in all marshes sampled.

Evaluation Results: As explained previously in this document, the analyses for all three rail subspecies and the western snowy plover included evaluations using two WVs, based on RfDs generated from different interspecies uncertainty factors (UF_A). The WV calculated for the California clapper rail with the UF_A of 1 is 0.042 mg/kg. Comparing this WV with the expected DC values from the trophic level concentrations under both the Average Concentration TL Approach (DC - 0.033 mg/kg) and the Highest TL Approach (DC - 0.015 mg/kg) indicate that the TRC is not likely to result in dietary exposure that would place California clapper rails at risk for adverse effects from methylmercury toxicity, as both DC values are substantially below the WV (see tables 5 & 7).

However, the WV calculated with the UF_A of 3 (0.014 mg/kg) produces different results. The DC value from the Average Concentration TL Approach (0.033 mg/kg) is 236 percent of this WV, indicating that dietary exposure in California clapper rails may place them at risk under this TL approach. The DC value from the Highest TL Approach (0.015 mg/kg) is only slightly above the WV. The small differential (<10%) between the two is well within reasonable bounds, recognizing the various uncertainties and assumptions inherent in this methodology, to conclude that dietary exposure resulting from applying the TRC under the Highest TL Approach should not place California clapper rails at risk for adverse effects from methylmercury toxicity.

The question of which UF_A is the most appropriate to represent the clapper rail's sensitivity relative to mallard ducks, the species used in establishing the avian test dose (Heinz, 1979), cannot yet be definitively answered. However, data collected in the last decade on California clapper rails in the San Francisco Bay region allows for a parallel evaluation of the protectiveness afforded by the two WV values and the UF_As on which they were based.

Schwarzbach *et al*. (in press) collected failed-to-hatch clapper rail eggs from various marshes around San Francisco Bay in 1991-1992 (south Bay) and 1998-1999 (north Bay). The eggs were

analyzed for a number of pollutants, including mercury. Mean egg total mercury concentrations were then calculated for both south Bay eggs (0.54 mg/kg fresh wet weight, range: 0.17 - 2.52) and north Bay eggs (0.36 mg/kg fww, range: 0.11 - 0.87). A subset of collected rail eggs was analyzed for methylmercury, with results demonstrating that methylmercury was on average 95 percent of the total mercury found. South and north Bay means could then be adjusted to 0.513 and 0.342 mg/kg methylmercury, respectively. The south Bay average is equivalent to the avian 'lowest observed adverse effects concentration' (LOAEC) seen in pheasants (Fimreite, 1971).

In a corollary investigation (Schwarzbach *et al.*, 1996), clapper rail prey organisms (*i.e.*, snails, crabs, mussels) were collected in 1992 and 1994 from the same Bay marshes used in rail egg collections. The prey collections from 1992 were analyzed for total mercury, while those from1994 were analyzed for methylmercury. Only the south Bay marsh collections included all three prey organisms. The mean methylmercury concentration for all prey organisms in the south Bay, assuming 75 percent moisture, was 0.036 mg/kg (range: 0.0357 - 0.0363). This value is lower than the WV (0.042 mg/kg) calculated to be protective of clapper rails using the UF_A of 1.

These data allowed the calculation of a diet-to-egg transfer factor for California clapper rails in south San Francisco Bay. Taking the mean rail egg concentration of 0.513 mg/kg divided by the mean prey concentration of 0.036 mg/kg results in a methylmercury diet-to-egg transfer factor of 14.25. Multiplying the WV (0.042 mg/kg) generated with the UF_A of 1 by the diet-to-egg transfer factor of 14.25 results in an estimated methylmercury concentration in the egg of 0.598 mg/kg, higher than what is presently found in south Bay rail eggs. Multiplying the alternate WV (0.014 mg/kg) generated with the UF_A of 3 results in an estimated methylmercury concentration in the egg of 0.199 mg/kg. Based on the egg injection work discussed previously (Heinz, pers. comm., 2003) and assessments of the rail's current reproductive status (Schwarzbach *et al.*, in press), it has been estimated that a value of 0.2 mg/kg fww methylmercury in rail eggs would be a reasonable and appropriate 'no observed adverse effects concentration' (NOAEC) (Schwarzbach, pers. comm., 2003).

Although these data are limited in that collecting failed-to-hatch eggs does not represent a random sample analysis of methylmercury concentrations, they did provide parallel support that a UF_A of 3 is necessary to determine an appropriately protective RfD (0.007 mg/kg bw/day), and subsequent WV (0.014 mg/kg), for the California clapper rail. Given this additional validation of the higher UF_A, it can then be concluded that applying the TRC only under the Highest TL Approach is necessary to maintain dietary exposure at the protective WV for California clapper rails.

VIII.D. Light-footed Clapper Rail

The light-footed clapper rail was federally listed as endangered on October 13, 1970 (35 Federal Register 16047) and state listed as endangered in California on June 27, 1971. The original recovery plan for this species was approved in July 1979 and a revision was published on June 24, 1985 (U.S. Fish and Wildlife Service, 1985b). Critical habitat has not been designated for

this species.

Life History: Rails use coastal salt marshes, lagoons, and their maritime environs (Zembal, 1989). The birds nest in the lower littoral zone of coastal salt marshes where dense stands of cordgrass (*Spartina foliosa*) are present. They also build nests in pickleweed (*Salicornia virginica*) (Massey *et al*., 1984). Rails have also been known to reside and nest in freshwater marshes, although this is not common (Thelander and Crabtree, 1994). They require shallow water and mudflats for foraging, with adjacent higher vegetation for cover during high water (Zeiner *et al*., 1990). Rails forage in all parts of the saltmarsh, concentrating their efforts in the lower marsh when the tide is out, and moving into the higher marsh as the tide advances (Zembal *et al*., 1989).

The pair bond in rails endures throughout the season, and often from year to year. Nesting usually begins in March and late nests have usually hatched by August. Nests are placed to avoid flooding by tides, yet in cover dense enough to be hidden from predators and to support the relatively large nest (Storey *et al*., 1988). Females lay approximately 4-8 eggs, which hatch in 18-27 days (U.S. Fish and Wildlife Service, 1985b). Both parents care for the young; while one forages, the other adult broods the chicks (U.S. Fish and Wildlife Service, 1985b). By the age of two days, chicks will accompany adults on foraging trips; however, adults have been observed feeding fully grown chicks of at least six weeks of age within 25 meters of their incubation nest (U.S. Fish and Wildlife Service, 1985b).

Very limited evidence exists for inter-marsh movements by rails, and this subspecies is resident in its home marsh except under unusual circumstances (Zembal, 1989). Within marsh movements are also confined and generally no greater than 400 meters (Zembal, 1989). Minimum home range sizes for nine rails that were studied using radio telemetry at Upper Newport Bay varied from approximately 0.3 to 1.7 hectares, with larger areas and daily movements by first year birds attempting to claim their first breeding territories (Zembal, 1989). Despite the lack of direct evidence for inter-marsh movement by rails, at least four sites where rails appeared to be extirpated for six or more years were subsequently re-occupied, indicating likely inter-marsh re-colonization (Zembal and Hoffman, 2001).

Historic and Current Range: The rail currently inhabits coastal marshes from the Carpinteria Marsh in Santa Barbara County, California, to Bahia de San Quintin, Baja California, Mexico (Zembal, 1989; Zembal *et al*., 1998). It is believed that most salt marshes along the coastline at one time supported clapper rails (Grinnell *et al*., 1918), but recent census data indicate that less than 50 percent of the coastal wetlands in California are currently occupied (Zembal *et al*., 1998).

Rangewide Trends and Current Threats: The first rail census in southern California was conducted in 1972-73, and the population was estimated at about 500 pairs (Wilbur, 1974). Annual surveys conducted from 1980 to 2001 showed an erratic trend in the population, with a peak estimate of 325 pairs in 1996 (Zembal and Hoffman, 2001). The most recent population census in 2001 found 217 pairs (Zembal and Hoffman, 2001). The three largest sub-populations

(at Newport Bay, Tijuana Estuary, and Seal Beach National Wildlife Refuge) comprised 86 percent of the breeding rails in southern California in 2001 (Zembal and Hoffman, 2001). Many smaller rail sub-populations are under threat of extirpation, but with appropriate management could become nuclei for recovery (U.S. Fish and Wildlife Service, 1985b). The number of marshes inhabited by breeding rails in coastal southern California has fluctuated widely since population censuses began in 1980. The number of occupied marshes declined from 19 marshes in 1984 to 8 in 1989, but increased to 16 occupied marshes in 1997 (Zembal *et al*., 1998).

Habitat loss at several major estuaries in southern California approaches ninety-nine percent (U.S. Fish and Wildlife Service, 1985b). Although salt-marsh habitat loss, degradation, and fragmentation are the leading threats to rails, they are also threatened by disturbance, diseases, contaminants, and predation by non-native red foxes (Thelander and Crabtree, 1994). Rails may also be hit by vehicles in marshes adjacent to or bisected by roads (Zembal *et al*., 1989).

Evaluation Results: As with the California clapper rail, two WVs were calculated for the light-footed clapper rail, based on UF_As of 1 or 3. However, due to the light-footed rail's smaller body weight, WVs are slightly less than those for the California rail. The UF_A of 1 resulted in a WV of 0.040 mg/kg, while the UF_A of 3 yielded a WV of 0.013 mg/kg.

Based on the light-footed rail's diet, which has a greater percentage of trophic level 3 organisms than in the California rail's diet, the trophic level concentrations expected under the Average Concentration TL Approach would produce a DC value of 0.053 mg/kg. This value is more than 400 percent of the lower WV (0.013 mg/kg). The Highest TL Approach produces a DC value of 0.024 mg/kg, 185 percent of the same WV. Both levels of WV exceedance demonstrate that, if 3 is the appropriate UF_A to determine a protective RfD and WV (0.013 mg/kg) for the light-footed clapper rail, the TRC under either TL approach is likely to result in dietary exposure that may place this subspecies at risk for adverse effects from methylmercury toxicity.

No information was found regarding diet-to-egg relationships for this subspecies, so no parallel assessment could be made regarding the appropriateness of 3 as the UF_A. Although it is reasonable to assume that both the light-footed and California clapper rails would be similarly sensitive to methylmercury, it is possible that the light-footed rail is better adapted to detoxify ingested methylmercury because of its more piscivorous diet (see Section III,D: Determination of Reference Dose). If so, then it may be more appropriate to consider the light-footed rail as an obligate piscivore, using the RfD and subsequent WV (0.040 mg/kg) generated with the UF_A of 1.

Comparison of the DC values expected from both TL approaches with the higher WV (0.040 mg/kg) produces variable results. The DC value from the Average Concentration TL Approach (0.053 mg/kg) is more than 130 percent of this WV, indicating dietary exposure is still likely to place these rails at risk of adverse effects from methylmercury toxicity. In contrast, the DC value from the Highest TL Approach (0.024 mg/kg) is only 60 percent of this higher WV, indicating a dietary exposure not likely to place light-footed rails at risk from the TRC.

Regardless of which UF_A (1 or 3) and subsequent WV (0.040 or 0.013) are used in the analysis, the trophic level concentrations expected under the Average Concentration TL Approach would result in a DC value substantially greater than either WV. Dietary exposure under this TL approach may place light-footed clapper rails at risk for adverse effects from methylmercury toxicity. However, comparison of the DC value expected from the Highest TL Approach with the two WVs results in conflicting conclusions. Assuming the UF_A of 1 is appropriate, the analysis suggests that applying the TRC under the Highest TL Approach would be sufficient to maintain dietary exposure at or below the corresponding protective WV (0.040 mg/kg). If the UF_A of 3 is the more appropriate value, then the TRC under this TL approach would result in a dietary exposure above the corresponding WV (0.013 mg/kg). Given the various uncertainties and assumptions used in these analyses (*e.g.*, dietary composition, food chain multipliers), the only conclusion that can be drawn at this point is that, of the two TL approaches evaluated, the Highest TL Approach poses less risk of a dietary exposure that could place light-footed clapper rails at risk for adverse effects from methylmercury toxicity. Further research must be conducted to verify whether the trophic level concentrations expected under the Highest TL Approach are sufficient or need to be lower to ensure adequate protection for the light-footed rail.

VIII.E. Yuma Clapper Rail

The Yuma clapper rail was federally listed as endangered on March 11, 1967 (32 Federal Register 4001). The Yuma Clapper Rail Recovery Plan, approved in 1983, provides background information on the species and identifies new or ongoing tasks necessary to achieve recovery of this species (U.S. Fish and Wildlife Service, 1983). The State of California added the bird to its list of rare wildlife in May of 1971 and later listed it as threatened on February 22, 1978.

Life History: Yuma clapper rail habitat is characterized by cattail (*Typha*), bulrush (*Scirpus*), or tule stands, and shallow, slow-moving water near high ground. Cattail and bulrush stands are often dissected by narrow channels of flowing water that may be covered by downed vegetation. These open channels are important for foraging. Rails commonly use areas with low stem densities and little residual vegetation. They are also found in the ecotone between emergent vegetation and higher ground, such as the shoreline, channel edge, or hummocks in a marsh. In studies conducted along the lower Colorado River, rails were found to use areas far from a vegetative edge during early winter (Conway *et al*., 1993). The depth of water used by clapper rails also varied with season, with shallower water used during the breeding season, and water of moderate depth used during the winter. Although clapper rails are often found in larger stands of vegetation, they have also been found to use patches of habitat within agricultural drains (Bennett and Ohmart, 1978).

The Yuma clapper rail begins breeding activities in February, with egg-laying from March to July in marshes along the Colorado River from the Nevada/California border south to the Colorado River Delta region in Mexico. Chicks generally fledge by mid-September (Eddleman and Conway, 1994). It builds its nest on a raised platform of vegetation concealed in dense marsh vegetation (Patten *et al*., in press). Males may build multiple nests, and the female chooses one

for egg-laying. Alternate nests are used as platforms for loafing, preening, and as brood platforms, but may also be useful for incubation if predators or high water disturb the primary nest (Eddleman and Conway, 1994). This subspecies is partially migratory, with many birds wintering in brackish marshes along the Gulf of California but some remain on their breeding grounds throughout the year (U.S. Bureau of Land Management, 2001). Yuma clapper rails are found around the Salton Sea, and in agricultural drains and canals that support marsh vegetation (i.e., cattail, giant bulrush, alkali bulrush, and common reed). This subspecies breeds only in the lower Colorado River Valley and in the Salton Sink, the latter area holding about 40 percent of the United States population (Setmire *et al*., 1990). The breeding site for the largest population of the Yuma clapper rail in the United States is at the Wister unit of the California Department of Fish and Game (CDFG) Imperial Wildlife Area, near the Salton Sea. The sea's elevation is important to the Yuma clapper rail (U.S. Department of the Interior, 1998) as clapper rails use shallow freshwater habitat that has formed at the mouths of many of the inflows to the Salton Sea. Yuma clapper rails avoid deeper water because it increases juvenile mortality (California Department of Fish and Game, 1990).

Historic and Current Range: The Yuma clapper rail occurs primarily in the lower Colorado River Valley in California, Arizona, and Mexico, and is a fairly common summer resident from Topock south to Yuma in the U.S. and at the Colorado River Delta in Mexico. There are also populations of this subspecies at the Salton Sea in California, and along the Gila and Salt Rivers to Picacho Reservoir and Blue Point in central Arizona (Rosenberg *et al*., 1991). In recent years, individual clapper rails have been heard at Laughlin Bay and Las Vegas Wash in southern Nevada (Nevada Division of Wildlife, 1998). Population centers for this subspecies include Imperial Wildlife Management Area (Wister Unit), Sonny Bono Salton Sea National Wildlife Refuge (NWR), Imperial NWR, Cibola NWR, Mittry Lake, West Pond, Bill Williams Delta, Topock Gorge, and Topock Marsh.

In California this species nests along the lower Colorado River, in wetlands along the Coachella Canal, the Imperial Valley, the upper end of the Salton Sea at the Whitewater River delta, and Salt Creek (NatureServe, 2001). Hydroelectric dams along the Colorado River have apparently increased the amount of marsh habitat, and population numbers of the Yuma clapper rail may have increased expanding the range northward in response to the increase in available habitat (U.S. Bureau of Land Management, 2001). Also, habitat was expanded through the creation of the Salton Sea in the early 1900s.

Rangewide Trends and Current Threats: The U.S. Fish and Wildlife Service (1983) estimated a total of 1,700 to 2,000 individuals throughout the range of the subspecies. Between 1990 and 1999, call counts conducted throughout the subspecies range in the U.S. have recorded 600 to 1,000 individuals. In 1985, Anderson and Ohmart (1985) estimated a population size of 750 birds along the Colorado River north of the international boundary. A substantial population of Yuma clapper rails exists in the Colorado River Delta in Mexico. Eddleman (1989) estimated that 450 to 970 rails inhabited this area in 1987. Piest and Campoy (1998) reported a total of 240 birds responding to taped calls in the Cienega de Santa Clara region of the Delta. These counts

are only estimates of the minimum number of birds present. The population is probably higher than these counts show, since up to 40 percent of the birds may not respond in call surveys (Piest and Campoy, 1998). Based on the call count surveys, the population of Yuma clapper rails in the U.S. appears stable (U.S. Fish and Wildlife Service, unpublished data). The range of the Yuma clapper rail has been expanding over the past 25 years, and the population may be increasing (Ohmart and Smith, 1973; Monson and Phillips, 1981; Rosenberg *et al*., 1991; McKernan and Braden, 1999). A recent genetic analysis showed that this subspecies is outbred; population numbers of the Yuma clapper rail have not become low enough to reduce genetic diversity (U.S. Bureau of Land Management, 2001).

The Yuma clapper rail apparently expanded its range in the early 1900's in response to changes in the vegetation along the Colorado River. Damming and associated changes in hydrology induced vegetation changes in some areas that favored rails. At the same time, damming and diversion of the Colorado River reduced the amount of water flowing into the Colorado River Delta, and reduced the availability of rail habitats in the Delta. Approximately two-thirds of the formerly extensive marshlands of the Delta disappeared following completion of Hoover Dam (Sykes, 1937).

Yuma clapper rail habitat has been further affected by channelization, fill, dredging projects, bank stabilization, and water management practices along the Colorado River. Rail habitat has also been adversely affected by the spread of salt cedar (*Tamarisk ramosissima*). Salt cedar consumes an unusually high amount of water, which results in reduced wetland areas for vegetation preferred by the rail.

Many of the currently occupied breeding sites in the United States are on State and Federal lands that are protected and managed for wildlife (U.S. Fish and Wildlife Service, 1983). However, adequate water supplies are needed to assure the long-term availability of this habitat. Wintering areas and needs are not well known and require further study before habitat preservation needs can be determined. Many of the Mexican breeding sites are located in the Rio Colorado Delta area and require adequate flows in the lower Colorado River for long-term use by Yuma clapper rails. The population of Yuma clapper rails at the Cienega de Santa Clara is threatened by the loss of the source of water that maintains the wetland habitat.
Other threats to the Yuma clapper rail include mosquito abatement activities, agricultural activities, development, and the displacement of native habitats by exotic vegetation (California Department of Fish and Game, 1991).

Evaluation Results: The two WVs (0.013 and 0.040 mg/kg) calculated for the Yuma clapper rail are the same as those used for the light-footed clapper rail. However, due to the Yuma rail's reliance on higher trophic level organisms for its diet, the DC values expected with each TL approach are substantially higher than those expected for either the light-footed or California clapper rails.

The WV for the Yuma rail calculated using the UF_A of 3 is 0.013 mg/kg. The DC value expected from trophic level concentrations under the Highest TL Approach is 0.057 mg/kg, more than 430 percent of the WV (see Table 7). The DC value from the Average Concentration TL Approach is 0.125 mg/kg, almost 1000 percent of the WV (see Table 5). Clearly, if 3 is the appropriate UF_A to determine a protective RfD and WV for the Yuma clapper rail, the TRC under either TL approach is likely to result in dietary exposure that may place this subspecies at risk for adverse effects from methylmercury toxicity.

The WV calculated using the UF_A of 1 is 0.040 mg/kg. This WV (0.040 mg/kg) is substantially closer than the previous WV to the DC value of 0.125 mg/kg expected from the Average Concentration TL Approach, but this DC is still more than 300 percent of this higher WV (see Table 5). This higher WV is even closer to the DC value of 0.057 mg/kg expected from the Highest TL Approach (see Table 7); however, a DC value exceeding the WV by more than 40 percent is still likely to result in a dietary exposure that may place Yuma rails at risk for adverse effects from methylmercury toxicity. Based on these comparisons, both TL approaches would still be insufficient to maintain dietary exposure in this subspecies at or below the calculated WVs.

VIII.F. Western Snowy Plover

The Pacific coast population of the western snowy plover was federally listed as threatened on March 5, 1993 (58 Federal Register 12864) and critical habitat was designated on December 7, 1999 (64 Federal Register 68508). A draft recovery plan for the species has been completed (U.S. Fish and Wildlife Service, 2001).

Life History: Western snowy plovers prefer coastal beaches that are relatively free from human disturbance and predation. Sand spits, dune-backed beaches, beaches at creek and river mouths, and salt pans at lagoons and estuaries are the preferred habitats for nesting. The attributes considered essential to the conservation of the coastal population of the western snowy plover can be found in the final ruling for the designation of critical habitat (64 Federal Register 68508). The primary constituent elements for the western snowy plover are those habitat components that are essential for the primary biological needs of foraging, nesting, rearing of young, roosting, and dispersal, or the capacity to develop those habitat components. The primary constituent elements of critical habitat for the species are provided by intertidal beaches (between mean low water and mean high tide), associated dune systems, and river estuaries. Important components of the beach/dune/estuarine ecosystem include surf-cast kelp, sparsely vegetated foredunes, interdunal flats, spits, washover areas, blowouts, intertidal flats, salt flats, and flat rocky outcrops. Several of these components (sparse vegetation, salt flats) are mimicked in artificial habitat types used less commonly by western snowy plovers (*i.e.*, dredge spoil sites and salt ponds and adjoining levees).

The breeding season for western snowy plovers extends from March to late September, with birds at more southerly locations breeding earlier. Most nesting occurs on unvegetated or

moderately vegetated, dune-backed beaches and sand spits. Other less common nesting habitats include salt pans, dredge spoils, and salt pond levees. Nest site fidelity is common, and mated birds from the previous breeding season frequently reunite. Nest sites are scrapes in the substrate, in which females lay eggs (typically three but up to six). Both sexes incubate eggs, with the female tending to incubate during the day and the male at night (Warriner *et al*., 1986). Snowy plovers often renest if eggs are lost. Hatching lasts from early April through mid-August, with chicks fledging approximately one month after hatching. Adult plovers tend chicks while feeding, often using distraction displays to lure predators and people away from chicks. Females generally desert both mates and broods by the sixth day after hatching, and thereafter the chicks are typically accompanied by only the male. While males rear broods, females obtain new mates and initiate new nests (Page *et al*., 1995)

Historic and Current Range: The Pacific coast population of the western snowy plover breeds primarily on coastal beaches from southern Washington to southern Baja California, Mexico. Historically, western snowy plovers bred or wintered at 157 locations on the Pacific coast, including 133 sites in California. Larger numbers of birds are found in southern and central California, in Monterey Bay (estimated 200 to 250 breeding adults), Morro Bay (estimated 85 to 93 breeding adults), Pismo Beach to Point Sal (estimated 130 to 246 breeding adults), Vandenberg Air Force Base (estimated 130 to 240 breeding adults), and the Oxnard Lowland (estimated 69 to105 breeding adults).

During the non-breeding season western snowy plovers may remain at breeding sites or may migrate to other locations. Most winter south of Bodega Bay, California. Many birds from the interior population winter on the central and southern coast of California.

Rangewide Trends and Current Threats: Historical records indicate that nesting western snowy plovers were once more widely distributed in coastal Washington, Oregon and California than they are currently. Only 1,200 to 1,900 adult western snowy plovers remain on the Pacific coast of the United States (Page *et al*., 1991). In 1995, approximately 1,000 western snowy plovers occurred in coastal California. Historically, western snowy plovers bred at 53 coastal locations in California prior to 1970. Only eight sites continue to support 78 percent of the remaining California coastal breeding population. These are San Francisco Bay, Monterey Bay, Morro Bay, the Callendar-Mussel Rock dunes area, the Point Sal to Point Conception area (Vandenberg Air Force Base), the Oxnard lowland, Santa Rosa Island, and San Nicolas Island (Page *et al*., 1991).

The Pacific coast population of the western snowy plover has experienced widespread loss of nesting habitat and reduced reproductive success at many nesting locations due to urban development and the encroachment of European beachgrass (*Ammophila arenaria*). Human activities such as walking, jogging, unleashed pets, horseback riding, and off-road vehicles can destroy the western snowy plover's cryptic nests and chicks. These activities can also hinder foraging behavior, cause separation of adults and their chicks, and flush adults off nests and away from chicks, thereby interfering with essential incubation and chick-rearing behaviors. Predation by coyotes, foxes, skunks, ravens, gulls, and raptors has been identified as a major factor limiting

western snowy plover reproductive success at many Pacific coast sites.

Evaluation Results: Compared to the other species considered in this evaluation, the western snowy plover is unique in that little of its overall diet is comprised of aquatic organisms. Although the species lives and nests along coastal and estuarine river beaches, the scientific literature indicates that the bulk of the plover diet comes from larval and adult terrestrial insects (primarily flies and beetles). Due to this dietary characteristic, all the analyses performed in this effort indicate that the TRC should not result in a dietary exposure that would place snowy plovers at risk for adverse effects from methylmercury toxicity (see Tables 5 & 7). Dietary concentration values expected from both of the TL approaches should remain substantially below the plover's calculated WV (0.026 mg/kg). Even when using the alternative reference dose (RfD) generated with the interspecies uncertainty factor (UF_A) of 3, expected DC values remain well below the corresponding lower WV (0.009 mg/kg).

These results must be interpreted with some caution, however, as recent research suggests plovers may be at risk from a unique dietary methylmercury exposure pathway not previously considered in toxicity assessments. Hothem and Powell (2000) collected 68 abandoned or inviable snowy plover eggs from five sites in southern California between 1994 and 1996. Twenty-three of these eggs were analyzed for metals and trace elements. Total mean mercury concentrations in these eggs ranged from 0.078 to 0.19 mg/kg. These values are substantially below accepted lowest observed adverse effects concentrations (LOAEC) for avian eggs, and the authors concluded that concentrations of mercury and other environmental contaminants were not sufficiently elevated in the study eggs to be contributing to population declines. However, snowy plover eggs collected in 2000 from Point Reyes National Seashore in northern California revealed highly elevated mercury concentrations (U.S. Fish and Wildlife Service, unpublished data). Nine failed-to-hatch eggs and two abandoned eggs were collected and analyzed for total mercury. Dry weight concentrations ranged from 0.9 to 12.48 mg/kg, with a mean of 2.56 mg/kg. Adjusted for percent moisture at the time of analysis and moisture loss from the time of laying, the mean fresh wet weight (fww) concentration in the failed and abandoned eggs was reported as 1.07 and 0.27 mg/kg, respectively, with a mean of 0.92 mg/kg for all 11 eggs. The maximum concentration detected from the failed eggs (12.48 mg/kg dry weight) adjusted to 3.1 mg/kg fww. This value is nearly as high as the highest concentration yet detected (3.3 mg/kg fww) in eggs of Fortser's terns, an exclusively piscivorous species, collected from the south San Francisco Bay area (Schwarzbach and Adelsbach, 2002). Mean and maximum concentrations in the failed eggs were substantially above accepted avian egg LOAECs [0.5 mg/kg (Fimreite, 1971); ~0.8 mg/kg (Heinz, 1979)], possibly high enough to account for egg failure through direct toxic effects to plover embryos.

The U.S. Fish and Wildlife Service investigators observed an order of magnitude variation in egg mercury concentrations between the different nests sampled along Point Reyes National Seashore in 2000, with no apparent spatial gradients. As mercury in eggs is thought to closely reflect recent dietary uptake (Walsh, 1990), the Point Reyes data indicated to the investigators that the degree of variation observed reflected a highly heterogenous source of dietary mercury. There

are no known mercury inputs to the coastal beaches used by breeding plovers; however, the investigators noted that an inoperative mercury mine continues to discharge mercury-laden sediments into Tomales Bay, east of the Point Reyes peninsula. Although breeding plovers likely do not forage in Tomales Bay, the investigators suggested that marine mammals foraging in this water body may serve as a mercury pathway into the plover diet. Marine pinnipeds are known to accumulate mercury, usually exhibiting the highest reported tissue concentrations among non-human mammals (Eisler, 2000). As snowy plovers are known to feed on insect larvae that develop on marine mammal carcasses (Page *et al*., 1995), the Point Reyes investigators hypothesized that the elevated plover egg mercury concentrations they observed were the result of localized consumption of invertebrates from pinniped carcasses washed ashore into plover breeding territories. This hypothesis is supported by the fact that at least four marine pinnipeds washed ashore at Point Reyes National Seashore during the 2000 plover breeding season, including a harbor seal carcass that was allowed to decompose on site near the plover nest with the maximum observed egg mercury concentration (Ruhlen and Abbott, 2000).

More work is needed to confirm whether plovers may be exposed to mercury via marine mammal carcasses, and it is not currently possible to incorporate this potential exposure pathway into the methodology developed for this evaluation. To do so would require an analysis of mercury biomagnification from pinniped prey items into the insect larvae developing on pinniped carcasses, information currently unavailable. Even if the hypothesis is confirmed, the mercury levels in Tomales Bay prey biota may already be substantially elevated above the trophic level concentrations expected under the human health TRC, due to the historic and ongoing mercury inputs from the upstream mine. As noted above, the analyses performed for this effort indicate that dietary exposure in snowy plovers should not place them at risk from methylmercury toxicity by either of the TL approaches described. However, given the uncertainties surrounding the potential marine mammal pathway and the plover's sensitive conservation status, applying the Highest TL approach to the TRC would provide the most reasonable assurance of protection.

VIII.G. Bald Eagle

The bald eagle was listed as federally endangered in 1978 (43 Federal Register 6230). The Pacific Bald Eagle Recovery Plan was released in 1986 for the recovery and maintenance of bald eagle populations in the 7-state Pacific recovery region (Idaho, Nevada, California, Oregon, Washington, Montana, and Wyoming) (U.S. Fish and Wildlife Service, 1986). In recent years, the status of bald eagle populations has improved throughout the United States. The bald eagle was downlisted from endangered to threatened on July 12, 1995, throughout the lower 48 states (60 Federal Register 36000). A proposed rule to remove the species from the list of endangered and threatened wildlife was made on July 6, 1999 (64 Federal Register 36454) but this rule has not been finalized. Critical habitat has not been designated for this species. In addition to the Endangered Species Act, the bald eagle is protected under the Migratory Bird Treaty Act of 1918, as amended (16 U.S.C. §§703-712) and the Bald Eagle Protection Act of 1940, as amended (16 U.S.C. §§668-668d).

Life History: The species is long-lived, and individuals do not reach sexual maturity until four or five years of age. Breeding generally occurs February to July (Zeiner *et al*., 1990) but breeding can be initiated as early as January via courtship, pair bonding, and territory establishment. The breeding season normally ends approximately August 31 when the fledglings have begun to disperse from the immediate nest site. One to three eggs are laid in a stick platform nest 50 to 200 feet above the ground and usually below the tree crown (Zeiner *et al*., 1990). Incubation may begin in late February to mid-March, with the nestling period extending to as late as the end of June. From June thru August, the chicks remain restricted to the nest until they are able to move around within their environment.

Nesting territories are normally associated with lakes, reservoirs, rivers, or large streams and are usually within two miles from water bodies that support an adequate food supply (Lehman, 1979; U.S. Fish and Wildlife Service, 1986). Most nesting territories in California occur from 1000 to 6000 feet elevation, but nesting can occur from near sea level to over 7000 feet (Jurek, 1988). The majority of nests in California are located in ponderosa pine and mixed-conifer stands and nest trees are most often ponderosa pine (*Pinus ponderosa*) (Jurek, 1988). Other site characteristics, such as relative tree height, tree diameter, species, position on the surrounding topography, distance from water, and distance from disturbance, also appear to influence nest site selection (Lehman *et al*., 1980; Anthony and Isaacs, 1981). Bald eagles often construct up to five nests within a territory and alternate between them from year to year (U.S. Fish and Wildlife Service, 1986). Nests are often reused and eagles will add new material to a nest each year (DeGraaf *et al*., 1991). Lehman (1979) found that 73 percent of nest sites surveyed were within one-half mile of a waterbody, 87 percent within 1 mile, and 100 percent within 2 miles.

Isolation from disturbances is an important feature of bald eagle wintering habitat. Wintering habitat is associated with open bodies of water, with some of the largest wintering bald eagle populations in the Klamath Basin (Detrich, 1981, 1982). Smaller concentrations of wintering birds are found at most of the larger lakes and man-made reservoirs in the mountainous interior of the northern half of the state and at scattered reservoirs in central and southwestern California. Some of California's breeding birds winter near their nesting territories.

Historic and Current Range: The bald eagle once nested throughout much of North America near coasts, rivers, lakes, and wetlands. The species experienced population declines throughout most of its range, including California, due to exposure to environmental contaminants, habitat loss and degradation, shooting, and other disturbances (Detrich, 1981; Stalmaster *et al*., 1985; U.S. Fish and Wildlife Service, 1986). The species' status has improved since the initial listing under the Endangered Species Act.

The bald eagle continues to be found throughout much of North America and breeds or winters throughout California, except in the desert areas (Zeiner *et al*., 1990; DeGraaf *et al*., 1991). In California, most breeding occurs in Butte, Lake, Lassen, Modoc, Plumas, Shasta, Siskiyou, and Trinity Counties (Zeiner *et al*., 1990). California's breeding population is resident year-long in most areas as the climate is relatively mild (Jurek, 1988). Between mid-October and December,

migratory bald eagles arrive in California from areas north and northeast of the state. The wintering populations remain in California through March or early April.

Rangewide Trends and Current Threats: Though the construction of dams has limited the range of anadromous fish, an important historic bald eagle prey base, reservoir construction and the stocking of fish in reservoirs in the west have provided bald eagles with habitat for population expansion (Detrich, 1981; U.S. Fish and Wildlife Service, 1986). The Califomia bald eagle nesting population has increased in recent years from under 30 occupied territories in 1977 to 151 occupied territories in 1999 (Jurek, 2000). Based upon annual wintering and breeding bird survey data, it is estimated that between 100-300 bald eagles winter on National Forests in the Sierra Nevada, and at least 151-180 pairs remain year-round to breed (U.S. Forest Service, 2000). Most of the breeding population is found in the northern third of the state, primarily on public lands. Seventy percent of nests surveyed in 1979 were located near reservoirs (Lehman, 1979) and this trend has continued, with population increases occurring at several reservoirs since the time of that study.

The Bald Eagle Recovery Plan identifies reasons for the decline of the bald eagle, and states that habitat loss is the most important long-term threat to bald eagle populations. Other threats to the bald eagle include recreational development and human activities affecting the suitability of breeding, wintering, and foraging areas. Bald eagles are susceptible to disturbance by human activity during the breeding season, especially during egg laying and incubation, and such disturbances can lead to nest desertion or disruption of breeding attempts (U.S. Fish and Wildlife Service, 1986). Types of disturbance include recreational activities, fluctuating fish populations and availability of roost trees as a result of reservoir level fluctuations, wild fire, fragmentation of habitat, home sites, campgrounds, mines, timber harvest, and roads. Human activities are more likely to disturb bald eagles when located near roosting, foraging, and nesting areas (Stalmaster and Kaiser, 1998; Stalmaster *et al*., 1985; U.S. Fish and Wildlife Service, 1986).

Evaluation Results: For this effort, a weighted risk approach was taken to determine the appropriate eagle diet for calculation of wildlife values, based on the highest trophic level composition reasonably likely to occur, from the predominant habitat type characteristic of California's breeding bald eagles. In effect, this diet represented the greatest potential for dietary methylmercury exposure in bald eagles. Although alternate diets with higher trophic level compositions could be hypothesized, the diet for this effort was determined using a robust dataset for breeding California eagles.

Results of the analyses performed indicate that applying the human health TRC under the Average Concentration TL Approach is likely to result in dietary exposure that may place bald eagles at risk for adverse effects from methylmercury toxicity. The eagle's dietary concentration (DC) of methylmercury expected from the trophic level concentrations under this approach would be more than 230 percent of the eagle's calculated WV (DC - 0.431 mg/kg, WV - 0.184 mg/kg) (see Table 5). While the extent of any potential adverse effects from this DC cannot be quantified, the degree of WV exceedance suggests a high probability that dietary methylmercury

exposure from the TRC could reach a level at which adverse effects to bald eagles may be expected.

In contrast, the DC expected from the concentrations under the Highest TL Approach (DC - 0.196 mg/kg) would be less than 10 percent above the eagle's WV (see Table 7). Given the small differential between the two values, and a recognition of the various uncertainties and assumptions (*e.g.*, LOAEL-to-NOAEL extrapolation, allometric-derived FIR) inherent in the methodology, it is reasonable to conclude that dietary exposure resulting from applying the TRC under the Highest TL Approach should not place bald eagles at risk for adverse effects from methylmercury toxicity.

IX. EVALUATION RESULTS SUMMARY

IX.A. Average Concentration Trophic Level Approach

Based on the analyses conducted for this evaluation, applying the TRC with the estimated trophic level methylmercury concentrations under the Average Concentration TL Approach may be sufficiently protective for only two of the seven species considered: southern sea otter and Western snowy plover. The five other species examined (California least tern; California, light-footed, and Yuma clapper rails; bald eagle) would likely have dietary exposures under this approach that may place them at risk for adverse effects from methylmercury toxicity. The California clapper rail would not have been considered at risk under this approach if the WV generated with the UF_A of 1 was appropriate to represent the rail's sensitivity to methylmercury toxicity, relative to mallard ducks. However, the parallel evaluation discussed previously demonstrated that the WV generated with the UF_A of 3 was more appropriate for this subspecies, resulting in the conclusion that California clapper rails would also likely have dietary exposures that may place them at risk under this TL approach.

IX.B. Highest Trophic Level Approach

This approach, with its lower estimated trophic level methylmercury concentrations, would provide a greater degree of protection than the prior alternative. Applying the TRC under the Highest TL Approach should be sufficiently protective for four of the seven species considered: southern sea otter, California clapper rail, Western snowy plover, and bald eagle. At this time, no conclusion can be drawn regarding the light-footed clapper rail. If this subspecies' sensitivity to methylmercury is the same as the California clapper rail (*i.e.*, the alternative WV generated with the UF_A of 3 is appropriate), and the analysis of its dietary composition is correct, the light-footed rail would likely have dietary exposures under this approach that may place them at risk. However, if other biological characteristics (*e.g.*, a greater ability to detoxify ingested methylmercury, lower diet-to-egg transfer efficiency) indicate the WV generated with the UF_A of 1 is more appropriate for the light-footed rail, the evaluation results suggest this TL approach should be sufficiently protective for this subspecies. Further research is required to definitively answer these questions. The evaluation for the Yuma clapper rail, regardless of the WV used in

the analysis, indicates this subspecies would likely have a dietary exposure under this approach that may place it at risk for adverse effects from methylmercury toxicity. The same questions surrounding relative sensitivity apply to this subspecies, and research should be initiated to answer these questions and determine appropriate trophic level methylmercury concentrations to provide sufficient protection against toxicity. Finally, although methylmercury concentrations for all three trophic levels are expected to be substantially lower under this approach, the estimated trophic level 3 concentration of 0.075 mg/kg would still not be low enough to remove the potential risk of adverse effects from dietary methylmercury exposure for the California least tern. Because of the tern's small body size and its diet of exclusively trophic level 3 fish, this species may be at an elevated risk from methylmercury toxicity.

X. CONSIDERATION OF OTHER TAXONOMIC GROUPS

As explained previously in this document, the evaluation of the TRC's potential to adversely affect federally listed species in California was conducted with the assumption that upper trophic level wildlife species (*i.e.*, piscivorous or omnivorous birds and mammals) would have the greatest inherent risk from methylmercury exposure, due to methylmercury's propensity to bioaccumulate and biomagnify as it moves upward through aquatic food chains. However, there are numerous other listed species in California to consider (see Appendix) which may be adversely affected by the methylmercury TRC. Once the TRC's protectiveness was evaluated for the upper trophic level birds and mammals, the scientific literature was reviewed to assess whether the methylmercury concentrations expected under each TL approach may be protective for the remaining taxonomic groups.

X.A. Fish

The methodology employed for birds and mammals in this effort was based on an assessment of potential toxicity through ingestion of methylmercury-contaminated fish, shellfish, and other aquatic organisms. For fish, assessment of risk from the TRC was based solely on the potential for adverse effects associated with the tissue methylmercury concentrations expected under each of the TL approaches. It should be noted, however, that muscle tissue-bound concentrations represent the amount of methylmercury sequestered from dietary input over a fish's lifetime. It is possible that levels of circulatory methylmercury, reflective of current dietary exposure, may be responsible for any adverse effects. This possibility is due to the fact that re-mobilization of muscle-bound methylmercury may be negligible unless a reduction in available food necessitates catabolic utilization of muscle-bound proteins. However, until further work on circulatory methylmercury is conducted, muscle tissue concentrations remain the most appropriate indicator for evaluating the impact of the TRC on fish.

A great deal of research has been conducted over the years on the bioaccumulation of mercury by fish, providing data on fish tissue mercury concentrations associated with both overt and subtle toxicological effects (see reviews by: Wiener and Spry, 1996; Jarvinen and Ankley, 1999; Eisler,

2000; Wiener *et al*., 2002). Both Wiener *et al*. (2002) and Eisler (2000) examined the relationships between body burden and toxicological significance in several fish species. All of the overt effects concentrations presented were approximately an order of magnitude above even the highest concentration expected in trophic level 4 fish (0.66 mg/kg) when applying the TRC under the Average Concentration TL Approach.

Wiener *et al*. (2002) stated that, because of the high neurotoxicity of methylmercury, exposure levels causing more subtle adverse behavioral effects are likely much lower than those that would result in overt toxicity. These sublethal neurotoxic effects can impair the ability of fish to locate, capture, and ingest prey and to avoid predators. Unfortunately, studies that demonstrate these effects are generally based on waterborne concentrations of mercury, with few providing data on subsequent fish tissue levels.

Fjeld *et al*. (1998) demonstrated long-term impairment in feeding behavior of grayling (*Thymallus thymallus*) that had been exposed as eggs to waterborne methylmercuric chloride. The 3 year old grayling that exhibited impairment developed from yolk-fry with mercury concentrations as low as 0.27 mg/kg. The yolk-fry concentration of 0.27 mg/kg resulted from eggs in the treatment group exposed to 0.8 ug/L methylmercuric chloride, much higher than environmentally realistic waterborne levels. Compared to the control group, 3 year old fish from the 0.8 ug/L treatment group exhibited a 15 percent reduction in feeding efficiency and a 49 percent reduction in competitive feeding ability.

Based on limited data indicating that mercury concentrations in embryos of methylmercury-exposed brook trout are approximately 20 percent of that in the maternal axial muscle tissue, Fjeld *et al*. (1998) calculated that their lowest observed adverse effects concentration (LOAEC) for grayling yolk-fry (0.27 mg/kg) would translate to a maternal muscle tissue concentration of 1.35 mg/kg. This is double the concentration expected in trophic level 4 fish (0.66 mg/kg) under the Average Concentration TL Approach. Extrapolating a maternal muscle methylmercury concentration from a waterborne-induced embryolarval concentration is tenuous for two reasons: the outermost membrane of fish eggs may retard the uptake of both inorganic and methylmercury from the water column, and maternally-derived egg concentrations may be more associated with dietary intake during egg formation rather than existing muscle-bound concentrations (Latif *et al*, 2001; Hammerschmidt *et al*., 1999). However, Hammerschmidt *et al*. (1999) sampled wild yellow perch (*Perca flavescens*) from four seepage lakes in northern Wisconsin and found that the concentration of total mercury in eggs ranged from 20 to 5 percent of the concentration in the maternal carcass. Using this range of concentration ratios, the embryolarval LOAEC of 0.27 mg/kg could translate to maternal muscle tissue concentrations from 1.35 mg/kg (5:1 adult-egg ratio) to 5.4 mg/kg (20:1 adult-egg ratio).

These data suggest that the adult fish tissue concentrations expected under either trophic level approach would result in egg and embryolarval concentrations substantially below the LOAEC (0.27 mg/kg) reported for grayling. How far below the LOAEC depends on the trophic level approach used and assumptions regarding the adult-egg concentration ratio. By using

conservative assumptions (*i.e.*, 5:1 adult-egg ratio), the tissue concentration expected for trophic level 4 fish (0.66 mg/kg) under the Average Concentration Trophic Level Approach would result in an egg concentration of 0.132 mg/kg, approximately half the grayling LOAEC. Applying the same adult-egg concentration ratio to the tissue concentration expected for trophic level 4 fish (0.3 mg/kg) under the Highest Trophic Level Approach would result in an egg concentration of 0.06 mg/kg, approximately one-fifth the grayling LOAEC. While Fjeld *et al*. (1998) made no conclusions regarding a NOAEC (no observed adverse effects concentration) in their experiment, they did not observe any feeding behavior impairment in their lowest dose treatment group. This treatment group was exposed to a waterborne methylmercury concentration of 0.16 ug/L, and the resulting yolk-fry had a mercury concentration of 0.09 mg/kg wet weight. Although it can be determined with some certainty that the egg mercury concentration (0.06 mg/kg) estimated from the trophic level 4 fish concentration under the Highest Trophic Level Approach would not result in feeding behavior impairments in grayling, the same cannot be said for the egg mercury concentration (0.132 mg/kg) estimated with the Average Concentration Trophic Level Approach. The relative magnitude of effects seen at the 0.27 mg/kg LOAEC for grayling yolk-fry (*i.e.*, 49% reduction in competitive feeding ability) suggests the potential for adverse effects may not be completely removed even when eggs have mercury concentrations around 0.132 mg/kg.

In a more recent study, Webber and Haines (2003) examined the potential for behavioral alterations in fish with environmentally realistic tissue methylmercury concentrations. They concluded that alterations in predator-avoidance behaviors in golden shiners (*Notemigonus crysoleucas*) with environmentally realistic tissue methylmercury concentrations (0.536 mg/kg) may increase vulnerability to predation. Golden shiners should be considered trophic level 3 fish, due to their natural diet of zooplankton and aquatic insects (Moyle, 2002). The effects concentration of 0.536 mg/kg is well above the concentrations expected for trophic level 3 fish under either of the TL approaches evaluated here (0.165 mg/kg - Average Concentration Trophic Level Approach; 0.075 mg/kg - Highest Trophic Level Approach). These data suggest that alterations in predator-avoidance behaviors would not be expected in trophic level 3 fish if the TRC is applied under either approach. Although these data do not allow for any definitive conclusions regarding adult trophic level 4 fish, the possibility that a tissue concentration of 0.536 mg/kg could result in adverse behavioral effects suggests that the more conservative trophic level concentrations expected from the Highest Trophic Level Approach may be warranted in order to ensure adequate protection for federally listed fish species.

In addition to the potential for sublethal neurotoxic effects, Wiener and Spry (1996) concluded that reduced reproductive success in wild fish populations is the most plausible adverse effect expected from environmentally realistic concentrations. They noted that methylmercury can impair reproduction by affecting gonadal development or spawning success in adult fish, or by reducing egg hatching success and embryolarval health and survival. Mercury concentrations affecting both hatching success and embryolarval health are directly linked to the adult female body burden (circulatory and/or muscle-bound concentrations), as the majority of mercury in developing eggs is methylmercury derived through maternal transfer (Wiener *et al*., 2002). However, only a small fraction of the total muscle-bound methylmercury is transferred to the egg

mass and eliminated during spawning (Wiener *et al*., 2002; Hammerschmidt *et al*., 1999). Several key studies on mercury and reproductive endpoints are discussed below.

Birge *et al*. (1979) describe the results of two experiments involving embryolarval stage rainbow trout (*Salmo gairdneri*) exposed to waterborne inorganic mercury. In one study, trout eggs exposed to approximately 100 ng/L exhibited reduced survival after four days, with 100 percent mortality after eight days (at approximately 200 - 300 ng/L). After days four and seven of the experiment, mercury content of the eggs was approximately 0.068 and 0.097 mg/kg, respectively. In a second study, trout eggs were placed in aquaria with mercury-enriched sediment and clean water. There was a 28 percent reduction in hatching success and a 49 percent reduction in 10-day survival with a sediment mercury concentration of approximately 1.05 mg/kg. In this treatment group, mercury in the water column was approximately 150 ng/L, and tissues from the hatched larvae contained approximately 0.041 mg/kg.

Both of the above experiments demonstrated substantial adverse effects at low embryolarval inorganic mercury concentrations. If the adult-egg concentration ratios from the previous discussion on grayling (Fjeld *et al*., 1998) were applied to these inorganic mercury concentrations in embryolarval rainbow trout (*e.g.*, 0.04 mg/kg larval concentration and 5:1 adult-egg ratio), adult muscle tissue concentrations as low as 0.2 mg/kg could be associated with severe reproductive effects. However, the adult-egg ratios are based on maternal transfer of accumulated mercury, which is predominantly methylmercury in both the adult tissue and the developing eggs (Wiener *et al*., 2002). The mechanisms of mercury bioaccumulation and maternal transfer prevent a reliable extrapolation of adult fish tissue methylmercury concentrations from concentrations of inorganic mercury in eggs or larvae. In addition, the waterborne concentrations of inorganic mercury (100 - 150 ng/L) used to achieve the observed effects concentrations in embryolarval rainbow trout are substantially above all but the most highly polluted natural waters (Wiener and Spry, 1996). These high waterborne concentrations necessary to see adverse effects in eggs may be due to the apparent ability of the outermost membrane on fertilized fish eggs to retard the uptake of both inorganic and methylmercury from the surrounding water column into the developing embryo (Hammerschmidt *et al*., 1999). In order to accurately assess adult fish muscle tissue levels associated with embryolarval effects, the effects should be related to maternally-derived methylmercury concentrations.

Matta *et al*. (2001) examined the effects of dietary methylmercury on reproduction and survival in three generations of mummichogs (*Fundulus heteroclitus*). Treatment groups were fed methylmercuric chloride-contaminated fish food until four target tissue concentrations were reached (0.2, 0.5, 1.0, and 11.0 mg/kg). Although adverse reproductive effects were observed in this study, they were only manifested in F_1 generation offspring of the treatment group containing tissue methylmercury concentrations of 11 and 12 mg/kg in males and females, respectively. These values are substantially higher than any of the trophic level concentrations expected with the TRC. Of greater importance from this study are the data indicating a significant increase in male mortality in the 0.5 mg/kg tissue concentration treatment group. Survival was somewhat reduced in the 0.2 mg/kg treatment group, but not significantly. However, the almost 50 percent

reduction in the 0.5 mg/kg group indicates significant mortality may occur at concentrations between 0.2 and 0.5 mg/kg. The mummichog is a trophic level 3 fish from the eastern seaboard, similar to the California killifish (*Fundulus parvipinnis*). Although the tissue concentrations associated with increased male mortality from this study (0.2 - 0.5 mg/kg) are considerably higher than the TL3 concentration (0.075 mg/kg) expected by applying the TRC under the Highest Trophic Level Approach, they are close to the TL3 concentration (0.165 mg/kg) expected under the Average Concentration Trophic Level Approach.

The influence of mercury exposure on more subtle reproductive parameters in natural settings was examined by Friedmann *et al*. (1996a). Two indices of gonadal function, gonadosomatic index (GSI) and gonadal sex steroid levels, were measured in northern pike (*Esox lucius*) collected from Lake Champlain, New York and Vermont, in 1994. Northern pike were selected because they are trophic level 4 fish, with a greater degree of mercury bioaccumulation than lower trophic level fish. The GSI was determined by the ratio of gonadal weight to total body weight. The mean total mercury concentration in muscle from the 14 fish sampled was 0.325 mg/kg (range: 0.117 - 0.623 mg/kg). The means for males (n = 7) and females (n = 7) were 0.347 and 0.303 mg/kg, respectively. The researchers found no significant correlation between mercury content, GSI, and gonadal sex steroids, suggesting that mercury exposure in natural settings might not exert as dramatic an effect on teleost fish reproduction as indicated by earlier laboratory findings. However, the researchers raised the possibility that the mercury levels they observed might have a more subtle influence on reproductive physiology which could be detected given a larger sample size.

To evaluate this possibility, the same researchers (Friedmann *et al*., 1996b) conducted a dietary methylmercury feeding experiment with juvenile walleye (*Stizstedion vitreum*). After six months of dietary exposure, fish in the low- and high-mercury diet groups had mean total mercury tissue concentrations of 0.254 and 2.37 mg/kg, respectively. The results for the low-mercury diet group are most relevant to this TRC analysis, as the mercury concentration in the test fish (0.254 mg/kg) is of the same magnitude as the concentrations expected in trophic level 4 fish under either trophic level approach. No significant differences from controls were seen in this low-mercury group for growth and mortality rates. The mean GSIs of male and female fish from both dietary groups were lower than in fish from the control group, but the differences were not statistically significant in the analysis of variance (ANOVA). However, when combining data from the two dietary groups, the mean GSI of male fish fed either mercury-contaminated diet was significantly lower than in males fed the control diet. Also, male fish in both groups exhibited varying degrees of testicular atrophy, greater in the high-mercury group. Mean GSIs for female fish in either treatment group were not significantly different from controls. Levels of plasma cortisol, which is important for stress response and immune function in teleost fish, were significantly lower in low-mercury fish than in control group fish. The above findings suggested to the authors that methylmercury at environmentally realistic fish tissue levels (0.254 mg/kg) may adversely affect reproductive success by impairing testicular development in young teleost fish and may reduce juvenile survival by impairing immune function.

However, in another study examining growth and reproductive endpoints in wild populations of mercury-contaminated fish, Friedmann *et al*. (2002) presented conflicting conclusions. Fifty-two male largemouth bass (*Micropterus salmoides*) were collected from three New Jersey water bodies of varying mercury contamination. Mean total mercury concentrations in muscle tissue were 0.30 mg/kg (Assunpink Lake), 1.23 mg/kg (Manasquan Reservoir), and 5.42 mg/kg (Atlantic City Reservoir). No significant differences between the three lakes were found for body weight, length, condition factor, or GSI. Also, no significant relationship was found between muscle mercury content and adrenocortical function, indicated by interrenal nuclear diameter and serum cortisol levels following stress. Liver somatic index (LSI) was significantly lower in fish from the Atlantic City Reservoir compared to the other two lakes, but this reduction could not be definitively correlated with mercury concentrations. The elevated mercury levels in fish from the Atlantic City Reservoir may have altered androgen profiles, as evidenced by greater levels of serum 11-ketotestosterone, but no cause-effect relationship could be established. Based on the above findings, the authors concluded that elevated mercury levels in fish (*i.e.*, as high as 5.42 mg/kg) do not substantially decrease indicators of general and reproductive health (*i.e.*, GSI). This finding is in contrast to the previous dietary mercury study with juvenile walleye which indicated that an even lower muscle concentration (2.37 mg/kg) was associated with impaired gonadal development (Friedmann *et al*., 1996b). As an explanation for this apparent discrepancy, Friedmann *et al*. (2002) pointed to findings that wild fish populations exposed to toxicants in their environment can develop adaptations that allow them to live in more polluted sites than are predicted with laboratory models. In further support of this explanation, the authors cite the observation by Friedmann *et al*. (1996a) that a correlation between muscle mercury content and reduced GSI did not exist in Lake Champlain northern pike.

Latif *et al*. (2001) collected female walleye during two successive spawning seasons from one mercury-contaminated lake and two relatively pristine lakes in Canada. Mean total mercury concentrations in muscle tissue, in mg/kg, were 0.182 (Lake Winnipeg), 0.194 (Lake Manitoba), and 2.701 (Clay Lake). Mean methylmercury concentrations in eggs (mg/kg), converted from reported dry weight concentrations assuming an 85 percent moisture content, were approximately 0.001 (Lake Manitoba), 0.002 (Lake Winnipeg), and 0.148 (Clay Lake). In addition to any maternally transferred methylmercury, eggs and subsequent larvae were then exposed to varying concentrations of waterborne methylmercury. The experimental results demonstrated a significant decline in hatching success and embryonic heart rate with increasing exposures of waterborne methylmercury, for all three lake stocks. However, after statistically adjusting for waterborne methylmercury effects, the maternally transferred methylmercury in eggs was not significantly correlated with either hatching success or embryonic heart rate. The authors noted that hatching success in eggs from Clay Lake females declined with increasing egg methylmercury concentrations, although the trend was not significant, and suggested that a larger sample size may reveal statistically significant declines. For the purposes of this evaluation, the data from this study indicate that fish tissue methylmercury concentrations in trophic level 4 fish (0.182, 0.194 mg/kg) similar to those expected with the TRC should not result in maternally deposited egg concentrations associated with reduced hatching success.

The effects of dietary methylmercury on multiple reproductive endpoints was also examined by Hammerschmidt *et al*. (2002). Using fathead minnows (*Pimephales promelas*), the researchers measured gonadal development of males and females, spawning success, days to spawning, reproductive effort of females, developmental success of embryos, hatching success of embryos, survival of larvae, and growth of larvae. No reductions in growth or survival were seen in adult fish from any of the treatment groups, regardless of the tissue concentrations. Developmental and hatching success of embryos were not measurably affected by mercury concentrations in either the diets or bodies of parental fish. Similarly, larval survival and growth were not correlated with dietary or tissue methylmercury concentrations. However, in one of the treatment groups, female fish fed the same diet during Phases 1 and 2 (continuous exposure) exhibited reduced gonadal development (based on GSI) with increasing body burden mercury concentrations. No threshold for this effect was presented, but the whole body tissue concentration from the low dose group was approximately 0.68 mg/kg in females (converted from reported dry weights assuming 80% moisture in whole body). The reduced GSI in these fish led to lower egg production (average daily number of eggs laid per gram of female carcass) with increasing mercury concentrations in the adult tissues. Fish fed the same diet during Phases 1 and 2 also exhibited reduced spawning success compared to fish fed the control diet. Male and female fish fed the low dose diet showed an average tissue concentration of 0.625 mg/kg, and had a spawning success rate of only 46 percent. Fish fed the control diet had an average tissue concentration of 0.08 mg/kg, and had a spawning success rate of 75 percent. In fish fed the continuous exposure diets, the number of days to spawning increased with increasing tissue mercury concentrations. In females, days to spawning was also inversely related to gonadal development.

The tissue concentrations in fish fed the low dose diet (average 0.625 mg/kg) during Phases 1 and 2 were substantially above the levels expected for trophic level 3 fish when applying the TRC under either trophic level approach. However, the 0.625 mg/kg average value is similar to the concentration expected in trophic level 4 fish (0.66 mg/kg) under the Average Concentration Trophic Level Approach. Based on the fathead minnow findings described above, Hammerschmidt *et al*. (2002) concluded that methylmercury decreased reproduction in adult fathead minnows at dietary concentrations realistically encountered by predatory fishes in mercury contaminated waters, with the implication that exposed fish populations could be adversely affected by this reproductive impairment.

None of the data examined for this evaluation provided definitive answers regarding the level of protection for fish afforded by the TRC. The trophic level methylmercury concentrations expected from applying the TRC under both trophic level approaches appear to be well below observed adverse effects concentrations described in the scientific literature. However, the trophic level concentrations expected under the Average Concentration Trophic Level Approach, which are higher than those under the Highest Trophic Level Approach, are much closer to these adverse effects concentrations. Although the best currently available data suggest that the TRC would be sufficiently protective of listed fish, regardless of the trophic level approach used, the increasing emphasis on examining more subtle methylmercury-induced effects may reveal even

lower tissue-based threshold effects concentrations.

X.B. Reptiles and Amphibians

Evaluating the TRC with respect to reptile and amphibian species was more problematic than the evaluation for fish, birds, and mammals. The TRC was developed as a methylmercury limit in the edible tissues of fish and shellfish. The protectiveness of the TRC could then be evaluated for fish, based on toxicity associated with various fish tissue concentrations, or for piscivorous and omnivorous birds and mammals, based on the ingestion of methylmercury contaminated organisms. An evaluation for reptiles and amphibians can be based on ingestion if the species of concern feeds primarily on aquatic organisms and if there are sufficient data to establish reference doses, food ingestion rates, and dietary composition. If these species of concern do not feed on aquatic organisms, a risk assessment based solely on toxicity endpoints associated with known tissue mercury concentrations may be performed. However, this type of assessment cannot be used to evaluate the TRC, as there is currently no reliable way to compare tissue mercury concentrations in reptiles and amphibians with the various trophic level fish tissue concentrations expected from the two approaches. Too little is presently known about mercury bioaccumulation in reptiles and amphibians to allow for any comparative risk prediction capability based on bioaccumulation in fish. The majority of the information presented below on the ecotoxicology of metals in reptiles and amphibians is from a comprehensive review by Linder and Grillitsch (2000).

No reptile mortality due to metal intoxication has ever been reported (Linder and Grillitsch, 2000); however, relevant ecotoxicological data on the effects of mercury on reptiles is severely lacking. Of the available studies, most have focused on tissue metal concentrations in free-ranging animals without reference to the ambient conditions giving rise to those concentrations. However, studies showing the highest tissue levels of mercury and other metals were associated with areas apparently having a high degree of environmental contamination. Linder and Grillitsch (2000) reported that only a few studies examined laboratory exposure to a defined dose, and none of these involved mercury. In a later review, Campbell and Campbell (2001) reviewed 20 studies examining inorganic contaminants and snakes, and found one (Hopkins *et al*., 1999) that examined effects concentrations. Unfortunately, neither the Hopkins *et al*.(1999) study nor the follow-up study examining the effects of chronic dietary exposure to trace inorganic elements (Hopkins *et al*., 2002) involved mercury. The remaining 19 studies reviewed by Campbell and Campbell (2001) only examined mercury concentrations in snake tissues, with no connection to exposure or effects. Linder and Grillitsch (2000) found that the available data indicate reptiles in general do not biomagnify metals to an extent that would correspond to their trophic level. In one study comparing whole body mercury concentrations in biota from several trophic levels, Winger *et al*. (1984) reported mercury levels corresponding to trophic level, being consistently highest in water snakes (*Natrix* spp.) and little green herons (*Butorides virescens*). However, mercury levels in the garter snake (*Thamnophis sirtalis*) were among the lowest of several vertebrate species examined, with the highest levels in piscivorous birds (Dustman *et al*, 1972). Linder and Grillitsch (2000) also reported that the available literature appears to support

the hypothesis that reptiles exhibit a generally low sensitivity to metals. However, these authors caution against drawing definitive conclusions regarding reptiles and metal contaminants, due to the almost complete absence of toxicological research under fairly defined experimental conditions, and the absence of any information on embryotoxic potential.

The dietary habits of both snakes considered in this evaluation [San Francisco garter snake (*Thamnophis sirtalis tetrataenia*) and giant garter snake (*Thamnophis gigas*)] indicate a strong dependence on aquatic ecosystems. The San Francisco garter snake is known to prey on red-legged frogs (*Rana aurora*), Pacific tree frogs (*Hyla regilla*), California newts (*Taricha torosa*), western toads (*Bufo boreas*), threespine stickleback (*Gasterosteus aculeatus*), and mosquitofish (*Gambusia affinis*) (U.S. Fish and Wildlife Service, 1985c). Known prey items of the giant garter snake include mosquitofish, common carp (*Cyprinus carpio*), Sacramento blackfish (*Orthodon microlepidouts*), and bullfrogs (*Rana catesbiana*) (U.S. Fish and Wildlife Service, 1999). It is reasonable to assume these snakes may also prey on other available fish and frog species.

These dietary habits clearly indicate that both snakes may be exposed to methylmercury through ingestion of fish and other aquatic-dependent prey. However, evaluating the effect of the TRC on these snakes based on ingestion of methylmercury contaminated prey is confounded by the lack of necessary data. Although it is possible to estimate a daily food ingestion rate for snakes from Nagy (2001) and to make assumptions regarding the trophic level composition of the diet, the existing toxicological data on snakes do not allow for determination of any reference dose. Without a scientifically determined effects concentration in snakes, no WVs can be generated. While the physiological similarities between birds and reptiles may suggest it is possible to take the avian test dose used in this effort, make certain assumptions regarding inter-taxonomic uncertainty, and then arrive at some reference dose and WVs for these snakes, any conclusions drawn from the subsequent evaluation of the TRC would be highly speculative. The combination of reptilian physiological and life history characteristics (*e.g.*, long life span, small home ranges, high trophic position, and ectothermic physiology) make such an extrapolation inappropriate (Hopkins *et al*., 2002). Nagy (2001) points out that the metabolic rate of reptiles results in daily food requirements drastically lower than both birds and mammals. A 1-kg reptile consumes only 9 percent of the amount eaten by a 1-kg bird and approximately 12 percent of the amount a 1-kg mammal requires. If snakes are no more sensitive to ingested methylmercury than are birds (*i.e.*, having the same reference dose), then the lower daily food ingestion rate resulting from the snake's metabolic needs might suggest that fish tissue methylmercury levels that are protective of birds should also be protective of snakes. Although the limited ecotoxicological data presented above may suggest that reptiles in general are less sensitive to methylmercury than other taxa, no definitive conclusions can be made regarding the protectiveness of the TRC for these species until dietary methylmercury effects concentrations can be established for snakes.

The toxicity of mercury has been studied to a much greater extent with amphibians than with reptiles. Most amphibian species have aquatic-dependent early life stages where exposure may be dominated by direct uptake of dissolved metals from water, while exposure through dietary

sources may become more predominant in the subsequent adult life stages (Linder and Grillitsch, 2000). The majority of available effects data for amphibians come from acute and chronic toxicity studies with early life stages of frogs, using waterborne concentrations of inorganic mercury (Linder and Grillitsch, 2000; U.S. Environmental Protection Agency, 1996; Birge *et al*., 1979). Lethality is the toxicological endpoint most commonly assessed in these studies, with the majority of embryo or larval LC50s (lethal concentration for 50% of test population) in the range of 10 - 100 ug/L (Linder and Grillitsch, 2000). It should be noted that several LC50s below 10 ug/L and above 100 ug/L have also been observed (Linder and Grillitsch, 2000; U.S. Environmental Protection Agency, 1996). Concentrations as low as 0.1 ug/L have resulted in up to 6 percent mortality of leopard frog (*Rana pipiens*) embryos (U.S. Environmental Protection Agency, 1996). Embryonic malformation is another commonly measured endpoint in mercury toxicity studies. Waterborne mercury concentrations associated with amphibian embryo malformations ranged from 2 - 75 ug mercuric chloride/L, with malformation rates ranging from 5 to greater than 10 percent (Birge *et al*., 1983).

Adverse effects have also been reported for amphibians exposed to methylmercuric chloride (U.S. Environmental Protection Agency, 1996). Concentrations of methylmercuric chloride between 0 - 4 ug/L resulted in an EC50 (effects concentration for 50% of test population) for embryo deformities in leopard frogs. No metamorphosis was seen in leopard frog tadpoles exposed to concentrations between 1 - 10 ug/L for 3 to 4 months. Greater than 10 percent deformity and mortality was observed in larvae of the African clawed frog (*Xenopus laevis*) exposed to 0.3 ug/L for more than 10 days.

Based on the limited data available, it appears that the early life stages of amphibians are the most sensitive to metal exposures (Linder and Grillitsch, 2000). All of the waterborne effects concentrations for mercury reported above are considerably higher than environmentally realistic levels. Although there will likely be a great deal of variation between water bodies within California, the waterborne concentrations of mercury associated with the TRC should be orders of magnitude below any of the effects concentrations described here. However, these water concentration toxicity data are insufficient to fully characterize risk from the TRC as they do not take into account dietary exposure in post-embryolarval stages or the potential for maternal transfer of bioaccumulated methylmercury into the eggs. Preliminary results from designed studies suggest that metals bioaccumulated into female amphibians may be depurated during egg development and laying (Linder and Grillitsch, 2000). This process, in combination with exposure through waterborne concentrations, could be toxicologically relevant for the embryolarval stages of amphibians.

Due to methylmercury's propensity to bioaccumulate throughout the lifetime of an animal that is dependent on the aquatic food chain, adverse effects in adult life stages may be possible from relatively low prey concentrations. Unfortunately, the effects of dietary exposure to methylmercury in later life stages of amphibians have not been adequately explored. The literature on the bioaccumulation of metals in amphibians is less developed than for reptiles, with only a few controlled experiments examining bioaccumulation from dietary sources (Linder and

Grillitsch, 2000). No data were found in the scientific literature specifically regarding mercury bioaccumulation in frogs, the only amphibian taxon considered in this evaluation of the TRC. However, the limited data on the uptake of metals by amphibians suggest that the bioaccumulation of methylmercury may be an important exposure pathway for frogs.

The single amphibian considered in this evaluation, the California red-legged frog (*Rana aurora draytonii*), feeds as an adult on both invertebrates and vertebrates. Vertebrate prey, such as the Pacific tree frog (*Hyla regilla*) and California mouse (*Peromyscus californicus*), can account for over half of the dietary biomass in large adults (U.S. Fish and Wildlife Service, 2002). It is not known how much of the frog's diet may be comprised of aquatic invertebrates, or whether small fish are ever consumed. The consumption of Pacific tree frogs may constitute an important methylmercury exposure pathway, if they are closely linked with a contaminated aquatic environment.

As discussed previously, the impact of the TRC can only be reliably evaluated for non-fish organisms if they feed on aquatic prey (*i.e.*, fish or aquatic invertebrates) and if there are sufficient data to determine an appropriate dietary test dose at which adverse effects in the organisms are observed. Although California red-legged frogs may consume substantial numbers of aquatic prey, the literature on amphibian ecotoxicology revealed no information indicating that any research has been done involving the effects of dietary exposure to mercury in amphibians (Linder and Grillitsch, 2000; U.S. Environmental Protection Agency, 1996; Birge *et al*., 1979). This lack of data eliminates the possibility of evaluating the TRC for red-legged frogs using a methylmercury ingestion approach.

The methodology used in this evaluation of the TRC is based on the assumption that upper trophic level wildlife species (*i.e.*, piscivorous and omnivorous birds and mammals) have the greatest inherent risk from exposure to methylmercury. No currently available information was found to contradict this assumption, although an increasing emphasis on ecotoxicological research with reptiles and amphibians may provide new data with which to compare these inter-taxonomic sensitivities. Consumption of aquatic organisms by the California red-legged frog and the two species of garter snakes may expose them to toxicologically relevant concentrations of methylmercury, although possibly less so than in those species (*e.g.*, piscivorous birds and mammals) with a greater daily dietary reliance on aquatic prey. The available scientific literature strongly suggests that both reptiles and amphibians can bioaccumulate methylmercury, although the degree to which this occurs has not been fully characterized. However, until the appropriate toxicological data are generated, no definitive conclusions can be drawn about the protectiveness of either TRC trophic level approach for the California red-legged frog, San Francisco garter snake, or giant garter snake.

XI. DISCUSSION

As explained previously, the objective of this effort was to evaluate whether promulgation of the EPA's human health criterion for methylmercury may affect any federally listed threatened or endangered species in California. To do this, a risk assessment methodology was developed and used to analyze the potential effect of the TRC on several of these listed species. The species selected for analysis were presumed to be at the greatest risk of dietary exposure, due to their high trophic position and/or dietary dependence on the aquatic ecosystem. The results of these analyses indicate that some of these species should be sufficiently protected against adverse effects from methylmercury toxicity, depending on the trophic level approach evaluated. For other species, the evaluation results suggest that the TRC may not be adequate to protect against adverse effects.

Risk assessments such as the one used in this effort are designed to gauge the *potential* for adverse effects. The WVs calculated in this document are assumed to represent protective dietary concentrations of methylmercury, at which no adverse effects are expected. Then, if the predicted DC value for any given species is at or below the corresponding WV, it may be concluded with reasonable confidence that adverse effects to that species are not likely to occur. In contrast, a DC value higher than the corresponding WV only results in a presumption of risk for adverse effects. This is due to the fact that WVs are derived from toxicity data for surrogate species, with various assumptions about interspecific sensitivities, dietary composition of the species of concern, and the use of uncertainty factors to estimate a dose at which no adverse effects should occur. Therefore, any presumption of risk for a species can only be definitively confirmed or dismissed by available scientific evidence that serves to remove these layers of uncertainty.

The Service's Environmental Contaminants Division believes the analyses presented in this document represent the most current state of knowledge regarding the risk to California's listed species from dietary methylmercury. The mammalian and avian test doses used in this effort, which serve as the toxicological foundation for this methodology, remain the best available benchmarks of effects concentrations for these taxonomic groups. Uncertainty factors have previously been applied to these test doses, initially for the GLI and then updated for the MSRC (U.S. Environmental Protection Agency, 1995d; 1997a, respectively), to establish reference doses for key piscivorous wildlife species at which no adverse effects would be expected. To date, no new evidence has been presented suggesting that the uncertainty factors used for this evaluation should be altered to establish higher reference doses for any of the species considered. In several cases, the dietary compositions used in species evaluations were based on limited empirical data; however, until new data are generated, these compositions remain the most reliable estimates. Finally, future controlled methylmercury dosing experiments with individuals of the species evaluated could potentially yield more accurate reference doses (*i.e.*, NOAELs); however, any such experiments are highly unlikely due to the regulatory status of these species as threatened or endangered.

For the reasons cited above, we believe the presumption of risk for certain species indicated by the results of our evaluation cannot presently be dismissed by the available scientific evidence. Those species for which the predicted DCs are significantly above the corresponding WVs (*i.e.*, >10% higher) would be considered at risk for adverse effects from methylmercury toxicity. Conclusions about the protectiveness of the TRC for each species, under both trophic level approaches evaluated, are summarized below in Table 8. These conclusions reflect the interpretation of the evaluation results by the Service's Environmental Contaminants Division only, and are not intended to represent the views of those EPA or Service scientists who helped develop the risk assessment methodology. In addition, these conclusions do not constitute the results of consultation under Section 7 of the ESA.

Table 8. Protectiveness of Tissue Residue Criterion for Seven California Species

Is the TRC Protective for...	Southern Sea Otter	Ca. Least Tern	Ca. Clapper Rail	Light-footed Clapper Rail	Yuma Clapper Rail	Western Snowy Plover	Bald Eagle
Under Average Concentration TL Approach?	Yes	**No**	Yes	**No**	**No**	Yes	**No**
- with Alternate WV Generated from UF_A of 3?	na	na	**No**	**No**	**No**	Yes	na
Under Highest TL Approach?	Yes	**No**	Yes	Yes	**No**	Yes	Yes
- with Alternate WV Generated from UF_A of 3?	na	na	Yes	**No**	**No**	Yes	na

Applying the TRC under the Average Concentration Trophic Level Approach would place five of the seven listed species at risk for adverse effects: California least tern; California, light-footed, and Yuma clapper rails; bald eagle. Only the southern sea otter and western snowy plover would be sufficiently protected under this approach. Applying the TRC under the Highest Trophic Level Approach would place two of the seven species, California least tern and Yuma clapper rail, at risk for adverse effects. The southern sea otter, California clapper rail, western snowy plover, and bald eagle should be sufficiently protected under this approach. No conclusions can be drawn at this time regarding the light-footed clapper rail, due to remaining uncertainty about this subspecies' sensitivity to methylmercury.

The two species determined to still be at risk under the Highest Trophic Level Approach are the California least tern and the Yuma clapper rail. As explained previously in this document, the methodology outlined in the Average Concentration Trophic Level Approach can be used to calculate the trophic level-specific methylmercury concentrations necessary to maintain any species' DC at or below its calculated WV. Using Equation 3 from this methodology and substituting any WV for the DC term, we can solve for the methylmercury concentration in trophic level 2 prey:

FDTL2 = WV / [(%TL2) + (%TL3 × MTL3) + (%TL4 × MTL3 × MTL4)]

Once the trophic level 2 concentration is calculated, the remaining trophic levels can be determined using our established food chain multiplier relationships:

FDTL3 = FDTL2 × MTL3
FDTL4 = FDTL3 × MTL4

Using the WVs determined for the least tern and Yuma clapper rail, along with the trophic level composition of their diets, the trophic level methylmercury concentrations required to maintain these WVs can be calculated (Table 9).

Table 9. Trophic Level Methylmercury Concentrations Calculated for California Least Tern and Yuma Clapper Rail

	California Least Tern (WV = 0.030 mg/kg)	Yuma Clapper Rail (WV generated with UF_A of 1 = 0.040 mg/kg)	Yuma Clapper Rail (WV generated with UF_A of 3 = 0.013 mg/kg)
FDTL2	0.005 mg/kg	0.009 mg/kg	0.003 mg/kg
FDTL3	0.030 mg/kg	0.053 mg/kg	0.017 mg/kg
FDTL4	0.120 mg/kg	0.210 mg/kg	0.068 mg/kg

Of the two approaches evaluated, the Highest Trophic Level Approach affords a greater degree of protection for California's listed bird and mammal species than the Average Concentration Trophic Level Approach. As stated previously, the best currently available data on mercury toxicity in fish suggest that the TRC under either approach should be sufficiently protective of all listed fish in California; however, the trophic level concentrations expected under the Average Concentration Trophic Level Approach would be much closer to observed adverse effects concentrations described in the scientific literature. Finally, although a lack of relevant data precludes any conclusions regarding the potential impact of the TRC on the reptile and amphibian species considered, the lower trophic level concentrations expected under the Highest Trophic Level Approach would afford a greater measure of protection than those expected under

the Average Concentration Trophic Level Approach. Based on the above conclusions, we believe that the TRC would not adequately protect all listed species in California; however, applying the TRC under the Highest Trophic Level Approach would reduce the number of species at risk.

Finally, it must be noted that the risk assessment methodology presented in this document was not applied to any wildlife species other than the federally listed species from the Appendix. However, other non-listed wildlife may be potentially at risk under the TRC, due to their dietary dependence on aquatic ecosystems. Using the same approach followed in this effort, regulatory agencies should be able to determine whether concentrations of methylmercury in fish tissue under the TRC may also pose a risk to these non-listed wildlife species.

Abstract: Environmental management decisions at mercury-contaminated sediment sites are predicated on the understanding of risks to various receptors, including fish. Toxicity reference values (TRVs) for interpreting risks to fish have been developed to assess mercury concentrations in fish or fish prey. These TRVs were systematically evaluated based on several lines of evidence. First, their conceptual basis and specific derivation were evaluated, including a close review of underlying toxicity studies. Second, case studies were reviewed to investigate whether TRVs are predictive of effects on fish populations in the field. Third, TRVs were compared with available information regarding preindustrial and present-day background concentrations of mercury in fish. The findings show that existing TRVs are highly uncertain, because they were developed using limited data from studies not designed for TRV derivation. Although field studies also entail uncertainty, several case studies indicate no evidence of adverse effects despite mercury exposures that exceed the available TRVs. Some TRVs also fall within the range of background mercury concentrations in predatory or prey fish. Lack of information on the selenium status of mercury-exposed fish is a critical confounding factor, and the form of methylmercury used in toxicity testing may also contribute to differences between TRV-based predictions and field observations of mercury effects on fish. On balance, the available information indicates that several of the TRVs reviewed are lower than necessary to protect fish populations. The 20% effect concentration from a previously published dose–response analysis appears closer to an effect threshold, based on available laboratory data. Additional research is needed to provide a stronger basis to establish dose–response relationships for mercury effects on fish. *Environ Toxicol Chem* 2016;35:529–549. © 2016 SETAC

Keywords: Methylmercury Reproductive toxicity Population-level effects Ecological risk assessment Dose–response modeling Tissue residue-effect relationships

INTRODUCTION

Numerous studies have investigated mercury bioaccumulation in fish [1–3], often focusing on fish as a vector for mercury exposure of humans and wildlife. Studies of mercury effects on fish themselves historically lagged behind assessments of fish consumers [4] but have been implemented more frequently in recent years [5]. Many of these studies have focused on biochemical and histological responses of fish to mercury [5,6], although a few studies have directly evaluated reproductive success or effects on fish populations. In recognition of the need to consider protection of fish populations in environmental decision-making, scientists have proposed toxicity reference values (TRVs) for mercury effects on fish based on previously published studies (Table 1).

Environmental management decisions at mercury-contaminated sediment sites entail many considerations, typically including the assessment of risks to fish, as well as risks to humans, aquatic-feeding wildlife, and benthic invertebrates. Depending on site characteristics, perceived risks to fish—based on comparisons with TRVs—can be among the controlling factors to determine sediment cleanup goals. Mercury TRVs for fish also may influence risk-based source control efforts for air and water emissions.

Likely reflecting the application of the precautionary principle to compensate for uncertainty, ecotoxicity data and results very often are interpreted conservatively during the derivation of TRVs. On the other hand, as articulated by US Environmental Protection Agency (USEPA) [7], cleanup actions to address ecological risks should not do more ecological harm than good, recognizing that cleanup actions can cause habitat disruption along with other unintended consequences (e.g., carbon emissions, contaminant suspension and release, or community quality of life impacts during construction). Toward that goal, risk assessors and managers should strive to base decisions on TRVs that are sufficiently protective without being overly protective. Given the implications of mercury TRVs for fish on broader environmental management goals, a critical review is warranted.

The present TRV review considers several lines of evidence. First, we evaluate the conceptual basis and specific derivation of prominent TRVs, including a close review of underlying laboratory toxicity studies. We also consider additional laboratory studies, most of which were published after the TRVs were developed. Second, we investigate whether the laboratory-based TRVs are predictive of effects on fish populations in the field, through a review of 8 case studies. Third, we compare the TRVs with available information regarding preindustrial and present-day background concentrations of mercury in fish. This approach offers utility beyond a simple critique of TRV developers' data

Table 1. Mercury toxicity reference values for protection of fish

TRV source	TRV (mg/kg, wet wt)	Description/basis
Adult whole-body concentration		
Beckvar et al. [8]	0.2	Tissue TEL: Geometric mean of LOAELs (15th percentile) and NOAELs (50th percentile); includes effects on reproduction, growth, development, and behavior
Dillon et al. [9]	0.77	EC20 calculated from multispecies dose–response curve; effects on reproduction and survival
Sandheinrich and Wiener [5]	0.3–0.5	Onset of effects on biochemistry, cells/tissues, and reproduction
Prey tissue concentration		
Depew et al. [16]	0.04	Reproductive effect threshold, highest NOAEL below lowest LOAEL
Depew et al. [16]	0.06	Biochemical effect threshold, highest NOAEL below lowest LOAEL
Depew et al. [16]	0.50	Behavioral effect threshold, highest NOAEL below lowest LOAEL
Depew et al. [16]	1.44	Growth effect threshold, highest NOAEL below lowest LOAEL
Depew et al. [16]	2.80	Mortality threshold, TEL

TRV = toxicity reference value; TEL = threshold-effect level; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level; EC20 = 20% effect concentration.

interpretation, by identifying independent datasets that can be used to test TRV-based predictions. Furthermore, our review of field case studies provides a unique compilation that may be useful to researchers and risk assessors. Based on our review, we also offer recommendations for research to support future development of improved TRVs for mercury effects on fish. In the interest of maintaining the focus in this analysis on direct effects on fish, this review does not attempt to put the TRVs that are protective of fish into a broader context of TRVs or guidelines that are protective of people or wildlife that consume fish; as noted above, fish consumers historically have been the focus of work to characterize concentrations of mercury in fish tissue.

TRV DERIVATION

In this section, we present the available mercury TRVs that have been derived for protection of fish and the derivation of those TRVs, followed by a critical review of fish tissue TRVs, fish tissue dose–response relationships, and fish prey TRVs. To our knowledge, the TRV sources reviewed here represent the only originally derived mercury TRVs for protection of fish published in the last 15 yr on the basis of adult or juvenile fish tissue or prey concentrations. Although TRVs are also available on the basis of early life stage tissue concentrations [8,9], such TRVs are not considered in this review for 2 reasons. First, mercury monitoring and exposure assessment is generally conducted using adult fish tissue analyses, and mercury concentrations in fish early life stages are not comparable to those in adult fish. Second, comparability of mercury concentrations is limited even among early life stage tissue analyses, because chemical concentrations in fish larvae and fry change rapidly as a result of growth dilution [10]. Thus, applicability of early life stage tissue-based TRVs is expected to be limited. However, effects on early life stages as a result of maternal transfer were included in the derivation of TRVs based on adult tissue concentrations. Aqueous mercury exposures and effects on fish and other aquatic life have been reviewed elsewhere [11] and are less relevant than tissue-based TRVs because of mercury's high capacity for bioaccumulation and the very low mercury concentrations normally occurring in water.

Fish tissue mercury concentrations are presented in the present review on a consistent basis to the extent possible. All tissue concentrations are reported on a wet weight basis unless stated otherwise. Mercury concentrations in fish tissue are generally assumed to consist primarily of methylmercury [12], such that total mercury and methylmercury concentrations in fish are used interchangeably. This assumption has the potential to introduce uncertainty, however, because the fish tissue TRV derivations include total mercury data for fish exposed in the laboratory to inorganic mercury [8,9], and because in rare instances environmentally exposed fish have been found to contain substantial amounts of inorganic mercury [13]. Some studies and case studies cited below provide mercury concentrations in fish muscle but not whole fish. In those cases, we estimated whole-body mercury concentrations using the following equation from Peterson et al. [14]:

$$\log\left(\mathrm{Hg}_{\text{whole-body}}\right) = 0.9005\log(\mathrm{Hg}_{\text{muscle}}) - 0.2712 \qquad (1)$$

This fillet–whole body conversion method is robust because it was derived from a large dataset, representing 13 freshwater fish species from 65 sites ($n = 210$), and showed high explanatory power ($r^2 = 0.96$) [14]. Normalization of fish tissue mercury concentrations based on fish length is also commonly employed for some purposes. This practice is not necessarily applicable to laboratory studies but is discussed further below with respect to field studies (see *Case Study Review* section). Lastly, unlike hydrophobic organic compounds, mercury tends to partition to skeletal muscle rather than lipids [15], so lipid normalization of mercury concentrations would not be meaningful.

Overview of TRVs

Table 1 presents prominent mercury TRVs for protection of fish [5,8,9,16]. These TRVs are based on compilations of laboratory studies reporting paired exposure and effects data (although Sandheinrich and Wiener [5] also considered some field studies) and are expressed as mercury concentrations in biota tissue. The listed TRVs reflect adult fish or prey tissue concentrations that are not expected to cause adverse effects, including adverse effects in the offspring exposed to mercury via maternal transfer. Most of the TRV sources express exposure on the basis of whole-body mercury concentrations in potentially affected fish [5,8,9]. Depew et al. [16], however, focused on methylmercury concentrations in fish diet, which apply to prey organisms (i.e., smaller fish, invertebrates, or plants, depending on the diet of the fish species being assessed). Laboratory studies used to derive the TRVs are identified in Table 2.

Beckvar et al. [8] developed a mercury TRV of 0.2 mg/kg for the protection of fish (including early life stages exposed through maternal transfer), based on whole-body tissue residues in juvenile and adult fish. To generate the TRV, Beckvar et al. [8] evaluated hypothesis testing results from published

Table 2. Summary of laboratory studies included in TRV derivation

Species	Ref.	Beckvar et al. [8]	Dillon et al. [9]	Depew et al. [16]	Sandheinrich and Wiener [5][a]	Comments
Atlantic croaker (*Micropogonias undulatus*)	[49]			X		Different diets among treatment groups (not a controlled comparison); larval swimming speed differed in response to vibration but not visual stimulus; ecological significance uncertain
Brook trout (*Salvelinus fontinalis*)	[28]	X	X			Statistically significant effect corresponds to spawning failure, but lesser effects not statistically significant (Was statistical power adequate?)
Fathead minnow (*Pimephales promelas*)	[45]	X	X			Fish exposed to inorganic mercury, while all other studies used methylmercury exposures; high variability at low doses
Fathead minnow (*P. promelas*)	[21]	X	X	X	X	Important comparison of exposure-timing effects; results show high variability; authors' statistical analysis does not identify NOAEL or LOAEL treatments
Fathead minnow (*P. promelas*)	[43]	X	X	X	X	Low control spawning rate (32%)
Fathead minnow (*P. promelas*)	[44]		X	X	X	Low control spawning rate (40%)
Golden shiner (*Notemigonus crysoleucas*)	[122]	X			X	Good study of shoaling-related behavior; applying laboratory behavioral results to population-level effects is uncertain
Mummichog (*Fundulus heterocilitus*)	[25]	X	X	X		Male mortality significant but potentially related to aggressive behavior (other studies indicate mortality endpoint is less sensitive); no effect on productivity over three generations, but only parental generation adults were dosed with methylmercury
Rainbow trout (*Oncorhynchus mykiss*)	[123]		X			Measured mortality but not reproduction; whole fish analyzed only for 1 treatment
Striped mullet (*Mugil cephalus*)	[24]	X				Ecological significance of fin regeneration endpoint uncertain; small magnitude of effect (low-dose group 10% lower than control)
Walleye (*Stizostedion vitreum*)	[23]	X	X	X	X	Control mortality (species hard to maintain in captivity); dose groups combined to achieve statistical significance (interpretation ambiguous); indirect relationship between gonadosomatic index and reproductive success
Medaka (*Oryzias latipes*)	[124]		X			Measured mortality but not reproduction

[a]Additional laboratory studies focusing on suborganismal endpoints were also considered by Sandheinrich and Wiener [5] but are not listed here for brevity.
TRV = toxicity reference value; LOAEL = lowest-observed-adverse-effect level; NOAEL = no-observed-adverse-effect level.

laboratory toxicity studies that were deemed to meet the following requirements: no-observed-adverse-effect level (NOAEL) and lowest-observed-adverse-effect level (LOAEL) provided for the same endpoint (although identified NOAELs frequently represented control treatments); control performance acceptable; whole-body concentrations measured; exposure duration not acute; and effects on survival, growth, reproduction, development, or behavior reported. Beckvar et al. [8] compared multiple derivation methods and recommended the tissue threshold-effect level method as the most appropriate approach for interpreting adult fish tissue mercury toxicity data. As described by Beckvar et al. [8], the tissue threshold-effect level is defined as the geometric mean of the 15th percentile in the effects dataset and the 50th percentile in the no-effects dataset. Beckvar et al. [8] indicated that the tissue threshold-effect level method was considered superior to the other methods evaluated because it is the only percentile-based method that represents all the available data (i.e., from both the effects and the no-effects datasets) and because, unlike some other methods, it yielded a TRV that exceeded control tissue mercury concentrations. Although Beckvar et al. [8] acknowledge that this TRV is most suitable as a screening level, it is susceptible to misinterpretation as an effects threshold in regulatory and management settings.

Whereas Beckvar et al. [8] focused on hypothesis testing (NOAELs and LOAELs), Dillon et al. [9] used more detailed information from the available toxicity studies to evaluate dose–response relationships. The Dillon et al. [9] analysis was limited to test endpoints directly related to fish survival and reproduction (including early life stage survival), which are the organism-level endpoints most directly relevant to effects on fish populations. For each exposure group and endpoint, Dillon et al. [9] calculated the percent difference from the control group. The net effect of multiple endpoints (e.g., survival, spawning success, hatching success, early life stage survival) was calculated by summing the percent effect identified for each endpoint. The results for each exposure group from each study were then assembled and interpreted collectively using nonlinear regression. Based on the fitted regression, the authors estimated a relatively low magnitude of effect (5.5%) at 0.2 mg/kg, the tissue TRV identified for adult and juvenile fish by Beckvar et al. [8]. The magnitudes of effect associated with tissue concentrations of 0.5 mg/kg, 1 mg/kg, and 3 mg/kg were estimated as 13%, 24%, and 50%, respectively. Although the objective of Dillon et al. [9] was to determine a dose–response function rather than a specific TRV, their analysis supports identification of specific mercury concentrations predicted to cause a given level of effect. Because a 20% effect level is often considered for ecological risk assessment purposes [17,18], we used the Dillon et al. [9] dose–response equation to identify a 20% effect concentration (EC20) of 0.77 mg/kg. The 95% confidence interval for the EC20 (estimated from Figure 1 in Dillon et al. [9]) is 0.4 mg/kg to 1.3 mg/kg.

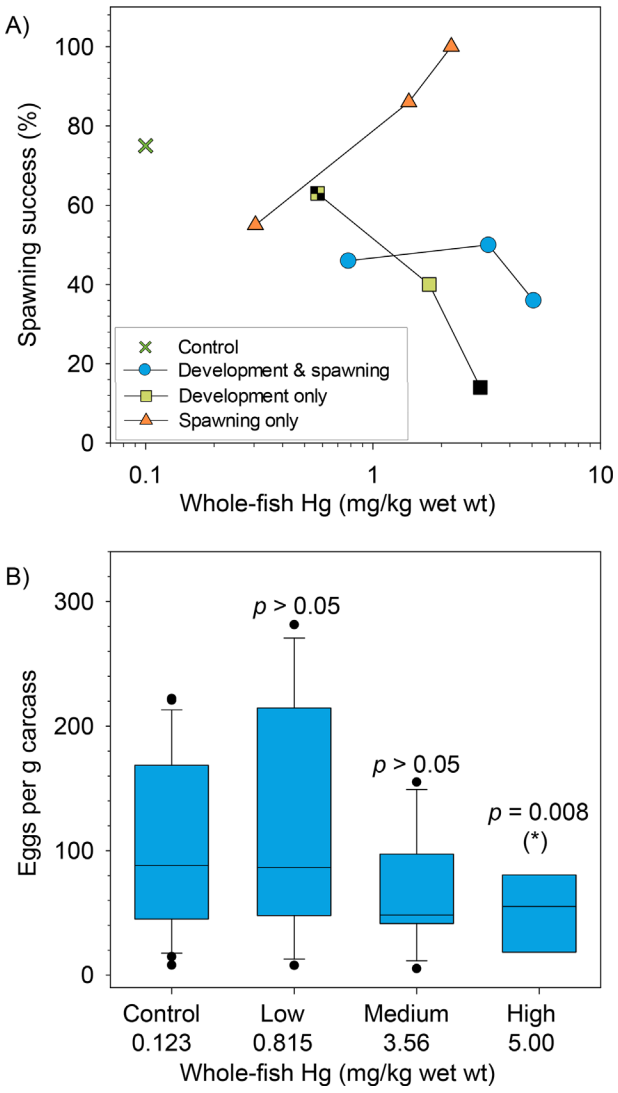

Figure 1. Statistical reanalysis of fathead minnow reproductive data from Hammerschmidt et al. [21]. (**A**) Effect of Hg on fathead minnow spawning. Black shading indicates a statistically significant difference from control. The result used as *toxic* for toxicity reference value (TRV) derivation is checkered. Symbols indicate the life stage during which fish received a mercury-spiked diet. (**B**) Effect of Hg on fathead minnow fecundity. Boxes, horizontal bars, error bars (whiskers), and points indicate interquartile ranges, medians, 10th and 90th percentiles, and extreme values, respectively. An asterisk (*) indicates statistically significant difference from the control.

Sandheinrich and Wiener [5] focused on the incidence of effects at fish tissue mercury concentrations exceeding the Beckvar et al. [8] TRV, including effects on biochemistry, cells, and tissues as well as reproductive and growth effects. Rather than applying a quantitative method to reduce the available data to a single TRV, Sandheinrich and Wiener [5] identified a concentration range (0.3–0.5 mg/kg in whole fish) associated with the onset of these effects in laboratory and field studies. The authors used these findings to justify application of the Beckvar et al. [8] TRV as a protective no-effect level in subsequent risk assessments [19,20].

Depew et al. [16] developed mercury TRVs for fish based on methylmercury concentrations in fish diet. This approach is consistent with evidence that dietary mercury intake during gonad development may be more closely linked than adult tissue mercury concentrations to reproductive effects [21,22]. The threshold concentrations proposed by Depew et al. [16] were based on 20 freshwater and marine/brackish studies presenting the results of laboratory experiments in which methylmercury was administered via diet, feeding strategy and experimental controls were deemed acceptable, and adult and/or juvenile toxicity endpoints were reported. Depew et al. [16] classified endpoints as severe (mortality), high (effects on growth and development or reproduction), or moderate (effects without defined ecological consequences). A NOAEL and/or a LOAEL were identified from each study for a given fish species and endpoint category, and species evaluated in multiple studies were represented by the geometric mean of results for each endpoint category. Depew et al. [16] calculated candidate threshold concentrations using 2 methods: first, as the highest NOAEL below the lowest LOAEL; and second, using the TEL approach, analogous to Beckvar et al. [8]. The TRV identified by Depew et al. [16] for reproductive effects is 0.04 mg/kg methylmercury in fish diet. Depew et al. [16] did not correlate the fish-diet TRV to whole-body mercury concentrations in potentially affected fish.

Review of fish tissue TRVs

Conceptually, the approach to TRV derivation used by Beckvar et al. [8], described in *Overview of TRVs*, is reasonable for development of screening-level TRVs; and, to be clear, Beckvar et al. [8] recommend using their resulting TRV solely for screening purposes. However, the implementation of this approach is limited by the availability of appropriate data. Sandheinrich and Wiener [5] incorporated additional data in their review by broadening the types of data they considered relevant to assessing adverse effects on fish to include suborganismal endpoints as well as field studies. Although this approach is more comprehensive, it increases uncertainty regarding linkages between the underlying data and the potential for effects on fish populations. Below, we discuss the merits and uncertainties of data underlying the Beckvar et al. [8] TRV, followed by a discussion of the conceptual approach employed by Sandheinrich and Wiener [5].

Beckvar et al. [8] included 8 studies in their TRV derivation for mercury in adult fish. The most sensitive studies tested mercury effects on walleye (*Sander vitreus*) [23], striped mullet (*Mugil cephalus*) [24], fathead minnow (*Pimephales promelas*) [21], and mummichog (*Fundulus heteroclitus*) [25]. Friedmann et al. [23] fed methylmercury-injected fish to juvenile walleye for 6 mo, after which low-dose walleye contained 0.25 mg/kg mercury and high-dose walleye contained 2.4 mg/kg mercury, on a whole-body wet-weight basis. Beckvar et al. [8] identified the lower exposure as a LOAEL for TRV derivation. However, gonadosomatic indices (i.e., gonad weight as a percentage of total body weight) did not differ from control results for either dose group, although the authors observed a significant difference when both dose groups were combined. Combining dose groups does not align with the assignment of treatment-specific NOAEL or LOAEL values for TRV derivation purposes. Testicular tissue showed significant cell atrophy in the high-dose group and "a lesser degree" of atrophy in the low-dose group. The significance of "a lesser degree" of testicular cell atrophy on reproductive function is unknown. In addition, walleye are difficult to maintain in captivity [23], and relatively high (28%) mortality in the control group suggests the possibility of interactions between captivity stress and contaminant stress in the test. By comparison, the same authors did not find significant relationships between gonadosomatic index and tissue mercury concentrations in field-collected northern pike or largemouth bass, despite concentrations similar

to and higher than those reported in the laboratory-exposed walleye [26,27]. In theory, this lack of agreement between field observations and laboratory predictions may reflect, at least in part, the ameliorating effects of selenium on mercury toxicity (see the *Discussion* section). However, neither study [26,27] analyzed field-collected fish tissue for selenium, and selenium concentrations in fish can be highly variable in the wild. Lastly, gonadosomatic index is not a direct measurement of reproductive success (i.e., organ weight is an indicator of only potential effects on offspring production). In light of the control mortality in the walleye study, the ambiguous statistical results, and the indirect relationship between the measured endpoints and reproductive success, the results of Friedmann et al. [23] are highly uncertain and provide a weak basis for TRV derivation.

Weis and Weis [24] tested the effect of aqueous methylmercury exposure on regrowth of amputated fins in striped mullet. After 13 d of regrowth, fin length was 10% lower than in the control group, a small but statistically significant difference. The corresponding tissue mercury concentration was 0.3 mg/kg, identified by Beckvar et al. [8] as a LOAEL. The relevance of fin regeneration rate to fish populations is uncertain.

Hammerschmidt et al. [21] studied the effects of dietary exposures of methylmercuric chloride on fathead minnow reproduction (Figure 1). Fish were exposed to methylmercuric chloride during sexual development, during spawning, or both. While no effects of methylmercury on hatching success or offspring survival were detected, spawning success was lower than in the control group for all groups exposed to mercury during sexual development. On this basis, Beckvar et al. [8] determined a LOAEL of 0.39 mg/kg wet weight (converted from a male tissue concentration of 1.97 mg/kg dry wt [21]). Although Hammerschmidt et al. [21] did report a significant reduction in reproductive potential with increasing exposure using the Cox regression model, they did not include an analysis of differences in spawning rates among the treatment groups, and therefore the analysis does not support development of a conventional NOAEL or LOAEL. When we evaluated all of the available spawning success data using a chi-squared test, only the treatment with the lowest spawning success (14%; tissue residue = 3.0 mg/kg, converted from dry wt; development-only exposure) yielded a statistically significant difference from the control ($p = 0.02$; Figure 1) due to low statistical power. In contrast to the development-only exposure groups, fish exposed only during spawning exhibited no dose-dependent change in spawning success, and Hammerschmidt et al. [21] considered them unaffected by mercury exposure. Spawning success in the spawning-only exposure groups ranged from 55% (lowest dose group) to 100% (highest dose group), indicating a high degree of variability in spawning success that runs counter to expectations if the observed variation had been the result of mercury exposure. Given the high variability, the sample sizes were not sufficient to support statistically robust determination of pairwise differences from control responses for spawning success. Interestingly, Beckvar et al. [8] gave a different interpretation to similar results for brook trout (*Salvelinus fontinalis*) [28], for which intermediate mercury exposures yielded substantial reductions in productivity that were not statistically significant. In that case, consistent with the researchers' [28] interpretation, Beckvar et al. [8] selected the statistically different treatment group as the basis for the brook trout LOAEL. The contrasting interpretation of these 2 studies by the researchers and subsequently by Beckvar et al. [8] illustrates the differences in interpretation that can arise for variable test endpoints such as fish reproduction when the statistical power of the toxicity tests does not meet the data quality needs of TRV developers.

Hammerschmidt et al. [21] also evaluated other reproductive endpoints, including male and female gonadosomatic indices, days to spawning, and daily fecundity (as eggs laid per gram carcass per day). Although most of these endpoints were significantly correlated to tissue mercury concentrations, Hammerschmidt et al. [21] did not perform statistical tests to discriminate which specific dose groups differed from controls. Using the underlying fecundity data (as eggs per gram carcass) for fish exposed during both development and spawning (C. Hammerschmidt, Wright State University, Dayton, OH, USA, personal communication), we conducted pairwise comparisons of each dose group with the control using *t* tests (Figure 1). Similar to spawning success, the difference in fecundity was significant only for the highest dose group ($p = 0.008$; whole-fish mercury = 5.0 mg/kg), although the data also suggest reduced fecundity in the middle dose group (whole-fish mercury = 3.5 mg/kg). The results of Hammerschmidt et al. [21] are important in identifying the possibility of effects on fish reproduction at environmentally relevant exposure levels, but variability in the underlying data leads to difficulties in identifying a specific LOAEL from the study.

Matta et al. [25] studied the effects of 4 concentrations of dietary methylmercuric chloride on 3 generations of mummichogs. Only adult F0 fish received the mercury-spiked diet, such that exposure to subsequent generations was limited to maternal transfer. None of the test organisms was dosed with methylmercury during gonad development. Based on the subsequent findings of Hammerschmidt et al. [21], no reproductive effects would be expected under such a dosing regime, and, indeed, no effects on mummichog reproductive success were observed over multiple generations. In the first generation, adult male mortality was elevated in all but the lowest dose group, although the magnitude of mortality did not show a concentration–response relationship. As noted by Depew et al. [16], the observed mortality may have been related to the increased aggressive behavior reported by Matta et al. [25] in first-generation adult males. Based on adult male mortality, Beckvar et al. [8] identified the NOAEL and LOAEL from Matta et al. [25] as 0.21 mg/kg and 0.44 mg/kg, respectively. However, Depew et al. [16] judged the LOAEL from Matta et al. [25] to be unsuitable as the basis for their mercury TRV for mortality effects, because the mercury exposure level was considerably lower than exposures associated with mortality or growth effects in several other fish species, and the observed mortality may have been behaviorally mediated rather than an expression of overt lethality. While the mortality was clearly an adverse effect on the affected individuals regardless of whether it was behaviorally mediated, there is greater uncertainty in extrapolating a behavioral effect from laboratory to field settings compared with overt lethality. To the extent that the male mummichog mortality results from Matta et al. [25] are used in ecological risk assessments or risk management decision-making, their interpretation should be qualified by the understanding that female survival was unaffected, and male abundance is less important to fish productivity than female abundance.

In summary, there is a high degree of uncertainty in all of the studies considered by Beckvar et al. [8] for evaluating effects of mercury in adult fish at whole-body concentrations between 0.2 mg/kg and 0.5 mg/kg. This concentration range is particularly relevant to environmental concentrations of mercury in larger fish within eastern North America [29]. The remaining

studies reviewed by Beckvar et al. [8] also are not without uncertainty, but we do not present a detailed review here because the LOAELs are all higher (0.52–5 mg/kg) and have less impact on the final TRV. However, these studies are incorporated as appropriate in the dose–response analyses discussed in the *Fish tissue dose–response analysis* section.

Sandheinrich and Wiener [5] made a case for adverse effects of mercury on fish at whole-body concentrations in the range of 0.3 mg/kg to 0.5 mg/kg. Aside from the studies reviewed in the present study, their evaluation primarily included studies of biochemical and physiological endpoints, as well as certain field studies. Biochemical and physiological endpoints are not necessarily directly linked to effects on fish populations, and the magnitude of response that would correspond to an ecologically relevant effect is generally unknown. For this reason, such endpoints often are excluded from TRV derivation [18]. As an example, Sandheinrich and Wiener [5] identified increased prevalence of macrophage aggregates in fish organs as an adverse effect, because macrophage aggregates collect components of cells damaged by oxidative stress. In contrast, Soulen et al. [30] recently identified macrophage aggregates as the site of mercury demethylation in fish, and Barst et al. [31] identified preferential accumulation of both mercury and selenium in fish macrophage aggregates, possibly indicating sequestration of mercury as an inert HgSe compound. Whether macrophage aggregates are indicators of cell damage, mercury detoxification, or both, none of these hypotheses sheds light on the magnitude of change in macrophage aggregate prevalence that would be associated with adverse effects at the organismal or population levels. As this example illustrates, inclusion of suborganismal endpoints does not provide clarity at the level of biological organization that is the focus of most environmental cleanup decisions.

Sandheinrich and Wiener [5] also evaluated field studies of fish condition (i.e., weight relative to length) at sites remote from local mercury point sources. Effects of mercury on fish condition are difficult to discern from such studies, because differences in fish mercury concentrations among water bodies are caused by factors that are also likely to affect fish condition, as well as fish populations and communities. These factors include watershed forest cover and extent of wetlands, sulfate and pH levels, and biological productivity [3,32,33]. In particular, higher primary productivity tends to reduce mercury concentrations in the food web because the bioavailable mercury mass is diluted by increased algal mass [3,34,35]. Similarly, fish growth efficiency also inversely affects mercury bioaccumulation through biodilution [3,36–38]. Therefore, lower fish condition could potentially be a cause—rather than an effect—of higher mercury concentrations in individual fish, particularly in the absence of elevated local mercury inputs. Consistent with this interpretation, fish growth in controlled experiments shows only limited sensitivity to mercury exposure, as reviewed by Depew et al. [16] and Wiener and Spry [4]. Based on these concerns, we excluded field studies focusing on fish condition from our review of field case studies. In summary, although it is more comprehensive, Sandheinrich and Wiener's [5] review does not resolve the data limitations and associated uncertainties that affect the Beckvar et al. [8] TRV, at least from the perspective of environmental management decision-making.

Fish tissue dose–response analysis

Dillon et al. [9] built on the screening-level TRV derivation of Beckvar et al. [8] to develop a dose–response relationship for mercury effects on fish. Conceptually, the dose–response analysis of Dillon et al. [9] should benefit environmental assessors and managers, in that it allows for consideration of severity of effect, proportion of population affected, and degree of protection sought through risk management decisions. Dillon et al. [9] focused on the most population-relevant toxicity endpoints (reproduction and survival, including early life stage survival), thus taking a less precautionary approach to uncertainties related to endpoints such as gonadosomatic indices and fin regeneration. The dose–response approach also eliminates hypothesis testing, although low test replication for reproductive endpoints remains a source of variability and uncertainty in the dataset.

Although the conceptual approach of Dillon et al. [9] has the potential to generate results that are reasonably well aligned with real-world effects on fish populations, we identified several specific decisions in the authors' implementation of this approach where alternative judgments reasonably could be supported. To evaluate whether these judgments, described below, affect the outcome of the dose–response analysis, we conducted a sensitivity analysis. We varied assumptions that we believe are open to reasonable scientific interpretation or debate, and we incorporated data from additional relevant studies. The dataset used in our sensitivity analysis is presented as Supplemental Data.

Modifications of Dillon et al. [9] dataset. First, we integrated the results for multiple endpoints by multiplication, rather than the additive approach of Dillon et al. [9]. The integration of endpoints by addition can produce effects that exceed 100%. Consider a hypothetical exposure in which one-half of F0 fish survive, one-half of the surviving fish spawn, and one-half of the spawned eggs hatch (all effects normalized to control). Adding the results of these endpoints would indicate 150% effect, whereas one can deduce intuitively that the number of hatched fish will actually be one-eighth of the control (i.e., an 87.5% reduction in number of offspring); that is, the endpoints are multiplicative rather than additive

$$\text{Net effect} = 100\% - \Pi(100\% - \text{endpoint}\,\%\,\text{effect}) \qquad (2)$$

Making this correction allows a larger number of endpoints to be integrated, as well as calculation of the overall effect of exposure on offspring production. We applied the multiplicative integration of endpoints without regard to whether control or mercury-exposed fish performed better for any given endpoint. This approach allowed random variations to cancel each other and also allowed for hormetic effects (if any). The approach can result in $<0\%$ effect ($>100\%$ performance), which could be illogical if applied outside the context of a comparison with controls; however, the alternative (excluding endpoints with performance better than control) would inherently result in overestimation of effects because of biased treatment of potentially random variation. Consistent with the application of Dillon et al. [9], aggregation of endpoints by multiplication should only be applied to endpoints that contribute directly to offspring production. For instance, in the hypothetical example above, growth data would not be incorporated. The outcome of this calculation is thus an estimate of the net effect of mercury exposure on reproduction (e.g., net production of viable offspring, if all relevant endpoints are reported) relative to control performance in each laboratory test.

Second, we expanded the number of endpoints integrated for each study, such that the resulting percent effect represented the net effect on production and survival of offspring. Dillon

et al. [9] did not evaluate all relevant endpoints for each study, likely because of the additivity issue noted above. For example, in evaluating Hammerschmidt et al.'s [21] fathead minnow study, Dillon et al. [9] considered only spawning success. However, Hammerschmidt et al. [21] also reported fecundity, development success, hatching success, and larval survival. We included all of these endpoints in our analysis.

Third, we narrowed the scope of the dose–response analysis to focus on reproduction, eliminating studies that only provided adult mortality data. However, we did incorporate parental and offspring mortality results in the calculation of net effect on production of viable offspring. The literature review of Dillon et al. [9] for the survival endpoint omitted several studies reporting low mortality associated with high mercury tissue residues. Among studies not included by Dillon et al. [9], Olson et al. [39] observed no mortality in fathead minnows at whole-body tissue mercury concentrations of 10.9 mg/kg during 48 wk of aqueous exposure. Similarly, mortality was not observed in rainbow trout fingerlings containing up to 30 mg/kg during 84 d of dietary exposure [40] or 12 mg/kg in a separate 15-wk dietary exposure [41] (converted from muscle concentration per Equation 1). In a 70-d experiment with sheepshead minnow (*Cyprinodon variegatus*) and inland silverside (*Menidia beryllina*), increased mortality occurred at whole-fish mercury concentrations exceeding 10 mg/kg (converted from dry weight) [42]. Although some of these studies predate current analytical and toxicity testing methods, they are contemporaneous with other studies included in Dillon et al.'s analysis [9], such that any analytical uncertainties are equally applicable to studies included and excluded by Dillon et al. [9]. These studies suggest that a dose–response analysis based on adult fish survival might not be protective of fish reproduction and early life stage survival.

Fourth, we omitted fathead minnow reproductive studies by Drevnick and Sandheinrich [43] and Sandheinrich and Miller [44], because control spawning rates in these studies (32–40%) were much lower than those achieved in other studies on fathead minnows (75–100% [21,45]). It is unclear why the control spawning rates were so low, and they raise the possibility of uncontrolled laboratory artifacts, specimen handling and stress, and/or study design flaws. In any case, the results reported by Drevnick and Sandheinrich [43] and Sandheinrich and Miller [44] were similar to those reported by Hammerschmidt et al. [21] except that the tissue mercury concentrations were higher, such that removing Drevnick and Sandheinrich [43] and Sandheinrich and Miller [44] from the dataset actually yields a more protective outcome than would otherwise result.

Fifth, for comparability with other studies, we included results from Hammerschmidt et al. [21] only for fathead minnows exposed to mercury during both development and spawning. Fish that were exposed only during development had depurated part of their tissue burden before being tested for toxicity. Conversely, fish that were exposed only during spawning were insensitive to reproductive effects despite substantial whole-body mercury concentrations. For the same reason, we excluded the mummichog data from Matta et al. [25], because only the F0 adults were dosed with mercury, which may have caused or contributed to the lack of reproductive effects despite the high tissue concentrations found in that study. We recognize that in the field, some fish are exposed to mercury during only part of their life cycle, and fish tissue-based dose–response data for continuously exposed fish may be either over- or underprotective in such cases, depending on which part of the life cycle experienced the mercury exposure. Nevertheless, if one is to pursue fish tissue-based TRVs for protection of fish at all, then consistency in the underlying dataset is needed to provide interpretable results.

Sixth, we omitted certain treatment groups from Snarski and Olson's [45] fathead minnow study in which the fish received a suboptimal diet. Snarski and Olson [45] evaluated survival and development of juvenile fathead minnows exposed to aqueous inorganic mercury. Two types of food were evaluated: dry trout starter and live brine shrimp. The control fish fed brine shrimp exhibited better and more uniform growth, and this diet was used exclusively in subsequent reproductive tests. These results suggest that the data for brine shrimp-fed fish should be preferred and, indeed, Beckvar et al. [8] did not consider results from the dry trout starter-fed treatment groups. Snarski and Olson [45] reported spinal development impairment only for fish fed dry trout starter; these results were considered by Dillon et al. [9] but eliminated from consideration for our sensitivity analysis.

Finally, 2 inaccuracies from the dataset of Dillon et al. [9] were corrected. For the brook trout study of McKim et al. [28], Dillon et al. [9] list as tissue concentrations for the F1 generation data that actually are for depurated F0 fish (and therefore are not applicable); we eliminated these data. Also, we could not reproduce the average wet weight tissue concentrations estimated by Dillon et al. [9] from dry weight male and female concentrations reported in Hammerschmidt et al. [21]. We recalculated the respective wet weight concentrations assuming the fish contained 75% moisture.

Additional toxicity studies. We identified 3 additional studies investigating effects of mercury exposure on fish reproductive parameters, which were not available to or considered by Dillon et al. [9]. Tatara et al. [46] reported results of a 4-yr, multigenerational mesocosm experiment studying effects of mercury-contaminated sediments on mosquitofish (*Gambusia holbrooki*). A limitation of the study conducted by Tatara et al. [46] (similar to other studies included in the dose–response dataset) is that none of the mercury treatment levels was low enough to be without adverse effects. Penglase et al. [47] evaluated the effects of dietary methylmercury and selenium exposure on female growth, survival, and behavior, as well as reproductive parameters in zebrafish (*Danio rerio*). For purposes of this sensitivity analysis, we only considered dose groups with low selenium, sufficient to meet selenium nutritional requirements. A limitation of the Penglase et al. [47] study is that the dose groups included only the control and 1 high-dose group. Stefansson et al. [48] evaluated effects of adult dietary methylmercury exposure on egg production in sheepshead minnow (*C. variegatus*). Their study was designed to evaluate maternal transfer exposure sources and not to derive TRVs; thus, there are limitations to its use in TRV development that relate to its consideration for a purpose other than was originally intended. For example, the sample size in the high-dose group was too small to test for statistical significance. Also, consistent with the study's intended purpose, Stefansson et al. [48] evaluated egg production and not spawning, hatching, or offspring viability. We included these additional studies in our analysis because they provide information comparable to the studies analyzed by Dillon et al. [9]. However, each of the additional studies has limitations for purposes of TRV development, so their inclusion does not fundamentally address the need for additional investigation of mercury effects on fish reproduction.

Statistical analysis of dose–response model fit. To evaluate the uncertainty associated with a multispecies dose–response relationship, statistical model fit was evaluated based on the approximate r^2, which is the proportion of variance explained by the model. A nonlinear regression was fit according to the same equation used by Dillon et al. [9]

$$Y = \frac{100}{1 + 10^{(log\ \mathrm{EC50} - log\ X)(Hill\ Slope)}} \quad (3)$$

where Y is the percent injury, X is the tissue residue in mg/kg wet weight, and EC50 is the effective concentration halfway between 0% and 100% injury. The results yield an approximate r^2 of 0.343. This low r^2 shows that the variability in response among species and across studies is too high to allow a reliable estimate of broadly applicable (i.e., multispecies) effect concentrations using this approach.

Sensitivity analysis conclusions. Figure 2 compares the modified dataset with the dataset developed by Dillon et al. [9]. The data for fathead minnow and brook trout suggest possible effects at mercury residues similar to the 0.77 mg/kg EC20 derived from the original dose–response analysis [9], although, as discussed, none of the effects at these lower tissue residues was statistically significant (see *Review of fish tissue TRVs*). Tests with other species were much less sensitive with respect to net production of offspring. Compared with the findings of Dillon et al. [9], the modified dataset still shows that the frequency of effects increases at tissue concentrations above the 0.77 mg/kg EC20. Because of the variability across studies, which may reflect differences among species as well as different study designs and test conditions, the combination of multiple species in the residue-effect curve is inherently problematic. In the modified dataset, it is possible to discern which species and which experiments contributed to those effects; in the Dillon et al. study [9], however, all data are plotted alike. The additional studies included in the modified dataset accentuate the observed variability, where essentially any outcome is possible at higher exposures. This result is consistent with confounding by unmeasured mercury–selenium interactions (see the *Discussion* section).

In summary, our sensitivity analysis indicates that the Dillon et al. [9] EC20 of 0.77 mg/kg is closer to a threshold for reproductive effects than is the Beckvar et al. [8] TRV, based on currently available laboratory toxicity data. Our analysis does not support 0.77 mg/kg as a true EC20 that is broadly applicable across a variety of fish populations and communities. However, this finding does not negate the benefits of using a dose–response approach to characterize mercury effects on fish. Instead, it underscores the need for high-quality investigations of mercury dose–response relationships for reproductive endpoints in multiple representative fish species.

Review of fish prey TRVs

Depew et al. [16] developed separate TRVs for different types of effects, including effects on survival, growth, and reproduction, as well as effects with unknown or poorly characterized ecological consequences (i.e., suborganismal and behavioral effects). Conceptually, this approach is useful in discriminating the nature of effects potentially associated with fish prey mercury concentrations in excess of each TRV. In their development of TRVs for reproductive effects of methylmercury in fish diet, Depew et al. [16] reviewed many of the same studies discussed above [21,23,25], and the same uncertainties that affected the use of the study results by Beckvar et al. [8] also affect the Depew et al. [16] evaluation. Appropriately, Depew et al. [16] state that their TRVs should be considered preliminary because of data limitations.

In addition to the previously discussed studies, the review by Depew et al. [16] of mercury effects on fish reproduction included a dietary LOAEL of 0.05 mg/kg based on Atlantic croaker (*Micropogonias undulatus*) larval behavior following parental dietary exposure to mercury and maternal transfer to offspring [49]. Diets in the latter study consisted of shrimp (control), blue marlin tissue (low-mercury group), and blue marlin supplemented with contaminated shrimp (high-mercury group). Differences in the compositions of diets for the different dose groups introduce uncertainty to the assessment, because in addition to varying methylmercury exposures, the control and treatment groups may have received different nutrition and selenium exposures, and they likely experienced different exposure to unmeasured co-contaminants. No significant differences among groups were observed for larval growth or responses to visual startle stimulus. Significant regressions were reported between egg mercury concentrations and certain behavioral variables (i.e., percentage of time active during routine behavior and duration and speed of response to vibratory startle stimulus); however, there was considerable overlap among individual responses in the 3 exposure groups. In addition, it is uncertain whether the observed behavioral trends would affect predator avoidance and larval survival. Although

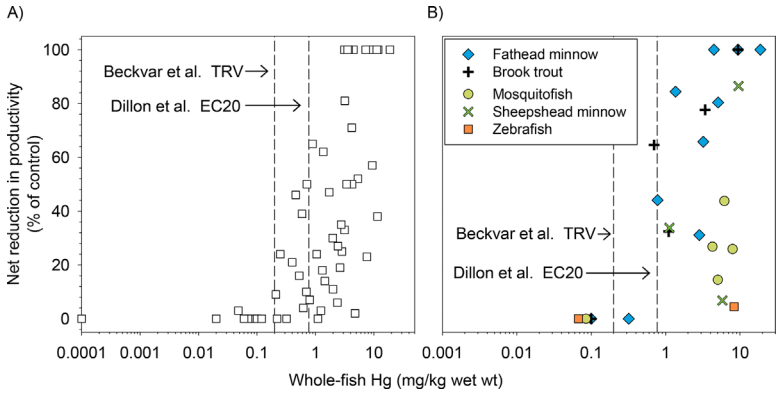

Figure 2. Comparison of (**A**) Dillon et al. [9] dose–response data set and (**B**) modified dose–response dataset. The modified dataset provides a sensitivity analysis of the impact of specific judgments incorporated in the dose–response analysis as well as the addition of new data. Dashed lines represent Beckvar et al. [8] toxicity reference value (TRV) and Dillon et al. [9] 20% effect concentration (EC20).

Murphy et al. [50] conducted a population modeling exploration using the Alvarez et al. [49] study results, Murphy et al. [50] did not suggest that their model accurately represented field conditions. The Alvarez et al. [49] study is of interest to generate further hypotheses about mercury effects on fish behavior, but it is not an appropriate basis for TRV development, because of its uncontrolled study design and the uncertain and indirect ecological consequences of the endpoints measured.

Furthermore, Depew et al. [16] identified the TRV for mercury effects on fish reproduction based on the highest NOAEL below the lowest LOAEL for reproduction. The only so-called NOAELs lower than the Alvarez et al. [49] LOAEL were actually control treatments from other studies. As a result, the reproductive TRV is equal to the mercury content of the control diet in the Friedmann et al. [23] walleye study. The same outcome would have resulted even if the Alvarez et al. [49] study had been excluded, because nearly all of the so-called NOAELs identified by Depew et al. [16] for reproductive endpoints were control treatments. Laboratory controls are nontoxic by definition. If a TRV derivation method produces a result within the range of control tissue concentrations, it probably does not indicate that control conditions are toxic, but rather that the derivation method or underlying data are at fault. The data available to develop a dietary TRV for mercury effects on fish reproduction are limited and highly uncertain. Because the resulting TRV is based on a control concentration, it is not an effect threshold and should not be used as such.

CASE STUDY REVIEW

Our review of mercury effects on fish populations and communities considered case studies at mercury-contaminated sites. The objective of this evaluation was to determine whether adverse effects were observed at fish or prey tissue concentrations consistent with the published TRVs discussed above. Using Google Scholar and other online searches, reference lists of pertinent papers, and direct inquiry to researchers, we searched broadly in the peer-reviewed and gray literature for studies targeting measures of fish reproductive success and recruitment, population age or size structure, population abundance, or fish community characteristics paired with mercury concentrations in fish tissue or fish diet. We focused on these effect endpoints because many, although not all, environmental management decisions are intended to protect environmental resources at the population or community level [7,51,52]. In other words, fish population attributes such as abundance, age composition, population growth, and population viability are typically considered more relevant from a management perspective than the health or persistence of individual organisms. Because the fish evaluated in these case studies are wild and living in their native habitats, their exposure to mercury is primarily via diet (for adults) and maternal transfer (for offspring).

Initially, we also considered inclusion of fish community monitoring studies conducted on a regional or national basis, as well as field studies evaluating fish growth or condition (weight relative to length) at sites remote from local mercury sources. However, we were able to obtain regional datasets of paired fish community and fish tissue mercury data only for regions where few fish contained mercury in excess of TRV concentrations. More importantly, interpretation of such studies is likely to be affected by confounding factors such as biodilution, as described previously (see section *Review of fish tissue TRVs*). We also did not include studies that evaluated relationships between mercury concentrations in field-collected fish and various effects on biochemistry, cells, and tissues. In the absence of quantitative linkages to relate the magnitude of biomarker or histopathological responses to effects on reproductive success or survival, the significance to fish populations of such suborganismal effects is difficult to interpret. However, if observed population effects associated with mercury were explained by effects on biochemistry, cells, and tissues, those relationships are noted.

We retained case studies that did not report statistical power, because omitting them would have eliminated the case study review. Few field studies conducted on fish or wildlife address statistical power, despite its importance in understanding the degree to which study design can detect significant differences between populations, if such differences in fact exist. Thus, where we report that no effects were observed in a field study, it is because no effects were detected but not necessarily because a lack of effects was statistically demonstrated.

Eight sites were identified where the requisite biological and mercury data were colocated spatially and temporally, as follows: South River, Virginia, USA; North Fork Holston River, Virginia, USA; Onondaga Lake, New York, USA; La Grande Hydroelectric Complex reservoirs, Quebec, Canada; Savannah River and associated streams, South Carolina, USA; Clear Lake, California, USA; East Fork Poplar Creek, Tennessee, USA; and the Hudson–Raritan Estuary, New Jersey, USA. These were the only sites identified that met the criteria for inclusion defined a priori and listed above (i.e., mercury-contaminated sites with tissue data and relevant reproductive, population, or community effects assessed). Most of the case studies address sites where mercury is the sole or primary contaminant. However, we also present information for 2 sites characterized by complex contaminant mixtures (East Fork Poplar Creek and the Hudson–Raritan Estuary). These sites are included because some have viewed them as mercury sites, although site investigators acknowledged the role of chemical mixtures, and because they provide useful examples of investigation tools that may be applicable at other sites. Results of the case study review are summarized in Table 3.

Normalization of mercury concentrations to a standard fish length is commonly performed for purposes of clarifying spatial and temporal trends in mercury monitoring programs [19,53,54]. Length normalization is performed because fish tissue mercury concentrations typically increase with increasing fish size, and variability in the size of sampled fish can thus add variability to such trend analyses. For purposes of relating tissue concentrations to potential effects, length normalization is not necessarily applicable, because toxic effects are presumably related to the concentration in each organism regardless of length. In contrast, length normalization is useful in cases where mercury exposure and effects are not measured in the same individuals (e.g., for population or community parameters) and the relationship between spatial trends in mercury exposure and effects is of interest. Regardless, length-normalized concentrations were available or calculable for only a minority of the case studies (i.e., South River, North Fork Holston River, La Grande Hydroelectric Complex). Each of the case studies is described below.

South River

Because of historical industrial operations in Waynesboro, Virginia (USA), mercury concentrations in fish tissue are elevated in much of the South River and downstream in the

Table 3. Summary of case studies evaluating effects on fish at mercury-contaminated sites

Site	Exposure (whole-body mercury; mg/kg wet wt)[a]	Effect	Ref.
South River, VA, USA	Smallmouth bass, sample location means: 0.48–1.36 Prey fish, sample location means: 0.10–1.29	No effect on population density or biomass, growth, condition, predation efficiency (based on stomach contents), community richness, or community structure (based on feeding guilds)	[55,56,64]
Onondaga Lake, NY, USA	Largemouth bass, mean: 0.81	No effect on population density, reproduction, or recruitment	[68,71; Tyszko, 2010[b]]
North Fork Holston River, VA, USA	Smallmouth bass, mean (range): 0.60 (0.27–1.13)	Above-average catch rates, high adult survival, high relative stock density	[60,72,74]
La Grande Reservoirs, QC, Canada	70-cm northern pike: 1.1–1.6; 40-cm walleye: 1.0; 60-cm lake trout: 1.0	No effect on population abundance, growth, or condition	[76]
Savannah River, SC, USA	Redbreast sunfish and 8 other species, sample location means: 0.08–0.47	Good fish community quality (based on Index of Biotic Integrity), no effect on fish condition or pathology	[77]
Clear Lake, CA, USA	Largemouth bass, mean (range): 0.18 (0.02–0.97)	Inconclusive (see text)	[83]
East Fork Poplar Creek, TN, USA	Redbreast sunfish: multiple chemicals	Decreased fecundity, altered population size structure, decreased biomass of sensitive species	[84,87,89]
Hudson-Raritan Estuary, NJ, USA	Mummichog, bluefish: multiple chemicals	Mummichog: decreased abundance mediated by effects on predation efficiency and predator avoidance Bluefish: reduced predation efficiency and growth	[65,96,97]

[a]Whole-body mercury concentrations measured for Savannah River and estimated from muscle concentrations per Peterson et al. [14] for remaining sites.
[b]S.M. Tyszko, 2010, Master's thesis, State University of New York, Syracuse, NY, USA.

South Fork Shenandoah River, compared with reference locations upstream and in the North River. Several aspects of fish population and community status have been evaluated in relation to mercury exposures in this system. As a top predator with high site fidelity, smallmouth bass (*Micropterus dolomieu*) contain relatively high mercury concentrations [55]. Average whole-body concentrations in smallmouth bass from South River sample locations downstream from mercury source areas ranged from 0.48 mg/kg to 1.36 mg/kg, as estimated from fillet data [56]. Mercury concentrations in South Fork Shenandoah River smallmouth bass showed much less spatial variation and averaged 0.61 mg/kg on a whole-body basis [56]. Mercury concentrations in whole smallmouth bass from reference locations in the North River and upstream South River are approximately 0.1 mg/kg [56]. Concentrations in prey fish were also measured at smallmouth bass population survey locations, with average length-normalized concentrations ranging from 0.11 mg/kg to 0.90 mg/kg in common shiner (*Luxilus cornutus*) and from 0.10 mg/kg to 1.29 mg/kg in longnose dace (*Rhinichthys cataractae*) [55]. Fish tissue mercury concentrations measured in conjunction with smallmouth bass population survey locations are given only on a length-normalized basis [55]; the specific length selected for standardization purposes is not stated.

Despite elevated mercury concentrations in smallmouth bass and their prey, population density and biomass of smallmouth bass downstream of Waynesboro are comparable to reference conditions and show no relationship to length-normalized mercury tissue concentrations [55] (Figure 3). Smallmouth bass growth (length vs age) and condition (weight relative to length) also show no differences from reference conditions [57]. Smallmouth bass recruitment has been evaluated in the South Fork Shenandoah River only. Recruitment is strongly influenced by flow conditions [58] and is qualitatively similar between the South Fork Shenandoah River and other nearby rivers [58–61]. Smallmouth bass in the South Fork Shenandoah River and several other rivers in the region (not including the South River) have suffered from mortality events apparently related to 1 or more pathogens [61,62]. The cause of these

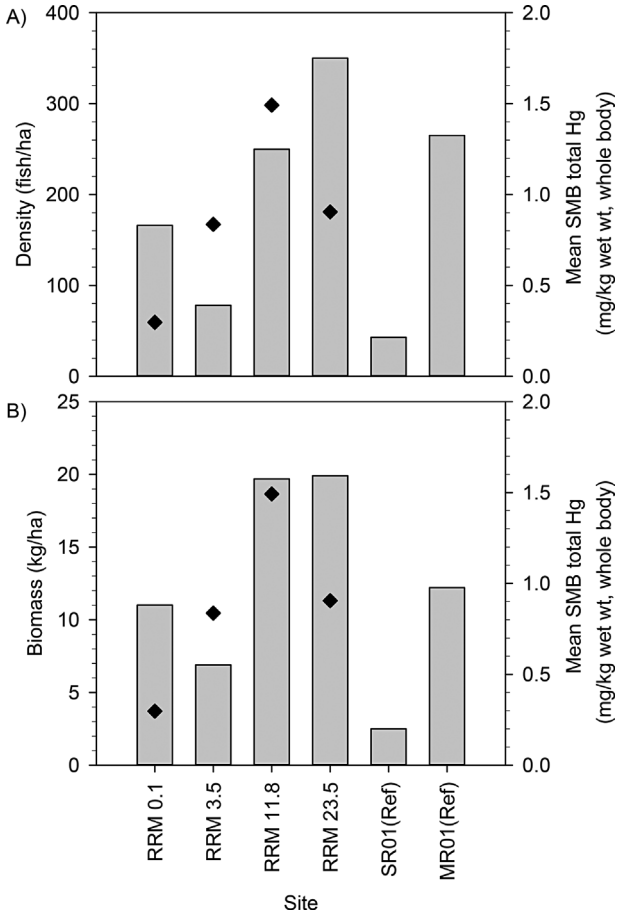

Figure 3. Comparison of smallmouth bass (SMB) (**A**) density and (**B**) biomass (bars) with whole-body mercury concentrations (diamonds) at South River stations (relative river miles [RRM] shown) and reference locations (upstream South River [SR] and Middle River [MR]) [55]. Paired smallmouth bass mercury concentrations were not analyzed from the reference stations, but other data [56] indicate whole-body mercury concentrations of approximately 0.1 mg/kg in smallmouth bass from uncontaminated reference locations in the vicinity.

outbreaks is not fully understood, but mercury has been evaluated and is not considered an important contributing factor given the geographic distribution of the outbreaks [62], whereas agricultural inputs such as arsenic and herbicides are suspected contributors to immunosuppression in the affected fish [63]. These mortality events have resulted in a lower proportion of older, larger smallmouth bass in the South Fork Shenandoah River population [59,60]. In addition to the population attributes described above, an investigation of fish diet provides an opportunity to examine predation efficiency in South River and South Fork Shenandoah River smallmouth bass. Specifically, an analysis of stomach contents found very similar diet composition and incidences of empty stomachs in fish from the 2 mercury-affected rivers compared with a North River reference area [64]. This result contrasts with findings in areas of the Hudson–Raritan Estuary, where dietary shifts and a high incidence of empty stomachs were observed in concert with impaired prey capture behavior in fish exposed to mixtures of contaminants [65] (see *Hudson-Raritan estuary*). Thus, multiple lines of evidence from the South River and South Fork Shenandoah River show no evidence of mercury-related impairment of smallmouth bass populations despite elevated mercury exposures.

Fish community data for the South River also indicate general similarity across mercury gradients and in comparison with reference conditions (Figure 4). Taxa richness at South River stations was equal to or higher than at reference stations, and the relative abundance of various feeding guilds was similar across stations [55]. Lower taxa richness and increased relative abundance of omnivorous fish have sometimes been considered indicators of anthropogenic impacts in rivers [66]; no such effects were observed in the South River. The only notable change in trophic composition is an increase in piscivore prevalence from upstream to downstream within the South River (Figure 4), which is consistent with increasing drainage area and river size. The absence of detectable adverse effects on the South River fish community is consistent with a study of physiological effects in rock bass (*Ambloplites rupestris*) collected from the South River upstream and downstream of Waynesboro, which found only limited physiological differences and concluded that "mercury is not having a significant impact on the rock bass" [67]. In summary, multiple measures of fish population and community condition have been evaluated in the South River and the South Fork Shenandoah River, and adverse effects as a result of mercury are not detectable despite fish mercury concentrations exceeding most of the TRVs shown in Table 1.

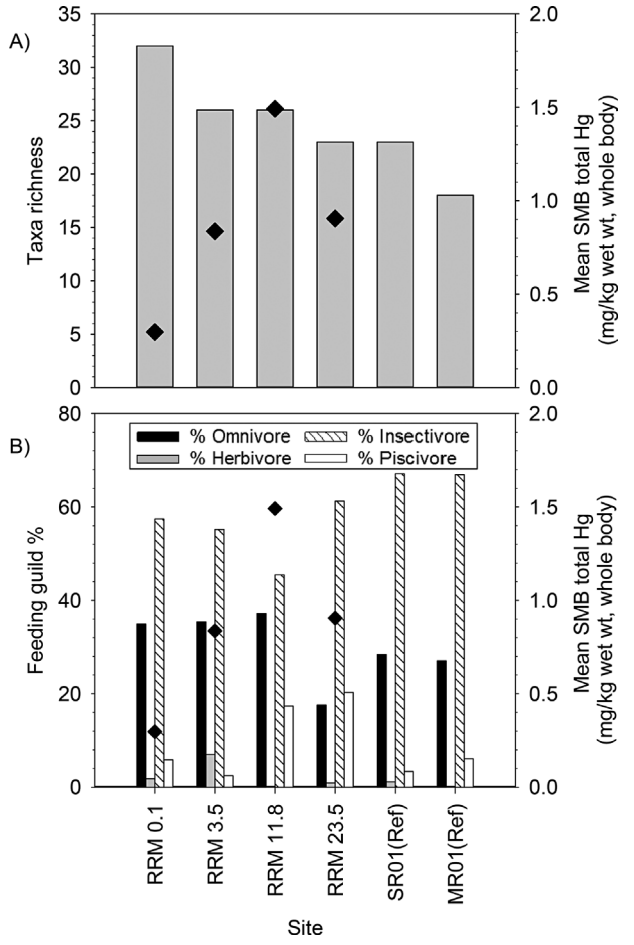

Figure 4. Comparison of fish (**A**) taxa richness and (**B**) feeding guild composition of fish community (bars) with whole-body mercury concentrations in smallmouth bass (SMB) (diamonds) at South River stations (relative river miles [RRM] shown) and reference locations (upstream South River [SR] and Middle River [MR]) [55]. Paired smallmouth bass mercury concentrations were not analyzed from the reference stations, but other data [56] indicate whole-body mercury concentrations of approximately 0.1 mg/kg in smallmouth bass from uncontaminated reference locations in the vicinity.

Onondaga Lake

Onondaga Lake, New York, is recovering from more than 125 yr of historical municipal and industrial discharges, including inputs of mercury. Dredging and capping of Onondaga Lake sediments began in summer 2012, and dredging was completed in 2014 to address historically impacted sediments. Major reductions in ammonia and phosphorous input into the lake have been achieved with the use of improved wastewater technology in 2004 to 2005 and more recent efforts to reduce combined sewer overflows into the lake [68].

Mercury concentrations in whole sport fish for all samples collected in 2009 to 2010 ranged from 0.0085 mg/kg to 2.2 mg/kg (estimated from fillet) [69,70]. The average mercury concentration in largemouth bass collected in 2008 was 0.81 mg/kg (estimated from fillet) [71]. A baseline assessment of largemouth bass in the littoral zone conducted in 2008 and 2009 showed that largemouth bass density and size structure was better than the New York State average for lakes (S.M. Tyszko, 2010, Master's thesis, State University of New York, Syracuse, NY, USA). Conversely, studies indicate a below-average smallmouth bass population [68]; however, this has been attributed to an increase in the macrophyte coverage that is preferred by largemouth bass [68]. Successful reproduction and recruitment of largemouth bass within the lake has been confirmed through surveys of fish nests and young-of-year fish [68]. Also, largemouth bass growth rates, condition, and survival rates are similar to statewide averages [68]. These findings demonstrate an apparent lack of reproductive or population-level effects on largemouth bass despite tissue mercury levels that exceed most of the TRVs shown in Table 1.

North Fork Holston River

Mactec Engineering and Consulting [72] assessed the North Fork Holston River system to evaluate historical mercury releases from the Saltville Waste Disposal Ponds Site. In 2005, mercury was analyzed in smallmouth bass, rock bass, hog suckers (*Hypentelium nigricans*), and sunfish (*Lepomis* spp.) sampled over a 70-mile area. Mean (range)

whole-body mercury concentrations were estimated from fillet analyses as 0.60 mg/kg (0.27–1.13 mg/kg), 0.51 mg/kg (0.31–0.72 mg/kg), 0.47 mg/kg (0.25–0.68 mg/kg), and 0.42 mg/kg (0.22–0.68 mg/kg), respectively. Thus, 100% of the samples contained mercury concentrations exceeding the Beckvar et al. [8] TRV of 0.2 mg/kg, and concentrations exceeding the Dillon et al. [9] EC20 of 0.77 mg/kg were observed in some smallmouth bass. Although mercury was not measured in fish from an upstream reference area, for comparison, the mean whole-body mercury concentration (estimated from fillet) for smallmouth bass collected across southwestern Virginia in 2004 to 2006, excluding North Fork Holston River, was 0.14 mg/kg ($n = 52$) [73].

The Virginia Department of Game and Inland Fisheries monitors smallmouth bass populations in 16 rivers statewide, including the North Fork Holston River [60]. Relative to other Virginia rivers, smallmouth bass in the North Fork Holston River have above-average catch rates (number of fish per hour), moderate growth rates, the highest adult survival rate (79% annually), and the highest relative stock density of "quality" fish (i.e., among smallmouth bass of catchable size, 57% are >28 cm) [60,74]. Although bass mortality in the North Fork Holston River may be somewhat decreased relative to other rivers because of a fish consumption advisory, Virginia Department of Game and Inland Fisheries [60] considers angling to be a minor contributor to bass mortality compared with other causes. Thus, the smallmouth bass population in the North Fork Holston River does not appear to be adversely affected despite tissue mercury concentrations consistently in excess of the Beckvar et al. [8] TRV.

La Grande Hydroelectric Complex

Increases in mercury bioaccumulation are characteristic of newly flooded reservoirs, as a result of conditions that favor mercury methylation [75]. A study of boreal reservoirs at the La Grande Hydroelectric Complex (Quebec, Canada) showed no adverse effects on fish despite 3- to 6-fold increases in fish mercury concentrations [76]. The researchers conducted the study from 1978 to 2003 at 16 stations in 3 reservoirs created from natural rivers and 3 natural reference lakes. Before flooding, mercury concentrations in whole piscivorous fish averaged 0.3 mg/kg to 0.4 mg/kg (estimated from muscle concentrations), based on 70-cm northern pike (*Esox lucius*), 40-cm walleye (*Stizostedion vitreum*), and 60-cm lake trout (*Salvelinus namaycush*). Although these mercury concentrations exceed the Beckvar et al. [8] TRV, they represent present-day background concentrations in the project area, where factors such as forested land cover may promote mercury bioaccumulation (see *Background Concentrations* section). Following reservoir creation, mercury bioaccumulation in these piscivorous fish species peaked approximately 10 yr after flooding, with average whole-body concentrations of 1.0 mg/kg to 1.6 mg/kg.

Schetagne and Therrien [76] measured fish population abundance in the La Grande reservoirs using a catch per unit effort approach, estimated as number of fish per net per day, and averaged by month and year. They evaluated fish health using a condition factor based on weight and length of fish. Fish growth was evaluated based on the relationship between age and length. Statistical and graphical evaluations demonstrated that fish abundance, growth, and condition improved even when mercury concentrations in fish increased. Increased primary and secondary productivity (i.e., food availability) in the newly filled reservoirs was apparently the most important factor affecting resident fish populations. Uncertainties in the Schetagne and Therrien [76] study include a lack of information on recruitment and a lack of temporally paired data from natural lakes (although the authors state that natural lakes were sampled for use as reference conditions, these data are not presented). Nevertheless, it is evident that effects of mercury on fish reproduction (if any) were not a limiting factor for these fish populations.

Savannah River, Savannah Creek, and stream basins

Former weapons manufacturing operations at the Savannah River Site (South Carolina, USA) resulted in mercury contamination of stream and river habitat. Site investigation activities in 1996 to 1998 included mercury analyses of fish samples and evaluation of fish communities in Savannah River, Savannah River Swamp, and several stream drainage basins of the Savannah River Site [77]. Elevated fish mercury concentrations were found in the Lower Three Runs stream (maximum = 0.86 mg/kg) and the Savannah River (maximum = 1.25 mg/kg). In 8 instances, representing both site and reference locations, colocated fish tissue mercury and Index of Biotic Integrity (IBI) scores were available for a given year. The tissue concentrations were reported as the average of 3 species for each location [77]. Nine species were represented, with only redbreast sunfish (*Lepomis auritus*) common to all locations; the variation in species sampled introduces variability in spatial comparisons. Whole-body fish tissue mercury concentrations also were not length-normalized, and fish length data were not available for us to perform normalizations. For the 8 sites evaluated here, whole-body mercury tissue concentrations ranged from 0.08 mg/kg to 0.47 mg/kg.

Fish communities were evaluated using an IBI calibrated for regional conditions by Paller et al. [78] (Table 4). The IBI approach integrates multiple fish community metrics that reflect categories of species richness and composition, trophic structure, fish abundance, and fish condition [79,80]. As formulated by Paller et al. [78], the scores of 12 metrics are added for each station to give an IBI with possible scores ranging from 12 (very poor) to 60 (excellent). The IBI approach has been criticized for combining disparate types of information, such that more specific responses to stressors could potentially be obscured [81]. Nevertheless, fish IBI studies have demonstrated the ability to detect adverse effects of a variety of stressors on fish communities [82]. Figure 5 compares the

Table 4. Index of Biological Integrity metrics used in Savannah River (SC, USA) evaluation

Category	Metrics[a]
Species richness and composition metrics	Percentage of expected number of total species (+), percentage of expected number of native minnow species (+), percentage of expected number of piscivorous species (+), percentage of expected number of madtom and darter species (+), percent native minnows (+), percent sunfish (–/+/–)
Indicator species metrics	Percent tolerant fish (–)
Trophic function metrics	Percent generalized insectivores (–)
Abundance and condition metrics	Fish abundance by stream order (+), percent with disease or anomalies (–)

[a]Indices of Biotic Integrity formulated for regional conditions applicable to Savannah River, South Carolina, USA [78].
(+) = metric score increases with higher metric value; (–) = metric score decreases with higher metric value; (–/+/–) = metric score is higher at moderate values compared with higher and lower metric values.

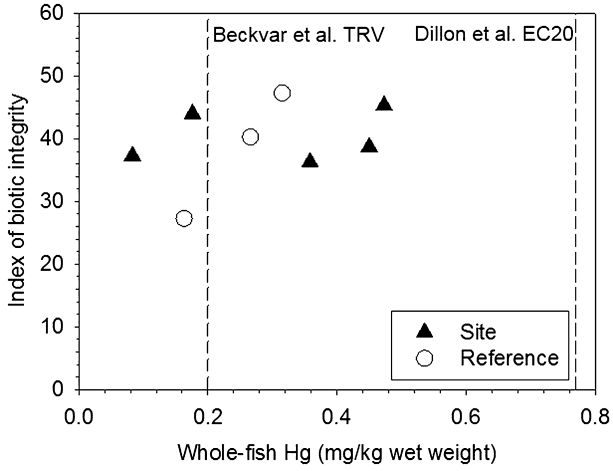

Figure 5. Whole-fish Hg concentrations versus Index of Biotic Integrity scores for Savannah River, Savannah Creek, and stream basins, South Carolina [77]. Dashed lines represent Beckvar et al. [8] toxicity reference value (TRV) and Dillon et al. [9] 20% effect concentration (EC20).

average IBI and average whole-body fish tissue mercury results; no relationship between mercury and IBI is apparent. In general, the authors reported good IBI, fish condition comparable to reference locations, and low fish pathology in the presence of contaminants and concluded that the contaminants that were present did not cause significant ecological degradation [77].

Clear Lake

Clear Lake, California, contains high concentrations of mercury in sediment and water as a result of historical mining operations. Mercury concentrations in whole largemouth bass throughout the lake ranged from 0.02 mg/kg to 0.97 mg/kg, with an average of 0.18 mg/kg (estimated from muscle concentrations) [83]. Suchanek et al. [83] reported a strong inverse relationship between fish abundance and distance from the mine, caused by either mercury exposures or habitat differences, including the extent of submerged aquatic vegetation cover. However, the authors' spatial trend analysis for mercury did not use length-normalized fish tissue concentrations, and linear regression analyses showed that relationships between fish length and mercury concentrations were similar for most areas of the lake [83]. Thus, it is unclear whether any size-independent trend in mercury tissue concentrations existed or was associated with the spatial trend in fish abundance. Overall, the Clear Lake case is inconclusive with regard to possible effects of mercury on fish populations.

East Fork Poplar Creek

As noted in the introduction to the case study review, East Fork Poplar Creek is 1 of 2 sites (along with the Hudson–Raritan Estuary) that are included in this review, even though site investigators acknowledge that mercury is 1 of multiple chemical stressors present. These 2 sites are reviewed here because they have sometimes been presented as mercury-dominated sites [84] and because they provide useful examples of investigation tools that may be applicable at other sites. The chemical mixture present in aquatic systems at the Oak Ridge Reservation (Oak Ridge, TN, USA) resulted from historical weapons development and manufacturing operations. The East Fork Poplar Creek was a primary receiving water for site discharges. Fish health and fish community quality have been studied extensively at the site [84–90]. Although adverse effects on fish have been observed, they are not solely attributed to mercury; other stressors identified by the authors include physical habitat quality and exposures to polychlorinated biphenyls (PCBs), other metals, and chlorine [84,88–90]. Whereas mercury concentrations in whole redbreast sunfish ranged up to 1 mg/kg, PCB concentrations in the same fish also ranged up to approximately 1 mg/kg [84,89]. Acute fish kills and chronic fish mortality were observed between 1990 and 1993 and were attributed to chlorine discharges and to episodic spills or releases of a variety of chemicals [90]. Thus, the East Fork Poplar Creek case study provides information on effects of a mixture of stressors, including mercury.

Adverse effects on redbreast sunfish associated with the highest contaminant exposures included lower fecundity compared with reference fish and population size structure weighted toward smaller fish [87]. Fish community analyses indicated no evidence of adverse effect on species richness and abundance, but the biomass of sensitive species was lower than in the reference fish community [84,89]. The researchers also investigated a range of biochemical and physiological characteristics. By themselves, these biomarkers would not have provided information on fish population or community status; but when considered together with attributes at higher levels of biological organization, they provide insight into potential causes and mechanisms of the observed adverse effects [87]. For example, responses of detoxification enzymes were taken to indicate toxicant exposure, and decreased fecundity was potentially linked to impaired manufacture of yolk proteins in the liver [87]. Consistent with the authors' conclusion that observed effects reflected multiple stressors, mercury concentrations in fish showed few correlations with a range of fish health biomarkers [88].

Hudson–Raritan Estuary

The Hudson–Raritan Estuary lies in one of the most urbanized and industrialized areas of North America and has a long history of contamination by many different chemicals [91]. Weis et al. [65,92–97] reported extensively on impacts of contaminated sediment exposures on fish, focusing on sites within the Hudson–Raritan Estuary. Their studies employed fish and contaminated sediment collected from a heavily industrialized salt marsh in Piles Creek (Linden, NJ, USA), which is a tributary of the Arthur Kill, and from heavily industrialized portions of the Hackensack River. Sediments from these waterways were impacted by metals (including mercury), pesticides, polycyclic aromatic hydrocarbons, and PCBs. Adverse effects on fish were observed but were not necessarily attributable to mercury.

Through field and laboratory investigations, Weis et al. evaluated effects on fish populations and aquatic community structure in contaminated and clean estuaries, as mediated by predator–prey relations (see Weis et al. [65] and Weis and Candelmo [97] for reviews). Methods included taxonomic and chemical analyses of fish stomach contents and available uneaten prey, laboratory tests of prey capture effort and effectiveness, and transplanting fish between contaminated and reference sites. Mummichogs exposed to contaminated sediment ate more detritus (based on stomach contents), were less effective predators, exhibited reduced predator avoidance, and were smaller and less abundant than their reference counterparts. Although similar effects could be induced by aqueous mercury exposure [95], and Piles Creek mummichogs contained elevated mercury concentrations (estimated from muscle as

approximately 0.5 mg/kg in whole fish [98]), Weis et al. [93] demonstrated that the observed effects were not specific to mercury and could be induced in mummichogs by various contaminants that likely were also stressors in Piles Creek.

Young-of-the-year bluefish (*Pomatomus saltatrix*) were similarly affected by chemical exposure. Bluefish fed prey from the Hackensack River had significantly elevated whole-body concentrations of PCBs (2.2 mg/kg), pesticides (0.26 mg/kg DDTs), and total mercury (1.52 mg/kg) compared with reference fish [96]. In the laboratory, bluefish displayed reduced feeding, spontaneous activity, and growth compared with the bluefish fed reference prey [96], whereas bluefish collected from the Hackensack River had a higher incidence of empty stomachs than those from the reference area [65]. Invertebrate prey also exhibited altered behaviors; but with less predation pressure, they grew larger and more numerous [65]. In these investigations, predators were more affected by contaminants than were their prey. In other settings, however, the net impact on benthic and fish population diversity and abundance would depend on whether and how the particular predator or prey is affected and the relative impacts on both [65].

Weis et al. [65] acknowledged that because the Hackensack River and Piles Creek sites are impacted by multiple chemicals, they "have not attempted to attribute the effects seen to any particular contaminant, [although they] have observed correlations of behavior with levels of mercury and PCBs." Their studies relied on a binary approach in which predator and prey were exposed to industrial or reference sediment—chemical isolation and chemical gradient experiments were not performed. Their work supports a compelling conceptual model of the ecological consequences of contaminant exposure at the study sites. However, given the presence of chemical mixtures, their method and results are not useful as tests of TRV-based predictions of mercury toxicity. Even if their underlying study design could support derivation of a mercury TRV, it would reflect a threshold that is only applicable to the combined effects of mercury in the presence of the particular mixture of chemical stressors in this system. Application of similar techniques to sites contaminated primarily with mercury would be needed to provide information more directly relevant to mercury TRV development and evaluation.

Case study summary

Through an extensive search of peer-reviewed and gray literature, we identified 8 mercury-contaminated sites with datasets that supported comparisons of mercury concentrations in fish or their prey and effects on fish populations or communities. Of these 8 sites, 5 found no detectable adverse effects despite mercury concentrations that exceeded multiple TRVs (South River, North Fork Holston River, Onondaga Lake, Savannah River, and La Grande Hydroelectric Complex). A mercury mine site (Clear Lake) yielded average fish tissue concentrations similar to the Beckvar et al. [8] TRV, and it was unclear whether any adverse effect occurred or whether fish distribution was simply a function of habitat characteristics. At the remaining 2 sites (East Fork Poplar Creek, the Hudson–Raritan Estuary), clear adverse effects on fish populations were associated with exposure to multiple contaminants including mercury. We identified no cases where adverse effects were detected in fish populations or communities that were clearly attributable to mercury, whereas multiple case studies did not detect adverse effects despite mercury exposures in excess of applicable TRVs. There are many possible explanations for the lack of agreement between field observations and laboratory predictions—such as compensatory mechanisms and development of tolerance, differences in levels of ecological organization considered in laboratory and field studies, ameliorating effects of selenium on mercury toxicity, and conservative approaches to TRV development. The *Discussion* section weighs these possible explanations and offers recommendations for further research.

BACKGROUND CONCENTRATIONS

Natural background concentrations of mercury in fish—those that were present prior to the industrial revolution and attributable to natural sources of mercury such as geothermal activity and volcanic emissions [99]—are relevant to assessing the reasonableness of mercury TRVs, because mercury is a naturally occurring element and fish have presumably evolved to tolerate mercury exposure at levels that typically occur naturally. We acknowledge that, in principal, some naturally occurring elements can pose a degree of risk to individual organisms even in the absence of anthropogenic sources, either because of mechanisms of toxicity characterized by a continuous risk function (i.e., lacking an effect threshold) or because of outlying extremes of naturally occurring concentrations or sensitivity in individual organisms. Nevertheless, it is apparent that fish populations have persisted for tens to hundreds of millions of years despite normal exposures to naturally occurring mercury. Therefore, reasonable TRVs should not predict adverse effects on fish populations at exposures consistent with typical preindustrial natural background conditions.

Recognizing that background concentrations have increased since the industrial revolution as a result of anthropogenic sources of mercury (e.g., power generation, artisanal gold mining [99]), present-day background data are somewhat less effective as a reality check on the reasonableness of TRVs. Characterization of naturally occurring mercury concentrations in fish, however, is challenging because of a paucity of preindustrial fish tissue data and the difficulty in differentiating natural and anthropogenic sources in present-day tissue data. Even for fish collected from remote locations, present-day background concentrations of mercury in fish do not reflect preindustrial natural background conditions as a result of global atmospheric deposition of mercury from anthropogenic sources, as well as anthropogenic increases in sulfate deposition [32,100,101]. Present-day background mercury concentrations in fish tissue are linked to atmospheric mercury deposition [101], as well as sulfate deposition and a variety of land cover and water quality characteristics [32].

Theoretically, museum specimens of fish collected before the industrial revolution could be a valuable source of data on natural background concentrations of mercury in fish. However, an extensive literature search identified virtually no pre-1850 fish tissue data from museum specimens. Inclusion of data from more recent museum specimens would risk overestimating natural background concentrations. Therefore, 3 other lines of evidence are considered in an effort to understand whether available TRVs are lower than background conditions: modeled natural background concentrations [102]; measured mercury concentrations in fish used as controls in toxicity tests [8]; and measured mercury concentrations in fish collected from remote areas [103,104], considered together with regional estimates of mercury deposition increases. Given the broad

array of fish monitoring studies available on present-day mercury concentrations, the studies supporting the second and third lines of evidence are intended to be representative, rather than exhaustive.

Hope and Louch [102] modeled fish tissue concentrations of methylmercury under a variety of scenarios reflective of pre-Anthropocene conditions, defined as *natural background* or the period prior to significant anthropogenic effects on the environment. This exercise used the USEPA's Spreadsheet-Based Ecological Risk Assessment for the Fate of Mercury (SERAFM) model. Hope and Louch [102] reported that mean natural background mercury concentrations in whole prey fish were estimated to range from 0.03 mg/kg to 0.1 mg/kg, with the lowest concentrations estimated for rivers and the highest estimated for stratified dystrophic lakes. Median concentrations in whole prey fish were somewhat lower than the means, ranging from 0.005 mg/kg to 0.03 mg/kg. For whole predatory fish, mean natural background concentrations of mercury were estimated to range from 0.1 mg/kg to 0.3 mg/kg. In the absence of empirical data (i.e., pre-Anthropocene fish samples), Hope and Louch's [102] model estimates cannot be validated directly, although the SERAFM model was validated under present-day conditions.

A second line of evidence relevant to present-day background conditions is provided by concentrations of mercury in control fish tissue from toxicity tests, as reported by Beckvar et al. [8]. Beckvar et al. [8] reported that concentrations of mercury in control fish mercury ranged from 0.04 mg/kg to 0.22 mg/kg. A range of 0.04 mg/kg to 0.1 mg/kg in control fish results when pre-1985 results are excluded [8] because of the analytical uncertainty associated with older analytical methods [105].

A third line of evidence also relevant to present-day background conditions is provided by several studies reporting mercury concentrations in fish collected from Canadian ecozones with relatively limited impacts from sulfate deposition [106] and mercury deposition [103]. For example, Depew et al. [104] reported median yellow perch mercury concentrations of 0.02 mg/kg and 0.06 mg/kg for the Boreal Plains and Prairies ecozones in central Canada. Selin et al. [103] estimate that mercury deposition in this region has increased approximately 2- to 3-fold relative to preindustrial mercury deposition, and it appears that the present-day prey fish mercury concentrations exceed estimated pre-Anthropocene concentrations by roughly the same margin. The La Grande Hydroelectric Complex case study (see section *La Grande Hydroelectric Complex*) provides a similar example for predatory fish. The site is located in northwestern Quebec, where anthropogenic increases in mercury and sulfate deposition are limited [103,106]. Whole-body mercury concentrations in piscivorous fish prior to dam construction in the area were estimated as 0.3 mg/kg to 0.4 mg/kg [76].

Taken together, the available information supports the suggestion by Hope and Louch [102] that the estimated pre-Anthropocene fish tissue mercury concentrations may serve as a reasonable, although approximate, floor level at or below which predictions of adverse effects attributable to mercury in fish are unrealistic. The prey tissue TRV of 0.04 mg/kg developed by Depew et al. [16] is consistent with background concentrations of mercury in lower trophic level fish, which is expected, given that the TRV was set equal to a mercury concentration in prey from a control treatment.

The Beckvar et al. [8] TRV of 0.2 mg/kg falls at the high end of present-day background concentrations of mercury in larger fish (Table 5), but fish tissue mercury concentrations

comparable to this TRV apparently can occur naturally under conditions that favor mercury methylation, such as in dystrophic lakes or in watersheds with abundant forest and wetland cover [32,35,102]. Taken together with the uncertainties in the data underlying this TRV (see section *Review of fish tissue TRVs*), it would appear that the Beckvar et al. [8] TRV is lower than necessary for protection of adult and early life stages of fish. The Dillon et al. [9] EC20 of 0.77 mg/kg is greater than both preindustrial or present-day background mercury concentrations in fish and may provide a more relevant TRV for protection of both adult fish and offspring exposed via maternal transfer, although field case studies reviewed in the present report suggest that even the Dillon et al. [9] value can overpredict adverse effects on fish.

DISCUSSION

The present review of TRV derivation and underlying data identified significant limitations in the available chronic toxicity data and high uncertainty in the resulting TRVs. The lowest of the available TRVs fall within the range of naturally occurring background mercury concentrations in fish, with the Depew et al. [16] prey tissue TRV falling well within background concentrations and the Beckvar et al. [8] fish tissue TRV falling toward the higher end of background concentrations in larger fish. The case study review provides no indication that these lower TRVs should be interpreted as threshold concentrations above which adverse effects on fish reproduction or fish populations may be expected. The Beckvar et al. [8] TRV was developed as a screening level (i.e., a TRV below which toxicity is not expected), and it can be argued that a screening-level TRV is not intended to be a predictive effect threshold. However, the case studies also do not validate Sandheinrich and Wiener's [5] estimate of 0.3 mg/kg to 0.5 mg/kg as a threshold for the onset of adverse effects, at least for the endpoints targeted in our review. The Dillon et al. [9] EC20 of 0.77 mg/kg appears closer to an effect threshold for reproductive effects in some species, based on laboratory toxicity data, but field studies did not detect adverse effects on fish at multiple sites where tissue concentrations equaled or substantially exceeded this level (i.e., South River, Onondaga Lake, La Grande Hydroelectric Complex). Although adverse effects on fish were detected in 2 case studies, severe contamination by other chemicals precluded attribution of effects to mercury in those cases.

There are many reasons why laboratory and field studies may differ with respect to observed and predicted effects of mercury on fish. Differences between laboratory and field conditions undoubtedly play a role; some differences are inevitable, while others could be remedied with improved study design and data collection. Discrepancies can also arise through the conservative interpretation of uncertain laboratory data in the absence of field verification. In addition to the uncertainties identified above in the TRV derivation review, several other important sources of uncertainty are identified below.

Differences in the levels of ecological organization considered in field studies and in laboratory bioassays that underpin TRVs often contribute to inconsistencies between observations from field studies and hazards predicted by exceedances of TRVs. This challenge is not unique to mercury exposures. As discussed by Barnthouse et al. [107] with regard to PCB effects on fish populations, field studies generally evaluate endpoints relevant to population- and community-level effects (e.g., population size, community diversity, biomass, condition, sex ratios, age structure), whereas TRVs are most often derived from laboratory toxicity bioassays on survival, growth, and reproduction of individual specimens. Survival, growth, and reproduction are certainly *linked* to population-level effects, but findings on individual organisms in the laboratory do not necessarily translate to population-level effects in the field because of factors such as adaptation and tolerance, competition, predator–prey interactions, migration, emigration, environmental variability, and density-dependence [65,108–112]. Maltby et al. [113] note that "the fact that some populations persist in stressed environments, even though adverse effects on individuals and the potential to cause population-level effects can be demonstrated, raises the possibility of compensatory mechanisms that ameliorate predicted adverse effects." Conversely, laboratory tests could also underestimate effects; for instance, Ankley [114] notes that "one factor that limits the predictive power of current laboratory tests is that they are relatively short-term assessments of conditions in which chronic toxicity may be a dominant process." Although mesocosm studies and field manipulations offer possible solutions to some of the challenges inherent in extrapolating from laboratory-derived TRVs to field outcomes, neither approach is yet in common use for assessing site-specific effects of mercury on fish. While the matter of assessment at different levels of ecological organization is not unique to mercury, other factors that also contribute to this disconnect are specific to mercury in fish, as discussed below.

Although still at a relatively early stage of research and in need of further study, the disconnect between field and laboratory studies may be partially related to differences in the form of mercury tested in the laboratory relative to that present in fish in the field. Whereas methylmercury effects on fish reproduction have been tested primarily using methylmercury chloride, methylmercury exists in fish in the form of methylmercury cysteine [115]. Methylmercury chloride is not an ion pair; the chloride component is covalently bound [115]. Thus, methylmercury chloride and methylmercury cysteine are not the same chemical and might not produce the same exposure–response relationships [115]. Only 1 comparison of the relative toxicity of these chemical forms is available. Harris et al. [115] reported that methylmercury cysteine is much less toxic to zebrafish on an acute basis than methylmercury chloride, but differences in toxicity on a chronic basis have not been tested. A difference in toxicokinetics is suggested by a rat bioaccumulation study, in which rats fed contaminated fish exhibited higher fecal excretion and lower mercury accumulation than rats fed uncontaminated fish spiked with methylmercury chloride [116]. Additional research is needed to clarify whether laboratory studies conducted with methylmercury chloride are directly applicable to interpreting fish tissue concentrations of methylmercury cysteine.

Furthermore, the antagonistic interaction between selenium and mercury toxicity has long been recognized [117–120] and can be expected to confound comparisons among mercury toxicity studies when selenium is not measured. In contrast to mercury, selenium is a biologically essential element for nervous system function that only becomes toxic at high concentrations. Exposure to mercury that might otherwise be expected to cause toxic effects can be mitigated in the presence of selenium. This reduction in mercury toxicity has been shown to be widespread among virtually all aquatic and terrestrial species. The onset of mercury toxicity roughly corresponds to when the molar concentration of mercury exceeds that of selenium in tissue or diet [117,118]. In addition to reducing toxicity, there is also strong evidence that the presence of

selenium can reduce mercury bioaccumulation [117,119]. Although the observed reduction in mercury toxicity by selenium is well known, the mechanism remained uncertain until recently. Historically, the mode of action was thought to be the protective binding of mercury by selenium, preventing the activation of direct effects of mercury on cellular processes and enzyme inhibition [117,119]. Other evidence suggests that other modes of actions, such as the formation of selenium–mercury complexes [119], enhanced demethylation of methylmercury, or an effect on the partitioning of mercury in organs and tissues or within individual cells [117–119], may also be important. However, more recent evidence suggests that mercury toxicity is in fact the result of selenium deficiency as a result of the sequestration of selenium by mercury [118,120], and thus the presence of an excess of selenium guards against the selenium deficiency caused by this sequestration. Penglase et al. [47] reported a synergistic toxicological effect of mercury and selenium on fish reproduction, under conditions of high exposure to both metals with tissue concentrations of mercury in excess of selenium. Additional research is needed to support the interpretation of mercury–selenium interactions for chronic effects on fish, especially in cases where selenium concentrations approach toxic levels. However, enough information is already available to consider mercury–selenium molar ratios as an important line of evidence for assessing the likelihood of adverse effects on fish as a result of mercury. Considering that very few of the mercury toxicity studies or case studies reviewed for the present study reported the selenium status of mercury-exposed fish, unmeasured mercury–selenium interactions are a significant source of uncertainty in applying the resulting toxicity data.

Another possible source of discrepancies between TRV-based predictions and case study results is differential sensitivity among fish species. Fish vary in their responses to mercury exposure, and differences in sensitivity are presumably subject to natural selection. It is logical that fish at higher trophic levels should be more mercury-tolerant than other fish, because mercury is naturally present at higher concentrations in piscivorous fish than in smaller fish. This consideration is especially applicable to marine species such as sharks and marlin, which contain notably high mercury concentrations [121]. Because piscivorous fish tend to be more difficult to maintain in the laboratory [23], most laboratory toxicity tests are necessarily conducted with smaller fish.

An additional consideration for any tissue-based dose–response relationship for mercury is that exposure before and during egg formation, rather than total maternal tissue burden at the time of spawning, is critical to effects of mercury on fish reproduction [21,22,48]. Thus, a tissue-based TRV derived from studies in which fish were exposed during both development and spawning is potentially problematic when applied to fish that move between areas of differing mercury exposure. Such TRVs could be either overprotective (i.e., in cases where fish accumulate mercury primarily after egg formation) or underprotective (i.e., when compared with tissue data for adult fish that experienced higher mercury exposures during egg formation and lower exposures subsequently). This issue lends conceptual support to the development of fish-protective TRVs based on mercury concentrations in fish diet rather than tissue, as attempted by Depew et al. [16]. However, the effort of Depew et al. [16] was hampered by limitations in the available data, as discussed (see section *Review of fish prey TRVs*).

CONCLUSIONS

At present, insufficient high-quality exposure–response data for critical endpoints presents the greatest challenge to identification of predictive effect thresholds and dose–response relationships for mercury effects on fish populations. Although data for fathead minnows and brook trout suggest the possibility of adverse reproductive effects (e.g., spawning, early life stage development and survival) corresponding to tissue residues below 1 mg/kg, none of the critical results are statistically significant. While definitive laboratory studies are lacking, the available laboratory and field studies suggest that the Beckvar et al. [8] TRV of 0.2 mg/kg is not a threshold above which adverse impacts on fish populations should be expected. Although limited, the available laboratory data suggest that the Dillon et al. [9] EC20 is closer than the Beckvar et al. [8] TRV to a fish tissue threshold for reproduction; but risk managers should use this and any other fish tissue TRV with caution, given the limited data and many uncertainties discussed in the present study. The Depew et al. [16] fish prey TRV is equal to a control concentration; it is not an effect threshold and should not be used as such. The available field studies demonstrate that, at least in some cases, fish populations can remain apparently unaffected despite mercury exposures well in excess of any of these TRVs.

Ultimately, the development of more effective mercury TRVs and dose–response relationships for protection of fish will require additional research. Statistically rigorous, controlled exposure–response studies for multiple species are needed to better characterize effects of dietary methylmercury exposure on fish reproduction. Although numerous studies have evaluated mercury effects on fish gonads [6], high-quality dose–response relationships relating mercury diet and tissue concentrations to reproductive outcomes remain a critical data gap. Further studies are needed to support interpretation of mercury–selenium interactions for chronic effects on fish, especially in cases where selenium concentrations approach toxic levels. Comparative studies with methylmercury cysteine are also needed to understand whether testing with methylmercury chloride introduces a significant bias in chronic laboratory studies. Additional fish population and community studies across mercury gradients are also warranted to evaluate whether effects on fish resulting from elevated mercury exposures actually occur. In the meantime, risk assessors are advised to consider the available data from field studies in addition to TRV comparisons, to measure the site-specific selenium status of fish, and to conduct site-specific investigations of fish populations if needed to support appropriate environmental management decisions.

Supplemental Data—The Supplemental Data are available on the Wiley Online Library at DOI: 10.1002/etc.3267.

Acknowledgment—Funding was provided by the Sediment Management Work Group. W. Gala, S. Brown, M. McCulloch, K. Christensen, R. Hoke, S.K. Driscoll, N. Gard, R.
