As noted in the Delta Region section above, phosphorus concentrations in the Delta (including Banks and Jones pumping plants) are not anticipated to change substantially on a long term-average basis. During January through March, phosphorus concentrations may increase as a result of more San Joaquin River water reaching Banks and Jones pumping plants and the higher concentration of phosphorus in the San Joaquin River. However, based on the DSM2 fingerprinting results (see Appendix 8D, *Source Water Fingerprinting Results*), together with source water concentrations show in Figure 8-56, the magnitude of this increase is expected to be negligible (<0.01 mg/L-P). Additionally, there are no state or federal objectives for phosphorus. Moreover, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Area, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that any seasonal increases in phosphorus concentrations at the levels expected under this alternative, should they occur, would increase the potential for problem algal blooms in the SWP and CVP Export Service Area.

Any increases in phosphorus concentrations that may occur in water exported via Banks and Jones pumping plants are not expected to result in adverse effects to beneficial uses of exported water or substantially degrade the quality of exported water, with regards to phosphorus.

NEPA Effects: In summary, based on the discussion above, effects on phosphorus of CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2, *Determination of Effects*) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Because phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration upstream of the Delta are not anticipated for any operational scenario of Alternative 4, relative to Existing Conditions.

Because phosphorus concentrations in the major source waters to the Delta are similar for much of the year, phosphorus concentrations in the Delta are not anticipated to change substantially on a long term-average basis under the operational scenarios of Alternative 4, relative to Existing Conditions. Algal growth rates are limited by availability of light in the Delta, and therefore any minor increases in phosphorus levels that may occur at some locations and times within the Delta would be expected to have little effect on primary productivity in the Delta.

The assessment of effects of phosphorus under the various operational scenarios of Alternative 4 in the SWP and CVP Export Service Areas is based on effects on phosphorus at the Banks and Jones pumping plants. As noted above, phosphorus concentrations in the Delta (including Banks and Jones pumping plants) are not anticipated to change substantially on a long term-average basis.

Based on the above, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas under any operational scenario of Alternative 4 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM11 include activities that create additional aquatic habitat within the affected environment, and therefore may increase the total amount of algae and plant-life within the Delta. These activities would not affect phosphorus loading to the affected environment, but may affect phosphorus dynamics and speciation. For example, water column concentrations of total phosphorus may increase or decrease in localized areas as a result of increased or decreased suspended solids, while ortho-phosphate concentrations may be locally altered as a result of changing planktonic and macroinvertebrate species contributing to the cycling of phosphorus within the affected environment. Additionally, depending on age, configuration, location, operation, and season, some of the restoration measures included under these conservation measures may function to remove or sequester phosphorus, but since presently, the specific design, operational criteria, and location of these activities are not well established, the degree to which this would occur is unknown. Overall, phosphorus concentrations are not expected to change substantially in the affected environment as a result of CM2–CM21. Because increases or decreases in phosphorus levels are, in general, expected to have little effect on productivity, any changes in phosphorus concentrations that may occur at certain locations within the affected environment are not anticipated to be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to phosphorus.

Because urban stormwater is a source of phosphorus in the affected environment, CM19, Urban Stormwater Treatment, is expected to slightly reduce phosphorus loading to the Delta, thus slightly decreasing phosphorus concentrations relative to the No Action Alternative. Implementation of CM12–CM18 and CM20–CM21 is not expected to substantially alter phosphorus concentrations in the affected environment.

The effects on phosphorus from implementing CM2–CM21 are considered to be not adverse.

CEQA Conclusion: There would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas due to implementation of CM2–CM21 under Alternative 4 relative to Existing Conditions. Because urban stormwater is a source of phosphorus in the affected environment, *CM19 Urban Stormwater Treatment*, is expected to slightly reduce phosphorus loading to the Delta. As such, implementation of these conservation measures is not expected to cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially due to these conservation measures, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Substantial point sources of selenium do not exist upstream in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Nonpoint sources of selenium within the watersheds of the Sacramento River and the eastern tributaries also are relatively low, resulting in generally low selenium concentrations in the reservoirs and rivers of those watersheds.

Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 4, Scenarios H1–H4, relative to Existing Conditions or the No Action Alternative, are expected to have negligible, if any, effects on reservoir and river selenium concentrations upstream of Freeport in the Sacramento River watershed or in the eastern tributaries upstream of the Delta.

Non-point sources of selenium in the San Joaquin River watershed are associated with discharges of subsurface agricultural drainage to the river and its tributaries. Selenium concentrations in the San Joaquin River upstream of the Delta comply with NTR criteria and Basin Plan objectives at Vernalis under Existing Conditions, and they are expected to do so under the No Action Alternative. This is because a TMDL has been developed by the Central Valley Water Board (2001), the Grassland Bypass Project has established limits that will result in reduced inputs of selenium to the Delta, and the Central Valley Water Board (2010d) and State Water Board (2010b, 2010c) have established Basin Plan objectives that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta, as previously discussed in 8.1.3.15.

Selenium concentrations at Vernalis are generally higher during lower San Joaquin River flows, with considerable variability in concentrations below about 3,000 cfs, as shown in Appendix 8M, *Selenium,* Table M-33 and Figures M-7 through M-20. Under the four operational scenarios of Alternative 4, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by 6% relative to Existing Conditions and would remain virtually the same relative to the No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Given these relatively small decreases in flows and the considerable variability in the relationship between selenium concentrations and flows in the San Joaquin River, it is expected that selenium concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under the operational scenarios of Alternative 4.

Thus, available information indicates selenium concentrations are well below the Basin Plan objective and are likely to remain so. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics. To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See Section 8.3.1.3, *Plan Area*, for more information.

Selenium concentrations and threshold comparisons for each of the 11 modeled Delta assessment locations under Alternative 4, relative to Existing Conditions and the No Action Alternative, are presented in Appendix 8M, *Selenium*, Table M-9b for water, Tables M-14a, through M-14d, and Tables M-24a through M-24d for most biota (whole-body fish (excluding sturgeon)), bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, and Tables M-30 through M-32 for sturgeon at the two western Delta locations. Figures 8-59b and 8-60b present graphical distributions of predicted selenium concentration changes (shown as changes in available assimilative capacity based on 1.3 µg/L) in water at each modeled assessment location for all years.

Appendix 8M, Figure M-22 provides more detail in the form of monthly patterns of selenium concentrations in water during the modeling period.

All scenarios (H1, H2, H3, and H4) under Alternative 4 would result in small changes in average selenium concentrations in water relative to Existing Conditions and No Action Alternative at all modeled Delta assessment locations (Appendix 8M, *Selenium*, Table M-9b). Long-term average concentrations at some interior and western Delta locations would increase by 0.01–0.05 µg/L for the entire period modeled (1976–1991), depending on operational scenario. These small increases in selenium concentrations in water would result in small reductions (4% or less) in available assimilative capacity for selenium, relative to the1.3 µg/L USEPA draft water quality criterion (Figures 8-59b and 8-60b). The long-term average selenium concentrations in water under Alternative 4 Scenarios H1–H4 (range 0.09–0.40 µg/L) would be similar to Existing Conditions (range 0.09–0.41 µg/L) and the No Action Alternative (range 0.09–0.38 µg/L), and would all be below the USEPA draft water quality criterion of 1.3 µg/L (Appendix 8M, *Selenium*, Table M-9b).

Relative to Existing Conditions and the No Action Alternative, all scenarios under Alternative 4 would result in small changes (approximately 1%) in estimated selenium concentrations in most biota (whole-body fish, bird eggs [invertebrate diet or fish diet], and fish fillets) throughout the Delta, with little difference among locations (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Tables M-24a through M-24d). Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0 (indicating low probability of adverse effects). Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years also are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by 14–19% relative to Existing Conditions and to the No Action Alternative in all years (from about 4.7 to 5.6 mg/kg dry weight), and those for sturgeon in the Sacramento River at Mallard Island are predicted to increase by 9–11% in all years (from about 4.4 to 4.9 mg/kg dry weight) (Appendix 8M, Tables M-30 and M-31), with the highest percent increase for Scenario H4. Selenium concentrations in sturgeon during drought years are expected to increase by about 3–9% at those locations, with the highest increase in San Joaquin River Antioch in drought years for Scenario H4 (Appendix 8M, Tables M-30 and M-31). Detection of small changes in whole-body sturgeon such as those estimated for the western Delta would require very large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 (indicating a higher probability for adverse effects) for drought years at both locations (as they do for Existing Conditions and the No Action Alternative) and would increase slightly, from 0.94 to 1.1, for all years in the San Joaquin River at Antioch (Appendix 8M, Table M-32).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in the appendix, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. (There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium.) Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on "fixed" K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Increased water residence times could increase the bioaccumulation of selenium in biota, thereby potentially increasing fish tissue and bird egg concentrations of selenium (see residence time discussion in Appendix 8M, *Selenium*, and Presser and Luoma [2010b]). Thus, residence time was assessed for its relevance to selenium bioaccumulation. Table 8-60a shows the time for neutrally buoyant particles to move through the Delta (surrogate for flow and residence time). Although an increase in residence time throughout the Delta is expected under the No Action Alternative, relative to Existing Conditions (because of climate change and sea level rise), the change is fairly small in most areas of the Delta.

Relative to Existing Conditions and the No Action Alternative, increases in residence times for Alternative 4 would be greater in the East Delta and South Delta than in other sub-regions. Relative to Existing Conditions, annual average residence times for Alternative 4 in the South Delta are expected to increase by more than 10 days (Table 8-60a). Relative to the No Action Alternative, annual average residence times for Alternative 4 in the South Delta are expected to increase by less than 10 days. Increases in residence times for other sub-regions would be smaller, especially as compared to Existing Conditions and the No Action Alternative (which are longer than those modeled for the South Delta). As mentioned above, these results incorporate hydrodynamic effects of both CM1 and CM2 and CM4, and the effects of CM1 cannot be distinguished from the effects of CM2 and CM4. However, it is expected that CM2 and CM4 are substantial drivers of the increased residence time.

Presser and Luoma (2010b) summarized and discussed selenium uptake in the Bay-Delta (including hydrologic conditions [e.g., Delta outflow and residence time for water], K_ds [the ratio of selenium concentrations in particulates, as the lowest level of the food chain, relative to the waterborne concentration], and associated tissue concentrations [especially in clams and their consumers, such as sturgeon]). When the Delta Outflow Index (daily average flow per month) decreased by five-fold (73,732 cfs in June 1998 to 12, 251 cfs in October 1998), residence time doubled (from 11 to 22 days) and the calculated mean K_d also doubled (from 3,198 to 6,501). However, when daily average Delta outflow in November 1999 was only 6,951 cfs (i.e., about one-half that in October 1998) and residence time was 70 days, the calculated mean K_d (7,614) did not increase proportionally.

Models are not available to quantitatively estimate the level of changes in selenium bioaccumulation as related to residence time, but the effects of residence time are incorporated in the bioaccumulation modeling for selenium that was based on higher K_d values for drought years in comparison to wet, normal, or all years; see Appendix 8M, *Selenium*. If increases in fish tissue or bird egg selenium were to occur, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. In consideration of this factor, although the Delta as a whole is a CWA Section 303(d)-listed water body for selenium, and although monitoring data of fish tissue or bird eggs in the Delta are sparse, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time from restoration areas would be a concern is the western Delta and Suisun Bay for sturgeon, as discussed above. As shown in Table 8-60a, the overall increase in residence time estimated in the western Delta is 4 days relative to Existing Conditions, and 2 days relative to the No Action Alternative. Given the available information, these increases are small enough that they are not expected to substantially affect selenium bioaccumulation in the western Delta. Because CM2 and CM4 are expected to be substantial drivers of the increased residence times, further discussion is included in Impact WQ-26 below.

In summary, relative to Existing Conditions and the No Action Alternative, all scenarios under Alternative 4 would result in essentially no change in selenium concentrations throughout the Delta for most biota (approximately 1% or less), although increases in selenium concentrations are predicted for sturgeon in the western Delta. The Low Toxicity Threshold Exceedance Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase from 0.94 for Existing Conditions and the No Action Alternative to 1.1 for Alternative 4. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, all scenarios under Alternative 4 would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon relative to the low benchmark and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium.

SWP/CVP Export Service Areas

Alternative 4 scenarios would result in small (0.05–0.08 μg/L) decreases in long-term average selenium concentrations in water at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative, for the entire period modeled (Appendix 8M, Table M-9b). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium at these pumping plants, relative to the 1.3 μg/L USEPA draft water quality criterion (Figures 8-59b and 8-60b). The long-term average selenium concentrations in water for Alternative 4, Scenarios H1–H4 (range 0.16–0.21 μg/L) would be well below the USEPA draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-9b).

Relative to Existing Conditions and the No Action Alternative, all scenarios under Alternative 4 would result in small changes (approximately 1%) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Tables M-24a through M-24d) at Banks and Jones pumping plants. Concentrations in biota would not exceed any selenium benchmarks for Alternative 4 (Figures 8-61a through 8-64b).

NEPA Effects: Selenium concentrations in water and biota very slightly increase progressively from Scenario H1 (smallest) to Scenario H4 (largest). However, based on the discussion above, the effects on selenium (both as waterborne and as bioaccumulated in biota) from all scenarios under Alternative 4 are not considered to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2, *Determination of Effects*) for the purpose of making the CEQA impact determination for selenium. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 4 scenarios, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate that all scenarios under Alternative 4 would result in essentially no change in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. The Low Toxicity Threshold Exceedance Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase slightly, from 0.94 for Existing Conditions to 1.1 for Alternative 4. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. Overall, Alternative 4 would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium.

Assessment of effects of selenium in the SWP. CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, all scenarios under Alternative 4 would cause no increase in the frequency with which applicable benchmarks would be exceeded, and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants.

Based on the above, selenium concentrations that would occur in water under all Alternative 4 scenarios would not cause additional exceedances of applicable state or federal numeric or narrative water quality objectives/criteria, or other relevant water quality effects thresholds identified for this assessment (Table 8-54), by frequency, magnitude, and geographic extent that would result in adverse effects to one or more beneficial uses within affected water bodies. In comparison to Existing Conditions, water quality conditions under all scenarios for Alternative 4 would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Water quality conditions under these alternative scenarios with respect to selenium would not cause long-term degradation of water quality in the affected environment, and therefore would not result in use of available assimilative capacity such that exceedances of water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. All scenarios under this alternative would not further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: In general, with the possible exception of changes in Delta hydrodynamics resulting from habitat restoration, CM2–CM21 would not substantially increase selenium concentrations in the water bodies of the affected environment. Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, and thus such effects of these restoration measures were included in the assessment of CM1 facilities operations and maintenance (see Impact WQ-25).

As discussed in Impact WQ-25, implementation of these conservation measures may increase water residence time within the restoration areas. Increased restoration area water residence times could increase the bioaccumulation of selenium in biota, thereby potentially increasing fish tissue and bird egg concentrations of selenium (see residence time discussion in Appendix 8M, *Selenium*, and Presser and Luoma [2010b]). Models are not available to quantitatively estimate the level of changes in selenium bioaccumulation as related to residence time, but the effects of residence time are incorporated in the bioaccumulation modeling for selenium that was based on higher K_d values for drought years in comparison to wet, normal, or all years; see Appendix 8M, *Selenium*. If increases in fish tissue or bird egg selenium were to occur, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. In consideration of this factor, although the Delta as a whole is a CWA Section 303(d)-listed water body for selenium, and although monitoring data of fish tissue or bird eggs in the Delta are sparse, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time from restoration areas would be a concern is the western Delta and Suisun Bay for sturgeon, as discussed above. As shown in Table 8-60a, the overall increase in residence time estimated in the western Delta is 4 days relative to Existing Conditions, and 2 days relative to the No Action Alternative. Given the available information, these increases are small enough that they are not expected to substantially affect selenium bioaccumulation in the western Delta.

The western Delta and Suisun Bay receive elevated selenium loads from North San Francisco Bay (including San Pablo Bay, Carquinez Strait, and Suisun Bay) and from the San Joaquin River. The San Francisco Bay Water Board is conducting a TMDL project to address selenium toxicity in the North San Francisco Bay (North Bay), defined to include a portion of the Delta, Suisun Bay, Carquinez Strait, San Pablo Bay, and the Central Bay (State Water Resources Control Board 2011). The North Bay selenium TMDL will identify and characterize selenium sources to the North Bay and the processes that control the uptake of selenium by wildlife. The TMDL will quantify selenium loads, develop and assign waste load and load allocations among sources, and include an implementation plan designed to achieve the TMDL and protect beneficial uses. Nonpoint sources of selenium in the San Joaquin Valley that contribute selenium to the San Joaquin River, and thus the Delta and Suisun Bay, will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b and 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta.

The South Delta receives elevated selenium loads from the San Joaquin River, and as Table 8-60a shows, residence times in this area are expected to increase on an annual average by 11 days relative to Existing Conditions, and 9 days relative to the No Action Alternative. However, as discussed in Impact WQ-25, biota concentrations in the South Delta are not approaching levels of concern. Furthermore, in contrast to Suisun Bay and possibly the western Delta in the future, the South Delta lacks the overbite clam (*Corbula* [*Potamocorbula*] *amurensis*), which is considered a key driver of selenium bioaccumulation in Suisun Bay, due to its high bioaccumulation of selenium and its role in the benthic foodweb that includes long-lived sturgeon. The south Delta does have *Corbicula fluminea*, another bivalve that bioaccumulates selenium, but to a lesser degree than the overbite clam (Lee et al. 2006). Also, as mentioned above, nonpoint sources of selenium in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b and 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Further, if selenium levels in the San Joaquin River are not sufficiently reduced via these efforts, it is expected that the State Water Board and Central Valley Water Board would initiate additional TMDLs to further control nonpoint sources of selenium. Given the available information, these increases are small enough that they are not expected to cause selenium concentrations in biota in the south Delta to approach or exceed thresholds of concern.

Wetland restoration areas will not be designed such that water flows in and does not flow out. Exchange of water between the restoration areas and existing Delta channels is an important design factor, since one goal of the restoration areas is to export food produced in these areas to the rest of the Delta (see BDCP Chapter 3, *Conservation Strategy*, Section 3.3, *Biological Goals and Objectives*). Thus, these areas can be thought of as “flow-through” systems. Consequently, although water residence times associated with BDCP restoration could increase, they are not expected to increase without bound, and selenium concentrations in the water column would not continue to build up and be recycled in sediments and organisms as may be the case within a closed system.

However, because increases in bioavailable selenium in the habitat restoration areas are uncertain, proposed avoidance and minimization measures would require evaluating risks of selenium exposure at a project level for each restoration area, minimizing to the extent feasible potential risk of additional bioaccumulation, and monitoring selenium levels in fish and/or wildlife to establish whether, or to what extent, additional bioaccumulation is occurring. See Appendix 3B, *Environmental Commitments, AMMs, and CMs,* for a description of the environmental commitment the project proponents are making with respect to Selenium Management; and Appendix 3.C of the BDCP for additional detail on this avoidance and minimization measure (AMM27). Data generated as part of the avoidance and minimization measures will assist the State and Regional Water Boards in determining whether beneficial uses are being impacted by selenium, and thus will provide the data necessary to support regulatory actions (including additional TMDL development), should such actions be warranted.

Given the factors discussed in the assessment above, any increases in bioaccumulation rates from waterborne selenium that could occur in some areas as a result of increased water residence time would not be of sufficient magnitude and geographic extent that any portion of the Delta would be expected to have measurably higher body burdens of selenium in aquatic organisms and, therefore, would not substantially increase risk for adverse effects to beneficial uses. Furthermore, although the Delta is a 303(d)-listed water body for selenium, given the discussion in the assessment above, it is unlikely that restoration areas would result in measurable increases in selenium in fish tissues or bird eggs such that the beneficial use impairment would be made discernibly worse.

Because it is unlikely that substantial increases in selenium in fish tissues or bird eggs would occur such that effects on aquatic life beneficial uses would be anticipated, and because of the avoidance and minimization measures that are designed to further minimize and evaluate the risk of such increases, the effects of WQ-26 are considered not adverse.

CEQA Conclusion**:** There would be no substantial, long-term increase in selenium concentrations in water in the rivers and reservoirs upstream of the Delta, water in the Delta, or the waters exported to the CVP and SWP service areas due to implementation of CM2–CM21 relative to Existing Conditions. Waterborne selenium concentrations under this alternative would not exceed applicable water quality objectives/criteria.

Given the factors discussed in the assessment above, any increases in bioaccumulation rates from waterborne selenium that could occur in some areas as a result of increased water residence times would not be of sufficient magnitude and geographic extent that any portion of the Delta would be expected to have measurably higher body burdens of selenium in aquatic organisms, and therefore would not substantially increase risk for adverse effects to beneficial uses. CM2–CM21 would not cause long-term degradation of water quality resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely. Also, CM2–CM21 would not result in substantially increased risk for adverse effects to any beneficial uses. Furthermore, although the Delta is a 303(d)-listed water body for selenium, given the discussion in the assessment above, it is unlikely that restoration areas would result in measurable increases in selenium in fish tissues or bird eggs such that the beneficial use impairment would be made discernibly worse.

Because it is unlikely that substantial increases in selenium in fish tissues or bird eggs would occur such that effects on aquatic life beneficial uses would be anticipated, and because of the avoidance and minimization measures that are designed to further minimize and evaluate the risk of such increases (see Appendix 3.C of the BDCP for more detail on AMM27) also described as the Selenium Management environmental commitment (see Appendix 3B, *Environmental Commitments, AMMs, and CMs*), this impact is considered less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Relative to Existing Conditions and the No Action Alternative, under Alternative 4, Scenarios H1–H4, sources of trace metals would not be expected to change substantially with exception to sources related to population growth, such as increased municipal wastewater discharges and development contributing to increased urban dry and wet weather runoff. Facility operations could have an effect on these sources if concentrations of dissolved metals were closely correlated to river flow, suggesting that changes in river flow, and the related capacity to dilute these sources, could ultimately have a substantial effect on long-term metals concentrations.

On the Sacramento River, available dissolved trace metals data and river flow at Freeport are poorly associated (Appendix 8N, *Trace Metals*, Figure 1). Similarly, dissolved copper, iron, and manganese concentrations on the San Joaquin River at Vernalis are poorly associated (Appendix 8N, Figure 2). While there is an insufficient number of data for the other trace metals to observe trends at Vernalis, it is reasonable to assume that these metals similarly show poor association to San Joaquin River flow, as shown for the corresponding dissolved metals on the Sacramento River.

Given the poor association of dissolved trace metal concentrations with flow, river flow rate and reservoir storage reductions that would occur under Alternative 4, Scenarios H1–H4, relative to Existing Conditions and the No Action Alternative, would not be expected to result in a substantial adverse change in trace metal concentrations in the reservoirs and rivers upstream of the Delta. As such, the Alternative 4, Scenarios H1–H4, would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to trace metals.

Delta

For metals of primarily aquatic life concern (copper, cadmium, chromium, lead, nickel, silver, and zinc), average and 95th percentile trace metal concentrations of the primary source waters to the Delta are very similar, with difference typically not greater than a factor of 2 to 5 (Appendix 8N, Tables 1–7). For example, average dissolved copper concentrations on the Sacramento River, San Joaquin River, and Bay (Martinez) are 1.7 μg/L, 2.4 μg/L, and 1.7 μg/L, respectively. The 95th percentile dissolved copper concentrations on the Sacramento River, San Joaquin River, and Bay (Martinez) are 3.4 μg/L, 4.5 μg/L, and 2.4 μg/L, respectively. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based without a WER adjustment (Tables 8-51 and 8-52). No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average and 95th percentile source water concentrations for copper, cadmium, chromium, lead, nickel, silver, and zinc do not exceed their respective criteria, more frequent exceedances of criteria in the Delta would not occur under the operational scenario for this alternative.

For metals of primarily human health and drinking water concern (arsenic, iron, manganese), average and 95th percentile concentrations are also very similar (Appendix 8N, *Trace Metals*, Tables 8–10). The arsenic criterion was established to protect human health from the effects of long-term chronic exposure, while secondary maximum contaminant levels for iron and manganese were established as reasonable goals for drinking water quality. The primary source water average concentrations for arsenic, iron, and manganese are below these criteria. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average water concentrations for arsenic, iron, and manganese do not exceed water quality criteria, more frequent exceedances of drinking water criteria in the Delta would not be expected to occur under this alternative.

Relative to Existing Conditions and the No Action Alternative, facilities operation under Alternative 4, Scenarios H1–H4, would result in negligible change in trace metal concentrations throughout the Delta. The operational scenarios of Alternative 4 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the Delta or substantially degrade the quality of water in the Delta, with regard to trace metals.

SWP/CVP Export Service Areas

Alternative 4, Scenarios H1–H4, would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities. As such, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP export service area waters under any operational scenario of Alternative 4, relative to Existing Conditions or the No Action Alternative. As such, Alternative 4, Scenarios H1–H4, would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment in the SWP and CVP Service Area or substantially degrade the quality of these water bodies, with regard to trace metals.

***NEPA Effects*:** In summary, relative to the No Action Alternative, Alternative 4, Scenarios H1–H4, would not cause a substantial increase in long-term average trace metals concentrations within the affected environment, nor would it cause an increased frequency of water quality objective/criteria exceedances within the affected environment. The effect on trace metals is determined not to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2, *Determination of Effects*) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

While greater water demands under the operational scenarios of Alternative 4 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based without a WER adjustment. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under any operational scenario of Alternative 4.

The assessment of Alternative 4, Scenarios H1–H4, effects on trace metals in the SWP/CVP Export Service Areas is based on assessment of changes in trace metal concentrations at Banks and Jones pumping plants. As just discussed regarding similarities in Delta source water trace metal concentrations, no operational scenario of Alternative 4 is expected to result in substantial changes in trace metal concentrations in Delta waters, including Banks and Jones pumping plants, therefore effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

Based on the above, there would be no substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area waters under any operational scenario of Alternative 4 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Implementation of CM2–CM21 present no new sources of trace metals to the affected environment, including areas upstream of the Delta, within the Delta, or in the SWP and CVP service areas. However, CM19, which would fund projects to contribute to reducing pollutant discharges in urban stormwater, would be expected to reduce trace metal loading to surface waters of the affected environment. The remaining conservation measures would not be expected to affect trace metal levels, because they are actions that do not affect the presence of trace metal sources. As they pertain to trace metals, implementation of these conservation measures would not be expected to adversely affect beneficial uses of the affected environment or substantially degrade water quality with respect to trace metals.

In summary, implementation of CM2–CM21 under Alternative 4 relative to Existing Conditions and the No Action Alternative, would have negligible, if any, effect on trace metals concentrations. The effect on trace metals from implementing CM2–CM21 is determined not to be adverse.

CEQA Conclusion: Implementation of CM2–CM21 under Alternative 4 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

TSS concentrations and turbidity levels in rivers upstream of the Delta are affected primarily by: 1) TSS concentrations and turbidity levels of the water released from the upstream reservoirs, 2) erosion occurring within the river channel beds, which is affected by river flow velocity and bank protection, 3) TSS concentrations and turbidity levels of tributary inflows, point-source inputs, and nonpoint runoff as influenced by surrounding land uses; and 4) phytoplankton, zooplankton and other biological material in the water.

Alternative 4, Scenarios H1–H4, would alter the magnitude and timing of water releases from reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative, which in turn would alter downstream river flows. With respect to TSS and turbidity, an increase in river flow is generally the concern, as this increases shear stress on the channel, suspending particles resulting in higher TSS concentrations and turbidity levels. Schoellhamer et al. (2007b) noted that suspended sediment concentration was more affected by season than flow, with the higher concentrations for a given flow rate occurring during "first flush events" and lower concentrations occurring during spring snowmelt events. Because of such a relationship, the changes in mean monthly average river flows under the operational scenarios of Alternative 4 are not expected to cause river TSS concentrations or turbidity levels (highs, lows, typical conditions) to be outside the ranges occurring under Existing Conditions or the No Action Alternative. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta.

Changes in land use that would occur relative to Existing Conditions and the No Action Alternative could have minor effects on TSS concentrations and turbidity levels throughout this portion of the affected environment. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes. These localized actions would generally require agency permits that would regulate and limit both their short-term and long-term effects on TSS concentrations and turbidity levels to less-than-substantial levels.

Delta

TSS concentrations and turbidity levels in Delta waters are affected by TSS concentrations and turbidity levels of the Delta inflows (and associated sediment load). TSS concentrations and turbidity levels within Delta waters also are affected by fluctuation in flows within the channels due to the tides, with sediments depositing as flow velocities and turbulence are low at periods of slack tide, and sediments becoming suspended when flow velocities and turbulence increase when tides are near the maximum. TSS and turbidity variations can also be attributed to phytoplankton, zooplankton and other biological material in the water.

Under Alternative 4, Scenarios H1–H4, any land use changes that may occur under this alternative would not be expected to have permanent, substantial effects on TSS concentrations and turbidity levels of Delta waters, relative to Existing Conditions or the No Action Alternative. Furthermore, this alternative would not cause the TSS concentrations or turbidity levels in the rivers contributing inflows to the Delta to be outside the ranges occurring under Existing Conditions or the No Action Alternative. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the Delta region. As such, any minor TSS and turbidity changes that may occur under Alternative 4, Scenarios H1–H4, would not be of sufficient frequency, magnitude, and geographic extent that would result in adverse effects on beneficial uses in the Delta region, or substantially degrade the quality of these water bodies, with regard to TSS and turbidity.

SWP/CVP Export Service Areas

The operational scenarios of Alternative 4 are expected to have minimal effect on TSS concentrations and turbidity levels in Delta waters, including water exported at the south Delta pumps, relative to Existing Conditions or the No Action Alternative. As such, Alternative 4 is expected to have minimal effect on TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters.

NEPA Effects: The effects on TSS and turbidity from implementing any operational scenario of Alternative 4 is determined to not be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2, *Determination of Effects*) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Changes in river flow rate and reservoir storage that would occur under the operational scenarios of Alternative 4, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes would be site-specific and temporal, which would be regulated to limit both their short-term and long-term effects on TSS and turbidity levels to less than substantial levels.

Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the Delta region, relative to Existing Conditions.

There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under any operational scenario of Alternative 4, relative to Existing Conditions, because as stated above, this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act Section 303(d) listed constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of CM2–CM21

NEPA Effects: Creation of habitat and open water through implementation of CM2–CM11 could affect Delta hydrodynamics and, thus, erosion and deposition potential in certain Delta channels. The magnitude of increases in TSS concentrations and turbidity levels in the affected channels due to higher potential of erosion cannot be readily quantified. The increases in TSS concentrations and turbidity levels in the affected channels could be substantial in localized areas, depending on how rapidly the Delta hydrodynamics are altered and the channels equilibrate with the new tidal flux regime, after implementation of this alternative. However, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years. Within the reconfigured channels there could be localized increases in TSS concentrations and turbidity levels, but within the greater Plan Area it is expected that the TSS concentrations and turbidity levels would not be substantially different from the levels under the No Action Alternative.

CM19, which would fund projects to contribute to reducing pollutant discharges in stormwater, would be expected to reduce TSS and turbidity in urban discharges relative to the No Action Alternative. The remaining conservation measures would not be expected to affect TSS concentrations and turbidity levels, because they are actions that do not affect the presence of TSS and turbidity sources.

The effects on TSS and turbidity from implementing CM2–CM21 is determined to not be adverse.

CEQA Conclusion: It is expected that the TSS concentrations and turbidity levels Upstream of the Delta, in the Plan Area, and the SWP/CVP Export Service Areas due to implementation of CM2–CM21 under Alternative 4 would not be substantially different relative to Existing Conditions, except within localized areas of the Delta modified through creation of habitat and open water. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels Upstream of the Delta, in the greater Plan Area, and in the SWP/CVP Export Service Areas are not expected to be substantially different, long-term water quality degradation is not expected relative to TSS and turbidity, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act Section 303(d) listed constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

This section addresses construction-related water quality effects to constituents of concern other than effects caused by changes in the operations and maintenance of CM1–CM21, which are addressed in terms of constituent-specific impact assessments elsewhere in this chapter. The conveyance features for CM1 under Alternative 4 would be very similar to those discussed for Alternative 1A and most of the construction activity would occur in the Delta. The primary difference between Alternative 4 and Alternative 1A is that under Alternative 4, there would be two fewer intakes and two fewer pumping plant locations, which would result in a reduced level of construction activity. However, construction techniques and locations of major features of the conveyance system within the Delta would be similar. Alternative 4 additionally would include construction of an operable barrier at the head of Old River. The remainder of the facilities constructed under Alternative 4, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A. Few, if any, of the CM1–CM21 actions involve construction work in the SWP and CVP Service Area or areas upstream of the Delta. The conservation measures, or components of measures, that are anticipated to be constructed in areas upstream of the Delta would be limited to: 1) *CM2 Yolo Bypass Fisheries Enhancement* (i.e., the Fremont Weir component of the action), 2) *CM18 Conservation Hatcheries* (i.e., the new hatchery facility), and 3) *CM19 Urban Stormwater Treatment*. Anticipated construction activities that may occur under CM11–CM21, if any, would involve relatively minor disturbances, and thus would not be anticipated to result in substantial discharges of any constituents of concern.

Within the Delta, the construction-related activities for Alternative 4 would be most extensive for CM1 involving the new water conveyance facilities. Construction of water conveyance facilities would involve vegetation removal, material storage and handling, excavation, overexcavation for facility foundations, surface grading, trenching, road construction, levee construction, construction site dewatering, soil stockpiling, RTM dewatering basin construction and storage operations, and other general facility construction activities (i.e., concrete, steel, carpentry, and other building trades) over approximately 7,500 acres during the course of constructing the facilities. Vegetation would be removed (via grubbing and clearing) and grading and other earthwork would be conducted at the intakes, pumping plants, the intermediate forebay, the expanded Clifton Court Forebay, culvert siphon between the northern cell of the expanded Clifton Court Forebay to a new canal to the Jones Pumping Plant and a siphon under the Byron Highway into a short segment of canal leading to the Banks Pumping Plant, borrow areas, RTM and spoil storage areas, setback and transition levees, sedimentation basins, solids handling facilities, transition structures, surge shafts and towers, substations, transmission line footings, access roads, concrete batch plants, fuel stations, bridge abutments, barge unloading facilities, and laydown areas. Construction of each intake would take nearly 4 years to complete.

Construction activities necessary to develop the new habitat restoration areas for CM2 and CM4–CM10 including restored tidal wetlands, floodplain, and related channel margin and off-channel habitats, would likely involve a variety of extensive conventional clearing and grading activities on relatively dry sites of the Delta that are currently separated from the Delta channels by levees. Construction would involve new setback levees, excavation and soil placement for new wetland and other habitat feature development, and a variety of potential in-water construction activities such as excavation, sediment dredging, levee breaching, and hauling and placement or disposal of excavated sediment or dredge material. Construction activities for the proposed restoration sites, due to the direct connectivity with Delta channels, have the potential to result in direct discharge of eroded soil and construction-related contaminants, or indirectly through erosion and site inundation during the weeks or months following construction prior to stabilization of newly contoured and restored landforms and colonization by vegetation.

***NEPA Effects*:** The types and magnitude of potential construction-related water quality effects associated with implementation of CM1–CM21 under Alternative 4 would be very similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. Potential construction-related water quality effects may include discharges of turbidity/TSS due to the erosion of disturbed soils and associated sedimentation entering surface water bodies or other construction-related wastes (e.g., concrete, asphalt, cleaning agents, paint, and trash). Construction activities also may result in temporary or permanent changes in stormwater generation or drainage and runoff patterns (i.e., velocity, volume, and direction) that may cause or contribute to soil erosion and offsite sedimentation, such as creation of additional impervious surfaces (e.g., pavement, buildings, compacted soils), blockage or restriction of existing drainage channels, or general surface drainage changes from grading and excavation activity. Additionally, the use of heavy earthmoving equipment may result in spills and leakage of oils, gasoline, diesel fuel, and related petroleum contaminants used in the fueling and operation of such construction equipment.

Land surface grading and excavation activities, or exposure of disturbed sites immediately following construction and prior to stabilization, could result in rainfall- and stormwater-related soil erosion, runoff, and offsite sedimentation in surface water bodies. The initial runoff following construction, or return of seasonal rains to previously disturbed sites, can result in runoff with peak pollutant levels and is referred to as “first flush” storm events. Soil erosion and runoff can also result in increased concentrations and loading of organic matter, nutrients (nitrogen and phosphorus), and other contaminants contained in the soil such as trace metals, pesticides, or animal-related pathogens. Graded and exposed soils also can be compacted by heavy machinery, resulting in reduced infiltration of rainfall and runoff, thus increasing the rate of runoff (and hence contaminants) to downstream water bodies.

Construction activities also would be anticipated to involve the transport, handling, and use of a variety of hazardous substances and non-hazardous materials that may adversely affect water quality if discharged inadvertently to construction sites or directly to water bodies. Typical construction-related contaminants include petroleum products for refueling and maintenance of machinery (e.g., fuel, oils, solvents), concrete, paints and other coatings, cleaning agents, debris and trash, and human wastes. Construction activities also would involve large material storage and laydown areas, and occasional accidental spills of hazardous materials stored and used for construction may occur. Contaminants released or spilled on bare soil also may result in groundwater contamination. Dewatering operations may contain elevated levels of suspended sediment or other constituents that may cause water quality degradation.

The intensity of construction activity along with the fate and transport characteristics of the chemicals used, would largely determine the magnitude, duration, and frequency of construction-related discharges and resulting concentrations and degradation associated with the specific constituents of concern. The potential water quality concerns associated with the major categories of contaminants that might be discharged as a result of construction activity include the following.

- Suspended sediment: May increase turbidity (i.e., reduce water clarity) that can affect aquatic organisms and increase the costs and effort of removal in municipal/industrial water supplies. Downstream sedimentation can affect aquatic habitat, or cause a nuisance if it affects functions of agricultural or municipal intakes, or boat navigation.

- Organic matter: May contribute turbidity and oxygen demanding substances (i.e., reduce DO levels) that can affect aquatic organisms. Organic carbon may increase the potential for disinfection byproduct formation in municipal drinking water supplies.

- Nutrients: May contribute nitrogen, phosphorus, and other key nutrients that can contribute to nuisance biostimulation of algae and vascular aquatic plants, which may affect municipal water supplies, recreation, aquatic life, and aesthetics.

- Petroleum hydrocarbons: May contribute toxic compounds to aquatic life, and oily sheens may reduce oxygen/gas transfer in water, foul aquatic habitats, and reduce water quality for municipal supplies, recreation, and aesthetics.

- Trace constituents (metals, pesticides, synthetic organic compounds): Compounds in eroded soil or construction-related materials (e.g., paints, coatings, cleaning agents) may be toxic to aquatic life.
- Pathogens: Bacteria, viruses, and protozoans may affect aquatic life and increase human health risks via municipal water supplies, reduced recreational water quality, or contaminated shellfish beds.
- Other inorganic compounds: Construction-related materials can contain inorganic compounds such as acidic/basic materials which can change pH and may adversely affect aquatic life and habitats. Concrete contains lime which can increase pH levels, and drilling fluids may alter pH.

Some construction-related contaminants, such as PAHs that may be in some fuel and oil petroleum byproducts, may be bioaccumulative in aquatic and terrestrial organisms. Construction activities also may disturb areas where bioaccumulative constituents are present in the soil (e.g., mercury, selenium, organochlorine pesticides, PCBs, and dioxin/furan compounds), or may disturb soils that contain constituents included on the Section 303(d) lists of impaired water bodies in the affected environment. While the 303(d)-listed Delta channels impaired by mercury are widespread, impairment by selenium, pesticides, PCBs, and dioxin/furan compounds is more limited, and there are no 303(d) listings for PAH impairment. Bioaccumulation of constituents in the aquatic foodchain, and 303(d)-related impaired water bodies, arise as a result of long-term loading of a constituent or a pervasive and widespread source of constituent discharge (e.g., mercury). However, as a result of the generally localized disturbances, and intermittent and temporary nature of construction-related activities, construction would not be anticipated to result in contaminant discharges of substantial magnitude or duration to contribute to long-term bioaccumulation processes, or cause measureable long-term degradation such that existing 303(d) impairments would be made discernibly worse or TMDL actions to reduce loading would be adversely affected.

The environmental commitments for construction-related water quality protection would be specifically designed as a part of the final design, included in construction contracts as a required element, and would be implemented for Alternative 4 to avoid, prevent, and minimize the potential discharges of constituents of concern to water bodies and associated adverse water quality effects and comply with state water quality regulations. Additionally, temporary and permanent changes in stormwater drainage and runoff would be minimized and avoided through construction of new or modified drainage facilities, as described in the Chapter 3, *Description of Alternatives*. Alternative 4 would include installation of temporary drainage bypass facilities, long-term cross drainage, and replacement of existing drainage facilities that would be disrupted due to construction of new facilities.

Construction-related activities under Alternative 4 would be conducted in accordance with the environmental commitment to develop and implement BMPs for all activities that may result in discharge of soil, sediment, or other construction-related contaminants to surface water bodies, and obtain authorization for the construction activities under the State Water Board's NPDES Stormwater General Permit for Stormwater Discharges Associated with Construction and Land Disturbance Activities (Order No. 2009-0009-DWQ/NPDES Permit No. CAS000002). The General Construction NPDES Permit requires the preparation and implementation of SWPPPs, which are the principal plans within the required PRDs that identify the proposed erosion control and pollution prevention BMPs that would be used to avoid and minimize construction-related erosion and contaminant discharges. The development of the SWPPPs, and applicability of other provisions of this General Construction Permit depends on the "risk" classification for the construction which is determined based on the potential for erosion to occur as well as the susceptibility of the receiving water to potential adverse effects of construction. While the determination of project risk level, and planning and development of the SWPPPs and BMPs to be implemented, would be completed as a part of final design and contracting for the work, the responsibility for compliance with the provisions of the General Construction Permit necessitates that BMPs are applied to all disturbance activities. In addition to the BMPs, the SWPPPs would include BMP inspection and monitoring activities, and identify responsibilities of all parties, contingency measures, agency contacts, and training requirements and documentation for those personnel responsible for installation, inspection, maintenance, and repair of BMPs. The General Construction Permit contains NALs and for pH and turbidity, and specifies storm event water quality monitoring to determine if construction is resulting in elevated discharges of these constituents, and monitoring for any non-visible contaminants determined to have been potentially released. If an NAL is determined to have been exceeded, the General Construction Permit requires the discharger to conduct a construction site and run-on evaluation to determine whether contaminant sources associated with the site's construction activity may have caused or contributed to the exceedance and immediately implement corrective actions if they are needed.

The BMPs that are routinely implemented in the construction industry and have proven successful at reducing adverse water quality effects include, but are not limited to, the following broad categories of actions (letters refer to categories of specific BMPs identified in Appendix 3B, *Environmental Commitments, AMMs, and CMs*), for which Appendix 3B identifies specific BMPs within these categories:

- Waste Management and Spill Prevention and Response (BMP categories A.2 and A.3): Waste management BMPs are designed to minimize exposure of waste materials at all construction sites and staging areas such as waste collection and disposal practices, containment and protection of wastes from wind and rain, and equipment cleaning measures. Spill prevention and response BMPs involve planning, equipment, and training for personnel for emergency event response.

- Erosion and Sedimentation Control (BMP categories A.4 and A.5): Erosion control BMPs are designed to prevent erosion processes or events including scheduling work to avoid rain events, stabilizing exposed soils; minimize offsite sediment runoff; remove sediment from onsite runoff before it leaves the site; and slow runoff rates across construction sites. Identification of appropriate temporary and long-term seeding, mulching, and other erosion control measures as necessary. Sedimentation BMPs are designed to minimize offsite sediment runoff once erosion has occurred involving drainage controls, perimeter controls, detention/sedimentation basins, or other containment features.

- Good Housekeeping and Non-Stormwater Discharge Management (BMP category A.6 and A.7): Good housekeeping BMPs are designed to reduce exposure of construction sites and materials storage to stormwater runoff including truck tire tracking control facilities; equipment washing; litter and construction debris; and designated refueling and equipment inspection/maintenance practices Non-stormwater discharge management BMPs involve runoff measures for contaminants not directly associated with rain or wind including vehicle washing and street cleaning operations.

- Construction Site Dewatering and Pipeline Testing (BMP category A.8). Dewatering BMPs involve actions to prevent discharge of contaminants present in dewatering of groundwater during construction, discharges of water from testing of pipelines or other facilities, or the indirect erosion that may be caused by dewatering discharges.
- BMP Inspection and Monitoring (BMP category A.9): Identification of clear objectives for evaluating compliance with SWPPP provisions, and specific BMP inspection and monitoring procedures, environmental awareness training, contractor and agency roles and responsibilities, reporting procedures, and communication protocols.

In addition to the Category "A" BMPs for surface land disturbances identified in the environmental commitments (Appendix 3B, *Environmental Commitments, AMMs, and CMs*), BMPs implemented for Alternative 4 also would include the Category "B" BMPs for tunnel/pipeline construction that involves actions primarily to avoid and minimize sediment and contaminant discharges associated with RTM excavation, hauling, and RTM dewatering operations. Additionally, habitat restoration activities under CM2 and CM4–CM10 would be subject to implementation of the Category "C" BMPs (In-Water Construction BMPs) and Category "D" BMPs (Tidal and Wetland Restoration) designed to minimize disturbance and direct discharge of turbidity/suspended solids to the water during in-water construction activities. Category "E" BMPs identify general permanent post-construction actions that would be implemented for all terrestrial, in-water, and habitat restoration activities and would involve planning, design, and development of final site stabilization, revegetation, and drainage control features.

Finally, acquisition of applicable environmental permits may be required for specific conservation measures, which as described for the No Action Alternative, may include specific WDRs or CWA Section 401 water quality certifications from the appropriate Regional Water Boards, CDFW Streambed Alteration Agreements, and USACE CWA Section 404 dredge and fill permits. These other permit processes may include requirements to implement additional action-specific BMPs that may reduce potential adverse discharge effects of constituents of concern.

The potential construction-related contaminant discharges that could result from projects defined under Alternative 4 would not be anticipated to result in adverse water quality effects at a magnitude, frequency, or regional extent that would cause substantial adverse effects to aquatic life. Relative to Existing Conditions, this assessment indicates the following.

- Projects would be managed under state water quality regulations and project-defined actions to avoid and minimize contaminant discharges.
- Individual projects would generally be dispersed, and involve infrequent and temporary activities, thus not likely resulting in substantial exceedances of water quality standards or long-term degradation.
- Potential construction-related contaminant discharges under the Alternative 4 would not cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Long-term water quality degradation is not anticipated, and hence would not be expected to adversely affect beneficial uses.
- By the intermittent and temporary frequency of construction-related activities and potential contaminant discharges, the constituent-specific effects would not be of substantial magnitude or duration to contribute to long-term bioaccumulation processes, or cause measureable long-

term degradation such that existing 303(d) impairments would be made discernibly worse or TMDL actions to reduce loading would be adversely affected.

Consequently, because the construction-related activities for the conservation measures would be conducted with implementation of environmental commitments, including but not limited to those identified in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, with respect to the Existing Conditions and No Action Alternative conditions, Alternative 4 would not be expected to cause constituent discharges of sufficient frequency and magnitude to result in a substantial increase of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern, and thus would not adversely affect any beneficial uses in the Delta.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

***CEQA Conclusion*:** Because environmental commitments would be implemented under Alternative 4 for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32: Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Impacts from *Microcystis* upstream of the Delta have only been documented in lakes such as Clear Lake, where eutrophic levels of nutrients give cyanobacteria a competitive advantage over other phytoplankton during the bloom season. Large reservoirs upstream of the Delta are typically characterized by low nutrient concentrations, where other phytoplankton outcompete cyanobacteria, including *Microcystis*. In the rivers and streams of the Sacramento River watershed, watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), and the San Joaquin River upstream of the Delta, under Existing Conditions and the No Action Alternative, bloom development is limited by high water velocity and low residence times. These conditions are not expected to change under the four operational scenarios of Alternative 4. Consequently, any modified reservoir operations under any of the four operational scenarios of Alternative 4 are not expected to promote *Microcystis* production upstream of the Delta, relative to Existing Conditions and the No Action Alternative.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics. To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related changes of water residence times and its effects on *Microcystis* production (i.e., CM1). Other effects of CM2 through CM21 not attributable to hydrodynamics are discussed within the impact header for CM2 through CM21.

Table 8-60a shows modeled long-term average residence times in the six Delta sub-regions during the *Microcystis* summer and fall bloom periods for Existing Conditions, No Action Alternative, and Operational Scenario H3 of Alternative 4. Modeled average residence times for Operational Scenarios H1, H2, and H4 of Alternative 4 are not available. However, during the summer and fall period, the operations and maintenance of Operational Scenarios H3 and H4 are identical, and operations and maintenance of Operational Scenarios H1 and H2 during the summer and fall periods are identical to those of Alternative 3. Thus, the assessment of effects of water residence times on *Microcystis* during the summer and fall bloom periods under Operational Scenarios H1 and H2 of Alternative 4 are based on the assumption that the changes in modeled residence times that would occur under these two operational scenarios would be equivalent to those that would occur under Alternative 3, as shown in Table 8-60a. Likewise, the assessment of effects of water residence times which would occur under Operational Scenario H4 assumes that the changes in modeled residence times that would occur under Operational Scenario H4 would be equivalent to those that would occur under Operational Scenario H3, as shown in Table 8-60a.

Under the four operational scenarios of Alternative 4, modeled long-term average residence times in the six Delta sub-regions during the *Microcystis* bloom season of June through October show varying levels of change, depending on sub-region and timeframe (Table 8-60a). Although an increase in residence time throughout the Delta is expected under the No Action Alternative, relative to Existing Conditions, because of climate change and sea level rise, the change is fairly small in most areas of the Delta. Below, residence times under Alternative 4 is compared to residence times under the No Action Alternative to remove the effect of climate change and sea level rise, thereby revealing the effect due to CM1 (i.e., operations) and the effect of the CM2 and CM4 restoration areas, which were accounted for in the modeling performed for CM1.

For Operational Scenarios H1 and H2 of Alternative 4 (as shown for Alternative 3 in Table 8-60a), relative to the No Action Alternative, water residence time is expected to increase 3–10 days in the North Delta (summer and fall); increase 24 days in the summer and decrease 3 days in the fall in the Cache Slough sub-region; increase 6 days in the West Delta (both summer and fall); increase 8 days in the summer and decrease 3 days in the fall in the East Delta; increase 4 days in the summer and decrease 3 days in the fall in the South Delta; and decrease 22 days in the summer and increase 20 days in the fall in the Suisun Marsh sub-region.

For Operational Scenarios H3 and H4 of Alternative 4 (as shown for Alternative 4 in Table 8-60a), relative to the No Action Alternative, water residence time is expected to increase 1–7 days in the North Delta (summer and fall); increase 18 days in the summer and decrease 6 days in the fall in the Cache Slough sub-region; increase 3–4 days in the West Delta (both summer and fall); increase 8–13 days in the East Delta (summer and fall); increase 6 days in the summer and 32 days in the fall in the South Delta; and decrease 23 days in the summer and increase 15 days in the fall in the Suisun Marsh sub-region.

The summer and fall period average residence times provide a general direction in which residence time may change under the four operational scenarios of Alternative 4 compared to the No Action Alternative. The changes in residence time are driven by a number of factors accounted for in the modeling, including the hydrodynamic effects of restoration actions planned under CM2 and CM4, diversion of Sacramento River water at the proposed north Delta intake facility, as well as changes in net Delta outflows. Variability in local residence times is expected within any Delta sub-region because major portions of the Delta are comprised of complex networks of intertwining channels, shallow back water areas, and submerged islands. Siting and design of restoration areas has substantial influence on the magnitude of residence time increases that would occur under Alternative 4. However, the expected residence time increases that would occur during the summer bloom period at various Delta locations under the four operational scenarios of Alternative 4, compared to the No Action Alternative, are in a direction and of magnitude that could lead to an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms throughout the Delta.

The relationship between Delta water temperatures, climate change, and changes in water deliveries from upstream reservoirs are discussed in Appendix 29C, *Climate Change and the Effects of Reservoir Operations on Water Temperatures in the Study Area*. In short, ambient meteorological conditions are the primary driver of Delta water temperatures, meaning that climate warming and not water operations will determine future water temperatures in the Delta. Climate projections for the Central Valley discussed in Appendix 5A, Section D, indicate substantial warming of ambient air temperatures with a median increase in annual temperature of about 1.1°C (2.0°F) by 2025 and 2.2°C (4.0°F) by 2060. The projected water temperature change ranges from 0.7 to 1.4°C (1.3 to 2.5°F) by 2025 and 1.6 to 2.7°C (2.9-4.9°F) by 2060. Increasing water temperatures could lead to earlier attainment of the water temperature threshold of 19°C required to initiate *Microcystis* bloom formation, and thus earlier occurrences of *Microcystis* blooms in the Delta, relative to Existing Conditions. Warmer water temperatures could also increase bloom duration and magnitude, relative to Existing Conditions. Elevated ambient water temperatures in the Delta, and thus an increase in *Microcystis* bloom duration and magnitude, are expected under Operational Scenarios H1–H4 of Alternative 4, relative to Existing Conditions, but these impacts are due entirely to climate change and not the project alternative. Because climate change is assumed under the No Action Alternative, potential water temperature-driven increases in *Microcystis* blooms in the Delta, relative to Existing Conditions, also would occur under the No Action Alternative. Therefore, no water temperature-driven increases in *Microcystis* blooms would occur in the Delta under Alternative 4, relative to the No Action Alternative.

SWP/CVP Export Service Areas

The assessment of effects from *Microcystis* in the SWP/CVP Export Service Areas is based on the assessment of *Microcystis* production in source waters to Banks and Jones Pumping plants, and upon the effects of residence time and water temperature on the potential for *Microcystis* blooms to occur in the Export Service Area.

Under Operational Scenarios H1–H4 of Alternative 4, exports from Banks and Jones pumping plants will consist of a mixture of Sacramento River water diverted around the Delta, with water quality characteristic of both upstream Sacramento River water, and Sacramento and San Joaquin River water that has flowed through various portions of the North, South, and West Delta. Water diverted from the Sacramento River in the North Delta is expected to be unaffected by *Microcystis* and microcystins. However, the fraction of water flowing through the Delta that reaches the existing south Delta intakes is expected to be influenced by an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms discussed in the *Delta* section above. Therefore, relative to Existing Conditions and the No Action Alternative, the addition of Sacramento River water from the North Delta under Alternative 4 serves to dilute *Microcystis* and microcystins in water diverted from the South Delta with water that is not expected to contain them. Because the degree to which *Microcystis* blooms, and thus microcystins concentrations, will increase in source water from the South Delta is unknown, it cannot be determined whether Alternative 4 will result in increased or decreased levels of microcystins in the mixture of source waters exported from Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative.

Microcystis blooms have not occurred in the Export Service Areas even though source waters to the SWP and CVP have been affected. Conditions in the Export Service Areas under the four operational scenarios of Alternative 4 may become more conducive to *Microcystis* bloom formation, relative to Existing Conditions, because water temperatures will increase in the Export Service Areas due to the expected increase in ambient air temperatures resulting from climate change. Residence times in this area are not expected to substantially change under the four operational scenarios of Alternative 4, relative to Existing Conditions. Conditions in the Export Service Areas under the four operational scenarios of Alternative 4 are not expected to become more conducive to *Microcystis* bloom formation, relative to the No Action Alternative, because neither water residence time nor water temperatures will increase in the Export Service Areas.

NEPA Effects: In summary, operations and maintenance under the four operational scenarios of Alternative 4, relative to the No Action Alternative, would result in long-term increases in hydraulic residence time of various Delta sub-regions during the summer and fall *Microcystis* bloom period. During this period, the increased residence time could result in a concurrent increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus microcystin levels, in affected areas of the Delta. As a result, Alternative 4 operation and maintenance activities would cause further degradation to water quality with respect to *Microcystis* in the Delta. Under the four operational scenarios of Alternative 4, relative to No Action Alternative, water exported to the SWP/CVP Export Service Area will be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River, diverted at the north Delta intakes. It cannot be determined whether operations and maintenance under Alternative 4 will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants. Mitigation Measure WQ-32a and WQ-32b are available to reduce the effects of degraded water quality in the Delta. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2, *Determination of Effects*) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under the various operational scenarios of Alternative 4 additional impacts from *Microcystis* in the reservoirs and watersheds upstream of the Delta are not expected, relative to Existing Conditions. Operations and maintenance occurring under any of the operational scenarios of Alternative 4 is not expected to change nutrient levels in upstream reservoirs or hydrodynamic conditions in upstream rivers and streams such that conditions would be more conductive to *Microcystis* production.

Relative to Existing Conditions, water temperatures and hydraulic residence times in the Delta are expected to increase under all operational scenarios of Alternative 4, resulting in an increase in the frequency, magnitude and geographic extent of *Microcystis* blooms in the Delta. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. Increases in Delta residence times are expected throughout the Delta during the summer and fall bloom period, due in small part to climate change and sea level rise, but due more proportionately to CM1 and the hydrodynamic impacts of restoration included in CM2 and CM4. The precise change in local residence times and *Microcystis* production expected within any Delta sub-region is unknown because conditions will vary across the complex networks of intertwining channels, shallow back water areas, and submerged islands that compose the Delta. Nonetheless, residence times are, in general, expected to increase during the *Microcystis* bloom period at various Delta locations under all operational scenarios of Alternative 4. Consequently, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance under the four operational scenarios of Alternative 4 and the hydrodynamic impacts of restoration (CM2 and CM4).

The assessment of effects of *Microcystis* on SWP/CVP Export Service Areas is based on the assessment of changes in *Microcystis* levels in export source waters, as well as the effects of temperature and residence time changes within the Export Service Areas on *Microcystis* production. Under the various operational scenarios of Alternative 4, relative to Existing Conditions, the potential for *Microcystis* to occur in the Export Service Area is expected to increase due to increasing water temperature, but this impact is driven entirely by climate change and not Alternative 4. Water exported from the Delta to the Export Service Area is expected to be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River. Because of this, it cannot be determined whether operations and maintenance under the four operational scenarios of Alternative 4, relative to existing conditions, will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants.

Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, because it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of the four operational scenarios of Alternative 4 and the hydrodynamic impacts of restoration (CM2 and CM4), long-term water quality degradation may occur and, thus, significant impacts on beneficial uses could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be significant.

Implementation of Mitigation Measure WQ-32a and WQ-32b may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of these mitigation measures to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

It remains to be determined whether, or to what degree, *Microcystis* production will increase in Delta areas as a result of increased residence times associated with the implementation of the four operational scenarios of the project alternative. Mitigation actions shall be focused on those incremental effects attributable to implementation of operations under the project alternative only. Development of mitigation actions for the incremental increase in *Microcystis* effects attributable to water temperature and residence time increases driven by climate change and sea level rise is not required because these changed conditions would occur with or without implementation of the project alternative. The goal of specific actions would be to reduce/avoid additional degradation of Delta water quality conditions with respect to occurrences of *Microcystis* blooms.

Additional evaluation will be conducted as part of the development of tidal habitat restoration areas to determine the feasibility of using site placement and design criteria to reduce or eliminate local conditions conducive to *Microcystis* production. Design criteria would be developed to provide guidelines for developing restoration areas to discourage *Microcystis* growth by maintaining adequate flushing, while maintaining the benefits of habitat restoration in terms of zooplankton production, fish food quality, and fish feeding success. For example, a target range of typical summer/fall hydraulic residence time that is long enough to promote phytoplankton growth, but not so long as to promote growth of *Microcystis*, could be used to aid restoration site design. However, currently there is not sufficient scientific certainty to evaluate whether or not longer residence times would result in greater *Microcystis* production, and also whether longer residence times might produce greater benefits to fish and other aquatic life than shorter residence times. This mitigation measure requires that residence time considerations be incorporated into restoration area site design for CM2 and CM4 using best available science at the time of design. It is possible that through these efforts, increases in *Microcystis* attributable to the project alternative, relative to Existing Conditions, could be mitigated. However, there may be instances where this design consideration may not be feasible, and thus, achieving *Microcystis* reduction pursuant to this mitigation measure would not be feasible.

Mitigation Measure WQ-32b: Investigate and Implement Operational Measures to Manage Water Residence Time

Because it is not known where, when, and to what extent *Microcystis* will be more abundant under CM1 than under Existing Conditions, specific mitigation measures cannot be described. However, this mitigation measure requires the project proponents to monitor for *Microcystis* abundance in the Delta and use appropriate statistical methods to determine whether increases in abundance are significant. This mitigation measure also requires that if *Microcystis* abundance increases, relative to Existing Conditions, the project proponents will investigate and evaluate measures that could be taken to reduce residence time in the affected areas of the Delta. Operational actions could include timing of temporary or operable barrier openings and closings, reservoir releases, and location of Delta exports (i.e., North Delta vs. South Delta pumping facilities). Depending on the location and severity of the increases, one or more of these actions may be feasible for reducing residence times. If so, these actions could mitigate increases in *Microcystis* under CM1 attributable to the project alternative, relative to Existing Conditions. However, it is possible that these actions would not be feasible because they would conflict with other project commitments, would cause their own environmental impacts, or would not be expected to reduce or mitigate increases in *Microcystis*. In this case, achieving *Microcystis* reduction pursuant to this mitigation measure would not be feasible.

Impact WQ-33: Effects on *Microcystis* Bloom Formation Resulting from Other Conservation Measures (CM2–CM21)

Implementation of CM3 and CM6–CM21 is unlikely to affect *Microcystis* abundance in the rivers and reservoirs upstream of the Delta, in the Delta region, or the waters exported to the CVP and SWP service areas. Implementation of CM5, Seasonally Inundated Floodplain Restoration, could result in increased local water temperatures in areas near restored seasonally inundated floodplains. However, floodplain inundation typically occurs during spring and winter months when *Microcystis* growth is limited in general by low water temperatures and by insufficient surface water irradiance, and water temperatures would not increase sufficiently due to floodplain inundation such that effects on *Microcystis* growth would occur. Therefore, implementation of CM5 is unlikely to affect *Microcystis* blooms in the project area. Implementation of CM13, Invasive Aquatic Vegetation Control, may increase turbidity and flow velocity, particularly in restored aquatic habitats, which could discourage *Microcystis* growth in these areas. To the extent that IAV removal would affect turbidity and water velocity, it is possible that IAV removal could, to some degree, help offset the increase in *Microcystis* production expected under Alternative 4, relative to the No Action Alternative.

As discussed in detail in Impact WQ-32, development of restoration areas which will occur under CM2 and CM4 could possibly increase the frequency, magnitude, and geographic extent of *Microcystis* blooms due to the hydrodynamic impacts that are expected to increase water residence times throughout various areas of the Delta relative to Existing Conditions and the No Action Alternative. Additionally, restoration activities that create shallow backwater areas, due to implementation of CM2 and CM4, could result in local warmer water that may encourage *Microcystis* growth during the summer bloom forming season and result in further degradation of water quality. Mitigation to specifically address the effects of local increases in water temperatures on *Microcystis* in the vicinity of such restoration areas is not available. Regardless of elevated water temperatures, sufficient residence time is required for *Microcystis* bloom formation. Thus, the combined effect on *Microcystis* from increased local water temperatures and increased water residence times may be reduced by implementation of Mitigation Measure WQ-32a. The effectiveness of these mitigation measures to result in feasible measures for reducing water quality effects is uncertain.

NEPA Effects: Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM2–CM21 are determined to be adverse.

CEQA Conclusions: Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Because restoration actions implemented under CM2 and CM4 will increase residence time throughout the Delta and create local areas of warmer water during the bloom season, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus long-term water quality degradation and significant impacts on beneficial uses, could occur. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM2–CM21 are determined to be significant.

Implementation of Mitigation Measure WQ-32a may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 4.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance (CM1) and Implementation of CM2–CM21

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 4 would have a less than significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- DO
- Pathogens
- Pesticides
- Trace Metals
- Turbidity and TSS

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Thus, changes in boron, DO, pathogens, pesticides, and turbidity and TSS in Delta outflow are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay.

The effects of Alternative 4 on bromide, chloride, and DOC, in the Delta were determined to be significant/adverse. Increases in bromide, chloride, and DOC concentrations are of concern in drinking water supplies; however, as described previously, the San Francisco Bay does not have a designated MUN use. Thus, changes in bromide, chloride, and DOC in Delta outflow would not adversely affect any beneficial uses of San Francisco Bay.

The effects of Alternative 4 on EC in the Delta were determined to be significant/adverse. Elevated EC, as assessed for this alternative, is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. As discussed above, San Francisco Bay does not have an AGR beneficial use designation. However, potential effects on bay salinity are discussed further below, with consideration to effects on fish and wildlife beneficial uses.

While effects of Alternative 4 on the nutrients ammonia, nitrate, and phosphorus were determined to be less than significant/not adverse, these constituents are addressed further below because the response of the seaward bays to changed nutrient concentrations/loading may differ from the response of the Delta. Because the potential change in *Microcystis* levels were found to be significant in the Delta, potential effects on *Microcystis* levels and microcystin concentrations in San Francisco Bay are discussed. Selenium and mercury are discussed further, because they are bioaccumulative constituents where changes in load due to both changes in Delta concentrations and exports are of concern.

Nutrients: Ammonia, Nitrate, and Phosphorus

Total nitrogen loads in Delta outflow to Suisun and San Pablo Bays under Alternative 4 would be dominated almost entirely by nitrate, because planned upgrades to the SRWTP will result in >95% removal of ammonia in its effluent. Total nitrogen loads to Suisun and San Pablo Bays would decrease by 24–28%, relative to Existing Conditions, and increase by 5–12%, relative to the No Action Alternative, depending on operations scenario (Appendix 8O, *San Francisco Bay Analysis*, Table O-1). The change in nitrogen loading to Suisun and San Pablo Bays under Alternative 4 would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. To the extent that algal growth increases in relation to a change in ammonia concentration, this would have net positive benefits, because current algal levels in these embayments are low. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay.

The phosphorus load exported from the Delta to Suisun and San Pablo Bays for Alternative 4 is estimated to increase by -1–+5%, relative to Existing Conditions and increase by 0–6% relative to the No Action Alternative (Appendix 8O, Table O-1). The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. Any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary (Senn and Novick 2014; Kimmerer and Thompson 2014). Therefore, the projected change in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay is not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Mercury

The estimated long-term average mercury and methylmercury loads in Delta exports are shown in Appendix 8O, Table O-2. Loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 4. Mercury load to the Bay is estimated to increase by 1–5 kg/year (<1–2%), relative to Existing Conditions, and to increase by -2–+2kg/year (-1–+1%), relative to the No Action Alternative, depending on operations scenario. Methylmercury load is estimated to increase by 0–0.13 kg/year (0–4%), relative to Existing Conditions, and increase by -0.09–+0.04 kg/year (-2–+1%) relative to the No Action Alternative. The estimated total mercury load to the Bay is 261–265 kg/year, which would be less than the San Francisco Bay mercury TMDL WLA for the Delta of 330 kg/year. The estimated changes in mercury and methylmercury loads would be within the overall uncertainty associated with the estimates of long-term average net Delta outflow and the long-term average mercury and methylmercury concentrations in Delta source waters. The estimated changes in mercury load under the alternative would also be substantially less than the considerable differences among estimates in the current mercury load to San Francisco Bay (San Francisco Bay Regional Water Quality Control Board 2006; David et al. 2009).

Given that the estimated incremental increases of mercury and methylmercury loading to San Francisco Bay would fall within the uncertainty of current mercury and methylmercury load estimates, the estimated changes in mercury and methylmerucy loads in Delta exports to San Francisco Bay due to Alternative 4 are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to mercury, or make the existing CWA Section 303(d) impairment measurably worse.

Salinity

Salinity throughout San Francisco Bay is largely a function of the tides, as well as to some extent the freshwater inflow from upstream. Thus, Delta outflow is the main mechanism by which the alternative could affect salinity in San Francisco Bay. According to the Delta Atlas (California Department of Water Resources 1995), average historical tidal flow through the Golden Gate Bridge is 2,300,000 cfs and average historical tidal flow at Chipps Island is 170,000 cfs. The historical average tidal flows are two to three orders of magnitude larger than the largest mean monthly change in Delta outflow due to the No Action Alternative (shown in Appendix 5A, Section C.7). Thus, the changes in Delta outflow due to Alternative 4 would be minor compared to tidal flows, and thus no substantial adverse effects on salinity, or fish and wildlife beneficial uses, downstream of the Delta are expected.

Selenium

Changes in source water fraction and net Delta outflow under Alternative 4, relative to Existing Conditions, are projected to cause the total selenium load to the North Bay to increase by 6–11%, relative to Existing Conditions, and increase by 2–8%, relative to the No Action Alternative, depending on operations scenario (Appendix 8O, *San Francisco Bay Analysis*, Table O-3). Changes in long-term average selenium concentrations of the North Bay are assumed to be proportional to changes in North Bay selenium loads. Under Alternative 4, the long-term average total selenium concentration of the North Bay is estimated to be 0.013–0.14 μg/L and the dissolved selenium concentration is estimated to be 0.12 μg/L, which would be 0.01 μg/L higher than Existing Conditions and the No Action Alternative (Appendix 8O, Table O-3). The dissolved selenium concentration would be below the target of 0.202 µg/L developed by Presser and Luoma (2013) to coincide with a white sturgeon whole-body fish tissue selenium concentration not greater than 8 mg/kg in the North Bay. The incremental increase in dissolved selenium concentrations in the North Bay, relative to Existing Conditions, would be negligible (0.01 µg/L) under this alternative. Thus, the estimated changes in selenium loads in Delta exports to San Francisco Bay due to Alternative 4 are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to selenium, or make the existing CWA Section 303(d) impairment measurably worse.

Microcystis

Microcystis has not been detected in embayments of the San Francisco Bay downstream of Suisun Bay. Low levels of microcystins occur throughout San Francisco Bay, but their concentrations do not correspond to *Microcystis* abundance, nor is there evidence that they have been transported downstream from *Microcystis* blooms that have occurred in the Delta (Senn and Novick 2013). The low levels of microcystins present in San Francisco Bay are likely derived from cyanobacteria besides *Microcystis*, such as *Cyanobium sp.* and *Synechocystis*, which are currently resident in the San Francisco Bay at levels well below bloom magnitude (Senn and Novick 2013). Elevated microcystin levels could occur at various locations in the Delta during *Microcystis* blooms under Alternative 4, but because of the sufficient dilution available in San Francisco Bay, downstream transport of Delta-derived microcystins are not expected to result in measurable changes in the microcystin levels of San Francisco Bay.

The absence of *Microcystis* in San Francisco Bay is likely directly related to its intolerance of elevated salinity, as its growth ceases and breakdown of its cellular tissues starts at salinities of 10–12.6 ppt (Tonk et al. 2007; Black et al. 2011). San Pablo Bay is the only embayment of San Francisco Bay downstream of Suisun Bay that would experience salinities of this magnitude for any significant duration of the year, although these and lower salinities would only occur under conditions of high Delta outflow. However, high Delta outflows occur during wet years and during the winter and spring runoff season, under which water temperatures are expected to be low, turbidity high, and water residence times low, making the environment of San Pablo Bay unsuitable for *Microcystis* growth. Additionally, these hydrodynamics conditions typically only occur when the potential for *Microcystis* blooms to occur upstream of, and thus potentially seed *Microcystis* to, San Pablo Bay are minimal. Alternative 4 is not expected to result in significant modification to net Delta outflows or the timing of high outflow events related to wet season runoff. Thus, the effects of Alternative 4 on *Microcystis* levels in San Francisco Bay are expected to be negligible.

NEPA Effects: Based on the discussion above, Alternative 4, relative to the No Action Alternative, would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, selenium, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, based on the discussion above, effects on the San Francisco Bay from implementation of CM1–CM21 are considered to be not adverse.

CEQA Conclusion: Based on the above, Alternative 4 would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. Further, based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals or turbidity or TSS are anticipated in the Delta, relative to Existing Conditions, therefore, no substantial changes these constituents' levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow. Adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in the Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus not have not been detected downstream of Suisun Bay. The 24–28% decrease in total nitrogen load and -1–+5% increase in phosphorus load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. The estimated increase in mercury load (1–5 kg/year; <1–2%) and methylmercury load (0.00–0.13 kg/year; 0–4%), relative to Existing Conditions, is within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA Section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. The estimated increase in selenium load would be 6–11%, but estimated total and dissolved selenium concentrations under this alternative would be nearly the same as Existing Conditions, and less than the target associated with white sturgeon whole-body fish tissue levels for the North Bay. Thus, the small increase in selenium load is not expected to contribute to water quality degradation, or make the CWA Section 303(d) selenium impairment measurably worse or cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant.

8.3.3.10 Alternative 5—Dual Conveyance with Pipeline/Tunnel and Intake 1 (3,000 cfs; Operational Scenario C)

Alternative 5 would comprise physical/structural components similar to those under Alternative 1A with the principal exception that Alternative 5 would convey up to 3,000 cfs of water from the north Delta to the south Delta. Diverted water would be conveyed through pipelines/tunnels from a single screened intake (i.e., Intake 1) located on the east bank of the Sacramento River between Clarksburg and Walnut Grove. Alternative 5 would include a 750-acre intermediate forebay and pumping plant. A new 600-acre Byron Tract Forebay, adjacent to and south of Clifton Court Forebay, would be constructed which would provide water to the south Delta pumping plants. Water supply and conveyance operations would follow the guidelines described as Scenario C, which includes Fall X2. CM2–CM21 would be implemented under this alternative, and would be the same as those under Alternative 1A with the exception of CM4, which would involve 25,000 acres of tidal habitat restoration instead of 65,000 acres under the other BDCP alternatives. See Chapter 3, *Description of Alternatives*, Section 3.5.10, for additional details on Alternative 5.

Effects of the Alternative on Delta Hydrodynamics

Under the No Action Alternative and Alternatives 1A–9, the following two primary factors can substantially affect water quality within the Delta:

- Within the south, west, and interior Delta, a decrease in the percentage of Sacramento River-sourced water and a concurrent increase in San Joaquin River-sourced water can increase the concentrations of numerous constituents (e.g., boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides, selenium). This source water replacement is caused by decreased exports of San Joaquin River water (due to increased Sacramento River water exports), or effects of climate change on timing of flows in the rivers. Changes in channel flows also can affect water residence time and many related physical, chemical, and biological variables.
- Particularly in the west Delta, sea water intrusion as a result of sea level rise or decreased Delta outflow can increase the concentration of salts (bromide, chloride) and levels of electrical conductivity. Conversely, increased Delta outflow (e.g., as a result of Fall X2 operations in wet and above normal water years) will decrease levels of these constituents, particularly in the west Delta.

Under Alternative 5, over the long term, average annual delta exports are anticipated to decrease by 358 TAF relative to Existing Conditions, and increase by 346 TAF relative to the No Action Alternative. Because, over the long-term, approximately 25% of the exported water would be from the new north Delta intakes, average monthly diversions at the south Delta intakes would be decreased because of the shift in diversions to the north Delta intakes (see Chapter 5, *Water Supply*, for more information). The result of this would be increased San Joaquin River water influence throughout the south, west, and interior Delta, and a corresponding decrease in Sacramento River water influence. This can be seen, for example, in Appendix 8D, ALT 5–Old River at Rock Slough for ALL years (1976–1991), which shows increased San Joaquin River (SJR) percentage and decreased Sacramento River (SAC) percentage under the alternative, relative to Existing Conditions and the No Action Alternative.

Under Alternative 5, long-term average annual Delta outflow is anticipated to increase 401 TAF relative to Existing Conditions, due to both changes in operations (including north Delta intake capacity of 3,000 cfs and numerous other components of Operational Scenario C) and climate change/sea level rise (see Chapter 5, *Water Supply*, for more information). Long-term average annual Delta outflow is anticipated to decrease under Alternative 5 by 349 TAF relative to the No Action Alternative, due only to changes in operations. The result of this is increased sea water intrusion in the west Delta. The increases in sea water intrusion (represented by an increase in San Francisco Bay (BAY) percentage) can be seen, for example, in Appendix 8D, ALT 5–Sacramento River at Mallard Island for ALL years (1976–1991).

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 5 would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

Assessment of effects of ammonia under Alternative 5 is the same as discussed under Alternative 1A, except that because flows in the Sacramento River at Freeport are different between the two alternatives, estimated monthly average and long term annual average predicted ammonia-N concentrations in the Sacramento River downstream of Freeport are different.

As Table 8-68 shows, estimated ammonia-N concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 5 and the No Action Alternative are expected to be similar. Minor increases in ammonia-N concentrations would occur during January through March, August, September, November, and December, and remaining months would be unchanged or have a minor decrease. A minor increase in the annual average concentration would occur under Alternative 5, compared to the No Action Alternative. Moreover, the estimated concentrations downstream of Freeport under Alternative 5 would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 5, relative to the No Action Alternative, are not expected to substantially increase ammonia concentrations at any Delta locations.

Table 8-68. Estimated Ammonia-N (mg-L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative and Alternative 5

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative	0.074	0.084	0.069	0.060	0.057	0.060	0.058	0.064	0.067	0.060	0.067	0.064	0.065
Alternative 5	0.072	0.088	0.070	0.061	0.058	0.061	0.058	0.064	0.064	0.060	0.070	0.067	0.066

Any negligible increases in ammonia-N concentrations that could occur at certain locations in the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

SWP/CVP Export Service Areas

The assessment of effects on ammonia in the SWP/CVP Export Service Area is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. Similar to the discussion for Alternative 1A, under Alternative 5 for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease, relative to Existing Conditions (in association with less diversion of water influenced by the SRWTP). This decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in adverse effects on beneficial uses or substantially degrade water quality of exported water, with regards to ammonia.

Furthermore, as discussed above for the Plan Area, for all areas of the Delta, including Banks and Jones pumping plants, ammonia-N concentrations are not expected to be substantially different under Alternative 5, relative to No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

NEPA Effects**:** In summary, based on the discussion above, effects on ammonia from implementation of CM1 are considered to be not adverse.

CEQA Conclusion**:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Ammonia-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to the lack of substantial point and nonpoint sources of ammonia-N upstream of the SRWTP in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 5, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river ammonia-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

Ammonia-N concentrations in the Sacramento River downstream of the SRWTP would be substantially lower under Alternative 5, relative to Existing Conditions, due to upgrades to the SRWTP that are assumed to be in place, and thus, ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water are expected to decrease. At locations which are not influenced notably by Sacramento River water, concentrations are expected to remain relatively unchanged, due to the similarity in SJR and BAY concentrations and the lack of expected changes in either of these concentrations.

The assessment of effects on ammonia in the SWP/CVP Export Service Areas is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. As discussed above for the Plan Area, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 5, relative to Existing Conditions.

Based on the above, there would be no substantial, long-term increase in ammonia-N concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 5 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia-N is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on ammonia under Alternative 5 would be the same as those discussed for Alternative 1A and are considered to be not adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on ammonia resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Effects of CM1 on boron under Alternative 5 in areas upstream of the Delta would be very similar to the effects discussed for Alternative 1A. There would be no expected change to the sources of boron in the Sacramento and eastside tributary watersheds, and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled long-term annual average lower San Joaquin

River flow at Vernalis would decrease slightly compared to Existing Conditions (in association with project operations, climate change, and increased water demands) and would be similar compared to the No Action Alternative considering only changes due to Alternative 5 operations. The reduced flow would result in possible increases in long-term average boron concentrations of up to about 3% relative to the Existing Conditions (Appendix 8F, *Boron*, Table Bo-32). The increased boron concentrations would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 5 would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Effects of CM1 on boron under Alternative 5 in the Delta would be similar to the effects discussed for Alternative 1A. Relative to the Existing Conditions and No Action Alternative, Alternative 5 would result in increased long-term average boron concentrations for the 16-year period modeled at interior and western Delta locations (by as much as 7% at the SF Mokelumne River at Staten Island, 2% at the San Joaquin River at Buckley Cove, 8% at Franks Tract, and 7% at Old River at Rock Slough) (Appendix 8F, *Boron*, Table Bo-14). This comparison to Existing Conditions reflects changes due to both Alternative 5 operations (including north Delta intake capacity of 3,000 cfs and numerous other components of Operational Scenario C) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes due only to operations.

Implementation of tidal habitat restoration under CM4 also may contribute to increased boron concentrations at western Delta assessment locations (more discussion of this phenomenon is included in Section 8.3.1.3), and thus would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations. The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 μg/L human health advisory objective (i.e., for children) or 500 μg/L agricultural objective at any of the eleven Delta assessment locations, which represents no change from the Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-3A). Reductions in long-term average assimilative capacity of up to 4% at interior Delta locations (i.e., Franks Tract and Old River at Rock Slough) would be small with respect to the 500 μg/L agricultural objective (Appendix 8F, *Boron*, Table Bo-15). However, because the absolute boron concentrations would still be well below the lowest 500 μg/L objective for the protection of the agricultural beneficial use under Alternative 5, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, Figure Bo-4).

SWP/CVP Export Service Areas

Effects of CM1 on boron under Alternative 5 in the Delta would be similar to the effects discussed for Alternative 1A. Under Alternative 5, long-term average boron concentrations would decrease by as much as 11% at the Banks Pumping Plant and Jones Pumping Plant relative to the Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-14) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading.

Maintenance of SWP and CVP facilities under Alternative 5 would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment. Maintenance activities would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative conditions, Alternative 5 would result in relatively small increases in long-term average boron concentrations in the Delta and not appreciably change boron levels in the lower San Joaquin River. However, the predicted changes would not be expected to cause exceedances of applicable objectives or further measurable water quality degradation, and thus would not constitute an adverse effect on water quality.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Boron is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 5, relative to Existing Conditions, would not be expected to result in a substantial adverse change in boron levels. Additionally, relative to Existing Conditions, Alternative 5 would not result in reductions in river flow rates (i.e., less dilution) or increased boron loading such that there would be any substantial increases in boron concentration upstream of the Delta in the San Joaquin River watershed.

Small increased boron levels predicted for interior and western Delta locations in response (i.e., up to 8% increase) to a shift in the Delta source water percentages and tidal habitat restoration under this alternative would not be expected to cause exceedances of objectives, or substantial degradation of these water bodies. Alternative 5 maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 5 would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to

Existing Conditions, Alternative 5 would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 5 would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on boron under Alternative 5 would be the same as those discussed for Alternative 1A and are determined to be not adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on boron resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 5 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 5 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. Consequently, Alternative 5 would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the eastside tributaries, or their associated reservoirs upstream of the Delta.

Under Alternative 5, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by 6%, relative to Existing Conditions, and would remain virtually the same relative to the No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). These decreases in flow would result in possible increases in long-term average bromide concentrations of about 3%, relative to Existing Conditions and less than <1% relative to the No Action Alternative (Appendix 8E, *Bromide*, Table 24). The small increases in lower San Joaquin River bromide levels that could occur under Alternative 5, relative to existing and the No Action Alternative conditions would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the lower San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to

the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Under Alternative 5, the geographic extent of effects pertaining to long-term average bromide concentrations in the Delta would be similar to that previously described for Alternative 1A, although the magnitude of predicted long-term change and relative frequency of concentration threshold exceedances would be different. Using the mass-balance modeling approach for bromide (see Section 8.3.1.3), relative to Existing Conditions, modeled long-term average bromide concentrations would increase at Staten Island, Emmaton, and Barker Slough, while modeled long-term average bromide concentrations would decrease at the other assessment locations (Appendix 8E, *Bromide*, Table 12). Overall effects would be greatest at Barker Slough, where predicted long-term average bromide concentrations would increase from 51 µg/L to 63 µg/L (23% relative increase) for the modeled 16-year hydrologic period and would increase from 54 µg/L to 98 µg/L (84% relative increase) for the modeled drought period. At Barker Slough, the predicted 50 µg/L exceedance frequency would decrease from 49% under Existing Conditions to 38% under Alternative 5, but would increase from 55% to 68% during the drought period. At Barker Slough, the predicted 100 µg/L exceedance frequency would increase from 0% under Existing Conditions to 18% under Alternative 5, and would increase from 0% to 38% during the drought period. In contrast, increases in bromide at Staten Island would result in a 50 µg/L bromide threshold exceedance increase from 47% under Existing Conditions to 67% under Alternative 5 (52% to 77% during the modeled drought period). However, unlike Barker Slough, modeling shows that long-term average bromide concentration at Staten Island would exceed the 100 µg/L assessment threshold concentration 1% under Existing Conditions and 2% under Alternative 5 (0% to 2% during the modeled drought period). The long-term average bromide concentrations would be 59 µg/L (62 µg/L for the modeled drought period) at Staten Island under Alternative 5. Changes in exceedance frequency of the 50 µg/L and 100 µg/L concentration thresholds, as well as relative change in long-term average concentration, at other assessment locations would be less substantial. This comparison to Existing Conditions reflects changes in bromide due to both Alternative 5 operations (including north Delta intake capacity of 3,000 cfs and numerous other components of Operational Scenario C) and climate change/sea level rise.

Due to the relatively small differences between modeled Existing Conditions and No Action baseline, changes in long-term average bromide concentrations and changes in exceedance frequencies relative to the No Action Alternative would be generally of similar magnitude to those previously described for the Existing Conditions comparison (Appendix 8E, *Bromide*, Table 12). Modeled long-term average bromide concentration increases would similarly be greatest at Barker Slough, where long-term average concentrations are predicted to increase by 27% (83% for the modeled drought period) relative to the No Action Alternative. However, unlike the Existing Conditions comparison, long-term average bromide concentrations at Buckley Cove, Rock Slough, and Contra Costa PP No. 1 would increase relative to No Action Alternative, although the increases would be relatively small (≤4%). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in bromide due only to Alternative 5 operations.

At Barker Slough, modeled long-term average bromide concentrations for the two baseline conditions are very similar (Appendix 8E, *Bromide*, Table 12). Such similarity demonstrates that the modeled Alternative 5 change in bromide is almost entirely due to Alternative 5 operations, and not climate change/sea level rise. Therefore, operations are the primary driver of effects on bromide at Barker Slough, regardless whether Alternative 5 is compared to Existing Conditions, or compared to the No Action Alternative.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) differed somewhat from what is presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 13). For most locations, the frequency of exceedance of the 50 μg/L and 100 μg/L were similar. The greatest difference between the methods was predicted for Barker Slough. The increases in frequency of exceedance of the 100 μg/L threshold, relative to Existing Conditions and the No Action Alternative, were not as great using this alternative EC to chloride and chloride to bromide relationship modeling approach as compared to that presented above from the mass-balance modeling approach. However, there were still substantial increases, resulting in 9% exceedance over the modeled period under Alternative 5, as compared to 1% under Existing Conditions and 2% under the No Action Alternative. For the drought period, exceedance frequency increased from 0% under Existing Conditions and the No Action Alternative, to 20% under Alternative 5.Because the mass-balance approach predicts a greater level of impact at Barker Slough, determination of impacts was based on the mass-balance results.

The increase in long-term average bromide concentrations predicted at Barker Slough, principally the relative increase in 100 μg/L exceedance frequency, would result in a substantial change in source water quality for existing drinking water treatment plants drawing water from the North Bay Aqueduct. As discussed for Alternative 1A, drinking water treatment plants obtaining water via the North Bay Aqueduct utilize a variety of conventional and enhanced treatment technologies in order to achieve DBP drinking water criteria. While the implications of such a modeled change in bromide at Barker Slough are difficult to predict, the substantial modeled increases could lead to adverse changes in the formation of disinfection byproducts such that considerable treatment plant upgrades may be necessary in order to achieve equivalent levels of health protection. Because many of the other modeled locations already frequently exceed the 100 μg/L threshold under Existing Conditions and the No Action Alternative, these locations likely already require treatment plant technologies to achieve equivalent levels of health protection, and thus no additional treatment technologies would be triggered by the small increases in the frequency of exceeding the 100 μg/L threshold. Hence, no further impact on the drinking water beneficial use would be expected at these locations.

The seasonal intakes at Mallard Slough and City of Antioch are infrequently used due to water quality constraints related to sea water intrusion. On a long-term average basis, bromide at these locations is in excess of 3,000 μg/L, but during seasonal periods of high Delta outflow can be <300 μg/L. Based on modeling using the mass-balance approach, use of the seasonal intakes at Mallard Slough and City of Antioch under Alternative 5 would experience a period average increase in bromide during the months when these intakes would most likely be utilized. For those wet and above normal water year types where mass balance modeling would predict water quality typically suitable for diversion, predicted long-term average bromide would increase from 103 μg/L to 128 μg/L (25% increase) at City of Antioch and would increase from 150 μg/L to 194 μg/L (30% increase) at Mallard Slough relative to Existing Conditions (Appendix 8E, *Bromide*, Table 25). Increases would be similar for the No Action Alternative comparison. Modeling results using the EC to chloride and chloride to bromide relationships show increases during these months, but the relative magnitude of the increases is much lower (Appendix 8E, *Bromide*, Table 26). Regardless of the differences in the data between the two modeling approaches, the decisions surrounding the use of these seasonal intakes is largely driven by acceptable water quality, and thus have historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at the City of Antioch and Mallard Slough intake would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

Important to the results presented above is the assumed habitat restoration footprint on both the temporal and spatial scales incorporated into the modeling. Modeling sensitivity analyses have indicated that habitat restoration (which are reflected in the modeling—see Section 8.3.1.3), not operations covered under CM1, are the driving factor in the modeled bromide increases. The timing, location, and specific design of habitat restoration will have effects on Delta hydrodynamics, and any deviations from modeled habitat restoration and implementation schedule will lead to different outcomes. Although habitat restoration near Barker Slough is an important factor contributing to modeled bromide concentrations at the North Bay Aqueduct, BDCP habitat restoration elsewhere in the Delta can also have large effects. Because of these uncertainties, and the possibility of adaptive management changes to BDCP restoration activities, including location, magnitude, and timing of restoration, the estimates are not predictive of the bromide levels that would actually occur in Barker Slough or elsewhere in the Delta.

SWP/CVP Export Service Areas

Under Alternative 5, improvement in long-term average bromide concentrations would occur at the Banks and Jones pumping plants. Long-term average bromide concentrations for the modeled 16-year hydrologic period at these locations would decrease by as much as 30% relative to Existing Conditions and 20% relative to No Action Alternative. Relative change in long-term average bromide concentration would be less during drought conditions (≤27%), but would still represent considerable improvement (Appendix 8E, *Bromide*, Table 12). As a result, less frequent bromide concentration exceedances of the 50 µg/L and 100 µg/L assessment thresholds would be predicted and an overall improvement in Export Service Areas water quality would be experienced respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also be observed since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in bromide is difficult to predict, the relative decrease in overall loading of bromide to the Export Service Areas would likely alleviate or lessen any expected increase in bromide concentrations at Vernalis (see discussion of Upstream of the Delta) as well as locations in the Delta receiving a large fraction of San Joaquin River water, such as much of the south Delta.

The discussion above is based on results of the mass-balance modeling approach. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) were consistent with the discussion above, and assessment of bromide using these data results in the same conclusions as are presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 13).

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 5 would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, Alternative 5 operations and maintenance, relative to the No Action Alternative, would result in small increases (i.e., <1%) in long-term average bromide concentrations at Vernalis related to relatively small declines in long-term average flow on the San Joaquin River. However, Alternative 5 operation and maintenance activities would cause substantial degradation to water quality with respect to bromide at Barker Slough, source of the North Bay Aqueduct. Resultant substantial change in long-term average bromide at Barker Slough could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-5 is available to reduce these effects (implementation of this measure along with a separate other commitment as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects).

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 5 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 5 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. However, south of the Delta, the San Joaquin River is a substantial source of bromide, primarily due to the use of irrigation water imported from the southern Delta. Concentrations of bromide at Vernalis are inversely correlated to net river flow. Under Alternative 5, long-term average flows at Vernalis would decrease only slightly, resulting in less than substantial predicted increases in long-term average bromide of about 3% relative to Existing Conditions.

Relative to Existing Conditions, Alternative 5 would result in small decreases in long-term average bromide concentration at most Delta assessment locations, with principal exceptions being the North Bay Aqueduct at Barker Slough, Staten Island, and Emmaton on the Sacramento River. Overall effects would be greatest at Barker Slough, where substantial increases in long-term average bromide concentrations would be predicted. The increase in long-term average bromide concentrations predicted for Barker Slough would result in a substantial change in source water quality to existing drinking water treatment plants drawing water from the North Bay Aqueduct. These modeled increases in bromide at Barker Slough could lead to adverse changes in the formation of disinfection byproducts at drinking water treatment plants such that considerable water treatment plant upgrades would be necessary in order to achieve equivalent levels of drinking water health protection.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Under Alternative 5, substantial improvement would occur at the Banks and Jones pumping plants, where predicted long-term average bromide concentrations are predicted to decrease by as much as 30% relative to Existing Conditions. An overall improvement in bromide-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 5 operation and maintenance would not result in any substantial change in long-term average bromide concentration upstream of the Delta. Furthermore, under Alternative 5, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to bromide. Bromide is not bioaccumulative, therefore change in long-term average bromide concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, bromide is not a constituent related to any 303(d) listings. Alternative 5 operation and maintenance activities would not cause substantial long-term degradation to water quality respective to bromide with the exception of water quality at Barker Slough, source of the North Bay Aqueduct. At Barker Slough, modeled long-term annual average concentrations of bromide would increase by 23%, and 84% during the modeled drought period. For the modeled 16-year hydrologic period the frequency of predicted bromide concentrations exceeding 100 μg/L would increase from 0% under Existing Conditions to 18% under Alternative 5, while for the modeled drought period, the frequency would increase from 0% to 38%. Substantial changes in long-term average bromide could necessitate changes in treatment plant operation or require treatment plant upgrades in order to maintain DBP compliance. The model predicted change at Barker Slough is substantial and, therefore, would represent a substantially increased risk for adverse effects on existing MUN beneficial uses should treatment upgrades not be undertaken. The impact is considered significant.

Implementation of Mitigation Measure WQ-5 along with a separate other commitment relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-5 is recommended to attempt to reduce the effect that increased bromide concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-5, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from bromide-related concentration effects on municipal water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementation of the North Bay Aqueduct AIP, acquiring alternative water supplies, or other actions to indirectly reduce the effects of elevated bromide and DOC in existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-5: Avoid, Minimize, or Offset, as Feasible, Adverse Water Quality Conditions

Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** CM2–CM21 proposed under Alternative 5 would be the same as those proposed under Alternative 1A, except that 25,000 acres rather than 65,000 acres of tidal habitat would be restored. As discussed for Alternative 1A, implementation of the CM2–CM21 would not present new or substantially changed sources of bromide to the study area. Some conservation measures may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution is not expected to substantially increase or present new sources of bromide. CM2–CM21 would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

In summary, implementation of CM2–CM21 under Alternative 5, relative to the No Action Alternative, would have negligible, if any, effects on bromide concentrations. The effects on bromide from implementing CM2–CM21 are determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A, except that 25,000 acres rather than 65,000 acres of tidal habitat would be restored. As discussed for Alternative 1A, implementation of the CM2–CM21 (CM2–CM21) would not present new or substantially changed sources of bromide to the study area. As such, effects on bromide resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 5 there would be no expected change to the sources of chloride in the Sacramento and eastside tributary watersheds. Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. The modeled long-term annual average flows on the lower San Joaquin River at Vernalis would decrease slightly compared to Existing Conditions and be similar compared to the No Action Alternative (as a result of climate change). The reduced flow would result in possible increases in long-term average chloride concentrations of about 2%, relative to the Existing Conditions and no change relative to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-62). Consequently, Alternative 5 would not be expected to cause exceedance of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to Existing Conditions, modeling predicts that Alternative 5 would result in similar or reduced long-term average chloride concentrations for the 16-year period modeled at most of the assessment locations, and, depending on modeling approach (see Section 8.3.1.3), would result in increased concentrations at the North Bay Aqueduct at Barker Slough (i.e., ≤18%), Sacramento River at Emmaton (i.e., ≤3%), and SF Mokelumne at Staten Island (i.e., ≤16%) (Appendix 8G, *Chloride*, Table Cl-31 and Table Cl-32). Additionally, implementation of tidal habitat restoration under CM4 would increase the tidal exchange volume in the Delta, and thus may contribute to increased chloride concentrations in the Bay source water as a result of increased salinity intrusion. More discussion of this phenomenon is included in Section 8.3.1.3. Consequently, while uncertain, the magnitude of chloride increases may be greater than indicated herein and would affect the western Delta assessment locations the most which are influenced to the greatest extent by the Bay source water. This comparison to Existing Conditions reflects changes in chloride due to both Alternative 5 operations (including north Delta intake capacity of 3,000 cfs and numerous other components of Operational Scenario C) and climate change/sea level rise.

Relative to the No Action Alternative conditions, the mass balance analysis of modeling results indicated that Alternative 5 would result in similar or reduced long-term average chloride concentrations for the 16-year period modeled at four of the assessment locations. Chloride concentrations would increase at the SF Mokelumne River at Staten Island (up to 19%) and the North Bay Aqueduct at Barker Slough (up to 23%) compared to the No Action Alternative conditions and increase only incrementally (3% or less) at five other stations (Appendix 8G, *Chloride*, Table Cl-31). The comparison to the No Action Alternative reflects changes in chloride due only to operations.

The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses–Relative to Existing Conditions

Estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at both the Antioch and Contra Costa Pumping Plant #1 locations. For Alternative 5, the modeled frequency of objective exceedance would remain unchanged at 7% of years under Existing Conditions and Alternative 5 (Appendix 8G, *Chloride*, Table Cl-64).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 5, the modeled frequency of objective exceedance would decrease by approximately one half, from 6% of modeled days under Existing Conditions, to 3% of modeled days under Alternative 5 (Appendix 8G, *Chloride*, Table Cl-63).

Given the limitations inherent to estimating future chloride concentrations (see Section 8.3.1.3), estimation of chloride concentrations through both amass balance approach and an EC-chloride relationship approach was used to evaluate the 250 mg/L Bay-Delta WQCP objectives in terms of both frequency of exceedance and use of assimilative capacity. When utilizing the mass balance approach to model monthly average chloride concentrations for the 16-year period, the predicted frequency of exceeding the 250 mg/L objective would decrease at the Contra Costa Canal at Pumping Plant #1 (Appendix 8G, *Chloride*, Table Cl-33 and Figure Cl-9). The frequency of exceedances would increase for the 16-year period modeled at the San Joaquin River at Antioch (i.e., from 66% under Existing Conditions to 72%) and Sacramento River at Mallard Island (i.e., from 85% under Existing Conditions to 87%) (Appendix 8G, Table Cl-33), and would cause further degradation at Antioch in March and April (i.e., maximum reduction of 45% of assimilative capacity for the 16-

year period modeled, and 100% reduction, or elimination of assimilative capacity, during the drought period modeled) (Appendix 8G, Table Cl-35 and Figure Cl-9).

In comparison, when utilizing the chloride-EC relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity would be similar to those discussed when utilizing the mass balance modeling approach (Appendix 8G, *Chloride*, Table Cl-34 and Table Cl-36). However, as with Alternative 1A the modeling approach utilizing the chloride-EC relationships predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

Based on the additional predicted annual and seasonal exceedances of the 250 mg/L Bay Delta WQCP objectives for chloride, and magnitude of associated long-term average water quality degradation in the western Delta, the potential exists for substantial adverse effects on the municipal and industrial beneficial uses through reduced opportunity for diversion of water with acceptable chloride levels.

303(d) Listed Water Bodies–Relative to Existing Conditions

With respect to the 303(d) listing for chloride in Tom Paine Slough, the monthly average chloride concentrations for the 16-year period modeled at Old River at Tracy Road, which represents the nearest DSM2-modeled location to Tom Paine in the south Delta, would generally be similar compared to Existing Conditions, and thus, would not be further degraded on a long-term basis (Appendix 8G, Figure Cl-10).

With respect to Suisun Marsh, the monthly average chloride concentrations for the 16-year period modeled would generally increase compared to Existing Conditions in some months during October through May at the Sacramento River at Collinsville (Appendix 8G, Figure Cl-11), Mallard Island (Appendix 8G, Figure Cl-9), and increase substantially at the Montezuma Slough at Beldon's Landing (i.e., over a doubling of concentration in December through February) (Appendix 8G, Figure Cl-12). Although modeling of Alternative 5 assumed no operation of the Montezuma Slough Salinity Control Gates, the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results for Suisun Marsh, but EC levels were still somewhat higher than EC levels under Existing Conditions for several locations and months. Although chloride was not specifically modeled in this sensitivity analysis, it is expected that chloride concentrations would be nearly proportional to EC levels in Suisun Marsh. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases in salinity are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term chloride increases in the Marsh. However, the chloride concentration increases at certain locations could be substantial, depending on siting and design of restoration areas. Thus, these increased chloride levels in Suisun Marsh are considered to contribute to additional, measureable long-term degradation that potentially would adversely affect the necessary actions to reduce chloride loading for any TMDL that is developed.

Municipal Beneficial Uses–Relative to No Action Alternative

Similar to the assessment conducted for Existing Conditions, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses. For Alternative 5, the modeled frequency of objective exceedance would increase from 0% under the No Action Alternative to 7% of years under Alternative 5 (Appendix 8G, *Chloride*, Table Cl-64). The increase was due to a single year, 1977, which fell just short of the required number of days (i.e., was within 6 days minimum number of required days < 150 mg/L). Given the uncertainty in the chloride modeling approach, it is likely that real time operations of the SWP and CVP could achieve compliance with this objective (see Section 8.3.1.1 for a discussion of chloride compliance modeling uncertainties and a description of real time operations of the SWP and CVP).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. For Alternative 5, the modeled frequency of objective exceedance would decrease slightly from 5% of modeled days under the No Action Alternative to 3% of modeled days under Alternative 5 (Appendix 8G, *Chloride*, Table Cl-63).

Similar to Existing Conditions, a comparative assessment of modeling approaches was utilized to evaluate the 250 mg/L Bay-Delta WQCP objectives in terms of both frequency of exceedance and use of assimilative capacity on a monthly average basis. When utilizing the mass balance approach to model monthly average chloride concentrations for the 16-year period, a small decrease in exceedance frequency would be predicted at the San Joaquin River at Antioch (i.e., from 73% for the No Action Alternative to 72%), however, available assimilative capacity would be reduced in April (i.e., up to 10% for the 16 year period modeled, and 100% [i.e., eliminated] for the drought period modeled) (Appendix 8G, *Chloride*, Table Cl-35). The exceedance frequency would increase slightly at the Sacramento River at Mallard Island (i.e., from 86% to 87%) and at the Contra Costa Canal at Pumping Plant #1 (i.e., from 14% to 18%) (Appendix 8G, Table Cl-33), along with reduced assimilative capacity at the Contra Costa Canal at Pumping Plant #1 in September (i.e., up to 56%), reflecting substantial degradation during when average concentrations would be near, or exceed, the objective (Appendix 8G, Table Cl-35).

In comparison, when utilizing the chloride-EC relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity would be similar to those discussed when utilizing the mass balance modeling approach (Appendix 8G, *Chloride*, Table Cl-34 and Table Cl-36). However, as with Alternative 1A, the modeling approach utilizing the chloride-EC relationships predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

Based on the additional predicted annual and seasonal exceedances of the 250 mg/L Bay Delta WQCP objectives for chloride, and the associated long-term average water quality degradation at interior and western Delta locations, the potential exists for substantial adverse effects on the municipal and industrial beneficial uses through reduced opportunity for diversion of water with acceptable chloride levels.

303(d) Listed Water Bodies–Relative to No Action Alternative

With respect to the 303(d) listing for chloride, Alternative 5 would generally result in changes similar to those discussed for the comparison to Existing Conditions. Monthly average chloride concentrations at Tom Paine Slough would not be further degraded on a long-term basis, based on results for Old River at Tracy Road, which represents the nearest DSM2-modeled location to Tom Paine in the south Delta (Appendix 8G, Figure Cl-10).

Monthly average chloride concentrations at source water channel locations for the Suisun Marsh (Appendix 8G, *Chloride*, Figures Cl-9, Cl-11, and Cl-12) would increase substantially in some months during October through May compared to the No Action Alternative conditions, but sensitivity analyses suggest that operation of the Salinity Control Gates and restoration area siting and design considerations could reduce these increases. However, the chloride concentration increases at certain locations could be substantial, depending on siting and design of restoration areas. Thus, these increased chloride levels in Suisun Marsh are considered to contribute to additional, measureable long-term degradation would occur in Suisun Marsh that potentially would adversely affect the necessary actions to reduce chloride loading for any TMDL that is developed.

SWP/CVP Export Service Areas

Under Alternative 5, long-term average chloride concentrations based on the mass balance analysis of modeling results for the 16-year period modeled at the Banks and Jones pumping plants would decrease by as much as 29% relative to Existing Conditions and 19% compared to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-31). The modeled frequency of exceedances of applicable water quality objectives/criteria would decrease relative to Existing Conditions and No Action Alternative, for both the 16-year period and the drought period modeled (Appendix 8G, *Chloride*, Table Cl-33). Consequently, water exported to the SWP/CVP service area would generally be of similar or better quality with regards to chloride relative to Existing Conditions and the No Action Alternative conditions.

Results of the modeling approach which used relationships between EC and chloride (see Section 8.3.1.3) were consistent with the discussion above, and assessment of chloride using these data results in the same conclusions as are presented above for the mass-balance approach (Appendix 8G, *Chloride*, Table Cl-32 and Table Cl-34).

Commensurate with the reduced chloride concentrations in water exported to the SWP/CVP service area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely alleviate or lessen any expected increase in chloride at Vernalis related to decreased annual average San Joaquin River flows (see discussion of Upstream of the Delta).

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative conditions, Alternative 5 would result in increased water quality degradation and frequency of exceedance of the 250 mg/L municipal and industrial objective at interior and western Delta locations on a monthly average chloride basis, and could contribute to measureable water quality degradation relative to the 303(d) impairment in Suisun Marsh. The predicted chloride increases constitute an adverse effect on water quality (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Additionally, the predicted changes relative to the No Action Alternative conditions indicate that in addition to the effects of climate change/sea level rise, implementation of CM1 and CM4 under Alternative 5 would contribute substantially to the adverse water quality effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 5, relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, the Alternative 5 would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, the Alternative 5 would result in substantially increased chloride concentrations in the Delta such that frequency of exceedance of the 250 mg/L Bay-Delta WQCP objective would increase at the San Joaquin River at Antioch (by 6%) and at Mallard Slough (by 2%), and long-term degradation may occur, that may result in adverse effects on the municipal and industrial water supply beneficial use (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Relative to the Existing Conditions, the modeled increased chloride concentrations and degradation in the western Delta could further contribute, at measurable levels, to the existing 303(d) listed impairment due to chloride in Suisun Marsh for the protection of fish and wildlife.

Chloride concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under Alternative 5 would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 5 maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas. However, based on these findings, this impact is determined to be significant due to increased chloride concentrations and degradation at western Delta locations and its effects on municipal and industrial water supply and fish and wildlife beneficial uses.

While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-7 is recommended to attempt to reduce the effect that increased chloride concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-7, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from chloride concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when chloride concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-7: Conduct Additional Evaluation and Modeling of Increased Chloride Levels and Develop and Implement Phased Mitigation Actions

Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Under Alternative 5, the types and geographic extent of effects on chloride concentrations in the Delta as a result of implementation of the other conservation measures (i.e., CM2–CM21) would be similar to, and undistinguishable from, those effects previously described for Alternative 1A. The conservation measures would present no new direct sources of chloride to the affected environment. Moreover, some habitat restoration conservation measures (CM4–CM10) would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored tidal wetlands, floodplain, and related channel margin and off-channel habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement compared to No Action Alternative conditions.

In summary, based on the discussion above, the effects on chloride from implementing CM2–CM21 are considered to be not adverse.

CEQA Conclusion: Implementation of the CM2–CM21 for Alternative 5 would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP service area. Replacement of irrigated agricultural land uses in the Delta with habitat restoration conservation measures may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects**:** Effects of CM1 on DO under Alternative 5 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: Effects of CM1 on DO under Alternative 5 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under the Alternative 1A.

Reservoir storage reductions that would occur under Alternative 5, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions that would occur would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state has begun to aggressively regulate the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters under Alternative 5, relative to Existing Conditions. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to ever increasing water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. This impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on DO under Alternative 5 would e the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on DO resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, their associated reservoirs, and the San Joaquin River upstream of the Delta under Alternative 5 are not expected to be outside the ranges occurring under Existing Conditions or that would occur under the No Action Alternative. Any minor changes in EC levels that could occur under Alternative 5 in water bodies upstream of the Delta would not be of sufficient magnitude, frequency and geographic extent that would cause adverse effects on beneficial uses or substantially degrade water quality with regard to EC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to Existing Conditions, Alternative 5 would result in an increase in the number of days the Bay-Delta WQCP EC objectives would be exceeded in the Sacramento River at Emmaton, San Joaquin River at San Andreas Landing, Jersey Point and Prisoners Point, and Old River at Tracy Bridge (Appendix 8H, *Electrical Conductivity*, Table EC-5).

The percentage of days the Emmaton EC objective would be exceeded for the entire period modeled (1976–1991) would increase from 6% under Existing Conditions to 25% under Alternative 5, and the percentage of days out of compliance would increase from 11% under Existing Conditions to 38% under Alternative 5.

The percentage of days the San Andreas Landing EC objective would be exceeded would increase from 1% under Existing Conditions to 5% under Alternative 5, and the percentage of days out of compliance with the EC objective would increase from 1% under Existing Conditions to 9% under Alternative 5. Sensitivity analyses were performed for Alternative 4 Scenario H3, and indicated that many similar exceedances were modeling artifacts, and the small number of remaining exceedances were small in magnitude, lasted only a few days, and could be addressed with real time operations of the SWP and CVP (see Section 8.3.1.1 for a description of real time operations of the SWP and

CVP). Due to similarities in the nature of the exceedances between alternatives, the findings from these analyses can be extended to this alternative as well.

The percentage of days the Jersey Point fish and wildlife EC objective would be exceeded and the percentage of days out of compliance for the entire period modeled would increase from 0% under Existing Conditions to 3% under Alternative 5. The percentage of days the Prisoners Point EC objective would be exceeded for the entire period modeled would increase from 6% under Existing Conditions to 8% under Alternative 5, and the percentage of days out of compliance with the EC objective would increase from 10% under Existing Conditions to 12% under Alternative 5. These changes are very small, and are likely within the uncertainty of the modeling approach. Nevertheless, further discussion of EC increases relative to this objective can be found in Appendix 8H, Attachment 2.

In Old River at Tracy Bridge, the percentage of days exceeding the EC objective would increase from 4% under Existing Conditions to 5% under Alternative 5; the percentage of days out of compliance would increase by <1% and would be 10% under both Existing Conditions and Alternative 5. These changes are minimal, but, regardless, as noted in Section 8.1.3.7, SWP and CVP operations have relatively little influence on salinity levels at this location, and the elevated salinity in south Delta channels is affected substantially by local salt contributions discharged into the San Joaquin River downstream of Vernalis. Thus, the modeling has limited ability to estimate salinity accurately in this region.

Average EC levels at the western and southern Delta compliance locations, except at Emmaton in the western Delta, would decrease from 2–35% for the entire period modeled and 3–32% during the drought period modeled (1987–1991) (Appendix 8H, *Electrical Conductivity*, Table EC-16). At Emmaton, average EC would increase by 3% for the entire period modeled and 10% for the drought period modeled. At the two interior Delta locations, there would be increases in average EC: the S. Fork Mokelumne River at Terminous average EC would increase 3% for the entire and drought periods modeled; and San Joaquin River at San Andreas Landing average EC would increase 5% for the entire period modeled and 10% during the drought period modeled. On average, EC would increase at Emmaton during February through August. Average EC would increase at San Andreas Landing from January through September. Average EC in the S. Fork Mokelumne River at Terminous would increase from March through December (Appendix 8H, Table EC-16). The comparison to Existing Conditions reflects changes in EC due to both Alternative 5 operations (including north Delta intake capacity of 3,000 cfs and numerous other components of Operational Scenario C) and climate change/sea level rise.

Relative to the No Action Alternative, the percentage of days exceeding EC objectives and percentage of days out of compliance would increase at: Sacramento River at Emmaton, San Joaquin River at Jersey Point, San Andreas Landing, and Prisoners Point; and Old River near Middle River and at Tracy Bridge (Appendix 8H, *Electrical Conductivity*, Table EC-5). The increase in percentage of days exceeding the EC objective would be 11% at Emmaton and 7% or less at the remaining locations. The increase in percentage of days out of compliance would be 13% at Emmaton and 11% or less at the remaining locations. For the entire period modeled, average EC levels would increase at: Sacramento River at Emmaton (2%), S. Fork Mokelumne River (4%), San Joaquin River at San Andreas Landing (10%), and San Joaquin River at Prisoners Point (4%) (Appendix 8H, Table EC-16). During the drought period modeled, average EC would increase at these same locations, except at Emmaton, by a similar percentage as well as the San Joaquin River at Brandt Bridge (1%). The comparison to the No Action Alternative reflects changes in EC due only to Alternative 5 operations (including north Delta intake capacity of 3,000 cfs and numerous other components of Operational Scenario C).

For Suisun Marsh, October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Long-term average EC would increase under Alternative 5, relative to Existing Conditions, during the months of March through May by 0.4–0.6 mS/cm in the Sacramento River at Collinsville (Appendix 8H, *Electrical Conductivity*, Table EC-21). Long-term average EC would decrease relative to Existing Conditions in Montezuma Slough at National Steel during October–May (Appendix 8H, Table EC-22). The most substantial increase would occur near Beldon Landing, with long-term average EC levels increasing by 1.6–5.0 mS/cm, depending on the month, at least doubling during some months the long-term average EC relative to Existing Conditions (Appendix 8H, Table EC-23). Sunrise Duck Club and Volanti Slough also would have long-term average EC increases during all months of 0.9–2.8 mS/cm (Appendix 8H, Tables EC-24 and EC-25). Modeling of this alternative assumed no operation of the Montezuma Slough Salinity Control Gates, but the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 Scenario H3 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results, but EC levels were still somewhat higher than EC levels under Existing Conditions and the No Action Alternative for several locations and months. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions and the No Action Alternative, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H Attachment 1 for more information on these sensitivity analyses). These analyses also indicate that increases are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term EC increases to be on the order of 1 mS/cm or less. Due to similarities in the nature of the EC increases between alternatives, the findings from these analyses can be extended to this alternative as well.

The degree to which the long-term average EC increases in Suisun Marsh would cause exceedance of Bay-Delta WQCP objectives is unknown, because these objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated "equivalent or better protection will be provided at the location" (State Water Resources Control Board 2006:14). The long-term average EC increase may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the marsh. However, the EC increases at certain locations could be substantial, depending on siting and design of restoration areas, and it is uncertain the degree to which current management plans for the Suisun Marsh would be able to address these substantially higher EC levels and protect beneficial uses. Thus, these increased EC levels in Suisun Marsh are considered to have a potentially adverse effect on marsh beneficial uses. Long-term average EC increases in Suisun Marsh under Alternative 5 relative to the No Action Alternative would be similar to the increases relative to Existing Conditions.

The western and southern Delta are CWA section 303(d) listed for elevated EC and the increased EC that could occur in the western Delta, relative to Existing Conditions and the No Action Alternative could lead to water quality degradation that would make beneficial use impairment measurably worse. Since there would be very little change in EC levels in the southern Delta and there is not expected to be an increase in frequency of exceedances of objectives, this alternative is not expected to make beneficial use impairment measurably worse in the southern Delta. Suisun Marsh also is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC concentrations could contribute to additional impairment.

SWP/CVP Export Service Area

At the Banks and Jones pumping plants, Alternative 5 would result in no exceedances of the Bay-Delta WQCP's 1,000 µmhos/cm EC objective for the entire period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-10). Thus, there would be no adverse effect on the beneficial uses in the SWP/CVP Export Service Areas using water pumped at this location under the Alternative 5.

At the Banks pumping plant, relative to Existing Conditions, average EC levels under Alternative 5 would decrease 19% for the entire period modeled and 18% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 13% for the entire period modeled and 12% during the drought period modeled. (Appendix 8H, *Electrical Conductivity*, Table EC-16)

At the Jones pumping plant, relative to Existing Conditions, average EC levels under Alternative 5 would decrease 15% for the entire period modeled and 16% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 11% for the entire period modeled and 12% during the drought period modeled. (Appendix 8H, *Electrical Conductivity*, Table EC-16).

Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 5 would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas; rather, Alternative 5 would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows (see EC impact discussion under the No Action Alternative).

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC. Alternative 5 would result in lower average EC levels relative to Existing Conditions and the No Action Alternative and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

***NEPA Effects*:** In summary, the increased frequency of exceedance of EC objectives and increased long-term and drought period average EC levels that would occur at western Delta compliance locations under Alternative 5, relative to the No Action Alternative, would contribute to adverse effects on the agricultural beneficial uses. In addition. the increased frequency of exceedance of the San Joaquin River at Prisoners Point EC objective and long-term and drought period average EC could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. Given that the western is Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives and long-term average and drought period average EC in these portions of the Delta has the potential to contribute to additional beneficial use impairment. The increases in long-term average EC levels that could occur in Suisun Marsh could further degrade existing EC levels and could contribute additional to adverse effects on the fish and wildlife beneficial uses. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC levels could contribute to additional beneficial use impairment. These increases in EC constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects (implementation of this measure along with a separate other commitment as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential EC-related changes would reduce these effects).

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

River flow rate and reservoir storage reductions that would occur under Alternative 5, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's aggressive regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 5 would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas. There would be no exceedance of the EC objective at the Jones and Banks pumping plants. Average EC levels for the entire period modeled would decrease at both plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

In the Plan Area, Alternative 5 would result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded for the entire period modeled (1976–1991): in the Sacramento River at Emmaton (agricultural objective; 19%; increase) and at Jersety Point (fish and wildlife objective, 3%), and the San Joaquin River at Prisoners Point (fish and wildlife objective; 2% increase) in the interior Delta. Further, long-term average EC levels would increase in the Sacramento River at Emmaton by 3% for the entire period modeled and 10% during the drought period modeled, and in the San Joaquin River at San Andreas Landing by 5% during for the entire period modeled and 10% during the drought period modeled. The increases in long-term and drought period average EC levels and increased frequency of exceedance of EC objectives that would occur in the Sacramento River at Emmaton, and the increased long-term and drought period average EC levels in the San Joaquin River at San Andreas Landing would potentially contribute to adverse effects on the agricultural beneficial uses in the western and interior Delta. Further, the increased frequency of exceedance of the fish and wildlife objective at Jersey Point and Prisoners Point could contribute to adverse effects on aquatic life (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The western Delta is Clean Water Act section 303(d) listed for elevated EC and the increased frequency of exceedance of EC objectives that would occur in this portions of the Delta could make beneficial use impairment measurably worse. This impact is considered to be significant.

Further, relative to Existing Conditions, Alternative 5 could result in substantial increases in long-term average EC during the months of October through May in Suisun Marsh. The increases in long-term average EC levels that would occur in Suisun Marsh could further degrade existing EC levels and thus contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in fish and wildlife. Suisun Marsh is Clean Water Act section 303(d) listed for elevated EC and the increases in long-term average EC that would occur in the marsh could make beneficial use impairment measurably worse. This impact is considered to be significant.

Implementation of Mitigation Measure WQ-11 along with a separate other commitment relating to the potential increased costs associated with EC-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-11 is recommended to attempt to reduce the effect that increased EC concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-11, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from EC concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when EC concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-11: Avoid, Minimize, or Offset, as Feasible, Reduced Water Quality Conditions

Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on EC under Alternative 5 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on EC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 5, the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries would be altered, relative to Existing Conditions and the No Action Alternative.

The Sacramento River at Freeport and San Joaquin River at Vernalis (as summarized for water quality average concentrations in Tables 8-48 and 8-49) were examined for flow/concentration relationships for mercury and methylmercury. No significant, predictive regression relationships were discovered for mercury or methylmercury, except for total mercury with flow at Freeport (monthly or annual) (Appendix 8I, Figures I-10 through I-13). Such a positive relationship between total mercury and flow is to be expected based on the association of mercury with suspended sediment and the mobilization of sediments during storm flows. However, the changes in flow in the Sacramento River under Alternative 5 relative to Existing Conditions and the No Action Alternative are not of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore mercury loading should not be substantially different due to changes in flow. In addition, even though it may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but will not change substantially relative to Existing Conditions or the No Action Alternative due to changes in flows under Alternative 5.

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

The water quality impacts of waterborne concentrations of mercury and methylmercury and fish tissue mercury concentrations were evaluated for 9 Delta locations. The analysis of percentage change in assimilative capacity of waterborne total mercury of Alternative 5 relative to the 25 ng/L ecological risk benchmark as compared to Existing Conditions showed the greatest decrease to be 0.9% at Old River at Rock Slough and the Contra Costa Pumping Plant, and 0.9% at Franks Tract relative to the No Action Alternative (Figures 8-53a and 8-54a). These changes are not expected to result in adverse effects to beneficial uses. Similarly, changes in methylmercury concentration are expected to be very small. The greatest annual average methylmercury concentration for drought conditions was 0.165 ng/L for the San Joaquin River at Buckley Cove which was slightly higher than Existing Conditions (0.161 ng/L) and slightly lower than the No Action Alternative (0.167 ng/L)(Appendix 8I, *Mercury*, Table I-6). All modeled input concentrations exceeded the methylmercury TMDL guidance objective of 0.06 ng/L, therefore percentage change in assimilative capacity was not evaluated for methylmercury.

Fish tissue estimates show only small or no increases in exceedance quotients based on long-term annual average concentrations for mercury at the Delta locations. The greatest change in exceedance quotients of 6–8% is expected for Franks Tract and Old River at Rock Slough relative to Existing Conditions and 7% for the Mokelumne River (South Fork) at Staten Island relative to the No Action Alternative (Figures 8-55a and8-55b; Appendix 8I, *Mercury*, Table I-12b). Because these increases are relatively small, and it is not evident that substantive increases are expected at numerous locations throughout the Delta, these changes are expected to be within the uncertainty inherent in the modeling approach, and would likely not be measurable in the environment. See Appendix 8I for a discussion of the uncertainty associated with the fish tissue estimates.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 5 are projected to be lower than Existing Conditions and the No Action Alternative at the Jones and Banks pumping plants (Appendix 8I, *Mercury*, Figures I-6 and I-7). Therefore, mercury shows an increased assimilative capacity at these locations (Figures 8-53a and 8-54a). Bass tissue mercury concentrations are also improved under Alternative 5, relative to Existing Conditions and the No Action Alternative (Figure 8-55a and 8-55b; Appendix 8I, *Mercury*, Tables I-12a and I-12b).

***NEPA Effects*:** Based on the above discussion, the effects of mercury and methylmercury in comparison of Alternative 5 to the No Action Alternative (as waterborne and bioaccumulated forms) are not considered to be adverse.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 5, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta will not be substantially different relative to Existing

Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. However, monthly average waterborne concentrations of total and methylmercury, over the period of record, are very similar to Existing Conditions. Similarly, estimates of fish tissue mercury concentrations show almost no differences would occur among sites for Alternative 5 as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP and CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 5 as compared to Existing Conditions.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to Existing Conditions, Alternative 5 would not increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Some habitat restoration activities under Alternative 5 would occur on lands in the Delta formerly used for irrigated agriculture. Tidal and other restoration proposed under Alternative 5 have the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the restored habitat. Therefore, increases in mercury methylation in the habitat restoration areas is possible but uncertain depending on the specific restoration design implemented at a particular Delta location. Models to estimate the potential for methylmercury formation in restored areas are not currently available. However, DSM2 modeling for Alternative 5 operations does incorporate assumptions for certain habitat restoration activities proposed under CM2 and CM4 (see Section 8.3.1.3) that result in changes to Delta hydrodynamics compared to the No Action Alternative. These modeled restoration assumptions provide some insight into potential hydrodynamic changes that could be expected related to implementing CM2 and CM4 and are considered in the evaluation of the potential for increased mercury and methylmercury concentrations under Alternative 5.

CM12 addresses the potential for methylmercury bioaccumulation associated with restoration activities and acknowledges the uncertainties associated with mitigating or minimizing this potential effect. CM12 proposes project-specific mercury management plans for restoration actions that will incorporate relevant approaches recommended in Phase 1 Methylmercury TMDL control studies. Specific approaches recommended under CM12 that are intended to minimize or mitigate for potential increases in methylmercury bioaccumulation at future restoration sites include:

- Characterizing mercury, methylmercury, organic carbon, iron, and sulfate concentrations to better inform restoration design,
- Sequestering methylmercury at restoration sites using low intensity chemical dosing techniques,
- Minimizing microbial methylation associated with anoxic conditions by reducing the amount of organic material at a restoration site,
- Designing restoration sites to enhance photo degeneration that converts methylmercury into a biologically unavailable, inorganic form of mercury,
- Remediating restoration site soils with iron to reduce methylation in sulfide rich soils, and
- Considering capping mercury laden sediments, where possible to reduce methylation potential at a site.

Because of the uncertainties associated with site-specific estimates of methylmercury concentrations and the uncertainties in source modeling and tissue modeling, the effectiveness of methylmercury management proposed under CM12 to reduce methylmercury concentrations would need to be evaluated separately for each restoration effort, as part of design and implementation. Because of this uncertainty and the known potential for methylmercury creation in the Delta this potential effect of implementing CM2–CM21 is considered adverse.

***CEQA Conclusion*:** There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the CVP and SWP service areas due to implementation of CM2–CM21 relative to Existing Conditions. However, uptake of mercury from water and/or methylation of inorganic mercury may increase to an unquantified degree as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Methylmercury is 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites under Alternative 5 would be guided by CM12 which requires development of site specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time although the potential to reduce methylmercury concentrations exists based on current research. Although the BDCP will implement CM12 with the goal to reduce this potential effect the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant. No mitigation measures would be available until specific restoration actions are proposed. Therefore this programmatic impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 5 would have negligible, if any, impact on nitrate concentrations in the rivers and reservoirs upstream of the Delta in the Sacramento River watershed relative to Existing Conditions and the No Action Alternative.

Under Alternative 5, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by an estimated 6%, relative to Existing Conditions, and would remain virtually the same relative to the No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Given these relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River (see Appendix 8J, *Nitrate*, Figure 2), it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by changes in flow rates under Alternative 5.

Any negligible changes in nitrate-N concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to nitrate.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Results of the mixing calculations indicate that under Alternative 5, relative to Existing Conditions and the No Action Alternative, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Tables 19 and 20). Although changes at specific Delta locations and for specific months may be substantial on a relative basis, the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds identified in Table 8-50. Long-term average nitrate concentrations are anticipated to remain below 1 mg/L-N at all 11 assessment locations except the San Joaquin River at Buckley Cove, where long-term average concentrations would be somewhat above 1 mg/L-N. Nevertheless, at this location, long-term average nitrate concentration would be somewhat reduced under Alternative 5, relative to Existing Conditions, and slightly increased relative to the No Action Alternative. No additional exceedances of the MCL are anticipated at any location (Appendix 8J, *Nitrate*, Table 19). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, was low or negligible (i.e., <4%) for all locations and months, except San Joaquin River at Buckley Cove in August, which showed a 5.6% use of assimilative capacity available under the No Action Alternative, for the drought period (1987–1991) (Appendix 8J, *Nitrate*, Table 21).

Nitrate concentrations will likely be higher than the modeling results indicate in certain locations. This includes in the Sacramento River between Freeport and Mallard Island and other areas in the Delta downstream of Freeport that are influenced by Sacramento River water. These increases are associated with ammonia and nitrate that are discharged from the SRWTP, which are not included in the modeling.

- Under Existing Conditions, most of the ammonia discharged from the SRWTP is converted to nitrate downstream of the facility's discharge at Freeport, and thus, nitrate concentrations under Existing Conditions in these areas are expected to be higher than the modeling predicts, the increase becoming greater with increasing distance downstream. However, the increase in nitrate concentrations downstream of the SRWTP is expected to be small—the existing increase appears to be from approximately 0.1 mg/L-N to approximately 0.4–0.5 mg/L-N over this reach, due to approximately a 1:1 conversion of ammonia-N to nitrate-N (Central Valley Water Board 2010a:32).
- Under Alternative 5, the planned upgrades to the SRWTP, which include nitrification/partial denitrification, would substantially decrease ammonia concentrations in the discharge, but would increase nitrate concentrations in the discharge up to 10 mg/L-N, which is substantially higher than under Existing Conditions.
- Overall, under Alternative 5, the nitrogen load from the SRWTP discharge is expected to decrease (by up to 50%), relative to Existing Conditions, due to nitrification/partial dentrification ugrades at the SRWTP facility. Thus, while concentrations of nitrate downstream of the facility are expected to be higher than modeling results indicate for both Existing Conditions and Alternative 5, the increase is expected to be greater under Existing Conditions than for Alternative 5 due to the upgrades that are assumed under Alternative 5.

The other areas in which nitrate concentrations will be higher than the modeling results indicate are immediately downstream of other wastewater treatment plants that practice nitrification, but not denitrification (e.g., City of Rio Vista Beach WWTF, Town of Discovery Bay WWTF, City of Stockton RWCF). For all such facilities in the Delta, the Regional Water Boards have issued NPDES permits that allow discharge of wastewater containing nitrate into the Delta, and under these permits, the State has determined that no beneficial uses are adversely affected by the discharge, and that the discharger's use of available assimilative capacity of the water body is acceptable. When dilution is necessary in order for the discharge to be in compliance with the Basin Plans (which incorporate the 10 mg/L-N MCL by reference), not all of the assimilative capacity of the receiving water is granted to the discharger. Thus, limited decreases in flows are not anticipated to result in systemic exceedances of the MCLs by these POTWs. Furthermore, NPDES permits are renewed on a 5-year basis, and thus, if under changes in flows, dilution was no longer sufficient to maintain nitrate below the MCL in the receiving water, the NPDES permit renewal process would address such cases.

Therefore, any increases in nitrate-N concentrations that may occur at certain locations within the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to nitrate.

SWP/CVP Export Service Areas

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N at the Banks and Jones pumping plants.

Results of the mixing calculations indicate that under Alternative 5, relative to Existing Conditions and the No Action Alternative, nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease on a long-term average annual basis (Appendix 8J, *Nitrate*, Tables 19 and 20). During the late summer, particularly in the drought period assessed, concentrations are expected to increase, but the absolute value of these changes (i.e., in mg/L-N) is small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Area, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.3 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP and CVP Export Service Area. No additional exceedances of the MCL are anticipated (Appendix 8J, *Nitrate*, Table 19). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the 10 mg/L-N MCL, was negligible (<4%) for both Banks and Jones pumping plants (Appendix 8J, *Nitrate*, Table 21).

Any increases in nitrate-N concentrations that may occur in water exported via Banks and Jones pumping plants are not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regards to nitrate.

NEPA Effects: In summary, based on the discussion above, the effects on nitrate from implementing CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Nitrate-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate-N upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers). Although higher in the San Joaquin River watershed, nitrate-N concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 5, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mixing calculations indicate that under Alternative 5, relative to Existing Conditions, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the MCL are anticipated at any location, and use of assimilative capacity available under Existing Conditions, relative to the drinking water MCL of 10 mg/L-N, was low or negligible (i.e., <4%) for virtually all locations and months.

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N concentrations at the Banks and Jones pumping plants. Results of the mixing calculations indicate that under Alternative 5, relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to change negligibly. No additional exceedances of the MCL are anticipated, and use of assimilative capacity available under Existing Conditions, relative to the MCL was negligible (i.e., <4%) for both Banks and Jones pumping plants for all months.

Based on the above, there would be no substantial, long-term increase in nitrate-N concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas under Alternative 5 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because nitrate concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on nitrate under Alternative 5 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on nitrate resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 5, there would be no substantial change to the sources of DOC within the watersheds upstream of the Delta. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows would not be expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Any negligible changes in DOC levels in water bodies upstream of the Delta under Alternative 5, relative to Existing Conditions and the No Action Alternative, would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to DOC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are

included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Under Alternative 5, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be similar to that previously described for Alternative 1A, although the magnitude of predicted long-term change and relative frequency of concentration threshold exceedances would be distributed differently. Modeled effects would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1., where for the 16-year hydrologic period and the modeled drought period, long-term average concentration increases ranging from 0.2–0.3 mg/L would be predicted (≤8% net increase) (Appendix 8K, *Organic Carbon,* DOC Table 6). Increases in long-term average concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at Rock Slough and Contra Costa PP No. 1 locations. For Rock Slough, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 64% under the Alternative 5 (an increase from 47% to 62% for the drought period), and concentrations exceeding 4 mg/L would increase from 30% to 32% (32% to 37% for the drought period). For Contra Costa PP No. 1, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 70% under Alternative 5 (45% to 75% for the drought period), and concentrations exceeding 4 mg/L would increase from 32% to 35% (35% to 40% for the drought period). Relative change in frequency of threshold exceedance for other assessment locations would be similar or less. While Alternative 5 would generally lead to slightly higher long-term average DOC concentrations (≤0.3 mg/L) at some municipal water intakes and Delta interior locations, the predicted change would not be expected to adversely affect MUN beneficial uses, or any other beneficial use. This comparison to Existing Conditions reflects changes in DOC due to both Alternative 5 operations (including north Delta intake capacity of 3,000 cfs and numerous other components of Operational Scenario C) and climate change/sea level rise.

In comparison, Alternative 5 relative to the No Action Alternative would generally result in a magnitude of change similar to that discussed for the comparison to Existing Conditions. Maximum increases of 0.1–0.2 mg/L DOC (i.e., ≤6%) would be predicted at Franks Tract, Rock Slough, and Contra Costa PP No. 1 relative to No Action Alternative (Appendix 8K, *Organic Carbon,* DOC Table 6). Threshold concentration exceedance frequency trends would also be similar to those discussed for the Existing Conditions comparison, with exception to the predicted 4 mg/L exceedance frequency at Buckley Cove. In comparison to the No Action Alternative, the frequency which long-term average DOC concentrations exceeded 4 mg/L at Buckley Cove would increase from 27% to 31% (42% to 53% for the modeled drought period). While the Alternative 5 would generally lead to slightly higher long-term average DOC concentrations at some Delta assessment locations when compared to No Action Alternative conditions, the predicted change would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, particularly when considering the relatively small change in long-term annual average concentration. Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in DOC due only to Alternative 5 operations.

As discussed for Alternative 1A, substantial change in ambient DOC concentrations would need to occur before significant changes in drinking water treatment plant design or operations are triggered. The increases in long-term average DOC concentrations estimated to occur at various Delta locations under Alternative 5 are of sufficiently small magnitude that they would not require existing drinking water treatment plants to substantially upgrade treatment for DOC removal above levels currently employed.

Relative to existing and No Action Alternative conditions, Alternative 5 would lead to predicted improvements in long-term average DOC concentrations at Barker Slough, as well as Banks and Jones pumping plants (discussed below). At Barker Slough, long-term average DOC concentrations would be predicted to decrease by as much as 0.1–0.2 mg/L depending on baseline conditions comparison and modeling period.

SWP/CVP Export Service Areas

Under Alternative 5, modeled long-term average DOC concentrations would decrease at Banks and Jones pumping plants for the modeled 16-year hydrologic period, relative to Existing Conditions and No Action Alternative. Relative to Existing Conditions, long-term average DOC concentrations at Banks would be predicted to decrease by 0.3 mg/L (0.1 mg/L during drought period) (Appendix 8K, *Organic Carbon,* DOC Table 6). At Jones, long-term average DOC concentrations would be predicted to decrease by 0.2 mg/L, but be predicted to increase by 0.1 mg/L for the modeled drought period. Such decreases in long-term average DOC, however, would not necessarily translate into lower exceedance frequencies for concentration thresholds. To the contrary, long-term average DOC concentrations at Banks exceeding 3 mg/L would increase from 64% under Existing Conditions to 69% under Alternative 5 (57% to 83% for the drought period), and at Jones would increase from 71% to 78% (72% to 93% for the drought period). Relative to the 4 mg/L concentration threshold, long-term average DOC concentrations at Banks would decrease from 33% under Existing Conditions to 27% under Alternative 5, but would increase slightly from 42% to 44% for the modeled drought period. At Jones, concentrations exceeding 4 mg/L would increase slightly from 26% to 27% (35% to 39% for the drought period). Frequency of exceedance comparisons to the No Action Alternative yield similar trends, but with slightly smaller 16-year hydrologic period and drought period changes. Overall, modeling results for the SWP/CVP Export Service Areas predict a slight long-term improvement in Export Service Areas water quality respective to DOC. This improvement is principally obtained through overall lower long-term average DOC concentrations at Banks and Jones.

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 5 would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area. Maintenance activities would not be expected to cause any substantial change in long-term average DOC concentrations such that MUN beneficial uses, or any other beneficial use, would be adversely affected.

***NEPA Effects*:** In summary, Alternative 5, relative to the No Action Alternative, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Long-term average DOC concentrations at Banks and Jones pumping plants are predicted to decrease by as much as 0.3 mg/L, while long-term average DOC concentrations for some Delta interior locations, including Contra Costa PP #1, are predicted to increase by as much as 0.2 mg/L. The increase in long-term average DOC concentration that could occur within the Delta interior would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters. The effect of Alternative 1A operations and maintenance (CM1) on DOC is determined not to be adverse.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

While greater water demands under the Alternative 5 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of DOC. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, Alternative 5 would result in relatively small increases (i.e., ≤8%) in long-term average DOC concentrations at some Delta interior locations, including Franks Tract, Rock Slough, and Contra Costa PP No. 1. However, these increases would not substantially increase the frequency with which long-term average DOC concentrations exceeds 2, 3, or 4 mg/L. While Alternative 5 would generally lead to slightly higher long-term average DOC concentrations (≤0.3 mg/L) within the Delta interior and some municipal water intakes, the predicted change would not be expected to adversely affect MUN beneficial uses, or any other beneficial use.

The assessment of Alternative 5 effects on DOC in the SWP/CVP Export Service Areas is based on assessment of changes in DOC concentrations at Banks and Jones pumping plants. Relative to Existing Conditions, long-term average DOC concentrations would decrease by as much as 0.3 mg/L at Banks and Jones pumping plants, although slightly more frequent export of >3 mg/L DOC water is predicted. Nevertheless, an overall improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 5 operation and maintenance would not result in any substantial change in long-term average DOC concentration upstream of the Delta or result in substantial increase in the frequency with which long-term average DOC concentrations exceeds 2, 3, or 4 mg/L levels at the 11 assessment locations analyzed for the Delta. Modeled long-term average DOC concentrations would increase by no more than 0.3 mg/L at any single Delta assessment location (i.e., ≤8% relative increase), with long-term average concentrations estimated to remain at or below 4.0 mg/L at all Delta locations assessed, with the exception of Buckley Cove on the San Joaquin River during the drought period modeled. Nevertheless, long-term average concentrations at Buckley Cove are expected to decrease slightly during the drought period, relative to Existing Conditions. The increases in long-term average DOC concentration that could occur within the Delta would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters or waters of the SWP/CVP Service Area. Because DOC is not bioaccumulative, the increases in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not 303(d) listed for any water body within the affected environment. Thus, the increases in long-term average DOC that could occur at various locations would not make any beneficial use impairment measurably worse. Because long-term average DOC concentrations are not expected to increase substantially, no long-term water quality degradation with respect to DOC is expected to occur and, thus, no adverse effects on beneficial uses would occur This impact is considered to be less than significant. No mitigation is required.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** CM2–CM21 proposed under Alternative 5 would be the same as those proposed under Alternative 1A, except that 25,000 acres rather than 65,000 acres of tidal habitat would be restored. Effects on DOC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A, except that the reduced acreage of proposed tidal habitat would reduce the overall Alternative 5-related DOC loading to the Delta. While this reduced acreage would result in reduced DOC loading relative to other action alternatives, CM4–CM7 and CM10 could still contribute substantial amounts of DOC to raw drinking water supplies, largely depending on final design and operational criteria for the related wetland and riparian habitat restoration activities. Substantially increased long-term average DOC in raw water supplies could lead to a need for treatment plant upgrades in order to appropriately manage DBP formation in treated drinking water. This potential for future DOC increases would lead to substantially greater associated risk of long-term adverse effects on the MUN beneficial use.

In summary, the habitat restoration elements of CM4–CM7 and CM10 under Alternative 5 would present new localized sources of DOC to the study area, and in some circumstances would substitute for existing sources related to replaced agriculture. Depending on localized hydrodynamics and proximity to municipal drinking water intakes, such restoration activities could contribute substantial amounts of DOC to municipal raw water. Substantial increases in municipal raw water DOC could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-18 is available to reduce these effects.

***CEQA Conclusion*:** Effects of CM4–CM7 and CM10 on DOC under Alternative 5 would be similar to those discussed for Alternative 1A, although the overall magnitude of effect is expected to be less due to the smaller acreage proposed for tidal habitat restoration. Regardless of the smaller proposed acreage, these restoration activities could present a substantial source of DOC loading to the Delta. Similar to Alternative 1A, this impact is considered to be significant and mitigation is required. It is uncertain whether implementation of Mitigation Measure WQ-18 would reduce identified impacts to a less-than-significant level. Hence, this impact remains significant and unavoidable.

In addition to and to supplement Mitigation Measure WQ-18, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from DOC concentration effects on municipal and industrial water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementing treatment for DOC and/or DBPs or DOC source control strategies. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to DOC.

Mitigation Measure WQ-18: Design Wetland and Riparian Habitat Features to Minimize Effects on Municipal Intakes

Please see Mitigation Measure WQ-18 under Impact WQ-18 in the discussion of Alternative 1A.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance (CM1)

***NEPA Effects*:** Effects of CM1 on pathogens under Alternative 5 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

***CEQA Conclusion*:** Effects of CM1 on pathogens under Alternative 5 would be the same as those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

River flow rate and reservoir storage reductions that would occur due to implementation of CM1 (water facilities and operations) under Alternative 5, relative to Existing Conditions, would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta, given the small magnitude of urban runoff contributions relative to the magnitude of river flows, that pathogen concentrations in the rivers have a minimal relationship to river flow rate, and the expected reduced pollutant loadings in response to NPDES stormwater-related regulations.

It is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens. This conclusion is based on the Pathogens Conceptual Model, which found that pathogen sources in close proximity to a Delta site appear to have the greatest influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative.

In the SWP/CVP Export Service Areas waters, relative to Existing Conditions, an increased proportion of water coming from the Sacramento River would not adversely affect beneficial uses in the SWP/CVP Export Service Areas. The pathogen levels in the Sacramento River are similar to or lower than the water diverted at the Delta export pumps. Further, it is localized sources of pathogens that appear to have the greatest influence on concentrations. Thus, an increased proportion of Sacramento River water diverted to the SWP/CVP Export Service Areas would result in minimal changes in pathogen levels in the SWP/CVP Export Service Areas waters.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is Clean Water Act section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on pathogens under Alternative 5 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on pathogens resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, under Alternative 5 no specific operations or maintenance activity of the SWP or CVP would substantially drive a change in pesticide use, and thus pesticide sources would remain unaffected upstream of the Delta. Nevertheless, changes in the timing and magnitude of reservoir releases could have an effect on available dilution capacity along river segments such as the Sacramento, Feather, American, and San Joaquin Rivers.

Under Alternative 5, winter (November–March) and summer (April–October) season average flow rates on the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis would change. Relative to existing condition and the No Action Alternative, seasonal average flow rates on the Sacramento would decrease no more than 3% during the summer and 4% during the winter (Appendix 8L, *Pesticides*, Tables 1–4). On the Feather River, average flow rates would decrease no more than 4% during the summer, but would increase by as much as 5% in the winter. American River average flow rates would decrease by as much as 15% in the summer and 1% in the winter. Seasonal average flow rates on the San Joaquin River would decrease by as much as 12% in the summer, but increase by as much as 1% in the winter. For the same reasons stated for the No Action Alternative, decreased seasonal average flow of ≤15% is not considered to be of sufficient magnitude to substantially increase pesticide concentrations or alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of water bodies upstream of the Delta.

Delta

Sources of diuron, OP and pyrethroid insecticides to the Plan Area include direct input of surface runoff from in-Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. Similar to Upstream of the Delta, CVP/SWP operations would not affect these sources.

Under Alternative 5, the distribution and mixing of Delta source waters would change. Percentage change in monthly average source water fraction was evaluated for the modeled 16-year (1976–1991) hydrologic period and a representative drought period (1987–1991), with special attention given to changes in San Joaquin River, Sacramento River and Delta Agriculture sources water fractions. Relative to Existing Conditions, under Alternative 5 modeled San Joaquin River fractions would increase greater than 10% (excluding Banks and Jones pumping plants) at Rock Slough and Contra Costa PP No. 1 (Appendix 8D, *Source Water Fingerprinting Results*). At Rock Slough, modeled San Joaquin River source water fractions would increase 16% during November (13% for the modeled drought period), while at Contra Costa PP No. 1 San Joaquin River source water fractions would increase 15% during November and 12% during March. Corresponding increases for the modeled drought period would not be greater than 8% at Contra Costa PP No. 1. Relative to Existing Conditions, there would be no modeled increases in Sacramento River fractions greater than 14% (with exception to Banks and Jones which are discussed below) and Delta agricultural fractions greater than 7%. These modeled changes in the source water fractions of Sacramento, San Joaquin and Delta agriculture water are not of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta.

When compared to the No Action Alternative, changes in source water fractions would be similar in season, geographic extent, and magnitude to those discussed for Existing Conditions with exception to Buckley Cove. Relative to the No Action Alternative, on a source water basis Buckley Cove is comprised predominantly of water of San Joaquin River origin (i.e., typically >80% San Joaquin River) for all months of the year but July and August. In July and August, the combined operational effects on Delta hydrodynamics of the Delta Cross Channel being open, the absence of a barrier at Head of Old River, and seasonally high exports from south Delta pumps results in substantially lower San Joaquin River source water fraction at Buckley Cove relative to all other months of the year. Under Alternative 5, however, modeled July and August San Joaquin River fractions at Buckley Cove would increase relative to the No Action Alternative, with increases of 12% in July (25% for the modeled drought period) and 22% in August (43% for the modeled drought period) (Appendix 8D, *Source Water Fingerprinting Results*). Despite these San Joaquin River increases, the resulting net San Joaquin River source water fraction for July and August would remain less than all other months. As a result, these modeled changes in the source water fractions are not of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta.

SWP/CVP Export Service Areas

Assessment of effects in SWP/CVP Export Service Areas is based on effects seen in the Plan Area at the Banks and Jones pumping plants. Under Alternative 5, Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants relative to Existing Conditions and the No Action Alternative (Appendix 8D, *Source Water Fingerprinting Results*). At Banks pumping plant, Sacramento source water fractions would generally increase from 14–28% for March through June (17% for April of the modeled drought period) and at Jones pumping plant Sacramento source water fractions would generally increase from 12–24% for January through June (15–27% for March through May of the modeled drought period). These increases in Sacramento source water fraction would primarily balance through equivalent decreases in San Joaquin River water. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of OP insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

NEPA Effects: In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers, under Alternative 5 relative to the No Action Alternative, are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. Similarly, modeled changes in source water fractions to the Delta are of insufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta or CVP/SWP export service areas. The effects on pesticides from operations and maintenance (CM1) are determined not to be adverse.

***CEQA Conclusion*:** Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Sources of pesticides upstream of the Delta include direct input of pesticide containing surface runoff from agriculture and urbanized areas. Flows in rivers receiving these discharges dilute these pesticide inputs. Relative to Existing Conditions, however, modeled changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta.

In the Delta, sources of pesticides include direct input of surface runoff from Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. While facilities operations and maintenance activities would not affect these sources, changes in Delta source water fraction could change the relative risk associated with pesticide related toxicity to aquatic life. Under Alternative 5, however, modeled changes in source water fractions relative to Existing Conditions are of insufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life within the Delta, nor would such changes result in adverse pesticide-related effects on any other beneficial uses of Delta waters.

The assessment of Alternative 5 effects on pesticides in the SWP/CVP Export Service Areas is based on assessment of changes predicted at Banks and Jones pumping plants. As just discussed regarding effects to pesticides in the Delta, modeled changes in source water fractions at the Banks and Jones pumping plants are of insufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life beneficial uses, or any other beneficial uses, in water bodies of the SWP and CVP export service area.

Based on the above, Alternative 5 would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta, at the 11 assessment locations analyzed for the Delta, or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions would not be expected to make any of these beneficial use impairments measurably worse. Because long-term average pesticide concentrations are not expected to increase substantially, no long-term water quality degradation with respect to pesticides is expected to occur and, thus, no adverse effects on beneficial uses would occur. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** CM2–CM21 proposed under Alternative 5 would be the same as those proposed under Alternative 1A, except that 25,000 acres rather than 65,000 acres of tidal habitat would be restored. As such, effects on pesticides resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A, except that the likely overall use of herbicides to control invasive aquatic vegetation would likely be reduced commensurate with the reduction in restored acres of tidal habitat. Nevertheless, herbicides directly applied to water could include adverse effects on non-target aquatic life, such as aquatic invertebrates and beneficial aquatic plants. As such, aquatic life toxicity objectives could be exceeded with sufficient frequency and magnitude such that beneficial uses would be impacted, thus constituting an adverse effect on water quality.

In summary, based on the discussion above, the effects on pesticides from implementing CM2-CM21 are considered to be adverse. Mitigation Measure WQ-22 would be available to reduce this adverse effect.

CEQA Conclusion**:** Effects of CM2–CM21 on pesticides under Alternative 5 are similar to conservation measures discussed for Alternative 1A. Potential environmental effects related only to CM13 are considered to be significant. Mitigation is required. While Mitigation Measure WQ-22 is available to partially reduce this impact of pesticides, no feasible mitigation is available that would reduce it to a level that would be less than significant.

Mitigation Measure WQ-22: Implement Least Toxic Integrated Pest Management Strategies

Please see Mitigation Measure WQ-22 under Impact WQ-22 in the discussion of Alternative 1A.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects**:** Effects of water facilities and operations (CM1) on phosphorus levels in water bodies of the affected environment under Alternative 5 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels discussed in detail for Alternative 1A also adequately represent the effects under Alternative 5, which are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Because phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration upstream of the Delta are not anticipated for Alternative 5, relative to Existing Conditions.

Because phosphorus concentrations in the major source waters to the Delta are similar for much of the year, phosphorus concentrations in the Delta are not anticipated to change substantially on a long term-average basis under Alternative 5, relative to Existing Conditions. Algal growth rates are limited by availability of light in the Delta, and therefore any minor increases in phosphorus levels that may occur at some locations and times within the Delta would be expected to have little effect on primary productivity in the Delta.

The assessment of effects of phosphorus under Alternative 5 in the SWP and CVP Export Service Areas is based on effects on phosphorus at the Banks and Jones pumping plants. As noted above, phosphorus concentrations in the Delta (including Banks and Jones pumping plants) are not anticipated to change substantially on a long term-average basis.

Based on the above, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas under Alternative 5 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on phosphorus levels in water bodies of the affected environment under Alternative 5 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels from implementing CM2–CM21 discussed in detail for Alternative 1A also adequately represent the effects of these same actions under Alternative 5, which are considered to be not adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on phosphorus resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 5 would have negligible, if any, effect on selenium concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in selenium concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to selenium.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics. To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, such as additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See Section 8.3.1.3 for more information.

Selenium concentrations and threshold comparisons for each of the 11 modeled Delta assessment locations under Alternative 5, relative to Existing Conditions and the No Action Alternative, are presented in Appendix 8M, *Selenium*, Table M-9a for water, Tables M-15 and M-25 for most biota (whole-body fish [excluding sturgeon], bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, and Tables M-30 through M-32 for sturgeon at the two western Delta locations. Figures 8-59a and 8-60a present graphical distributions of predicted selenium concentration changes (shown as changes in available assimilative capacity based on 1.3 µg/L) in water at each modeled assessment location for all years. Appendix 8M, Figure M-23 provides more detail in the form of monthly patterns of selenium concentrations in water during the modeling period.

Alternative 5 would result in small changes in average selenium concentrations in water at all modeled Delta assessment locations relative to Existing Conditions and the No Action Alternative (Appendix 8M, *Selenium*, Table M-9a). Long-term average concentrations at some interior and western Delta locations would increase by 0.01–0.02 µg/L for the entire period modeled (1976–1991). These small increases in selenium concentrations in water would result in small reductions (1–2% or less) in available assimilative capacity for selenium, relative to the 1.3 µg/L USEPA draft water quality criterion (Figures 8-59a and 8-60a). The long-term average selenium concentrations in water for Alternative 5 (range 0.09–0.39 µg/L) would be similar to those for Existing Conditions (range 0.09–0.41 µg/L) and the No Action Alternative (range 0.09–0.38 µg/L), and would be well below the USEPA draft water quality criterion of 1.3 µg/L (Appendix 8M, *Selenium*, Table M-9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 5 would result in very small changes (less than 1%) in estimated selenium concentrations in most biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, with little difference among locations (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-25). Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0 (indicating low probability of adverse effects). Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years also are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by about 7% relative to Existing Conditions and the No Action Alternative in all years (from about 4.7 to 5.0 mg/kg dry weight), and those for sturgeon in the Sacramento River at Mallard Island are predicted to increase by about 4% in all years (from about 4.4 to 4.6 mg/kg dry weight) (Appendix 8M, Tables M-30 and M-31). Selenium concentrations in sturgeon during drought years are expected to increase by only 2–5% at those locations (Appendix 8M, Tables M-30 and M-

31). Detection of small changes in whole-body sturgeon such as those estimated for the western Delta would require very large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 (indicating a higher probability for adverse effects) for drought years at both locations (as they do for Existing Conditions and the No Action Alternative); however, for the entire period modeled, the quotient would not be exceeded at either location (Appendix 8M, Table M-32).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in the appendix, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. (There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium.) Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on “fixed” K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Increased water residence times could increase the bioaccumulation of selenium in biota, thereby potentially increasing fish tissue and bird egg concentrations of selenium (see residence time discussion in Appendix 8M, *Selenium*, and Presser and Luoma [2010b]). Thus, residence time was assessed for its relevance to selenium bioaccumulation. Table 8-60a shows the time for neutrally buoyant particles to move through the Delta (surrogate for flow and residence time). Although an increase in residence time throughout the Delta is expected under the No Action Alternative, relative to Existing Conditions (because of climate change and sea level rise), the change is fairly small in most areas of the Delta.

Relative to Existing Conditions and the No Action Alternative, increases in residence times for Alternative 5 would be greater in the East Delta than in other sub-regions. Relative to Existing Conditions, annual average residence times for Alternative 5 in the East Delta are expected to increase by more than 16 days (Table 8-60a). Relative to the No Action Alternative, annual average residence times for Alternative 5 in the East Delta are expected to increase by less than 9 days. Increases in residence times for other sub-regions would be smaller, especially as compared to Existing Conditions and the No Action Alternative (which are longer than those modeled for the South Delta). As mentioned above, these results incorporate hydrodynamic effects of both CM1 and CM2 and CM4, and the effects of CM1 cannot be distinguished from the effects of CM2 and CM4. However, it is expected that CM2 and CM4 are substantial drivers of the increased residence time.

Presser and Luoma (2010b) summarized and discussed selenium uptake in the Bay-Delta (including hydrologic conditions [e.g., Delta outflow and residence time for water], K_ds [the ratio of selenium concentrations in particulates, as the lowest level of the food chain, relative to the water-borne concentration], and associated tissue concentrations [especially in clams and their consumers, such as sturgeon]). When the Delta Outflow Index (daily average flow per month) decreased by five-fold (73,732 cfs in June 1998 to 12,251 cfs in October 1998), residence time doubled (from 11 to 22 days) and the calculated mean K_d also doubled (from 3,198 to 6,501). However, when daily average Delta outflow in November 1999 was only 6,951 cfs (i.e., about one-half that in October 1998) and residence time was 70 days, the calculated mean K_d (7,614) did not increase proportionally.

Models are not available to quantitatively estimate the level of changes in selenium bioaccumulation as related to residence time, but the effects of residence time are incorporated in the bioaccumulation modeling for selenium that was based on higher K_d values for drought years in comparison to wet, normal, or all years; see Appendix 8M, *Selenium*. If increases in fish tissue or bird egg selenium were to occur, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. In consideration of this factor, although the Delta as a whole is a CWA Section 303(d)-listed water body for selenium, and although monitoring data of fish tissue or bird eggs in the Delta are sparse, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time from restoration areas would be a concern is the western Delta and Suisun Bay for sturgeon, as discussed above. As shown in Table 8-60a, the overall increase in residence time estimated in the western Delta is 5 days relative to Existing Conditions, and 3 days relative to the No Action Alternative. Given the available information, these increases are small enough that they are not expected to substantially affect selenium bioaccumulation in the western Delta. Because CM2 and CM4 are expected to be substantial drivers of the increased residence times, further discussion is included in Impact WQ-26 below,

In summary, relative to Existing Conditions and the No Action Alternative, Alternative 5 would result in essentially no change in selenium concentrations throughout the Delta for most biota (less than 1%), although increases in selenium concentrations are predicted for sturgeon in the western Delta. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, Alternative 5 would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon relative to the low benchmark and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium.

SWP/CVP Export Service Areas

Alternative 5 would result in small decreases in long-term average selenium concentrations in water at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative, for the entire period modeled (Appendix 8M, *Selenium*, Table M-9a). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium of 2–4%. Furthermore, the long-term average selenium concentrations in water for Alternative 5 (range 0.19–0.25 μg/L) would be well below the USEPA draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 5 would result in very small changes (less than 1%) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet] bird eggs [fish diet], and fish fillets) (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-25) at Banks and Jones pumping plants. Concentrations in biota would not exceed any selenium benchmarks for Alternative 5 (Figures 8-61a through 8-64b).

NEPA Effects: Based on the discussion above, the effects on selenium (both as waterborne and as bioaccumulated in biota) from Alternative 5 are not considered to be adverse.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for selenium. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 5, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate that Alternative 5 would result in essentially no change in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. The Low Toxicity Threshold Exceedance Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase slightly, from 0.94 for Existing Conditions to 1.0 for Alternative 5. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. Overall, Alternative 5 would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 5 would cause no increase in the frequency with which applicable benchmarks would be exceeded and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants.

Based on the above, selenium concentrations that would occur in water under Alternative 5 would not cause additional exceedances of applicable state or federal numeric or narrative water quality objectives/criteria, or other relevant water quality effects thresholds identified for this assessment (Table 8-54), by frequency, magnitude, and geographic extent that would result in adverse effects to one or more beneficial uses within affected water bodies. In comparison to Existing Conditions and the No Action Alternative, water quality conditions under this alternative would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Water quality conditions under this alternative with respect to selenium would not cause long-term degradation of water quality in the affected environment, and therefore would not result in use of available assimilative capacity such that exceedances of water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. This alternative would not further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the 303(d)-listed impairment of beneficial use to be made discernibly worse. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on selenium under Alternative 5 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on selenium resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 5 would result in negligible, and likely immeasurable, increases in trace metal concentrations in the rivers and reservoirs upstream of the Delta, relative to Existing Conditions and the No Action Alternative. Effects due to the operation and maintenance of the conveyance facilities are expected to be immeasurable, on an annual and long-term average basis. As such, Alternative 5 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to trace metals.

Delta

For the same reasons stated for the No Action Alternative, Alternative 5 would not result in substantial increases in trace metal concentrations in the Delta relative to Existing Conditions and the No Action Alternative. Effects due to the operation and maintenance of the conveyance facilities are expected to be negligible, on a long-term average basis. As such, Alternative 5 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the Delta or substantially degrade the quality of Delta waters, with regard to trace metals.

SWP/CVP Export Service Areas

For the same reasons stated for the No Action Alternative, Alternative 5 would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities. As such, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP export service area waters under Alternative 5, relative to Existing Conditions and the No Action Alternative. As such, Alternative 5 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment in the SWP and CVP Service Area or substantially degrade the quality of these water bodies, with regard to trace metals.

***NEPA Effects*:** In summary, Alternative 5, relative to the No Action Alternative, would not cause a substantial increase in long-term average trace metals concentrations within the affected environment, nor would it cause an increased frequency of water quality objective/criteria exceedances within the affected environment. The effect on trace metals is determined not to be adverse.

CEQA Conclusion: Effects of CM1 on trace metals under Alternative 5 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

While greater water demands under the Alternative 5 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95^{th} percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95^{th} percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based without a WER adjustment. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under the Alternative 5.

The assessment of the Alternative 5 effects on trace metals in the SWP/CVP Export Service Areas is based on assessment of changes in trace metal concentrations at Banks and Jones pumping plants. As just discussed regarding similarities in Delta source water trace metal concentrations, the Alternative 5 is not expected to result in substantial changes in trace metal concentrations in Delta waters, including Banks and Jones pumping plants, therefore effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

Based on the above, there would be no substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area waters under Alternative 5 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** CM2–CM21 proposed under Alternative 5 would be the same as those proposed under Alternative 1A, except that 25,000 acres rather than 65,000 acres of tidal habitat would be restored. Effects on trace metals resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. As they pertain to trace metals, implementation of CM2–CM21 would not be expected to adversely affect beneficial uses of the affected environment or substantially degrade water quality with respect to trace metals.

In summary, implementation of CM2–CM21 under Alternative 5, relative to the No Action Alternative, would have negligible, if any, effect on trace metals concentrations. The effect on trace metals from implementing CM2–CM21 is determined not to be adverse.

CEQA Conclusion: Implementation of CM2–CM21 under Alternative 5 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance (CM1)

***NEPA Effects*:** Effects of CM1 on TSS and turbidity under Alternative 5 would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM1 is determined to not be adverse.

***CEQA Conclusion*:** Effects of CM1 on TSS and turbidity under Alternative 5 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Changes river flow rate and reservoir storage that would occur under Alternative 5, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes would be site-specific and temporal, which would be regulated to limit both their short-term and long-term effects on TSS and turbidity levels to less than substantial levels.

Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the Delta region, relative to Existing Conditions.

There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative 5, relative to Existing Conditions, because as stated above, this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act section 303(d) listed constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on TSS and turbidity under Alternative 5 would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM2–CM21 is determined to not be adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 5 would be similar to conservation measures proposed under Alternative 1A. As such, effects on TSS and turbidity resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

The conveyance features for CM1 under Alternative 5 would be very similar to those discussed for Alternative 1A. The primary difference between Alternative 5 and Alternative 1A is that under Alternative 5, there would be four fewer intakes and four fewer pumping plant locations, which would result in a reduced level of construction activity. However, construction techniques and locations of major features of the conveyance system within the Delta would be similar. The remainder of the facilities constructed under Alternative 5, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A. However, under Alternative 5, there would only be up to 25,000 acres of tidal marsh habitat restored (as opposed to 65,000 acres under the majority of the other alternatives), thus resulting in less in-water construction-related disturbances.

NEPA Effects: The types of potential construction-related water quality effects associated with implementation of CM1–CM21 under Alternative 5 would be very similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. However, the construction of fewer intakes and smaller conveyance features for CM1, and less tidal marsh habitat restoration, under Alternative 5 would be anticipated to result in a lower magnitude of construction-related activities. Nevertheless, the construction of CM1, and any individual components necessitated by CM2, and CM4–CM10, with the implementation of the BMPs specified in Appendix 3B, *Environmental Commitments, AMMs, and CMs,* and other agency permitted construction requirements would result in the potential water quality effects being largely avoided and minimized. The specific environmental commitments that would be implemented under Alternative 5 would be similar to those described for Alternative 1A. Consequently, relative to Existing Conditions, Alternative 5 would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP and CVP service area.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

CEQA Conclusion: Because environmental commitments would be implemented under Alternative 5 for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32. Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance (CM1)

Effects of facilities and operations (CM1) on *Microcystis* abundance, and thus microcystins concentrations, in water bodies of the affected environment under Alternative 5 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. This is because factors that affect *Microcystis* abundance in waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Services Areas under Alternative 1A would similarly change under Alternative 5, relative to Existing

Conditions and the No Action Alternative. For the Delta in particular, there are differences in the direction and magnitude of water residence time changes during the *Microcystis* bloom period among the six Delta sub-regions under Alternative 5 compared to Alternative 1A, relative to Existing Conditions and No Action Alternative. However, under Alternative 5, relative to Existing Conditions and No Action Alternative, water residence times during the *Microcystis* bloom period in various Delta sub-regions are expected to increase to a degree that could, similar to Alternative 1A, lead to an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms throughout the Delta.

Similar to Alternative 1A, elevated ambient water temperatures relative to Existing Conditions would occur in the Delta under Alternative 5, which could lead to earlier occurrences of *Microcystis* blooms in the Delta, and increase the overall duration and magnitude of blooms. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. While *Microcystis* blooms have not occurred in the Export Service Areas, conditions in the Export Service Areas under Alternative 5 may become more conducive to *Microcystis* bloom formation, relative to Existing Conditions, because water temperatures will increase in the Export Service Areas due to the expected increase in ambient air temperatures resulting from climate change.

NEPA Effects: Effects of water facilities and operations (CM1) on *Microcystis* in water bodies of the affected environment under Alternative 5 would be very similar to (i.e., nearly the same) to those discussed for Alternative 1A. In summary, Alternative 5 operations and maintenance, relative to the No Action Alternative, would result in long-term increases in hydraulic residence time of various Delta sub-regions during the summer and fall *Microcystis* bloom period. During this period, the increased residence time could result in a concurrent increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus microcystin levels, in affected areas of the Delta. As a result, Alternative 5 operation and maintenance activities would cause further degradation to water quality with respect to *Microcystis* in the Delta. Under Alternative 5, relative to No Action Alternative, water exported to the SWP/CVP Export Service Area will be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River, diverted at the north Delta intakes. It cannot be determined whether operations and maintenance under Alternative 5 will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants. Mitigation Measure WQ-32a and WQ-32b are available to reduce the effects of degraded water quality in the Delta. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 5, additional impacts from *Microcystis* in the reservoirs and watersheds upstream of the Delta are not expected, relative to Existing Conditions. Operations and maintenance occurring under Alternative 5 is not expected to change nutrient levels in upstream reservoirs or hydrodynamic conditions in upstream rivers and streams such that conditions would be more conductive to *Microcystis* production.

Relative to Existing Conditions, water temperatures and hydraulic residence times in the Delta are expected to increase under Alternative 5, resulting in an increase in the frequency, magnitude and geographic extent of *Microcystis* blooms in the Delta. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. Increases in Delta residence times are expected throughout the Delta during the summer and fall bloom period, due in small part to climate change and sea level rise, but due more proportionately to CM1 and the hydrodynamic impacts of restoration included in CM2 and CM4. The precise change in local residence times and *Microcystis* production expected within any Delta sub-region is unknown because conditions will vary across the complex networks of intertwining channels, shallow back water areas, and submerged islands that compose the Delta. Nonetheless, Delta residence times are, in general, expected to increase due to Alternative 5. Consequently, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 5 and the hydrodynamic impacts of restoration (CM2 and CM4).

The assessment of effects of *Microcystis* on SWP/CVP Export Service Areas is based on the assessment of changes in *Microcystis* levels in export source waters, as well as the effects of temperature and residence time changes within the Export Service Areas on *Microcystis* production. Under Alternative 5, relative to Existing Conditions, the potential for *Microcystis* to occur in the Export Service Area is expected to increase due to increasing water temperature, but this impact is driven entirely by climate change and not Alternative 5. Water exported from the Delta to the Export Service Area is expected to be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River. Because of this, it cannot be determined whether operations and maintenance under Alternative 5, relative to existing conditions, will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants.

Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, because it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 5 and the hydrodynamic impacts of restoration (CM2 and CM4), long-term water quality degradation may occur and, thus, significant impacts on beneficial uses could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be significant.

Implementation of Mitigation Measure WQ-32a and WQ-32b may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of these mitigation measures to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Mitigation Measure WQ-32b: Investigate and Implement Operational Measures to Manage Water Residence Time

Please see Mitigation Measure WQ-32b under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-33. Effects on *Microcystis* Bloom Formation Resulting from Other Conservation Measures (CM2–CM21)

The effects of CM2–CM21 on *Microcystis* under Alternative 5 would be the same as those discussed for Alternative 1A. In summary, potential environmental effects related to CM2 and CM4 could result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta, relative to Existing Conditions and the No Action Alternative, as a result of increased residence times for Delta waters from implementing CM2 and CM4 restoration areas. Because the hydrodynamic effects associated with implementing CM2 and CM4 were incorporated into the modeling used to assess CM1, a detailed assessment of the effects of implementing CM2 and CM4 on *Microcystis* blooms in the Delta via their effects on Delta water residence time is provided under CM1 (above). The effects of CM2 and CM4 on *Microcystis* may be reduced by implementation of Mitigation Measures WQ-32a. The effectiveness of the mitigation measure to result in feasible measures for reducing water quality effects is uncertain. CM3 and CM5–CM21 would not result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta.

NEPA Effects: Effects of CM2–CM21 on *Microcystis* under Alternative 5 would be the same as those discussed for Alternative 1A and are considered to be adverse.

CEQA Conclusion: Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Because restoration actions implemented under CM2 and CM4 will increase residence time throughout the Delta and create local areas of warmer water during the bloom season, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus long-term water quality degradation and significant impacts on beneficial uses, could occur. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM2–CM21 are determined to be significant.

Implementation of Mitigation Measure WQ-32a may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance (CM1) and Implementation of CM2–CM21

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 5 would have a less than significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- DO
- Pathogens
- Pesticides
- Trace Metals
- Turbidity and TSS

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Thus, changes in boron, DO, pathogens, pesticides, and turbidity and TSS in Delta outflow are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay.

The effects of Alternative 5 on bromide, chloride, and DOC, in the Delta were determined to be significant/adverse. Increases in bromide, chloride, and DOC concentrations are of concern in drinking water supplies; however, as described previously, the San Francisco Bay does not have a designated MUN use. Thus, changes in bromide, chloride, and DOC in Delta outflow would not adversely effect any beneficial uses of San Francisco Bay.

Elevated EC, as assessed for this alternative, is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. As discussed above, San Francisco Bay does not have an AGR beneficial use designation. Further, as discussed for the No Action Alternative, changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow, which would be the primary driver of salinity changes, would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow.

Also, as discussed for the No Action Alternative, adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in San Francisco Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus have not been detected downstream of Suisun Bay.

While effects of Alternative 5 on the nutrients ammonia, nitrate, and phosphorus were determined to be less than significant/not adverse, these constituents are addressed further below because the response of the seaward bays to changed nutrient concentrations/loading may differ from the response of the Delta. Selenium and mercury are discussed further, because they are bioaccumulative constituents where changes in load due to both changes in Delta concentrations and exports are of concern.

Nutrients: Ammonia, Nitrate, and Phosphorus

Total nitrogen loads in Delta outflow to Suisun and San Pablo Bays under Alternative 5 would be dominated almost entirely by nitrate, because planned upgrades to the SRWTP will result in >95% removal of ammonia in its effluent. Total nitrogen loads to Suisun and San Pablo Bays would decrease by 31%, relative to Existing Conditions, and increase by 2%, relative to the No Action Alternative (Appendix 8O, *San Francisco Bay Analysis*, Table O-1). The change in nitrogen loading to Suisun and San Pablo Bays under Alternative 5 would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. To the extent that algal growth increases in relation to a change in ammonia concentration, this would have net positive benefits, because current algal levels in these embayments are low. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay.

The phosphorus load exported from the Delta to Suisun and San Pablo Bays for Alternative 5 is estimated to increase by 3%, relative to Existing Conditions, and decrease by 2% relative to the No Action Alternative (Appendix 8O, Table O-1). The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. Any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary (Senn and Novick 2014; Kimmerer and Thompson 2014). Therefore, the projected change in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay is not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Mercury

The estimated long-term average mercury and methylmercury loads in Delta exports are shown in Appendix 8O, Table O-2. Loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 5. Mercury load to the Bay is estimated to increase by 3 kg/year (1%), relative to Existing Conditions, and be unchanged relative to the No Action Alternative. Methylmercury load is estimated to increase by 0.06 kg/year (2%), relative to Existing Conditions, and decrease by 0.03 kg/year (1%) relative to the No Action Alternative. The estimated total mercury load to the Bay is 263 kg/year, which would be less than the San Francisco Bay mercury TMDL WLA for the Delta of 330 kg/year. The estimated changes in mercury and methylmercury loads would be within the overall uncertainty associated with the estimates of long-term average net Delta outflow and the long-term average mercury and methylmercury concentrations in Delta source waters. The estimated changes in mercury load under the alternative would also be substantially less than the considerable differences among estimates in the current mercury load to San Francisco Bay (San Francisco Bay Regional Water Quality Control Board 2006; David et al. 2009).

Given that the estimated incremental increases of mercury and methylmercury loading to San Francisco Bay would fall within the uncertainty of current mercury and methylmercury load estimates, the estimated changes in mercury and methylmerucy loads in Delta exports to San Francisco Bay due to Alternative 5 are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to mercury, or make the existing CWA Section 303(d) impairment measurably worse.

Selenium

Changes in source water fraction and net Delta outflow under Alternative 5, relative to Existing Conditions, are projected to cause the total selenium load to the North Bay to increase by 4%, relative to Existing Conditions, and increase by 1%, relative to the No Action Alternative (Appendix 8O, *San Francisco Bay Analysis*, Table O-3). Changes in long-term average selenium concentrations of the North Bay are assumed to be proportional to changes in North Bay selenium loads. Under Alternative 5, the long-term average total selenium concentration of the North Bay is estimated to be 0.13µg/L and the dissolved selenium concentration is estimated to be 0.11 µg/L, which would be the same as Existing Conditions and the No Action Alternative (Appendix 8O, Table O-3). The dissolved selenium concentration would be below the target of 0.202 µg/L developed by Presser or Luoma (2013) to coincide with a white sturgeon whole-body fish tissue selenium concentration not greater than 8 mg/kg in the North Bay. The incremental increase in dissolved selenium concentrations in the North Bay, relative to Existing Conditions, would be negligible (0.00 µg/L) under this alternative. Thus, the estimated changes in selenium loads in Delta exports to San Francisco Bay due to Alternative 5 are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to selenium, or make the existing CWA Section 303(d) impairment measurably worse.

NEPA Effects: Based on the discussion above, Alternative 5, relative to the No Action Alternative, would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, selenium, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, based on the discussion above, effects on the San Francisco Bay from implementation of CM1–CM21 are considered to be not adverse.

CEQA Conclusion: Based on the above, Alternative 5 would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. Further, based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals or turbidity or TSS are anticipated in the Delta, relative to Existing Conditions, therefore, no substantial changes these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow. Adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in the Bay, because *Microcystis* are intolerant of the

Bay's high salinity and, thus not have not been detected downstream of Suisun Bay. The 31% decrease in total nitrogen load and 3% increase in phosphorus load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. The estimated increase in mercury load (3 kg/year; 1%) and methylmercury load (0.06 kg/year; 2%), relative to Existing Conditions, is within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. The estimated increase in selenium load would be 4%, but estimated total and dissolved selenium concentrations under this alternative would be the same as Existing Conditions, and less than the target associated with white sturgeon whole-body fish tissue levels for the North Bay. Thus, the small increase in selenium load is not expected to contribute to water quality degradation, or make the CWA section 303(d) selenium impairment measurably worse or cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant.

8.3.3.11 Alternative 6A—Isolated Conveyance with Pipeline/Tunnel and Intakes 1–5 (15,000 cfs; Operational Scenario D)

Alternative 6A would comprise physical/structural components similar to those under Alternative 1A with the principal exception that Alternative 6A would be an "isolated" conveyance, no longer involving operation of the existing SWP and CVP south Delta export facilities for Clifton Court Forebay and Jones Pumping Plant. Alternative 6A would convey up to 15,000 cfs of water from the north Delta to the south Delta through pipelines/tunnels from five screened intakes (i.e., Intakes 1 through 5) on the east bank of the Sacramento River between Clarksburg and Walnut Grove. Alternative 6A would include a 750-acre intermediate forebay and pumping plant. A new 600-acre Byron Tract Forebay, adjacent to and south of Clifton Court Forebay, would be constructed which would provide water to the south Delta pumping plants. However, this. Water supply and conveyance operations would follow the guidelines described as Scenario D, which includes Fall X2. CM2–CM21 would be implemented under this alternative, and would be the same as those under Alternative 1A. See Chapter 3, *Description of Alternatives*, Section 3.5.11, for additional details on Alternative 6A.

Effects of the Alternative on Delta Hydrodynamics

Under the No Action Alternative and Alternatives 1A–9, the following two primary factors can substantially affect water quality within the Delta:

- Within the south, west, and interior Delta, a decrease in the percentage of Sacramento River-sourced water and a concurrent increase in San Joaquin River-sourced water can increase the concentrations of numerous constituents (e.g., boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides, selenium). This source water replacement is caused by decreased exports of San Joaquin River water (due to increased Sacramento River water exports), or effects of climate change on timing of flows in the rivers. Changes in channel flows also can affect water residence time and many related physical, chemical, and biological variables.

- Particularly in the west Delta, sea water intrusion as a result of sea level rise or decreased Delta outflow can increase the concentration of salts (bromide, chloride) and levels of electrical conductivity. Conversely, increased Delta outflow (e.g., as a result of Fall X2 operations in wet and above normal water years) will decrease levels of these constituents, particularly in the west Delta.

The primary differences between Alternative 6A and Alternative 1A are that all of the Delta exports would be via the north Delta diversion intakes, with none through the existing south Delta intakes, and operations include the meeting of Fall X2.

Under Alternative 6A, over the long term, average annual delta exports are anticipated to decrease by 1,386 TAF relative to Existing Conditions, and by 682 TAF relative to the No Action Alternative. All of the exported water will be from the new north Delta intakes, and none of the diversions would be from the existing south Delta intakes (see Chapter 5, *Water Supply*, for more information). The result of this is greatly increased San Joaquin River water influence throughout the south, west, and interior Delta, and a corresponding decrease in Sacramento River water influence. This can be seen, for example, in Appendix 8D, ALT 6–Old River at Rock Slough for ALL years (1976–1991), which shows increased San Joaquin River (SJR) percentage and decreased Sacramento River (SAC) percentage under the alternative, relative to Existing Conditions and the No Action Alternative.

Under Alternative 6A, long-term average annual Delta outflow is anticipated to increase 1,383 TAF relative to Existing Conditions, due to both changes in operations (including north Delta intake capacity of 15,000 cfs and numerous other components of Operational Scenario D) and climate change/sea level rise (see Chapter 5, *Water Supply*, for more information). The result of this would be decreased sea water intrusion in the west Delta. The decrease of sea water intrusion in the west Delta under Alternative 6A would be greater relative to Existing Conditions because Existing Conditions do not include operations to meet Fall X2, whereas the No Action Alternative and Alternative 6A do. Long-term average annual Delta outflow is anticipated to increase under Alternative 6A by 633 TAF relative to the No Action Alternative, due only to changes in operations. The decreases in sea water intrusion (represented by an decrease in San Francisco Bay (BAY) percentage) can be seen, for example, in Appendix 8D, ALT 6A–Sacramento River at Mallard Island for ALL years (1976–1991).

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 6A would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

Assessment of effects of ammonia under Alternative 6A is the same as discussed under Alternative 1A, except that because flows in the Sacramento River at Freeport are different between the two alternatives, estimated monthly average and long term annual average predicted ammonia-N concentrations in the Sacramento River downstream of Freeport are different.

As Table 8-69 shows, estimated ammonia-N concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 6A and the No Action Alternative are expected to be similar. Minor increases in ammonia-N concentrations would occur during January through April, and July through December, and remaining months would be unchanged. A minor increase in the annual average concentration would occur under Alternative 6A, compared to the No Action Alternative. Moreover, the estimated concentrations downstream of Freeport under Alternative 6A would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 6A, relative to the No Action Alternative, are not expected to substantially increase ammonia concentrations at any Delta locations.

Table 8-69. Estimated Ammonia-N (mg-L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative and Alternative 6A

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative	0.074	0.084	0.069	0.060	0.057	0.060	0.058	0.064	0.067	0.060	0.067	0.064	0.065
Alternative 6A	0.075	0.086	0.070	0.061	0.058	0.061	0.059	0.064	0.067	0.062	0.068	0.066	0.066

Any negligible increases in ammonia-N concentrations that could occur at certain locations in the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

SWP/CVP Export Service Areas

The assessment of effects on ammonia in the SWP/CVP Export Service Area is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. Similar to the discussion for Alternative 1A, under Alternative 6A for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease, relative to Existing Conditions (in association with diversion of water not influenced by the SRWTP). This decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in adverse effects on beneficial uses or substantially degrade water quality of exported water, with regards to ammonia.

Furthermore, as discussed above for the Plan Area, for all areas of the Delta, including Banks and Jones pumping plants, ammonia-N concentrations are not expected to be substantially different under Alternative 6A, relative to No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

***NEPA Effects*:** In summary, based on the discussion above, effects on ammonia from implementation of CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Ammonia-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to the lack of substantial point and nonpoint sources of ammonia-N upstream of the SRWTP in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 6A, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river ammonia-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

Ammonia-N concentrations in the Sacramento River downstream of the SRWTP would be substantially lower under Alternative 6A, relative to Existing Conditions, due to upgrades to the SRWTP that are assumed to be in place, and thus, ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water are expected to decrease. At locations which are not influenced notably by Sacramento River water, concentrations are expected to remain relatively unchanged, due to the similarity in SJR and BAY concentrations and the lack of expected changes in either of these concentrations.

The assessment of effects on ammonia in the SWP/CVP Export Service Areas is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. As discussed above for the Plan Area, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 6A, relative to Existing Conditions.

Based on the above, there would be no substantial, long-term increase in ammonia-N concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 6A relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/ criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia-N is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on ammonia under Alternative 6A would be the same as those discussed for Alternative 1A and are considered to be not adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on ammonia resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Effects of CM1 on boron under Alternative 6A in areas upstream of the Delta would be very similar to the effects discussed for Alternative 1A. There would be no expected change to the sources of boron in the Sacramento and eastside tributary watersheds, and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled long-term annual average lower San Joaquin River flow at Vernalis would decrease slightly compared to Existing Conditions (in association with project operations, climate change, and increased water demands) and would be similar compared to the No Action Alternative considering only changes due to Alternative 6A operations. The reduced flow would result in possible increases in long-term average boron concentrations of up to about 3% relative to Existing Conditions (Appendix 8F, *Boron*, Table Bo-32). The increased boron concentrations would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 6A would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to the Existing Conditions and No Action Alternative, Alternative 6A would result in generally widespread increased long-term average boron concentrations for the 16-year period modeled at the interior and western Delta locations (by as much as 14% at the SF Mokelumne River at Staten Island, 4% at the San Joaquin River at Buckley Cove, 43% at Franks Tract, and 74% at Old River at Rock Slough) (Appendix 8F, *Boron*, Table Bo-16). The comparison to Existing Conditions reflects changes due to both Alternative 6A operations (including north Delta intake capacity of 15,000 cfs and numerous other components of Operational Scenario D) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes due only to operations.

Implementation of tidal habitat restoration under CM4 also may contribute to increased boron concentrations at western Delta assessment locations (more discussion of this phenomenon is included in Section 8.3.1.3), and thus would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations. The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 µg/L human health advisory objective (i.e., for children) or 500 µg/L agricultural objective at any of the eleven Delta assessment locations, which represents no change from the Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-3A). The increased concentrations at interior Delta locations would result in moderate reductions in the long-term average assimilative capacity of up to 21% at Franks Tract and up to 43% at Old River at Rock Slough locations (Appendix 8F, *Boron*, Table Bo-17). However, because the absolute boron concentrations would still be well below the lowest 500 µg/L objective for the protection of the agricultural beneficial use under Alternative 6A, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, Figure Bo-4).

SWP/CVP Export Service Areas

Effects of CM1 on boron under Alternative 6A in the Delta would be similar to the effects discussed for Alternative 1A. Under Alternative 6A, long-term average boron concentrations would decrease by as much as 56% at the Banks Pumping Plant and by as much 63% at Jones Pumping Plant relative to Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-16) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading.

Maintenance of SWP and CVP facilities under Alternative 6A would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment. Maintenance activities would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative conditions, Alternative 6 would result in relatively small long-term average increases in boron levels in the San Joaquin River and moderate increases in the interior and western Delta locations Delta. However, the predicted changes in the Delta would not be expected to result in exceedances of applicable objectives or further water quality degradation such that objectives would likely be exceeded or there would be substantially increased risk of adverse effects on water quality.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Boron is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 6, relative to

Existing Conditions, would not be expected to result in a substantial adverse change in boron levels. Additionally, relative to Existing Conditions, Alternative 6A would not result in reductions in river flow rates (i.e., less dilution) or increased boron loading such that there would be any substantial increases in boron concentration upstream of the Delta in the San Joaquin River watershed.

Moderate increased boron levels (i.e., up to 75% increased concentration) and degradation predicted for interior and western Delta locations in response to a shift in the Delta source water percentages and tidal habitat restoration under this alternative would not be expected to cause exceedances of objectives. Alternative 6A maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 6A would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to Existing Conditions, Alternative 6A would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 6A, while widespread in particular at interior Delta locations, would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Consequently, Alternative 6A would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on boron under Alternative 6A would be the same as those discussed for Alternative 1A and are determined to be not adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on boron resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 6A there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 6A would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. Consequently, Alternative 6A would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the eastside tributaries, or their associated reservoirs upstream of the Delta.

Under Alternative 6A, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by 6%, relative to Existing Conditions and would remain virtually the same relative to the No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). These decreases in flow would result in possible increases in long-term average bromide concentrations of about 3%, relative to Existing Conditions and less than <1% relative to the No Action Alternative (Appendix 8E, *Bromide*, Table 24). The small increases in lower San Joaquin River bromide levels that could occur under Alternative 6A, relative to existing and the No Action Alternative conditions would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the lower San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Using the mass-balance modeling approach for bromide (see Section 8.3.1.3), relative to Existing Conditions, Alternative 6A would result in increases in long-term average bromide concentrations at Staten Island and Barker Slough, while long-term average concentrations would decrease at the other assessment locations (Appendix 8E, *Bromide*, Table 14). At Barker Slough, predicted long-term average bromide concentrations would increase from 51 μg/L to 61 μg/L (19% relative increase) for the modeled 16-year hydrologic period and would increase from 54 μg/L to 92 μg/L (73% relative increase) for the modeled drought period. At Barker Slough, the predicted 50 μg/L exceedance frequency would decrease from 49% under Existing Conditions to 38% under Alternative 6A, but would increase from 55% to 63% during the drought period. At Barker Slough, the predicted 100 μg/L exceedance frequency would increase from 0% under Existing Conditions to 17% under Alternative 6A, and would increase from 0% to 37% during the drought period. At Staten Island, predicted long-term average bromide concentrations would increase from 50 μg/L to 70 μg/L (41% relative increase) for the modeled 16-year hydrologic period and would increase from 51 μg/L to 70 μg/L (37% relative increase) for the modeled drought period. At Staten Island, increases in average bromide concentrations would correspond to an increased frequency of 50 μg/l threshold exceedance, from 47% under Existing Conditions to 85% under Alternative 6A (52% to 88% for the modeled drought period), and an increase from 1% to 10% (0% to 5% for the modeled drought period) for the 100 μg/L threshold. Changes in exceedance frequency of the 50 μg/L and 100 μg/L concentration thresholds at other assessment locations would be less considerable. This comparison to Existing Conditions reflects changes in bromide due to both Alternative 6A operations (including north Delta intake capacity of 15,000 cfs and numerous other components of Operational Scenario D) and climate change/sea level rise.

Due to the relatively small differences between modeled Existing Conditions and No Action baselines, changes in long-term average bromide concentrations and changes in exceedance frequencies relative to the No Action Alternative would be generally of similar magnitude to those previously described for the Existing Conditions comparison (Appendix 8E, *Bromide*, Table 14). Modeled long-term average bromide concentration increases at Barker Slough are predicted to increase by 22% (72% for the modeled drought period) relative to the No Action Alternative.

Modeled long-term average bromide concentration increases at Staten Island are predicted to increase by 45% (41% for the modeled drought period) relative to the No Action Alternative. However, unlike the Existing Conditions comparison, long-term average bromide concentrations at Buckley Cove would increase relative to the No Action Alternative, although the increases would be relatively small (≤4%). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in bromide due only to Alternative 6A operations.

At Barker Slough, modeled long-term average bromide concentrations for the two baseline conditions are very similar (Appendix 8E, *Bromide*, Table 14). Such similarity demonstrates that the modeled Alternative 6A change in bromide is almost entirely due to Alternative 6A operations, and not climate change/sea level rise. Therefore, operations are the primary driver of effects on bromide at Barker Slough, regardless whether Alternative 6A is compared to Existing Conditions, or compared to the No Action Alternative.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) differed somewhat from what is presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 15). For most locations, the frequency of exceedance of the 50 µg/L and 100 µg/L were similar. The greatest difference between the methods was predicted for Barker Slough. The increases in frequency of exceedance of the 100 µg/L threshold, relative to Existing Conditions and the No Action Alternative, were not as great using this alternative EC to chloride and chloride to bromide relationship modeling approach as compared to that presented above from the mass-balance modeling approach. However, there were still substantial increases, resulting in 6% exceedance over the modeled period under Alternative 6A, as compared to 1% under Existing Conditions and 2% under the No Action Alternative. For the drought period, exceedance frequency increased from 0% under Existing Conditions and the No Action Alternative, to 17% under Alternative 6A. Because the mass-balance approach predicts a greater level of impact at Barker Slough, determination of impacts was based on the mass-balance results.

The increase in long-term average bromide concentrations predicted at Barker Slough, principally the relative increase in 100 µg/L exceedance frequency, would result in a substantial change in source water quality for existing drinking water treatment plants drawing water from the North Bay Aqueduct. As discussed for Alternative 1A, drinking water treatment plants obtaining water via the North Bay Aqueduct utilize a variety of conventional and enhanced treatment technologies in order to achieve DBP drinking water criteria. While the implications of such a modeled change in bromide at Barker Slough are difficult to predict, the substantial modeled increases could lead to adverse changes in the formation of disinfection byproducts such that considerable treatment plant upgrades may be necessary in order to achieve equivalent levels of health protection. Increases at Staten Island are also considerable, although there are no existing or foreseeable municipal intakes in the immediate vicinity. Because many of the other modeled locations already frequently exceed the 100 µg/L threshold under Existing Conditions and the No Action Alternative, these locations likely already require treatment plant technologies to achieve equivalent levels of health protection, and thus no additional treatment technologies would be triggered by the small increases in the frequency of exceeding the 100 µg/L threshold. Hence, no further impact on the drinking water beneficial use would be expected at these locations.

The seasonal intakes at Mallard Slough and City of Antioch are infrequently used due to water quality constraints related to sea water intrusion. On a long-term average basis, bromide at these locations is in excess of 3,000 µg/L, but during seasonal periods of high Delta outflow can be <300 µg/L. Based on modeling using the mass-balance approach, use of the seasonal intakes at Mallard

Slough and City of Antioch under Alternative 6A would experience a period average increase in bromide during the months when these intakes would most likely be utilized. For those wet and above normal water year types where mass balance modeling would predict water quality typically suitable for diversion, predicted long-term average bromide would increase from 103 μg/L to 162 μg/L (58% increase) at City of Antioch and would increase from 150 μg/L to 199 μg/L (33% increase) at Mallard Slough relative to Existing Conditions (Appendix 8E, *Bromide*, Table 25). Increases would be similar for the No Action Alternative comparison. Modeling results using the EC to chloride and chloride to bromide relationships show increases during these months, but the relative magnitude of the increases is much lower (Appendix 8E, *Bromide*, Table 26). Regardless of the differences in the data between the two modeling approaches, the decisions surrounding the use of these seasonal intakes is largely driven by acceptable water quality, and thus have historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at the City of Antioch and Mallard Slough intake would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

Based on modeling using the mass-balance approach, relative to existing and No Action Alternative conditions, Alternative 6A would lead to predicted improvements in long-term average bromide concentrations at Franks Tract, Rock Slough, and Contra Costa PP No. 1, in addition to Banks and Jones (discussed below). At these locations, long-term average bromide concentrations would be predicted to decrease by as much as 41–61%, depending on baseline comparison. Modeling results using the EC to chloride and chloride to bromide relationships generally do not show similar decreases for Rock Slough and Contra Costa PP No. 1, but rather, predict small increases. Based on the small magnitude of increases predicted, these increases would not adversely affect beneficial uses at those locations.

Important to the results presented above is the assumed habitat restoration footprint on both the temporal and spatial scales incorporated into the modeling. Modeling sensitivity analyses have indicated that habitat restoration (which are reflected in the modeling—see Section 8.3.1.3), not operations covered under CM1, are the driving factor in the modeled bromide increases. The timing, location, and specific design of habitat restoration will have effects on Delta hydrodynamics, and any deviations from modeled habitat restoration and implementation schedule will lead to different outcomes. Although habitat restoration near Barker Slough is an important factor contributing to modeled bromide concentrations at the North Bay Aqueduct, BDCP habitat restoration elsewhere in the Delta can also have large effects. Because of these uncertainties, and the possibility of adaptive management changes to BDCP restoration activities, including location, magnitude, and timing of restoration, the estimates are not predictive of the bromide levels that would actually occur in Barker Slough or elsewhere in the Delta.

SWP/CVP Export Service Areas

Under Alternative 6A, improvement in long-term average bromide concentrations would occur at the Banks and Jones pumping plants. Long-term average bromide concentrations for the modeled 16-year hydrologic period at these locations would decrease by as much as 96% relative to Existing Conditions and the No Action Alternative (Appendix 8E, *Bromide*, Table 14). As a result, exceedances of the 50 μg/L and 100 μg/L assessment thresholds would be completely eliminated, resulting in considerable overall improvement in Export Service Areas water quality respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also be observed since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San

Joaquin River improvement in bromide is difficult to predict, the relative decrease in overall loading of bromide to the Export Service Areas would likely alleviate or lessen any expected increase in bromide concentrations at Vernalis (see discussion of Upstream of the Delta) as well as locations in the Delta receiving a large fraction of San Joaquin River water, such as much of the south Delta.

The discussion above is based on results of the mass-balance modeling approach. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) were consistent with the discussion above, and assessment of bromide using these data results in the same conclusions as are presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 15).

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 6A would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

***NEPA Effects*:** In summary, Alternative 6A operations and maintenance, relative to the No Action Alternative, would result in small increases (i.e., <1%) in long-term average bromide concentrations at Vernalis related to relatively small declines in long-term average flow on the San Joaquin River. However, Alternative 6A operation and maintenance activities would cause substantial degradation to water quality with respect to bromide at Barker Slough, source of the North Bay Aqueduct. Resultant substantial change in long-term average bromide at Barker Slough could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-5 is available to reduce these effects. Implementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 6A there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 6A would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. However, south of the Delta, the San Joaquin River is a substantial source of bromide, primarily due to the use of irrigation water imported from the southern Delta. Concentrations of bromide at Vernalis are inversely correlated to net river flow. Under Alternative 6A, long-term average flows at Vernalis would decrease only slightly, resulting in less than substantial predicted increases in long-term average bromide of about 3% relative to Existing Conditions.

Relative to Existing Conditions, Alternative 6A would result in substantial increases in long-term average bromide concentration at Barker Slough and Staten Island. There are no existing or foreseeable municipal drinking water intakes in the vicinity of Staten Island, but Barker Slough is the source of the North Bay Aqueduct. The increase in long-term average bromide concentrations predicted for Barker Slough would result in a substantial change in source water quality to existing drinking water treatment plants drawing water from the North Bay Aqueduct. These modeled increases in bromide at Barker Slough could lead to adverse changes in the formation of disinfection byproducts at drinking water treatment plants such that considerable water treatment plant upgrades would be necessary in order to achieve equivalent levels of drinking water health protection.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Under Alternative 6A, substantial improvement would occur at the Banks and Jones pumping plants, where predicted long-term average bromide concentrations are predicted to decrease by as much as 96% relative to Existing Conditions. An overall improvement in bromide-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 6A operation and maintenance would not result in any substantial change in long-term average bromide concentration upstream of the Delta. Furthermore, under Alternative 6A, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to bromide. Bromide is not bioaccumulative, therefore change in long-term average bromide concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, bromide is not a constituent related to any 303(d) listings. Alternative 6A operation and maintenance activities would not cause substantial long-term degradation to water quality respective to bromide with the exception of water quality at Barker Slough and at Staten Island in the eastern Delta. There are no existing or foreseeable municipal intakes in the vicinity of Staten Island, but Barker Slough is the source of the North Bay Aqueduct. At Barker Slough, modeled long-term annual average concentrations of bromide would increase by 19%, and 73% during the modeled drought period. For the modeled 16-year hydrologic period the frequency of predicted bromide concentrations exceeding 100 µg/L would increase from 0% under Existing Conditions to 17% under Alternative 6A, while for the modeled drought period, the frequency would increase from 0% to 37%. Substantial changes in long-term average bromide could necessitate changes in treatment plant operation or require treatment plant upgrades in order to maintain DBP compliance. The model predicted change at Barker Slough is substantial and, therefore, would represent a substantially increased risk for adverse effects on existing MUN beneficial uses should treatment upgrades not be undertaken. The impact is considered significant.

Implementation of Mitigation Measure WQ-5 along with a separate other commitment relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-5 is recommended to attempt to reduce the effect that increased bromide concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-5, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from bromide-related concentration effects on municipal water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementation of the North Bay Aqueduct AIP, acquiring alternative water supplies, or other actions to indirectly reduce the effects of elevated bromide and DOC in existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-5: Avoid, Minimize, or Offset, as Feasible, Adverse Water Quality Conditions

Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 proposed under Alternative 6A would be the same as those proposed under Alternative 1A. As discussed for Alternative 1A, implementation of the CM2–CM21 would not present new or substantially changed sources of bromide to the study area. Some conservation measures may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution is not expected to substantially increase or present new sources of bromide. CM2–CM21 would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

In summary, implementation of CM2–CM21 under Alternative 6A, relative to the No Action Alternative, would have negligible, if any, effects on bromide concentrations. The effects on bromide from implementing CM2–CM21 are determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on bromide resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 6A there would be no expected change to the sources of chloride in the Sacramento and eastside tributary watersheds. Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. The modeled long-term annual average flows on the lower San Joaquin River at Vernalis would decrease slightly compared to Existing Conditions and be similar compared to the No Action Alternative (as a result of climate change). The reduced flow would result in possible increases in long-term average chloride concentrations of about 2%, relative to the Existing Conditions and no change relative to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-62). Consequently, Alternative 6A would not be expected to cause exceedance of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to the Existing Conditions and No Action Alternative, the predicted long-term average chloride concentrations under Alternative 6A for the 16-year period modeled would be substantially reduced at most of the assessment locations (Appendix 8G, *Chloride*, Table Cl-37 and Table Cl-38). Moreover, the direction and magnitude of predicted changes for Alternative 6A are similar between the alternatives, thus, the effects relative to Existing Conditions and the No Action Alternative are discussed together. Depending on the modeling approach (see Section 8.3.1.3), the average chloride concentrations would be increased at the North Bay Aqueduct at Barker Slough (i.e., ≤15%) and SF Mokelumne at Staten Island (i.e., ≤37%). Additionally, implementation of tidal habitat restoration under CM4 would increase the tidal exchange volume in the Delta, and thus may contribute to increased chloride concentrations in the Bay source water as a result of increased salinity intrusion. More discussion of this phenomenon is included in Section 8.3.1.3. Consequently, while uncertain, the magnitude of chloride increases may be greater than indicated herein and would affect the western Delta assessment locations the most which are influenced to the greatest extent by the Bay source water. The comparison to Existing Conditions reflects changes in chloride due to both Alternative 6A operations (including north Delta intake capacity of 15,000 cfs and numerous other components of Operational Scenario D) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes in chloride due only to operations. The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses

Estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at both the Antioch and Contra Costa Pumping Plant #1 locations. For Alternative 6A, the modeled frequency of objective exceedance would remain unchanged at 7% of years under Existing Conditions and Alternative 6A (Appendix 8G, *Chloride*, Table Cl-64). The modeled frequency of objective exceedance would increase from 0% of years under the No Action Alternative to 7% under Alternative 6A. However, the increase was due to a single year, 1977, which fell just short of the required number of days (i.e., was within 9 days minimum number of required days < 150 mg/L). Given the uncertainty in the chloride modeling approach, it is likely that real time operations of the SWP and CVP could achieve compliance with this objective (see Section 8.3.1.1 for a discussion of chloride compliance modeling uncertainties and a description of real time operations of the SWP and CVP).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 6A, the modeled frequency of objective exceedance would be eliminated, from 6% of modeled days under Existing Conditions and 5% under the No Action Alternative to 0% of modeled days under Alternative 6A (Appendix 8G, *Chloride*, Table Cl-63).

Given the limitations inherent to estimating future chloride concentrations (see Section 8.3.1.3), estimation of chloride concentrations through both a mass balance approach and an EC-chloride relationship approach was used to evaluate the 250 mg/L Bay-Delta WQCP objectives in terms of both frequency of exceedance and use of assimilative capacity. When utilizing the mass balance approach to model monthly average chloride concentrations for the 16-year period, the predicted frequency of exceeding the 250 mg/L objective would be eliminated at the Contra Costa Canal at Pumping Plant #1 (24% for Existing Conditions to 0% for Alternative 6A), thus indicating complete compliance with this objective would be achieved (Appendix 8G, Chloride, Table Cl-39 and Figure Cl-9). The frequency of exceedances at the San Joaquin River at Antioch also would decrease compared to all of the alternative scenarios (i.e., 9% from 66% for Existing Conditions to 57%) with no substantial change predicted for Mallard Island (i.e., maximum increase of 1%) (Appendix 8G, Table Cl-39). However, available assimilative capacity would be reduced relative to Existing Conditions in April (i.e., up to 21%) (Appendix 8G, Table Cl-41) reflecting substantial degradation during a month when average concentrations would be near, or exceed, the objective.

In comparison, when utilizing the chloride-EC relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance generally agreed, but use of assimilative capacity were predicted to be larger at some locations (Appendix 8G, *Chloride*, Table Cl-40 and Table Cl-42). Specifically, while the model predicted exceedance frequency would decrease at the Contra Costa Canal at Pumping Plant #1 and Rock Slough locations, use of assimilative capacity would increase substantially for the months of February through June. (i.e., maximum of 81% in March for the modeled drought period). Due to such seasonal long-term average water quality degradation at these locations, the potential exists for substantial adverse effects on the municipal and industrial beneficial uses through reduced opportunity for diversion of water with acceptable chloride levels.

303(d) Listed Water Bodies

With respect to the 303(d) listing for chloride in Tom Paine Slough, the monthly average chloride concentrations for the 16-year period modeled at Old River at Tracy Road, which represents the nearest DSM2-modeled location to Tom Paine in the south Delta, would generally be similar compared to Existing Conditions and No Action Alternative, and thus, would not be further degraded on a long-term basis (Appendix 8G, Figure Cl-10).

With respect to Suisun Marsh, the monthly average chloride concentrations for the 16-year period modeled would generally increase compared to Existing Conditions and No Action Alternative in some months during October through May at the Sacramento River at Collinsville (Appendix 8G, Figure Cl-11), Mallard Island (Appendix 8G, Figure Cl-9), and increase substantially at Montezuma Slough at Beldon's Landing (i.e., over a doubling of concentration in December through February) (Appendix 8G, Figure Cl-12), Although modeling of Alternative 6A assumed no operation of the Montezuma Slough Salinity Control Gates, the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results for Suisun Marsh, but EC levels were still somewhat higher than EC levels under Existing Conditions for several locations and months. Although chloride was not specifically modeled in this sensitivity analysis, it is expected that chloride concentrations would be nearly proportional to EC levels in Suisun Marsh. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases in salinity are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term chloride increases in the Marsh. However, the chloride concentration increases at certain locations could be substantial, depending on siting and design of restoration areas. Thus, these increased chloride levels in Suisun Marsh are considered to contribute to additional, measureable long-term degradation that potentially would adversely affect the necessary actions to reduce chloride loading for any TMDL that is developed.

SWP/CVP Export Service Areas

Under Alternative 6A, long-term average chloride concentrations based on the mass balance analysis of modeling results for the 16-year period modeled at the Banks and Jones pumping plants would decrease by approximately 95% relative to Existing Conditions and No Action Alternative (Appendix 8G, *Chloride*, Table Cl-37). The modeled low-frequency exceedances of objectives present under the Existing Conditions and No Action Alternative would be eliminated under Alternative 6A (Appendix 8G, *Chloride*, Table Cl-39). Consequently, water exported into the SWP/CVP service area would generally be improved with regards to chloride relative to Existing Conditions and No Action Alternative conditions.

Results of the modeling approach which used relationships between EC and chloride (see Section 8.3.1.3) were consistent with the discussion above, and assessment of chloride using these data results in the same conclusions as are presented above for the mass-balance approach (Appendix 8G, *Chloride*, Table Cl-38 and Table Cl-40).

Commensurate with the reduced chloride concentrations in water exported to the service area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely alleviate or lessen any expected increase in chloride at Vernalis related to decreased annual average San Joaquin River flows (see discussion of Upstream of the Delta).

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative conditions, Alternative 6A would result in substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1, Antioch, and Rock Slough, and could result in increased concentrations with respect to the 303(d) impairment in Suisun Marsh. The predicted chloride increases constitute an adverse effect on water quality (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Additionally, the predicted changes relative to the No Action Alternative conditions indicate that in addition to the effects of climate change/sea level rise, implementation of CM1 and CM4 under Alternative 6A would contribute substantially to the adverse water quality effects.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 6A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, the Alternative 6A would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, Alternative 6A operations would result in substantially reduced chloride concentrations in the Delta such that exceedances of the 250 mg/L Bay-Delta WQCP objective at the San Joaquin River at Antioch and Mallard Slough would be reduced. Nevertheless, due to the substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1 and Rock Slough, the potential exists for adverse effects on the municipal and industrial beneficial uses at these locations (see Mitigation Measure WQ-7 below; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Moreover, the modeled increased chloride concentrations and degradation in the western Delta could still occur and further contribute, at measurable levels, to the existing 303(d) listed impairment due to chloride in Suisun Marsh for the protection of fish and wildlife. Based on these findings, this impact is determined to be significant due to increased degradation relative to the 250 mg/L objective in the western Delta as well as potential increased degradation relative to the 303(d) listing in Suisun Marsh.

Chloride concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under Alternative 6A would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 6A maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas. However, based on these findings, this impact is determined to be significant due to increased chloride concentrations and degradation in Suisun Marsh and its effects on fish and wildlife beneficial uses.

While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-7 is recommended to attempt to reduce the effect that increased chloride concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-7, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from chloride concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when chloride concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-7: Conduct Additional Evaluation and Modeling of Increased Chloride Levels and Develop and Implement Phased Mitigation Actions

Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Under Alternative 6A, the types and geographic extent of effects on chloride concentrations in the Delta as a result of implementation of the other conservation measures (i.e., CM2–CM21) would be similar to, and undistinguishable from, those effects previously described for Alternative 1A. The conservation measures would present no new direct sources of chloride to the affected environment. Moreover, some habitat restoration conservation measures (CM4–10) would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored tidal wetlands, floodplain, and related channel margin and off-channel habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement compared to No Action Alternative conditions.

In summary, based on the discussion above, the effects on chloride from implementing CM2-CM21 are considered to be not adverse.

CEQA Conclusion: Implementation of the CM2–CM21 for Alternative 6A would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP service area. Replacement of irrigated agricultural land uses in the Delta with habitat restoration conservation measures may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects: Effects of CM1 on DO under Alternative 6A would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: Effects of CM1 on DO under Alternative 6A would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under the Alternative 1A.

Reservoir storage reductions that would occur under Alternative 6A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions that would occur would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state has begun to aggressively regulate the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters under Alternative 6A, relative to Existing Conditions. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to ever increasing water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. This impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on DO under Alternative 6A would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on DO resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, their associated reservoirs, and the San Joaquin River upstream of the Delta under Alternative 6A are not expected to be outside the ranges occurring under Existing Conditions or would occur under the No Action Alternative. Any minor changes in EC levels that could occur under Alternative 6A in water bodies upstream of the Delta would not be of sufficient magnitude, frequency and geographic extent that would cause adverse effects on beneficial uses or substantially degrade water quality with regard to EC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to Existing Conditions, Alternative 6A would result in an increase in the number of days the Bay-Delta WQCP EC objectives for fish and wildlife protection (which apply during April and May in all but critical water year types) would be exceeded in the San Joaquin River at Jersey Point and Prisoners Point (Appendix 8H, *Electrical Conductivity*, Table EC-6), and an increase in exceedance of the agricultural EC objective for the Sacramento River at Emmaton.

The percentage of days the fish and wildlife EC objective would be exceeded at Jersey Point for the entire period modeled (1976–1991) would increase from 0% under Existing Conditions to 3% under Alternative 6A, and the percentage of days out of compliance with the EC objective would increase from 0% under Existing Conditions to 5% under Alternative 6A. The percentage of days the EC objective would be exceeded at Prisoners Point for the entire period modeled would increase from 6% under Existing Conditions to 40% under Alternative 6A, and the percentage of days out of compliance with the EC objective would increase from 10% under Existing Conditions to 40% under Alternative 6A. Sensitivity analyses conducted for Alternative 4 Scenario H3 indicated that removing all tidal restoration areas would reduce the number of exceedances, but there would still be substantially more exceedances than under Existing Conditions or the No Action Alternative. Results of the sensitivity analyses indicate that the exceedances are partially a function of the operations of the alternative itself, perhaps due to Head of Old River Barrier assumptions and south Delta export differences (see Appendix 8H, Attachment 1, for more discussion of these sensitivity analyses). Due to similarities in the nature of the exceedances between alternatives, the findings from these analyses can be extended to this alternative as well. Appendix 8H, Attachment 2, contains a more detailed assessment of the likelihood of these exceedances impacting aquatic life beneficial uses. Specifically, Appendix 8H, Attachment 2, discusses whether these exceedances might have indirect effects on striped bass spawning in the Delta, and concludes that the high level of uncertainty precludes making a definitive determination.

At Emmaton, the percentage of days the EC objective would be exceeded would increase from 6% under Existing Conditions to 32% under Alternative 6A, and the percentage of days out of compliance would increase from 11% under Existing Conditions to 44% under Alternative 6A.

Average EC levels at the western and southern Delta compliance locations and San Joaquin River at San Andreas Landing (an interior Delta location) would decrease from 2–56% for the entire period modeled and 3–52% during the drought period modeled (1987–1991) (Appendix 8H, *Electrical Conductivity*, Table EC-17). In the S. Fork Mokelumne River at Terminous, average EC would increase 7% for the entire period modeled and 6% during the drought period modeled. Average EC in the S. Fork Mokelumne River at Terminous (an interior Delta location) would increase during all months (Appendix 8H, Table EC-17). The western Delta is Clean Water Act section 303(d) listed as impaired due to elevated EC and there would be an increased exceedance of the EC objective at Emmaton. Thus, relative to Existing Conditions, Alternative 6A could contribute to additional impairment of section 303(d) listed waters. The comparison to Existing Conditions reflects changes in EC due to both Alternative 6A operations (including north Delta intake capacity of 15,000 cfs and numerous other components of Operational Scenario D) and climate change/sea level rise.

Relative to the No Action Alternative, the change in percentage compliance with Bay-Delta WQCP EC objectives under Alternative 6A would be similar to that described above relative to Existing Conditions for the Sacramento River at Emmaton, and the San Joaquin River at Jersey Point and Prisoners Point. In addition, there would also be a slight increase (<1%) in the percentage of days the EC objective would be exceeded in Old River at Tracy Bridge for the entire period modeled. For the entire period modeled, average EC levels would increase at: S. Fork Mokelumne River at Terminous; San Joaquin River at Brandt Bridge and Prisoners Point; and Old River at Tracy Bridge. The greatest average EC increase would occur in the S. Fork Mokelumne River at Terminous (8%); the average EC increase at the other locations would be <1–3% (Appendix 8H, *Electrical Conductivity*, Table EC-17). During the drought period modeled, average EC would increase at the same locations, except San Joaquin River at Prisoners Point. The greatest average EC increase during the drought period modeled would occur in the S. Fork Mokelumne River at Terminous (7%); the increase at the other locations would be 1–2% (Appendix 8H, Table EC-17). Given that the western Delta is Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives at Emmaton, relative to the No Action Alternative, has the potential to contribute to additional impairment and potentially adversely affect beneficial uses. The comparison to the No Action Alternative reflects changes in EC due only to Alternative 6A operations (including north Delta intake capacity of 15,000 cfs and numerous other components of Operational Scenario D).

For Suisun Marsh, October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Long-term average EC would increase under Alternative 6A, relative to Existing Conditions, during the months of April and May by 0.2–0.4 mS/cm in the Sacramento River at Collinsville (Appendix 8H, *Electrical Conductivity*, Table EC-21). Long-term average EC would decrease relative to Existing Conditions in Montezuma Slough at National Steel during October–May (Appendix 8H, Table EC-22). The most substantial increase would occur near Beldon Landing, with long-term average EC levels increasing by 0.8–2.2 mS/cm, depending on the month, nearly doubling during some months the long-term average EC relative to Existing Conditions (Appendix 8H, Table EC-23). Sunrise Duck Club and Volanti Slough also would have long-term average EC increases during February–May of 0.4–1.7 mS/cm (Appendix 8H, Tables EC-24 and EC-25). Modeling of this alternative assumed no operation of the Montezuma Slough Salinity Control Gates, but the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 Scenario H3 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results, but EC levels were still somewhat higher than EC levels under Existing Conditions and the No Action Alternative for several locations and months. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions and the No Action Alternative, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term EC increases to be on the order of 1 mS/cm or less. Due to similarities in the nature of the EC increases between alternatives, the findings from these analyses can be extended to this alternative as well.

The degree to which the long-term average EC increases in Suisun Marsh would cause exceedance of Bay-Delta WQCP objectives is unknown, because these objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated "equivalent or better protection will be provided at the location" (State Water Resources Control Board 2006:14). The long-term average EC increase may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the marsh. However, the EC increases at certain locations could be substantial, depending on siting and design of restoration areas, and it is uncertain the degree to which current management plans for the Suisun Marsh would be able to address these substantially higher EC levels and protect beneficial uses. Thus, these increased EC levels in Suisun Marsh are considered to have a potentially adverse effect on marsh beneficial uses. Long-term average EC increases in Suisun Marsh under Alternative 6A relative to the No Action Alternative would be similar to the increases relative to Existing Conditions. Suisun Marsh also is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC concentrations could contribute to additional impairment.

SWP/CVP Export Service Areas

At the Banks and Jones pumping plants, Alternative 6A would result in no exceedances of the Bay-Delta WQCP's 1,000 µmhos/cm EC objective for the entire period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-10). Thus, there would be no adverse effect on the beneficial uses in the SWP/CVP Export Service Areas using water pumped at this location under the Alternative 6A.

At the Banks pumping plant, relative to Existing Conditions, average EC levels under Alternative 6A would decrease substantially on average: 67% for the entire period modeled and 73% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 64% for the entire period modeled and 71% during the drought period modeled. (Appendix 8H, Table EC-17)

At the Jones pumping plant, relative to Existing Conditions, average EC levels under Alternative 6A would also decrease substantially: 68% for the entire period modeled and 74% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 67% for the entire period modeled and 73% during the drought period modeled. (Appendix 8H, Table EC-17)

Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 6A would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas; rather, Alternative 6A would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows (see EC impact discussion under the No Action Alternative).

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC. Alternative 6A would result in lower average EC levels relative to Existing Conditions and the No Action Alternative and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

NEPA Effects: In summary, the increased frequency of exceedance of EC objectives in the western Delta under Alternative 6A, relative to the No Action Alternative, would contribute to adverse effects on the agricultural beneficial uses. In addition. the increased frequency of exceedance of the San Joaquin River at Prisoners Point and Jersey Point EC objectives and long-term and drought period average EC at Prisoners Point could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. The western and southern Delta are CWA section 303(d) listed as impaired due to elevated EC, and the increase in incidence of exceedance of EC objectives in the western portion of the Delta have the potential to contribute to additional beneficial use impairment. The increases in long-term average EC levels that could occur in Suisun Marsh would further degrade existing EC levels and could contribute to adverse effects on the fish and wildlife beneficial uses. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC levels could contribute to additional beneficial use impairment. These increases in EC constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects. Iimplementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential EC-related changes would reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

River flow rate and reservoir storage reductions that would occur under Alternative 6A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's aggressive regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 6A would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas. There would be no exceedance of the EC objective at the Jones and Banks pumping plants. Average EC levels for the entire period modeled would decrease at both plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

Alternative 6A would result in an increase in the frequency with which Bay-Delta WQCP EC objectives for fish and wildlife protection are exceeded in the San Joaquin River at Jersey Point (from 0% under Existing Conditions to 3% under Alternative 6A) and Prisoners Point (from 6% under Existing Conditions to 40% under Alternative 6A), and an increase in the EC agricultural objectives at Emmaton for the entire period modeled (1976–1991). Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. Portions of the Delta on the Clean Water Act section 303(d) list as impaired due to elevated EC would not have increased long-term average EC levels relative to Existing Conditions, However, at Emmaton, which is in the western Delta, there would be an increased frequency of exceedance of the EC objective. Thus, Alternative 6A could contribute to additional impairment of section 303(d) listed waters. The increased frequency of exceedance of fish and wildlife EC objectives at Prisoners Point and Jersey Point could adversely affect aquatic life beneficial uses specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. This impact is considered to be significant.

Further, relative to Existing Conditions, Alternative 6A could result in substantial increases in long-term average EC during the months of October through May in Suisun Marsh. The increases in long-term average EC levels that would occur in Suisun Marsh could further degrade existing EC levels and thus contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in wildlife. Suisun Marsh is Clean Water Act section 303(d) listed for elevated EC and the increases in long-term average EC that would occur in the marsh could make beneficial use impairment measurably worse. This impact is considered to be significant.

Implementation of Mitigation Measure WQ-11 along with a separate other commitment relating to the potential increased costs associated with EC-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-11 is recommended to attempt to reduce the effect that increased EC concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-11, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments,* *AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from EC concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when EC concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-11: Avoid, Minimize, or Offset, as Feasible, Reduced Water Quality Conditions

Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on EC under Alternative 6A would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on EC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under the Alternative 6A, the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries would be altered, relative to Existing Conditions and the No Action Alternative.

The Sacramento River at Freeport and San Joaquin River at Vernalis (as summarized for water quality average concentrations in Tables 8-48 and 8-49) were examined for flow/concentration relationships for mercury and methylmercury. No significant, predictive regression relationships were discovered for mercury or methylmercury, except for total mercury with flow at Freeport (monthly or annual) (Appendix 8I, Figures I-10 through I-13). Such a positive relationship between total mercury and flow is to be expected based on the association of mercury with suspended sediment and the mobilization of sediments during storm flows. However, the changes in flow in the Sacramento River under Alternative 6A relative to Existing Conditions and the No Action Alternative are not of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore mercury loading should not be substantially different due to changes in flow. In addition, even though it may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but will not change substantially relative to Existing Conditions or the No Action Alternative due to changes in flows under Alternative 6A.

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

The water quality impacts of waterborne concentrations of mercury and methylmercury and fish tissue mercury concentrations were evaluated for 9 Delta locations. The analysis of percentage change in assimilative capacity of waterborne total mercury of Alternative 6A relative to the 25 ng/L ecological risk benchmark as compared to Existing Conditions showed the greatest decrease to be 9.2% at the Contra Costa Pumping Plant, 9.1% at the Contra Costa Pumping Plant relative to the No Action Alternative (Figures 8-53a and 8-54a). These changes are not expected to result in adverse effects to beneficial use. Similarly, changes in methylmercury concentration are expected to be relatively small. The greatest annual average methylmercury concentration for drought conditions was 0.165 ng/L for the San Joaquin River at Buckley Cove which was slightly higher than Existing Conditions (0.161 ng/L) and slightly lower than the No Action Alternative (0.167 ng/L) (Appendix 8I, Table I-6). All modeled input concentrations exceeded the methylmercury TMDL guidance objective of 0.06 ng/L, therefore percentage change in assimilative capacity was not evaluated for methylmercury.

Fish tissue estimates show substantial percentage increases in concentration and exceedance quotients for mercury at some Delta locations. The greatest increases in exceedance quotients (ranging from 33 to 64%) are expected for Franks Tract and Old River at Rock Slough relative to Existing Conditions and the No Action Alternative (Figure 8-55a and 8-55b; Appendix 8I, Table I-13b). Because these increases are substantial, and it is evident that substantive increases are expected at numerous locations throughout the Delta, these changes may be measurable in the environment. See Appendix 8I for a discussion of the uncertainty associated with the fish tissue estimates.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 6A are projected to be lower than Existing Conditions and the No Action Alternative (Appendix 8I, *Mercury*, Figures I-4 and I-5). Therefore, mercury shows an increased assimilative capacity at these locations (Figures 8-53a and 8-54a).

The largest improvements in bass tissue mercury concentrations and exceedance quotients for Alternative 6A, relative to Existing Conditions and the No Action Alternative at any location within the Delta are expected for the export pump locations (specifically, at Jones Pumping plant, 41% improvement relative to Existing Conditions, 43% relative to the No Action Alternative) (Figures 8-55a and 8-55b; Appendix 8I, *Mercury*, Table I-13b).

NEPA Effects: Based on the above discussion, the effects of mercury and methylmercury in comparison of Alternative 6A to the No Action Alternative (as waterborne and bioaccumulated forms) are considered to be adverse for the case of fish tissue bioaccumulation at some locations.

CEQA Conclusion**:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 6A, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta will not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. Monthly average waterborne concentrations of total and methylmercury, over the period of record, are very similar to Existing Conditions, but showed notable increases at some locations. Estimates of fish tissue mercury concentrations show substantial increases would occur for several sites for Alternative 6A as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP and CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 6A as compared to Existing Conditions.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. However, increases in fish tissue mercury concentrations are substantial, and changes in fish tissue mercury concentrations would make existing mercury-related impairment in the Delta measurably worse. In comparison to Existing Conditions, Alternative 6A would increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. This impact is considered to be significant. Feasible or effective actions to reduce the effects on mercury resulting from CM1 are unknown. General mercury management measures through CM12, or actions taken by other entities or programs such as TMDL implementation, may minimize or reduce sources and inputs of mercury to the Delta and methylmercury formation. However, it is uncertain whether this impact would be reduced to a level that would be less than significant as a result of CM12 or other future actions. Therefore, the impact would be significant and unavoidable.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Some habitat restoration activities under Alternative 6A would occur on lands in the Delta formerly used for irrigated agriculture. Tidal and other restoration proposed under Alternative 6A have the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the restored habitat. Therefore, increases in mercury methylation in the habitat restoration areas is possible but uncertain depending on the specific restoration design implemented at a particular Delta location. Models to estimate the potential for methylmercury formation in restored areas are not currently available. However, DSM2 modeling for Alternative 6A operations does incorporate assumptions for certain habitat restoration activities proposed under CM2 and CM4 (see Section 8.3.1.3) that result in changes to Delta hydrodynamics compared to the No Action Alternative. These modeled restoration assumptions provide some insight into potential hydrodynamic changes that could be expected related to implementing CM2 and CM4 and are considered in the evaluation of the potential for increased mercury and methylmercury concentrations under Alternative 6A.

CM12 addresses the potential for methylmercury bioaccumulation associated with restoration activities and acknowledges the uncertainties associated with mitigating or minimizing this potential effect. CM12 proposes project-specific mercury management plans for restoration actions that will incorporate relevant approaches recommended in Phase 1 Methylmercury TMDL control studies. Specific approaches recommended under CM12 that are intended to minimize or mitigate for potential increases in methylmercury bioaccumulation at future restoration sites include:

- Characterizing mercury, methylmercury, organic carbon, iron, and sulfate concentrations to better inform restoration design,
- Sequestering methylmercury at restoration sites using low intensity chemical dosing techniques,
- Minimizing microbial methylation associated with anoxic conditions by reducing the amount of organic material at a restoration site,
- Designing restoration sites to enhance photo degeneration that converts methylmercury into a biologically unavailable, inorganic form of mercury,
- Remediating restoration site soils with iron to reduce methylation in sulfide rich soils, and
- Considering capping mercury laden sediments, where possible to reduce methylation potential at a site.

Because of the uncertainties associated with site-specific estimates of methylmercury concentrations and the uncertainties in source modeling and tissue modeling, the effectiveness of methylmercury management proposed under CM12 to reduce methylmercury concentrations would need to be evaluated separately for each restoration effort, as part of design and implementation. Because of this uncertainty and the known potential for methylmercury creation in the Delta this potential effect of implementing CM2–CM21 is considered adverse.

***CEQA Conclusion*:** There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the CVP and SWP service areas due to implementation of CM2–CM21 relative to Existing Conditions. However, uptake of mercury from water and/or methylation of inorganic mercury may increase to an unquantified degree as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Methylmercury is 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites under Alternative 6A would be guided by CM12 which requires development of site specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time although the potential to reduce methylmercury concentrations exists based on current research. Although the BDCP will implement CM12 with the goal to reduce this potential effect the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant. No mitigation measures would be available until specific restoration actions are proposed. Therefore this programmatic impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 6A would have negligible, if any, impact on nitrate concentrations in the rivers and reservoirs upstream of the Delta in the Sacramento River watershed relative to Existing Conditions and the No Action Alternative.

Under Alternative 6A, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by an estimated 6%, relative to Existing Conditions, and would remain virtually the same relative to the No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Given these relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River (see Appendix 8J, *Nitrate*, Figure 2), it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by changes in flow rates under Alternative 6A.

Any negligible changes in nitrate-N concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to nitrate.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to

the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Results of the mixing calculations indicate that under Alternative 6A, relative to Existing Conditions and the No Action Alternative, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Tables 22 and 23). Long-term average nitrate concentrations are anticipated to increase at most locations in the Delta. The increase would be greatest at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1 (all >100% increase). Long-term average concentrations were estimated to increase to 0.78, 1.23 and 1.33 mg/L-N for Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1, respectively, due primarily to increased San Joaquin River water percentage at these locations (see Appendix 8D, *Source Water Fingerprinting Results*). Although changes at specific Delta locations and for specific months may be substantial on a relative basis, the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds identified in Table 8-50. No additional exceedances of the MCL are anticipated at any location (Appendix 8J, Table 22). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, was up to approximately 14% at Old River at Rock Slough and Contra Costa Pumping Plant #1, and averaged approximately 8–9% on a long-term average basis (Appendix 8J, Table 24). Similarly, the use of available assimilative capacity at Franks Tract was up to approximately 7%, and averaged 3–4% over the long term. The concentrations estimated for these locations would not increase the likelihood of exceeding the 10 mg/L-N MCL, nor would they increase the risk for adverse effects to beneficial uses. At all other locations, use of assimilative capacity was negligible (<5%), except San Joaquin River at Buckley Cove in August, which showed a 7.3% use of the assimilative capacity that was available under the No Action Alternative, for the drought period (1987–1991) (Appendix 8J, Table 24).

Nitrate concentrations will likely be higher than the modeling results indicate in certain locations. This includes in the Sacramento River between Freeport and Mallard Island and other areas in the Delta downstream of Freeport that are influenced by Sacramento River water. These increases are associated with ammonia and nitrate that are discharged from the SRWTP, which are not included in the modeling.

- Under Existing Conditions, most of the ammonia discharged from the SRWTP is converted to nitrate downstream of the facility's discharge at Freeport, and thus, nitrate concentrations under Existing Conditions in these areas are expected to be higher than the modeling predicts, the increase becoming greater with increasing distance downstream. However, the increase in nitrate concentrations downstream of the SRWTP is expected to be small—the existing increase appears to be from approximately 0.1 mg/L-N to approximately 0.4–0.5 mg/L-N over this reach, due to approximately a 1:1 conversion of ammonia-N to nitrate-N (Central Valley Water Board 2010a:32).
- Under Alternative 6A, the planned upgrades to the SRWTP, which include nitrification/partial denitrification, would substantially decrease ammonia concentrations in the discharge, but would increase nitrate concentrations in the discharge up to 10 mg/L-N, which is substantially higher than under Existing Conditions.
- Overall, under Alternative 6A, the nitrogen load from the SRWTP discharge is expected to decrease (by up to 50%), relative to Existing Conditions, due to nitrification/partial

dentrification ugrades at the SRWTP facility. Thus, while concentrations of nitrate downstream of the facility are expected to be higher than modeling results indicate for both Existing Conditions and Alternative 6A, the increase is expected to be greater under Existing Conditions than for Alternative 6A due to the upgrades that are assumed under Alternative 6A.

The other areas in which nitrate concentrations will be higher than the modeling results indicate are immediately downstream of other wastewater treatment plants that practice nitrification, but not denitrification (e.g., City of Rio Vista Beach WWTF, Town of Discovery Bay WWTF, City of Stockton RWCF). For all such facilities in the Delta, the Regional Water Boards have issued NPDES permits that allow discharge of wastewater containing nitrate into the Delta, and under these permits, the State has determined that no beneficial uses are adversely affected by the discharge, and that the discharger's use of available assimilative capacity of the water body is acceptable. When dilution is necessary in order for the discharge to be in compliance with the Basin Plans (which incorporate the 10 mg/L-N MCL by reference), not all of the assimilative capacity of the receiving water is granted to the discharger. Thus, limited decreases in flows are not anticipated to result in systemic exceedances of the MCLs by these POTWs. Furthermore, NPDES permits are renewed on a 5-year basis, and thus, if under changes in flows, dilution was no longer sufficient to maintain nitrate below the MCL in the receiving water, the NPDES permit renewal process would address such cases.

Therefore, any increases in nitrate-N concentrations that may occur at certain locations within the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to nitrate.

SWP/CVP Export Service Areas

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N at the Banks and Jones pumping plants.

Results of the mixing calculations indicate that under Alternative 6A, relative to Existing Conditions and the No Action Alternative, nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease on a long-term average annual basis, and on an average monthly basis for every month of the year (Appendix 8J, *Nitrate*, Tables 22 and 23). No additional exceedances of the MCL are anticipated (Appendix 8J, Table 22). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, there was no use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the 10 mg/L-N MCL, for both Banks and Jones pumping plants (Appendix 8J, Table 24).

Therefore, implementation of this alternative is not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regards to nitrate.

***NEPA Effects*:** In summary, based on the discussion above, the effects on nitrate from implementing CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Nitrate-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate-N upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers). Although higher in the San Joaquin River watershed, nitrate-N concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 6A, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mixing calculations indicate that under Alternative 6A, relative to Existing Conditions, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the MCL are anticipated at any location, and use of assimilative capacity available under Existing Conditions, relative to the drinking water MCL of 10 mg/L-N, was not of sufficient magnitude to increase the risk of substantially effecting beneficial uses.

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N concentrations at the Banks and Jones pumping plants. Results of the mixing calculations indicate that under Alternative 6A, relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease. No additional exceedances of the MCL are anticipated, and there was no use of assimilative capacity available under Existing Conditions, relative to the MCL, for both Banks and Jones pumping plants for all months.

Based on the above, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. No long-term water quality degradation is expected to occur such that exceedance of criteria is more likely or such that there is an increased risk of adverse impacts to beneficial uses. Nitrate is not 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on nitrate under Alternative 6A would be the same as those discussed for Alternative 1A and are considered not to be adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on nitrate resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 6A, there would be no substantial change to the sources of DOC within the watersheds upstream of the Delta. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows would not be expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Any negligible changes in DOC levels in water bodies upstream of the Delta under Alternative 6A, relative to Existing Conditions and the No Action Alternative, would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to DOC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Under Alternative 6A, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be similar to that previously described for Alternative 1A, although the magnitude of predicted long-term increase and relative frequency of concentration threshold exceedances would be substantially greater. Modeled effects would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1., where for the 16-year hydrologic period and the modeled drought period, long-term average concentration increases ranging from 1.0–1.6 mg/L would be predicted (≤46% net increase) resulting in long-term average DOC concentrations greater than 4 mg/L at all three Delta interior locations (Appendix 8K, *Organic Carbon,* DOC Table 7). Long-term average increases of 0.2–0.6 mg/L (≤20% net increase) would also occur at Staten Island, Emmaton, Antioch and Mallard Island. Increases in long-term average concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at Rock Slough and Contra Costa PP No. 1 locations. For Rock Slough, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 100% under the Alternative 6A (an increase from 47% to 100% for the drought period), and concentrations exceeding 4 mg/L would increase from 30% to 79% (32% to 95% for the drought period). For Contra Costa PP No. 1, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 100% under Alternative 6A (45% to 100% for the drought period), and concentrations exceeding 4 mg/L would increase from 32% to 84% (35% to 95% for the drought period). Relative change in frequency of threshold exceedance for other assessment locations would be similar or less. This comparison to Existing Conditions reflects changes in DOC due to both Alternative 6A operations (including north Delta intake capacity of 15,000 cfs and numerous other components of Operational Scenario D) and climate change/sea level rise.

In comparison, Alternative 6A relative to the No Action Alternative N would generally result in a magnitude of change similar to that discussed for the comparison to Existing Conditions. Maximum increases of 1.0 to 1.5 mg/L DOC (i.e., ≤41%) would be predicted at Franks Tract, Rock Slough, and Contra Costa PP No. 1 relative to the No Action Alternative (Appendix 8K, *Organic Carbon,* DOC Table 7). Threshold concentration exceedance frequency trends would also be similar to those discussed for the Existing Conditions comparison, with exception to the predicted 4 mg/L exceedance frequency at Buckley Cove. In comparison to the No Action Alternative, the frequency which long-term average DOC concentrations exceeded 4 mg/L at Buckley Cove would increase from 27% to 30% (42% to 53% for the modeled drought period). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in DOC due only to Alternative 6A operations.

The increases in long-term average DOC concentrations estimated to occur at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are considered substantial and could potentially trigger significant changes in drinking water treatment plant design or operations. In particular, assessment locations at Rock Slough and Contra Costa PP No. 1 represent municipal intakes servicing existing drinking water treatment plants. Under Alternative 6A, drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. While treatment technologies sufficient to achieve the necessary DOC removals exist, implementation of such technologies would likely require substantial investment in new or modified infrastructure.

Relative to existing and No Action Alternative conditions, Alternative 6A would lead to predicted improvements in long-term average DOC concentrations at Barker Slough, as well as Banks and Jones pumping plants (discussed below). Predicted long-term average DOC concentrations at Barker Slough would decrease approximately 0.1 mg/L (including the drought period), depending on baseline conditions comparison and modeling period.

SWP/CVP Export Service Areas

Under Alternative 6A, modeled long-term average DOC concentrations would decrease at Banks and Jones pumping plants for both the modeled 16-year hydrologic period and the modeled drought period. Modeled decreases would generally be similar between Existing Conditions and the No Action Alternative. Relative to Existing Conditions, long-term average DOC concentrations at Banks would be predicted to decrease by 1.5 mg/L (1.8 mg/L during drought period) (Appendix 8K, *Organic Carbon,* DOC Table 7). At Jones, long-term average DOC concentrations would be predicted to decrease by 1.5 mg/L (1.7 mg/L during drought period). Such substantial improvement in long-term average DOC concentrations would include fewer exceedances of concentration thresholds. At both Banks and Jones, average DOC concentrations exceeding the 2 mg/L concentration threshold would decrease from 100% under Existing Conditions and the No Action Alternative to 39% under Alternative 6A (100% to 33% during the drought period), while concentrations exceeding 4 mg/L would nearly be eliminated (i.e., ≤10% exceedance frequency). Such modeled improvement would correspond to substantial improvement in Export Service Areas water quality, respective to DOC.

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 6A would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area. Maintenance activities would not be expected to cause any substantial change in long-term average DOC concentrations such that MUN beneficial uses, or any other beneficial use, would be adversely affected.

NEPA Effects: In summary, Alternative 6A, relative to the No Action Alternative, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Long-term average DOC concentrations at Banks and Jones pumping plants are predicted to decrease by as much as 1.9 mg/L, while long-term average DOC concentrations for some Delta interior locations, including Franks Tract, Rock Slough and Contra Costa PP #1, are predicted to increase by as much as 1.5 mg/L. Resultant substantial changes in long-term average DOC at these Delta interior locations could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality and MUN beneficial uses. Mitigation Measure WQ-17 is available to reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

While greater water demands under the Alternative 6A would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of DOC. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, Alternative 6A would result in substantial increases (i.e., 1.0–1.6 mg/L) in long-term average DOC concentrations at some Delta interior locations, and would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1. At these locations the predicted changes in DOC would substantially increase the frequency with which long-term average concentrations exceeds 2, 3, or 4 mg/L. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Such predicted magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial.

The assessment of Alternative 6A effects on DOC in the SWP/CVP Export Service Areas is based on assessment of changes in DOC concentrations at Banks and Jones pumping plants. Relative to Existing Conditions, long-term average DOC concentrations would decrease by as much as 1.8 mg/L at Banks and Jones pumping plants. The frequency with which long-term average DOC concentrations would exceed 2, 3, or 4 mg/L would be substantially reduced, where predicted exceedances of >4 mg/L would be nearly eliminated (i.e., ≤10% exceedance frequency). As a result, substantial improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 6A operation and maintenance would not result in any substantial change in long-term average DOC concentration upstream of the Delta. Furthermore, under Alternative 6A, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to DOC. DOC is not bioaccumulative, therefore change in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, DOC is not a constituent related to any 303(d) listings. Nevertheless, new and modified conveyance facilities proposed under Alternative 6A would result in a substantial increase in long-term average DOC concentrations (i.e., 1.0–1.6 mg/L, equivalent to ≤46% relative increase) at Franks Tract, Rock Slough, and Contra Costa PP No.1. In particular, under Alternative 6A, model predicted long-term average DOC concentrations would be greater than 4 mg/L at Rock Slough and Contra Costa PP No. 1 with commensurate substantial increases in the frequency with which average DOC concentrations exceed 2, 3, and 4 mg/L levels. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Therefore, such a magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial uses at Rock Slough and Contra Costa PP No. 1 should such treatment upgrades not be undertaken. The impact is considered significant and mitigation is required. While Mitigation Measure WQ-17 is available to partially reduce this impact of DOC, the feasibility and effectiveness of this mitigation measure is uncertain and therefore implementation would not necessarily reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Mitigation Measure WQ-17: Consult with Delta Water Purveyors to Identify Means to Avoid, Minimize, or Offset Increases in Long-Term Average DOC Concentrations

To reduce the effect of CM1 operations on increased DOC concentrations specifically predicted to occur at municipal water purveyors obtaining raw source water through south Delta intakes at Rock Slough and those associated with Contra Costa PP No. 1, the BDCP proponents shall consult with the purveyors (i.e., Contra Costa water district and entities to which they supply raw water) to identify the means to either avoid, minimize, or offset increases in long-term average DOC concentrations that affect the beneficial use of the water. The BDCP proponents shall consult with these entities to determine existing DBP concentrations (as system-wide running averages), and then implement any combination of measures sufficient to maintaining these concentrations at existing levels in treated drinking water of affected water purveyors. Such actions may include, but not be limited to: 1) upgrading and maintaining adequate drinking water treatment systems, 2) developing or obtaining replacement surface water supplies from other water rights holders, 3) developing replacement groundwater supplies, or 4) physically routing a portion of the water diverted from the Sacramento River through the associated new conveyance pipelines/tunnel to affected purveyors.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 proposed under Alternative 6A would be the same as those proposed under Alternative 1A. As such, effects on DOC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A, although the isolated conveyance facilities of Alternative 6A would effectively isolate SWP and CVP export facilities in the southern Delta from the influence of potential new or modified sources of DOC relative to CM4–CM7 and CM10. However, the potential for CM4–CM7 and CM10 to contribute substantial amounts of DOC to raw drinking water supplies to the other Delta municipal intakes would remain, and could possibly be measurably worse in actual comparison to the dual conveyance project alternatives. With relatively less low DOC Sacramento River water in the Delta, there effectively would be less dilution of interior Delta DOC sources, leading to effectively higher long-term average DOC concentrations. Substantially increased long-term average DOC in raw water supplies could lead to a need for treatment plant upgrades in order to appropriately manage DBP formation in treated drinking water. This potential for future DOC increases would lead to substantially greater associated risk of long-term adverse effects on the MUN beneficial use.

In summary, the habitat restoration elements of CM4–CM7 and CM10 under Alternative 6A would present new localized sources of DOC to the study area, and in some circumstances would substitute for existing sources related to replaced agriculture. Depending on localized hydrodynamics and proximity to municipal drinking water intakes, such restoration activities could contribute substantial amounts of DOC to municipal raw water. Substantial increases in municipal raw water DOC could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-18 is available to reduce these effects.

CEQA Conclusion: Effects of CM4–CM7 and CM10 on DOC under Alternative 6A would be similar, and possibly greater, to those discussed for Alternative 1A, except that SWP and CVP export facilities would be isolated from these effects by Alternative 6A design. Similar to the discussion for Alternative 1A, this impact is considered to be significant and mitigation is required. It is uncertain whether implementation of Mitigation Measure WQ-18 would reduce identified impacts to a less-than-significant level. Hence, this impact remains significant and unavoidable.

In addition to and to supplement Mitigation Measure WQ-18, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from DOC concentration effects on municipal and industrial water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementing treatment for DOC and/or DBPs or DOC source control strategies. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to DOC.

Mitigation Measure WQ-18: Design Wetland and Riparian Habitat Features to Minimize Effects on Municipal Intakes

Please see Mitigation Measure WQ-18 under Impact WQ-18 in the discussion of Alternative 1A.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects: Effects of CM1 on pathogens under Alternative 6A would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: Effects of CM1 on pathogens under Alternative 6A would be the same as those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

River flow rate and reservoir storage reductions that would occur due to implementation of CM1 (water facilities and operations) under Alternative 6A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta, given the small magnitude of urban runoff contributions relative to the magnitude of river flows, that pathogen concentrations in the rivers have a minimal relationship to river flow rate, and the expected reduced pollutant loadings in response to NPDES stormwater-related regulations.

It is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens. This conclusion is based on the Pathogens Conceptual Model, which found that pathogen sources in close proximity to a Delta site appear to have the greatest influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative.

In the SWP/CVP Export Service Areas waters, relative to Existing Conditions, an increased proportion of water coming from the Sacramento River would not adversely affect beneficial uses in the SWP/CVP Export Service Areas. The pathogen levels in the Sacramento River are similar to or lower than the water diverted at the Delta export pumps. Further, it is localized sources of pathogens that appear to have the greatest influence on concentrations. Thus, an increased proportion of Sacramento River water diverted to the SWP/CVP Export Service Areas would result in minimal changes in pathogen levels in the SWP/CVP Export Service Areas waters.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is Clean Water Act section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on pathogens under Alternative 6A would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on pathogens resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, under Alternative 6A no specific operations or maintenance activity of the SWP or CVP would substantially drive a change in pesticide use, and thus pesticide sources would remain unaffected upstream of the Delta. Nevertheless, changes in the timing and magnitude of reservoir releases could have an effect on available dilution capacity along river segments such as the Sacramento, Feather, American, and San Joaquin Rivers.

Under Alternative 6A, winter (November–March) and summer (April–October) season average flow rates on the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis would change. Relative to existing condition and the No Action Alternative, seasonal average flow rates on the Sacramento would decrease no more than 6% during the summer and 3% during the winter (Appendix 8L, *Pesticides*, Tables 1–4). On the Feather River, average flow rates would decrease no more than 7% during the summer, but would increase by as much as 9% in the winter. American River average flow rates would decrease by as much as 17% in the summer but would increase by as much as 7% in the winter. Seasonal average flow rates on the San Joaquin River would decrease by as much as 12% in the summer, but increase by as much as 1% in the winter. For the same reasons stated for the No Action Alternative, decreased seasonal average flow of ≤17% is not considered to be of sufficient magnitude to substantially increase pesticide concentrations or alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of water bodies upstream of the Delta.

Delta

Sources of diuron, OP and pyrethroid insecticides to the Plan Area include direct input of surface runoff from in-Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. Similar to Upstream of the Delta, CVP/SWP operations would not affect these sources.

Under Alternative 6A, the distribution and mixing of Delta source waters would change. Percentage change in monthly average source water fraction was evaluated for the modeled 16-year (1976–1991) hydrologic period and a representative drought period (1987–1991), with special attention given to changes in San Joaquin River, Sacramento River and Delta Agriculture sources water fractions. Relative to Existing Conditions, under Alternative 6A modeled San Joaquin River fractions would increase greater than 10% at Buckley Cove (drought period only), Franks Tract, Rock Slough, Contra Costa PP No. 1, and the San Joaquin River at Antioch (Appendix 8D, *Source Water Fingerprinting Results*). At Buckley Cove, San Joaquin River source water fractions when modeled for the drought period would increase by 13% in July and 19% in August. At Antioch, San Joaquin River source water fractions when modeled for the 16-year hydrologic period would increase by 11–19% from October through June (11% for January through March of the modeled drought period). While these changes at Buckley Cove and Antioch are not considered substantial, changes in San Joaquin River source water fraction in the Delta interior would be considerable. At Franks Tract, modeled San Joaquin River source water fractions would increase between 14–34% for the entire calendar year of January through December (12–28% for October through June of the modeled drought period). Changes at Rock Slough and Contra Costa PP No. 1 would be very similar, where modeled San Joaquin River source water fractions would increase from 26–76% (11–74% for the modeled drought period) for the entire calendar year. Relative to Existing Conditions, there would be no modeled increases in Sacramento River fractions greater than 14% (with exception to Banks and Jones which are discussed below) and Delta agricultural fractions greater than 19%. Increases in San Joaquin River source water fraction at Franks Tract, Rock Slough, and Contra Costa PP No. 1 would primarily balance through decreases in Sacramento River water, and as a result the San Joaquin River would account for greater than 50% of the total source water volume at Franks Tract between March through May (<50% for all months during the modeled drought period), and would be 50%, and as much as 80% during October through May at Rock Slough and Contra Costa PP No. 1 for both the modeled drought and 16-year hydrologic periods. While the source water and potential pesticide related toxicity co-occurrence predictions do not mean adverse effects would occur, such considerable modeled increases in early summer source water fraction at Franks Tract and winter and summer source water fractions at Rock Slough and Contra Costa PP No. 1 could substantially alter the long-term risk of pesticide-related toxicity to aquatic life, given the apparent greater incidence of pesticides in the San Joaquin River.

When compared to the No Action Alternative, changes in source water fractions would be similar in season, geographic extent, and magnitude to those discussed for Existing Conditions with exception to Buckley Cove. Relative to the No Action Alternative, on a source water basis Buckley Cove is comprised predominantly of water of San Joaquin River origin (i.e., typically >80% San Joaquin River) for all months of the year but July and August. In July and August, the combined operational effects on Delta hydrodynamics of the Delta Cross Channel being open, the absence of a barrier at Head of Old River, and seasonally high exports from south Delta pumps results in substantially lower San Joaquin River source water fraction at Buckley Cove relative to all other months of the year. Under Alternative 6A, however, modeled July and August San Joaquin River fractions at Buckley Cove would increase relative to the No Action Alternative, with increases of 20% in July (36% for the modeled drought period) and 27% in August (52% for the modeled drought period) (Appendix 8D, *Source Water Fingerprinting Results*). Despite these San Joaquin River increases, the resulting net San Joaquin River source water fraction for July and August would remain less than all other months. Although these modeled changes in the source water fractions at Buckley Cover are not of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, relative to the No Action Alternative, changes in source water fractions at Rock Slough, Contra Costa PP No. 1 and Franks Tract could substantially alter the long-term risk of pesticide-related toxicity to aquatic life, given the apparent greater incidence of pesticides in the San Joaquin River.

These predicted adverse effects on pesticides at Delta interior locations relative to Existing Conditions and the No Action Alternative fundamentally assume that the present pattern of pesticide incidence in surface water will occur at similar levels into the future. In reality, however, the makeup and character of the pesticide use market in the late long-term (i.e., the year 2060) will not be exactly as it is today. Current use of chlorpyrifos and diazinon is on the decline with their replacement by pyrethroids on the rise, yet in this assessment it is the apparent greater incidence of diazinon and chlorpyrifos on the San Joaquin River that serves as the basis for concluding that substantially increased San Joaquin River source water fraction would correspond to an increased risk of pesticide-related toxicity to aquatic life. By 2060, however, alternative pesticides, such as neonicitinoids and biologicals, will likely be a more substantial contributing part of the existing mix of pesticides, and perhaps more prominent. The trend in the development of future-use pesticides is towards reduced risk pesticides, including more biopesticides, with greater targeted specificity, fewer residues, and lower overall non-target toxicity. By 2060 existing chlorpyrifos and diazinon TMDLs for the Sacramento and San Joaquin Rivers will have been in effect for more than 50 years. Moreover, it is reasonable to expect that CWA section 303(d) listings and future additional listings will have developed TMDLs by 2060. To the extent these existing and future TMDL's address current and future-use pesticides, a greater degree of pesticide related source control can be anticipated. Nevertheless, forecasting whether these various efforts will ultimately be successful at resolving current pesticide related impairments requires considerable speculation. While the fundamental assumptions that have guided this assessment of pesticides may be somewhat altered by 2060, these assumptions are informed by actual studies and monitoring data collected from the recent past and, therefore, judging project alternative effects in the future remain most accurate through use of these informed assumptions rather than based on assumptions founded upon future speculative conditions.

SWP/CVP Export Service Areas

Assessment of effects in SWP/CVP Export Service Areas is based on effects seen in the Plan Area at the Banks and Jones pumping plants. Under Alternative 6A, Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants relative to Existing Conditions and the No Action Alternative (Appendix 8D, *Source Water Fingerprinting Results*). At Banks pumping plant, Sacramento source water fractions would generally increase from 19–79% for the entire period of January through December (12–56% for January through December of the modeled drought period) and at Jones pumping plant Sacramento source water fractions would generally increase from 33–96% for the entire period of January through December (17–89% for January through December of the modeled drought period). These increases in Sacramento source water fraction would primarily balance through equivalent decreases in San Joaquin River water. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of OP insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

***NEPA Effects*:** In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers, under Alternative 6A relative to the No Action Alternative, are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. However, modeled increases in San Joaquin River fraction at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are of sufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta. The effects on pesticides from operations and maintenance (CM1) are determined to be adverse and unavoidable.

***CEQA Conclusion*:** Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Sources of pesticides upstream of the Delta include direct input of pesticide containing surface runoff from agriculture and urbanized areas. Flows in rivers receiving these discharges dilute these pesticide inputs. Relative to Existing Conditions, however, modeled changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta.

In the Delta, sources of pesticides include direct input of surface runoff from Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. While facilities operations and maintenance activities would not affect these sources, changes in Delta source water fraction could change the relative risk associated with pesticide related toxicity to aquatic life. Under Alternative 6A, modeled long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would increase considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase.

The assessment of Alternative 6A effects on pesticides in the SWP/CVP Export Service Areas is based on assessment of changes predicted at Banks and Jones pumping plants. Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants and would generally represent an improvement in export water quality respective to pesticides.

Based on the above, Alternative 6A would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions would not be expected to make any of these beneficial use impairments measurably worse, with principal exception to locations in the Delta that would receive a substantially greater fraction San Joaquin River water under Alternative 6A. Long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would change considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase. Additionally, the potential for increased incidence of pesticide related toxicity could include pesticides such as chlorpyrifos and diazinon for which existing 303(d) listings exist for the Delta, and thus existing beneficial use impairment could be made discernibly worse. The impact is considered to be significant and unavoidable. There is no feasible mitigation available to reduce the effect of this significant impact.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** CM2–CM21 proposed under Alternative 6A would be the same as those proposed under Alternative 1A. As such, effects on pesticides resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. In summary, CM13 proposes the use of herbicides to control invasive aquatic vegetation around habitat restoration sites. Herbicides directly applied to water could include adverse effects on non-target aquatic life, such as aquatic invertebrates and beneficial aquatic plants. As such, aquatic life toxicity objectives could be exceeded with sufficient frequency and magnitude such that beneficial uses would be impacted, thus constituting an adverse effect on water quality.

In summary, based on the discussion above, the effects on pesticides from implementing CM2–CM21 are considered to be adverse. Mitigation Measure WQ-22 would be available to reduce this adverse effect.

***CEQA Conclusion*:** Effects of CM2–CM21 on pesticides under Alternative 6A are similar to those discussed for Alternative 1A. Potential environmental effects related only to CM13 are considered to be significant. Mitigation is required. While Mitigation Measure WQ-22 is available to partially reduce this impact of pesticides, no feasible mitigation is available that would reduce it to a level that would be less than significant.

Mitigation Measure WQ-22: Implement Least Toxic Integrated Pest Management Strategies

Please see Mitigation Measure WQ-22 under Impact WQ-22 in the discussion of Alternative 1A.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects**:** Effects of water facilities and operations (CM1) on phosphorus levels in water bodies of the affected environment under Alternative 6A would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels discussed in detail for Alternative 1A also adequately represent the effects under Alternative 6A, which are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Because phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration upstream of the Delta are not anticipated for Alternative 6A, relative to Existing Conditions.

Because phosphorus concentrations in the major source waters to the Delta are similar for much of the year, phosphorus concentrations in the Delta are not anticipated to change substantially on a long term-average basis under Alternative 6A, relative to Existing Conditions. Algal growth rates are limited by availability of light in the Delta, and therefore any minor increases in phosphorus levels that may occur at some locations and times within the Delta would be expected to have little effect on primary productivity in the Delta.

The assessment of effects of phosphorus under Alternative 6A in the SWP and CVP Export Service Areas is based on effects on phosphorus at the Banks and Jones pumping plants. As noted above, phosphorus concentrations in the Delta (including Banks and Jones pumping plants) are not anticipated to change substantially on a long term-average basis.

Based on the above, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas under Alternative 6A relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on phosphorus levels in water bodies of the affected environment under Alternative 6A would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels from implementing CM2–CM21 discussed in detail for Alternative 1A also adequately represent the effects of these same actions under Alternative 6A, which are considered to be not adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on phosphorus resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 6A would have negligible, if any, effect on selenium concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in selenium concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to selenium.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics. To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, such as additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See Section 8.3.1.3 for more information.

Selenium concentrations and threshold comparisons for each of the 11 modeled Delta assessment locations under Alternative 5, relative to Existing Conditions and the No Action Alternative, are presented in Appendix 8M, *Selenium*, Table M-9a for water, Tables M-16 and M-26 for most biota (whole-body fish [excluding sturgeon], bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, and Tables M-30 through M-32 for sturgeon at the two western Delta locations. Figures 8-59a and 8-60a present graphical distributions of predicted selenium concentration changes (shown as changes in available assimilative capacity based on 1.3 μg/L) in water at each modeled assessment location for all years. Appendix 8M, Figure M-23 provides more detail in the form of monthly patterns of selenium concentrations in water during the modeling period.

Alternative 6A would result in small to moderate changes in average selenium concentrations in water at all modeled Delta assessment locations relative to Existing Conditions and the No Action Alternative (Appendix 8M, *Selenium*, Table M-9a). Long-term average concentrations at interior and western Delta locations would increase by 0.01–0.17 μg/L for the entire period modeled (1976–1991). These increases in selenium concentrations in water would result in reductions in available assimilative capacity of 1–16%, relative to the 1.3 μg/L USEPA draft water quality criterion (Figures 8-59a and 8-60a). The long-term average selenium concentrations in water for Alternative 6A (range 0.09–0.40 μg/L) would be similar to Existing Conditions (range 0.09–0.41 μg/L) and the No Action Alternative (range 0.09–0.38 μg/L), and all would be below the USEPA draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 6A would generally result in small increases (less than 4%) in estimated selenium concentrations in most biota (whole-body fish (excluding sturgeon), bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, with little difference among locations (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-26). Despite the small increases in selenium concentrations in biota, Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0 (indicating low probability of adverse effects). Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years also are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by about 41% relative to Existing Conditions and 42% relative to the No Action Alternative in all years (from about 4.7 to 6.6 mg/kg dry weight). Likewise, those for sturgeon in the Sacramento River at Mallard Island are predicted to increase by about 24% in all years (from about 4.4 to 5.5 mg/kg dry weight) (Appendix 8M, Tables M-30 and M-31). Selenium concentrations in sturgeon during drought years are expected to increase by about 14% and 28% at those locations. Detection of small changes in whole-body sturgeon such as those estimated for the western Delta may require large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at both locations (as they do for Existing Conditions and the No Action Alternative) and for all years at both locations, whereas Existing Conditions and the No Action Alternative do not (quotients increase from 0.94 to 1.3 at San Joaquin at Antioch, and from 0.88 to 1.1 at Sacramento River at Mallard Island (Appendix 8M, Table M-32). High Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years in the San Joaquin River at Antioch, whereas Existing Conditions and the No Action Alternative do not (quotient increases from 0.85–0.86 to 1.1) (Appendix 8M, Table M-32).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in the appendix, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. (There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium.) Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on "fixed" K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Increased water residence times could increase the bioaccumulation of selenium in biota, thereby potentially increasing fish tissue and bird egg concentrations of selenium (see residence time discussion in Appendix 8M, *Selenium*, and Presser and Luoma [2010b]). Thus, residence time was assessed for its relevance to selenium bioaccumulation. Table 8-60a shows the time for neutrally buoyant particles to move through the Delta (surrogate for flow and residence time). Although an increase in residence time throughout the Delta is expected under the No Action Alternative, relative to Existing Conditions (because of climate change and sea level rise), the change is fairly small in most areas of the Delta.

Relative to Existing Conditions and the No Action Alternative, increases in residence times for Alternative 6A would be greater in the South Delta and East Delta than in other sub-regions. Relative to Existing Conditions, annual average residence times for Alternative 6A in the South Delta are expected to increase by more than 53 days (Table 8-60a). and in the East Delta increase by more than 32 days. Increases in residence times for other sub-regions would be smaller, especially as compared to Existing Conditions and the No Action Alternative (which are longer than those modeled for the South Delta). As mentioned above, these results incorporate hydrodynamic effects of both CM1 and CM2 and CM4, and the effects of CM1 cannot be distinguished from the effects of CM2 and CM4. However, it is expected that CM2 and CM4 are substantial drivers of the increased residence time.

Presser and Luoma (2010b) summarized and discussed selenium uptake in the Bay-Delta (including hydrologic conditions [e.g., Delta outflow and residence time for water], K_ds [the ratio of selenium concentrations in particulates, as the lowest level of the food chain, relative to the water-borne concentration], and associated tissue concentrations [especially in clams and their consumers, such as sturgeon]). When the Delta Outflow Index (daily average flow per month) decreased by five-fold (73,732 cfs in June 1998 to 12,251 cfs in October 1998), residence time doubled (from 11 to 22 days) and the calculated mean K_d also doubled (from 3,198 to 6,501). However, when daily average Delta outflow in November 1999 was only 6,951 cfs (i.e., about one-half that in October 1998) and residence time was 70 days, the calculated mean K_d (7,614) did not increase proportionally.

Models are not available to quantitatively estimate the level of changes in selenium bioaccumulation as related to residence time, but the effects of residence time are incorporated in the bioaccumulation modeling for selenium that was based on higher K_d values for drought years in comparison to wet, normal, or all years; see Appendix 8M, *Selenium*. If increases in fish tissue or bird egg selenium were to occur, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. In consideration of this factor, although the Delta as a whole is a CWA Section 303(d)-listed water body for selenium, and although monitoring data of fish tissue or bird eggs in the Delta are sparse, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time from restoration areas would be a concern is the western Delta and Suisun Bay for sturgeon, as discussed above. As shown in Table 8-60a, the overall increase in residence time estimated in the western Delta is 6 days relative to Existing Conditions, and 4 days relative to the No Action Alternative. Given the available information, these increases are small enough that they are not expected to substantially affect selenium bioaccumulation in the western Delta. Because CM2 and CM4 are expected to be substantial drivers of the increased residence times, further discussion is included in Impact WQ-26 below.

In summary, relative to Existing Conditions and the No Action Alternative, Alternative 6A would result in small increases in selenium concentrations throughout the Delta for most biota (less than 4%), although larger increases in selenium concentrations are predicted for sturgeon in the western Delta. The Low Toxicity Threshold Exceedance Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase from 0.94 for Existing Conditions and the No Action Alternative to 1.3, and from 0.88 to 1.1 at Sacramento River at Mallard Island. The High Toxicity Threshold Exceedance Quotient for selenium concentrations for sturgeon at Antioch in drought years would increase from 0.85 for Existing Conditions and 0.86 for the No Action Alternative to 1.1, indicating a high potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, the predicted increases for Alternative 6A are high enough that they may represent a measurable increase in body burdens of sturgeon, which would constitute an adverse impact.

SWP/CVP Export Service Areas

Alternative 6A would result in moderate (0.12–0.19 μg/L) decreases in long-term average selenium concentrations in water at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative, for the entire period modeled (Appendix 8M, *Selenium*, Table M-9a). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium at these pumping plants of 11–20%, relative to the 1.3 μg/L USEPA draft water quality criterion (Figures 8-59a and 8-60a). Furthermore the modeled selenium concentrations in water for Alternative 6A (0.09 μg/L) would be below the USEPA draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 6A would result in small changes (less than 5%) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) at export service areas (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-26). Concentrations in biota would not exceed any selenium benchmarks for Alternative 6A (Figures 8-61a through 8-64b).

NEPA Effects: Based on the discussion above, the effects on selenium from Alternative 6A are considered to be adverse. This determination is reached because selenium concentrations in whole-body sturgeon modeled at two western Delta locations would increase by an average of 27%, which may represent a measurable increase in the environment. Because both low and high toxicity benchmarks would be exceeded, these potentially measurable increases represent an adverse impact.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for selenium. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 6A, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate that Alternative 6A would result in small changes in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. Relative to Existing Conditions, modeling estimates indicate that Alternative 6A would increase selenium concentrations in whole-body sturgeon modeled at two western Delta locations by an average of 27%, which may represent a measurable increase in the environment. Because both low and high toxicity benchmarks are already exceeded under Existing Conditions, these potentially measurable increases represent a potential adverse impact on fish and wildlife beneficial uses.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 6A would cause no increase in the frequency with which applicable benchmarks would be exceeded and would improve the quality of water in selenium concentrations at the Banks and Jones pumping plants locations.

Based on the above, although waterborne selenium concentrations would not exceed applicable water quality objectives/criteria; however, significant impacts on some beneficial uses of waters in the Delta could occur because high toxicity benchmarks may be exceeded (where they are not under Existing Conditions), and uptake of selenium from water to biota may measurably increase. In comparison to Existing Conditions, water quality conditions under this alternative would increase levels of selenium (a bioaccumulative pollutant) by frequency, magnitude, and geographic extent such that the affected environment may have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish); however, impacts to humans consuming those organisms are not expected to occur. Water quality conditions under this alternative with respect to selenium would cause long-term degradation of water quality in the western Delta. Except in the vicinity of the western Delta for sturgeon, water quality conditions under this alternative would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms. The greater level of selenium bioaccumulation in the western Delta would further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA 303(d)-listed impairment of beneficial use to be made discernibly worse. This impact is considered significant. *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on selenium under Alternative 6A would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on selenium resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 6A would result in negligible, and likely immeasurable, increases in trace metal concentrations in the rivers and reservoirs upstream of the Delta, relative to Existing Conditions and the No Action Alternative. Effects due to the operation and maintenance of the conveyance facilities are expected to be immeasurable, on an annual and long-term average basis. As such, Alternative 6A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to trace metals.

Delta

For the same reasons stated for the No Action Alternative, Alternative 6A would not result in substantial increases in trace metal concentrations in the Delta relative to Existing Conditions and the No Action Alternative. However, substantial changes in source water fraction would occur in the south Delta (Appendix 8D, *Source Water Fingerprinting Results*). Throughout much of the south Delta, San Joaquin River water would replace Sacramento River water, with the future trace metals profile largely reflecting that of the San Joaquin River. As discussed for the No Action Alternative, trace metal concentration profiles between the San Joaquin and Sacramento Rivers are very similar and currently meet Basin Plan objectives and CTR criteria. While the change in trace metal concentrations in the south Delta would likely be measurable, Alternative 6A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the Delta or substantially degrade the quality of Delta waters with regard to trace metals.

SWP/CVP Export Service Areas

For the same reasons stated for the No Action Alternative, Alternative 6A would not result in substantial increases in trace metal concentrations in SWP/CVP export service area waters under Alternative 6A, relative to Existing Conditions and the No Action Alternative. Unlike current conditions, however, water delivered to the SWP and CVP export service area would be entirely sourced to the Sacramento River, and thus the future trace metals profile would reflect that of the Sacramento River. While the change in trace metal concentrations in SWP and CVP export service area would likely be measurable, Alternative 6A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment in the SWP/CVP service area or substantially degrade the quality of these water bodies, with regard to trace metals.

NEPA Effects: In summary, Alternative 6A, relative to the No Action Alternative, would not cause a substantial increase in long-term average trace metals concentrations within the affected environment, nor would it cause an increased frequency of water quality objective/criteria exceedances within the affected environment. The effect on trace metals is determined not to be adverse.

CEQA Conclusion: Effects of CM1 on trace metals under Alternative 6A would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

While greater water demands under the Alternative 6A would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based without a WER adjustment. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under the Alternative 6A.

The assessment of the Alternative 6A effects on trace metals in the SWP/CVP Export Service Areas is based on assessment of changes in trace metal concentrations at Banks and Jones pumping plants. As just discussed regarding similarities in Delta source water trace metal concentrations, the Alternative 6A is not expected to result in substantial changes in trace metal concentrations in Delta waters, including Banks and Jones pumping plants, therefore effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

Based on the above, there would be no substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area waters under Alternative 6A relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** CM2–CM21 proposed under Alternative 6A would be the same as those proposed under Alternative 1A. As such, effects on trace metals resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. As they pertain to trace metals, implementation of CM2–CM21 would not be expected to adversely affect beneficial uses of the affected environment or substantially degrade water quality with respect to trace metals.

In summary, implementation of CM2–CM21 under Alternative 6A, relative to the No Action Alternative, would have negligible, if any, effect on trace metals concentrations. The effect on trace metals from implementing CM2–CM21 is determined not to be adverse.

CEQA Conclusion: Implementation of CM2–CM21 under Alternative 6A would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects**:** Effects of CM1 on TSS and turbidity under Alternative 6A would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM1 is determined to not be adverse.

CEQA Conclusion**:** Effects of CM1 on TSS and turbidity under Alternative 6A would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Changes river flow rate and reservoir storage that would occur under Alternative 6A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes would be site-specific and temporal, which would be regulated to limit both their short-term and long-term effects on TSS and turbidity levels to less than substantial levels.

Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the Delta region, relative to Existing Conditions.

There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative 6A, relative to Existing Conditions, because as stated above, this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act section 303(d) listed constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on TSS and turbidity under Alternative 6A would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM2–CM21 is determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 6A would be similar to conservation measures proposed under Alternative 1A. As such, effects on TSS and turbidity resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

The conveyance features for CM1 under Alternative 6A would be very similar to those discussed for Alternative 1A. The primary difference between Alternative 6A and Alternative 1A is that under Alternative 6A, there would be additional features constructed to create the isolated conveyance system. As such, construction techniques and locations of major features of the conveyance system within the Delta would be similar. The remainder of the facilities constructed under Alternative 6A, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A.

***NEPA Effects*:** The types and magnitude of potential construction-related water quality effects associated with implementation of CM1–CM21 under Alternative 6A would be very similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. Nevertheless, the construction of CM1, and any individual components necessitated by CM2, and CM4–CM10, with the implementation of the BMPs specified in Appendix 3B*, Environmental Commitments, AMMs, and CMs,* and other agency permitted construction requirements would result in the potential water quality effects being largely avoided and minimized. The specific environmental commitments that would be implemented under Alternative 6A would be similar to those described for Alternative 1A (refer to Chapter 3, *Description of Alternatives*, and Appendix 3B for additional information regarding the environmental commitments and environmental permits). Consequently, relative to Existing Conditions, Alternative 6A would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP and CVP service area.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

***CEQA Conclusion*:** Because environmental commitments would be implemented under Alternative 6A for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32. Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance (CM1)

Effects of facilities and operations (CM1) on *Microcystis* abundance, and thus microcystins concentrations, in water bodies of the affected environment under Alternative 6A would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. This is because factors that affect *Microcystis* abundance in waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Services Areas under Alternative 1A would similarly change under Alternative 6A, relative to Existing Conditions and the No Action Alternative. For the Delta in particular, there are differences in the direction and magnitude of water residence time changes during the *Microcystis* bloom period among the six Delta sub-regions under Alternative 6A compared to Alternative 1A, relative to Existing Conditions and No Action Alternative. However, under Alternative 6A, relative to Existing Conditions and No Action Alternative, water residence times during the *Microcystis* bloom period in various Delta sub-regions are expected to increase to a degree that could, similar to Alternative 1A, lead to an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms throughout the Delta. Water exported from the Delta under Alternative 1A will be a mixture of *Microcystis*-affected water from the existing south Delta intake and unaffected Sacramento River water from the north Delta intake, which contrasts to Alternative 6, under which water exported to the SWP/CVP Export Service Areas consist entirely of water from the Sacramento River from the north Delta that is in unaffected by *Microcystis*. Because of this, the effects of *Microcystis* on and the microcystin concentrations of water exported to the SWP/CVP Export Service Areas could decrease under Alternative 6A, relative to Existing Conditions.

Similar to Alternative 1A, elevated ambient water temperatures relative to Existing Conditions would occur in the Delta under Alternative 6A, which could lead to earlier occurrences of *Microcystis* blooms in the Delta, and increase the overall duration and magnitude of blooms. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. While *Microcystis* blooms have not occurred in the Export Service Areas, conditions in the Export Service Areas under Alternative 6A may become more conducive to *Microcystis* bloom formation, relative to Existing Conditions, because water temperatures will increase in the Export Service Areas due to the expected increase in ambient air temperatures resulting from climate change.

NEPA Effects: Effects of water facilities and operations (CM1) on *Microcystis* in water bodies of the affected environment under Alternative 6A would be very similar to (i.e., nearly the same) to those discussed for Alternative 1A. In summary, Alternative 6A operations and maintenance, relative to the No Action Alternative, would result in long-term increases in hydraulic residence time of various Delta sub-regions during the summer and fall *Microcystis* bloom period. During this period, the increased residence time could result in a concurrent increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus microcystin levels, in affected areas of the Delta. As a result, Alternative 6A operation and maintenance activities would cause further degradation to water quality with respect to *Microcystis* in the Delta. Under Alternative 6A, relative to No Action Alternative, water exported to the SWP/CVP Export Service Area will be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River, diverted at the north Delta intakes. It cannot be determined whether operations and maintenance under Alternative 6A will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants. Mitigation Measure WQ-32a and WQ-32b are available to reduce the effects of degraded water quality in the Delta. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 6A, additional impacts from *Microcystis* in the reservoirs and watersheds upstream of the Delta are not expected, relative to Existing Conditions. Operations and maintenance occurring under Alternative 6A is not expected to change nutrient levels in upstream reservoirs or hydrodynamic conditions in upstream rivers and streams such that conditions would be more conductive to *Microcystis* production.

Relative to Existing Conditions, water temperatures and hydraulic residence times in the Delta are expected to increase under Alternative 6A, resulting in an increase in the frequency, magnitude and geographic extent of *Microcystis* blooms in the Delta. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. Increases in Delta residence times are expected throughout the Delta during the summer and fall bloom period, due in small part to climate change and sea level rise, but due more proportionately to CM1 and the hydrodynamic impacts of restoration included in CM2 and CM4. The precise change in local residence times and *Microcystis* production expected within any Delta sub-region is unknown because conditions will vary across the complex networks of intertwining channels, shallow back water areas, and submerged islands that compose the Delta. Nonetheless, Delta residence times are, in general, expected to increase due to Alternative 6A. Consequently, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 6A and the hydrodynamic impacts of restoration (CM2 and CM4).

The assessment of effects of *Microcystis* on SWP/CVP Export Service Areas is based on the assessment of changes in *Microcystis* levels in export source waters, as well as the effects of temperature and residence time changes within the Export Service Areas on *Microcystis* production. Under Alternative 6A, relative to Existing Conditions, the potential for *Microcystis* to occur in the Export Service Area is expected to increase due to increasing water temperature, but this impact is driven entirely by climate change and not Alternative 6A. Water exported from the Delta to the Export Service Area will consist entirely of Sacramento River water from the north Delta which is unaffected by *Microcystis*. Operations and maintenance (CM1) under Alternative 6A, relative to existing conditions, is not expected to result in increased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants.

Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, because it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 6A and the hydrodynamic impacts of restoration (CM2 and CM4), long-term water quality degradation may occur and, thus, significant impacts on beneficial uses could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be significant.

Implementation of Mitigation Measure WQ-32a and WQ-32b may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of these mitigation measures to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Mitigation Measure WQ-32b: Investigate and Implement Operational Measures to Manage Water Residence Time

Please see Mitigation Measure WQ-32b under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-33. Effects on *Microcystis* Bloom Formation Resulting from Other Conservation Measures (CM2–CM21)

The effects of CM2–CM21 on *Microcystis* under Alternative 6A would be the same as those discussed for Alternative 1A. In summary, implementation of CM2 and CM4 could result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta, relative to Existing Conditions and the No Action Alternative, as a result of increased residence times for Delta waters. Because the hydrodynamic effects associated with implementing CM2 and CM4 were incorporated into the modeling used to assess CM1, a detailed assessment of the effects of implementing CM2 and CM4 on *Microcystis* blooms in the Delta via their effects on Delta water residence time is provided under CM1 (above). The effects of CM2 and CM4 on *Microcystis* may be reduced by implementation of Mitigation Measures WQ-32a. The effectiveness of the mitigation measure to result in feasible measures for reducing water quality effects is uncertain. CM3 and CM5–CM21 would not result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta.

NEPA Effects: Effects of CM2–CM21 on *Microcystis* under Alternative 6A would be the same as those discussed for Alternative 1A and are considered to be adverse.

CEQA Conclusion: Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans.Because restoration actions implemented under CM2 and CM4 will increase residence time throughout the Delta and create local areas of warmer water during the bloom season, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus long-term water quality degradation and significant impacts on beneficial uses, could occur. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM2–CM21 are determined to be significant.

Implementation of Mitigation Measure WQ-32a may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance (CM1) and Implementation of CM2–CM21

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 6A would have a less than significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- DO
- Pathogens
- Pesticides
- Trace Metals
- Turbidity and TSS

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Thus, changes in boron, DO, pathogens, pesticides, and turbidity and TSS in Delta outflow are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay.

The effects of Alternative 6A on bromide, chloride, and DOC, in the Delta were determined to be significant/adverse. Increases in bromide, chloride, and DOC concentrations are of concern in drinking water supplies; however, as described previously, the San Francisco Bay does not have a designated MUN use. Thus, changes in bromide, chloride, and DOC in Delta outflow would not adversely effect any beneficial uses of San Francisco Bay.

Elevated EC, as assessed for this alternative, is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. As discussed above, San Francisco Bay does not have an AGR beneficial use designation. Further, as discussed for the No Action Alternative, changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow, which would be the primary driver of salinity changes, would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow.

Also, as discussed for the No Action Alternative, adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in San Francisco Bay, because

Microcystis are intolerant of the Bay's high salinity and, thus have not been detected downstream of Suisun Bay.

While effects of Alternative 6A on the nutrients ammonia, nitrate, and phosphorus were determined to be less than significant/not adverse, these constituents are addressed further below because the response of the seaward bays to changed nutrient concentrations/loading may differ from the response of the Delta. Selenium and mercury are discussed further, because they are bioaccumulative constituents where changes in load due to both changes in Delta concentrations and exports are of concern.

Nutrients: Ammonia, Nitrate, and Phosphorus

Total nitrogen loads in Delta outflow to Suisun and San Pablo Bays under Alternative 6A would be dominated almost entirely by nitrate, because planned upgrades to the SRWTP will result in >95% removal of ammonia in its effluent. Total nitrogen loads to Suisun and San Pablo Bays would decrease by 5%, relative to Existing Conditions, and increase by 40%, relative to the No Action Alternative (Appendix 8O, *San Francisco Bay Analysis*, Table O-1). The change in nitrogen loading to Suisun and San Pablo Bays under Alternative 6A would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. To the extent that algal growth increases in relation to a change in ammonia concentration, this would have net positive benefits, because current algal levels in these embayments are low. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay.

The phosphorus load exported from the Delta to Suisun and San Pablo Bays for Alternative 6A is estimated to increase by 9%, relative to Existing Conditions, and increase by 4% relative to the No Action Alternative (Appendix 8O, Table O-1)). The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. Any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary (Senn and Novick 2014; Kimmerer and Thompson 2014). Therefore, the projected change in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay is not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Mercury

The estimated long-term average mercury and methylmercury loads in Delta exports are shown in Appendix 8O, Table O-2. Loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 6A. Mercury load to the Bay is estimated to increase by 12 kg/year (5%), relative to Existing Conditions, and 9 kg/year (3%), relative to the No Action Alternative. Methylmercury load is estimated to increase by 0.37 kg/year (10%), relative to Existing Conditions, and increase by 0.28 kg/year (7%) relative to the No Action Alternative. The estimated total mercury load to the Bay is 272 kg/year, which would be less than the San Francisco Bay mercury TMDL WLA for the Delta of 330 kg/year. The estimated changes in mercury and methylmercury loads would be within the overall uncertainty associated with the estimates of long-term average net Delta outflow and the long-term average mercury and methylmercury concentrations in Delta source waters. The estimated changes in mercury load under the alternative would also be substantially less than the considerable differences among estimates in the current mercury load to San Francisco Bay (San Francisco Bay Regional Water Quality Control Board 2006; David et al. 2009).

Given that the estimated incremental increases of mercury and methylmercury loading to San Francisco Bay would fall within the uncertainty of current mercury and methylmercury load estimates, the estimated changes in mercury and methylmerucy loads in Delta exports to San Francisco Bay due to Alternative 6A are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to mercury, or make the existing CWA Section 303(d) impairment measurably worse.

Selenium

Changes in source water fraction and net Delta outflow under Alternative 6A, relative to Existing Conditions, are projected to cause the total selenium load to the North Bay to increase by 24%, relative to Existing Conditions, and increase by 20%, relative to the No Action Alternative (Appendix 8O, Table O-3). Changes in long-term average selenium concentrations of the North Bay are assumed to be proportional to changes in North Bay selenium loads. Under Alternative 6A, the long-term average total selenium concentration of the North Bay is estimated to be 0.16µg/L and the dissolved selenium concentration is estimated to be 0.14 µg/L, which would be a 0.03 µg/L increase relative to Existing Conditions and the No Action Alternative (Appendix 8O, Table O-3). The dissolved selenium concentration would be below the target of 0.202 µg/L developed by Presser or Luoma (2013) to coincide with a white sturgeon whole-body fish tissue selenium concentration not greater than 8 mg/kg in the North Bay.

The incremental increase in dissolved selenium concentrations projected to occur under Alternative 6A, relative to Existing Conditions and the No Action Alternative, would be higher than under Alternatives 1A–5, but still low (0.03 µg/L). The increased dissolved selenium concentration would be within the overall uncertainty of the analytical methods used to measure selenium in water column samples; however, it also would be within the uncertainty associated with estimating numeric water column selenium thresholds (Pressor and Luoma 2013). As described in Section 8.3.1.8, there have been improvements in selenium concentrations in the tissue of diving ducks and muscle of white sturgeon since the initial CWA Section 303(d) listing of the North Bay for selenium impairments, and selenium concentrations in white sturgeon muscle have also generally been below the USEPA's draft recommended fish muscle tissue concentration of 11.8 mg/kg dry weight (San Francisco Estuary Institute 2014). However, as described under Impact WQ-25, though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases for Alternative 6A are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Because the projected incremental increases in dissolved selenium could cause measurable changes in water column concentrations, and these incremental increases would be within the uncertainty in the target water column threshold for dissolved selenium for protection against adverse bioaccumulative effects in the North Bay ecosystem, and modeling predicts concentrations in the western Delta may represent a measurable increase in body burdens of sturgeon, there is potential that the incremental increase in dissolved selenium concentration projected to occur in the North Bay under Alternative 6A could result in adverse effects beneficial uses.

NEPA Effects: Based on the discussion above, Alternative 6A, relative to the No Action Alternative, would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, based on the discussion above, effects on the San Francisco Bay from implementation of CM1–CM21 are considered to be not adverse with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. However, Alternative 6A could result in increases in selenium concentrations in the North San Francisco Bay that could result in adverse effects to fish and wildlife beneficial uses. This effect is considered to be adverse.

CEQA Conclusion: Based on the above, Alternative 6A would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Further, based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals or turbidity or TSS are anticipated in the Delta, relative to Existing Conditions, therefore, no substantial changes these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow. Adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in the Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus not have not been detected downstream of Suisun Bay. The 5% decrease in total nitrogen load and 40% increase in phosphorus load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. The estimated increase in mercury load (9 kg/year; 3%) and methylmercury load (0.37 kg/year; 10%), relative to Existing Conditions, is within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans.

In regard to selenium, the estimated increase in selenium load would be 24% and the estimated increase in dissolved selenium concentrations would be 0.03 μg/L. Though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Thus, the increase in selenium load may make the CWA section 303(d) selenium impairment measurably worse and cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish and wildlife. This impact is considered to be significant. *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

8.3.3.12 Alternative 6B—Isolated Conveyance with East Alignment and Intakes 1–5 (15,000 cfs; Operational Scenario D)

Alternative 6B would comprise physical/structural components similar to those under Alternative 1B with the principal exception that Alternative 6B would be an “isolated” conveyance, no longer involving operation of the existing SWP and CVP south Delta export facilities for Clifton Court Forebay and Jones Pumping Plant. Alternative 6B would utilize five screened intakes (i.e., Intakes 1 through 5) to convey up to 15,000 cfs of water from the north Delta to the south Delta through a canal along the east side of the Delta. An intermediate pumping plant north of the town of Holt would be constructed as well as a new 600-acre Byron Tract Forebay located adjacent to Clifton Court Forebay. Water supply and conveyance operations would follow the guidelines described as Scenario D, which includes Fall X2. CM2–CM21 would be implemented under this alternative, and these conservation measures would be the same as those under Alternative 1A. See Chapter 3, *Description of Alternatives,* Section 3.5.12, for additional details on Alternative 6B.

Water Quality Effects Resulting from Facilities Operations and Maintenance (CM1)

Alternative 6B has the same diversion and conveyance operations as Alternative 6A. The primary difference between the two alternatives is that conveyance under Alternative 6B would be in a lined or unlined canal, instead of pipeline. Because there would be no difference in conveyance capacity or operations, there would be no differences between these two alternatives in upstream of Delta river flows or reservoir operations, Delta inflow, source fractions to various Delta locations, and hydrodynamics in the Delta. Conveyance of water in an open channel instead of a pipeline may result in differing physical properties (e.g., DO, pH, temperature) of the water upon reaching the south Delta export pumps than if the water was conveyed in a pipeline. However, the physical properties of water arriving at the south Delta export pumps would continue to change and would equilibrate to similar levels as Alternative 6A as it is conveyed throughout the SWP/CVP Export Service Areas. Because no substantial differences in water quality effects are anticipated anywhere in the affected environment under Alternative 6B compared to those described in detail for Alternative 6A, the water quality effects described for Alternative 6A also appropriately characterize effects under Alternative 6B.

Water Quality Effects Resulting from Implementation of CM2–CM21

Alternative 6B has the same conservation measures as Alternative 6A. Because no substantial differences in water quality effects are anticipated anywhere in the affected environment under Alternative 6B compared to those described in detail for Alternative 6A, the water quality effects described for Alternative 6A also appropriately characterize effects under Alternative 6B.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

NEPA Effects: The primary difference between Alternative 6B and Alternative 1A is that under Alternative 6B, a canal would be constructed for conservation measure CM1 along the eastern side of the Delta to convey the Sacramento River water south, rather than the tunnel/pipeline features. As such, construction techniques and locations of major features of the conveyance system within the Delta would be different (see Chapter 3, *Description of Alternatives,* Section 3.5.12). The remainder of the facilities constructed under Alternative 6B, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A.

The types of potential construction-related water quality effects associated with implementation of CM1 under Alternative 6B would be very similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. However, given the substantial differences in the conveyance features under CM1 with construction of a canal, there could be differences in the location, magnitude, duration, and frequency of construction activities and related water quality effects. In particular, relative to the Existing Conditions and No Action Alternative conditions, construction of the major intakes and canal features for CM1 under Alternative 6B would involve extensive general construction activities, material handling/storage/placement activities, surface soil grading/excavation/disposal and associated exposure of disturbed sites to erosion and runoff, and construction site dewatering operations. Nevertheless, the construction of CM1, and any individual components necessitated by CM2, and CM4–CM10, with the implementation of the BMPs specified in Appendix 3B*, Environmental Commitments, AMMs, and CMs,* and other agency permitted construction requirements would result in the potential water quality effects being largely avoided and minimized. The specific environmental commitments that would be implemented under Alternative 6B would be similar to those described for Alternative 1A with the exception that Category "B" BMPs for RTM dewatering basin construction and operations, if necessary at all, would be much reduced. Consequently, relative to Existing Conditions, Alternative 6B would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP and CVP service area.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

***CEQA Conclusion*:** Construction-related contaminant discharges would be temporary and intermittent in nature and would involve negligible, if any, discharges of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Because environmental commitments would be implemented under Alternative 6B for construction-related activities along with agency-issued permits that also contain construction related mitigation requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

8.3.3.13 Alternative 6C—Isolated Conveyance with West Alignment and Intakes W1–W5 (15,000 cfs; Operational Scenario D)

Alternative 6C would comprise physical/structural components similar to those under Alternative 1C with the principal exception that Alternative 6B would be an "isolated" conveyance, no longer involving operation of the existing SWP and CVP south Delta export facilities for Clifton Court Forebay and Jones Pumping Plant. Alternative 6C would utilize five screened intakes (i.e., Intakes 1 through 5) to convey up to 15,000 cfs of water from the north Delta to the south Delta through a series of canals and tunnels along the west side of the Delta. An intermediate pumping plant would be utilized and a new 600-acre forebay at Byron Tract would be constructed adjacent Clifton Court Forebay. There would be no intermediate forebay. Water supply and conveyance operations would follow the guidelines described as Scenario D, which includes Fall X2. CM2–CM21 would be implemented under this alternative, and these conservation measures would be the same as those under Alternative 1A. See Chapter 3, *Description of Alternatives,* Section 3.5.13, for additional details on Alternative 6C.

Water Quality Effects Resulting from Facilities Operations and Maintenance (CM1)

Alternative 6C has the same diversion and conveyance operations as Alternative 6A. The primary differences between the two alternatives are that conveyance under Alternative 6C would be in a lined or unlined canal, instead of pipeline, and the alignment of the canal would be along the western side of the Delta, rather than the eastern side. Because there would be no difference in conveyance capacity or operations, there would be no differences between these two alternatives in upstream of Delta river flows or reservoir operations, Delta inflow, source fractions to various Delta locations, and hydrodynamics in the Delta. Conveyance of water in an open channel instead of a pipeline may result in differing physical properties (e.g., DO, pH, temperature) of the water upon reaching the south Delta export pumps than if the water was conveyed in a pipeline. However, the physical properties of water arriving at the south Delta export pumps would continue to change and would equilibrate to similar levels as Alternative 6A as it is conveyed throughout the SWP/CVP Export Service Areas. Because no substantial differences in water quality effects are anticipated anywhere in the affected environment under Alternative 6C compared to those described in detail for Alternative 6A, the water quality effects described for Alternative 6A also appropriately characterize effects under Alternative 6C.

Water Quality Effects Resulting from Implementation of CM2–CM21

Alternative 6C has the same conservation measures as Alternative 6A. Because no substantial differences in water quality effects are anticipated anywhere in the affected environment under Alternative 6C compared to those described in detail for Alternative 6A, the water quality effects described for Alternative 6A also appropriately characterize effects under Alternative 6C.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

NEPA Effects: The primary difference between Alternative 6C and Alternative 1A is that under Alternative 6C, a canal would be constructed for CM1 along the western side of the Delta to convey the Sacramento River water south, in addition to the tunnel/pipeline features. As such, construction techniques and locations of major features of the conveyance system within the Delta would be different (see Chapter 3, *Description of Alternatives,* Section 3.5.13). The remainder of the facilities constructed under Alternative 6C, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A.

The types of potential construction-related water quality effects associated with implementation of CM1 under Alternative 6C would be very similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. Given the substantial differences in the conveyance features under CM1 with construction of a canal in addition to the tunnel/pipeline features, there could be differences in the location, magnitude, duration, and frequency of construction activities and related water quality effects. In particular, relative to the Existing Conditions and No Action Alternative conditions, construction of the major intakes and canal features for CM1 under Alternative 6C would involve extensive general construction activities, material handling/storage/placement activities, surface soil grading/excavation/disposal and associated exposure of disturbed sites to erosion and runoff, and construction site dewatering operations. Nevertheless, the construction of CM1, and any individual components necessitated by CM2, and CM4–CM10, with the implementation of the BMPs specified in Appendix 3B*, Environmental Commitments, AMMs, and CMs,* and other agency permitted construction requirements would result in the potential water quality effects being largely avoided and minimized. The specific environmental commitments that would be implemented under Alternative 6C would be similar to those described for Alternative 1A. However, this alternative would involve environmental commitments associated with both tunnel/pipeline and canal construction activities. Consequently, relative to Existing Conditions, Alternative 6C would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP and CVP service area.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

CEQA Conclusion: Construction-related contaminant discharges would be temporary and intermittent in nature and would involve negligible, if any, discharges of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Because environmental commitments would be implemented under Alternative 6C for construction-related activities along with agency-issued permits that also contain construction related mitigation requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

8.3.3.14 Alternative 7—Dual Conveyance with Pipeline/Tunnel, Intakes 2, 3, and 5, and Enhanced Aquatic Conservation (9,000 cfs; Operational Scenario E)

Alternative 7 would comprise physical/structural components similar to those under Alternative 1A with the principal exception that Alternative 7 would construct only three intakes and intake pumping plants (i.e., Intakes 2, 3, and 5). Alternative 7 would convey up to 9,000 cfs of water from the north Delta to the south Delta through pipelines/tunnels from three screened intakes on the east bank of the Sacramento River between Clarksburg and Walnut Grove. A 750-acre intermediate forebay and pumping plant would be constructed near Hood. A new 600-acre Byron Tract Forebay, adjacent to and south of Clifton Court Forebay, would be constructed which would provide water to the south Delta pumping plants. Water supply and conveyance operations would follow the guidelines described as Scenario E, which includes Fall X2. The modifications under this enhanced aquatic alternative are intended to further improve fish and wildlife habitat, especially along the San Joaquin River. CM2–CM21 (CM2–CM21) would be implemented under this alternative, and would be the same as those under Alternative 1A, except that 40 linear miles rather than 20 linear miles of channel margin habitat would be enhanced, and 20,000 acres rather than 10,000 acres of seasonally inundated floodplain would be restored. See Chapter 3, *Description of Alternatives*, Section 3.5.14, for additional details on Alternative 7.

Effects of the Alternative on Delta Hydrodynamics

Under the No Action Alternative and Alternatives 1A–9, the following two primary factors can substantially affect water quality within the Delta:

- Within the south, west, and interior Delta, a decrease in the percentage of Sacramento River-sourced water and a concurrent increase in San Joaquin River-sourced water can increase the concentrations of numerous constituents (e.g., boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides, selenium). This source water replacement is caused by decreased exports of San Joaquin River water (due to increased Sacramento River water exports), or effects of climate change on timing of flows in the rivers. Changes in channel flows also can affect water residence time and many related physical, chemical, and biological variables.
- Particularly in the west Delta, sea water intrusion as a result of sea level rise or decreased Delta outflow can increase the concentration of salts (bromide, chloride) and levels of electrical conductivity. Conversely, increased Delta outflow (e.g., as a result of Fall X2 operations in wet and above normal water years) will decrease levels of these constituents, particularly in the west Delta.

Under Alternative 7, over the long term, average annual delta exports are anticipated to decrease by 1,389 TAF relative to Existing Conditions, and by 682 TAF relative to the No Action Alternative. Since, over the long-term, approximately 62% of the exported water will be from the new north Delta intakes, average monthly diversions at the south Delta intakes would be decreased because of the shift in diversions to the north Delta intakes (see Chapter 5, *Water Supply*, for more information). The result of this is greatly increased San Joaquin River water influence throughout the south, west, and interior Delta, and a corresponding decrease in Sacramento River water influence. This can be seen, for example, in Appendix 8D, ALT 7–Old River at Rock Slough for ALL years (1976–1991), which shows increased San Joaquin River (SJR) percentage and decreased Sacramento River (SAC) percentage under the alternative, relative to Existing Conditions and the No Action Alternative.

Under Alternative 7, long-term average annual Delta outflow is anticipated to increase 1,383 TAF relative to Existing Conditions, due to both changes in operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise (see Chapter 5, *Water Supply*, for more information). The result of this would be decreased sea water intrusion in the west Delta. The decrease of sea water intrusion in the west Delta under Alternative 7 would be greater relative to the Existing Conditions because Existing Conditions do not include operations to meet Fall X2, whereas the No Action Alternative and Alternative 7 do. Long-term average annual Delta outflow is anticipated to increase under Alternative 7 by 683 TAF relative to the No Action Alternative, due only to changes in operations. The decreases in sea water intrusion (represented by an decrease in San Francisco Bay (BAY) percentage) can be seen, for example, in Appendix 8D, ALT 7–Sacramento River at Mallard Island for ALL years (1976–1991).

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 7 would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

Assessment of effects of ammonia under Alternative 7 is the same as discussed under Alternative 1A, except that because flows in the Sacramento River at Freeport are different between the two alternatives, estimated monthly average and long term annual average predicted ammonia-N concentrations in the Sacramento River downstream of Freeport are different.

As Table 8-70 shows, estimated ammonia-N concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 7 and the No Action Alternative are expected to be similar. Minor increases in ammonia-N concentrations would occur during January through March, July through September, November, and December, and remaining months would be unchanged or have a minor decrease. A minor increase in the annual average concentration would occur under Alternative 7, compared to the No Action Alternative. Moreover, the estimated concentrations downstream of Freeport under Alternative 7 would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 7, relative to the No Action Alternative, are not expected to substantially increase ammonia concentrations at any Delta locations.

Table 8-70. Estimated Ammonia-N (mg-L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative and Alternative 7

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative	0.074	0.084	0.069	0.060	0.057	0.060	0.058	0.064	0.067	0.060	0.067	0.064	0.065
Alternative 7	0.073	0.086	0.070	0.061	0.058	0.061	0.058	0.064	0.065	0.061	0.069	0.066	0.066

Any negligible increases in ammonia-N concentrations that could occur at certain locations in the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

SWP/CVP Export Service Areas

The assessment of effects on ammonia in the SWP/CVP Export Service Area is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. Similar to the discussion for Alternative 1A, under Alternative 7 for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease, relative to Existing Conditions (in association with less diversion of water influenced by the SRWTP). This decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in adverse effects on beneficial uses or substantially degrade water quality of exported water, with regards to ammonia.

Furthermore, as discussed above for the Plan Area, for all areas of the Delta, including Banks and Jones pumping plants, ammonia-N concentrations are not expected to be substantially different under Alternative 7, relative to No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

***NEPA Effects*:** In summary, based on the discussion above, effects on ammonia from implementation of CM1 are considered to be not adverse.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Ammonia-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to the lack of substantial point and nonpoint sources of ammonia-N upstream of the SRWTP in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 7, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river ammonia-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

Ammonia-N concentrations in the Sacramento River downstream of the SRWTP would be substantially lower under Alternative 7, relative to Existing Conditions, due to upgrades to the SRWTP that are assumed to be in place, and thus, ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water are expected to decrease. At locations which are not influenced notably by Sacramento River water, concentrations are expected to remain relatively unchanged, due to the similarity in SJR and BAY concentrations and the lack of expected changes in either of these concentrations.

The assessment of effects on ammonia in the SWP/CVP Export Service Areas is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. As discussed above for the Plan Area, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 7, relative to Existing Conditions.

There would be no substantial, long-term increase in ammonia-N concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 7 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia-N is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on ammonia under Alternative 7 would be the same as those discussed for Alternative 1A and are considered to be not adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on ammonia resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Effects of CM1 on boron under Alternative 7 in areas upstream of the Delta would be very similar to the effects discussed for Alternative 1A. There would be no expected change to the sources of boron in the Sacramento and eastside tributary watersheds, and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled long-term annual average lower San Joaquin

River flow at Vernalis would decrease slightly compared to Existing Conditions (in association with project operations, climate change, and increased water demands) and would be similar compared to the No Action Alternative considering only changes due to Alternative 7 operations. The reduced flow would result in possible increases in long-term average boron concentrations of up to about 3% relative to the Existing Conditions (Appendix 8F, *Boron*, Table Bo-32). The increased boron concentrations would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 7 would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Effects of CM1 on boron under Alternative 7 in the Delta would be similar to the effects discussed for Alternative 1A. Relative to the Existing Conditions and No Action Alternative, Alternative 7 would result in increased long-term average boron concentrations for the 16-year period modeled at interior and western Delta locations (by as much as 10% at the SF Mokelumne River at Staten Island, 33% at Franks Tract, and 56% at Old River at Rock Slough) (Appendix 8F, *Boron*, Table Bo-18). The comparison to Existing Conditions reflects changes due to both Alternative 7 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes due only to operations.

Implementation of tidal habitat restoration under CM4 also may contribute to increased boron concentrations at western Delta assessment locations (more discussion of this phenomenon is included in Section 8.3.1.3), and thus would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations. The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 μg/L human health advisory objective (i.e., for children) or 500 μg/L agricultural objective at any of the eleven Delta assessment locations, which represents no change from the Existing Conditions and the No Action Alternative (Appendix 8F, *Boron*, Table Bo-3A). The increased concentrations at interior Delta locations would result in moderate reductions in the long-term average assimilative capacity of up to 33% at Franks Tract and up to 56% at Old River at Rock Slough locations (Appendix 8F, Table Bo-19). However, because the absolute boron concentrations would still be well below the lowest 500 μg/L objective for the protection of the agricultural beneficial use under Alternative 7, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, Figure Bo-5).

SWP/CVP Export Service Areas

Effects of CM1 on boron under Alternative 7 in the Delta would be similar to the effects discussed for Alternative 1A. Under Alternative 7, long-term average boron concentrations would decrease by as much as 41% at the Banks Pumping Plant and by as much as 48% at Jones Pumping Plant relative to Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-18) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading.

Maintenance of SWP and CVP facilities under Alternative 7 would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment. Maintenance activities would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment.

***NEPA Effects*:** In summary, relative to the No Action Alternative conditions, Alternative 7 would result in relatively small long-term average increases in boron levels in the San Joaquin River and moderate increases in the interior and western Delta locations Delta. However, the predicted changes in the Delta would not be expected to result in exceedances of applicable objectives or further water quality degradation such that objectives would likely be exceeded or there would be substantially increased risk of adverse effects on water quality.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Boron is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 7, relative to Existing Conditions, would not be expected to result in a substantial adverse change in boron levels. Additionally, relative to Existing Conditions, Alternative 7 would not result in reductions in river flow rates (i.e., less dilution) or increased boron loading such that there would be any substantial increases in boron concentration upstream of the Delta in the San Joaquin River watershed.

Moderate increased boron levels (i.e., up to 56% increased concentration) and degradation predicted for interior and western Delta locations in response to a shift in the Delta source water percentages and tidal habitat restoration under this alternative would not be expected to cause exceedances of objectives. Alternative 7 maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 7 would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to Existing Conditions, Alternative 7 would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 7, while widespread in particular at interior Delta locations, would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Consequently, Alternative 7 would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on boron under Alternative 7 would be the same as those discussed for Alternative 1A and are determined to be not adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on boron resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 7 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 7 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. Consequently, Alternative 7 would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the eastside tributaries, or their associated reservoirs upstream of the Delta.

Under Alternative 7, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by 6%, relative to Existing Conditions, and would remain virtually the same relative to the No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Similar to the No Action Alternative, these decreases in flow would result in possible increases in long-term average bromide concentrations of about 3%, relative to Existing Conditions and less than <1% relative to No Action Alternative (Appendix 8E, *Bromide*, Table 24). The small increases in lower San Joaquin River bromide levels that could occur under Alternative 7, relative to existing and the No Action Alternative conditions would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the lower San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Using the mass-balance modeling approach for bromide (see Section 8.3.1.3), relative to Existing Conditions, Alternative 7 would result in increases in long-term average bromide concentrations at Staten Island and Barker Slough (for the modeled drought period only), while long-term average concentrations would decrease at the other assessment locations (Appendix 8E, *Bromide*, Table 16). At Barker Slough, predicted long-term average bromide concentrations would decrease from 51 μg/L to 50 μg/L (2% relative decrease) for the modeled 16-year hydrologic period, but would increase from 54 μg/L to 72 μg/L (34% relative increase) for the modeled drought period. At Barker Slough, the predicted 50 μg/L exceedance frequency would decrease from 49% under Existing Conditions to 29% under Alternative 7, but would increase slightly from 55% to 57% during the drought period. At Barker Slough, the predicted 100 μg/L exceedance frequency would increase from 0% under Existing Conditions to 8% under Alternative 7, and would increase from 0% to 22% during the drought period. At Staten Island, predicted long-term average bromide concentrations would increase from 50 μg/L to 63 μg/L (27% relative increase) for the modeled 16-year hydrologic period and would increase from 51 μg/L to 64 μg/L (25% relative increase) for the modeled drought period. At Staten Island, increases in average bromide concentrations would correspond to an increased frequency of 50 μg/l threshold exceedance, from 47% under Existing Conditions to 80% under Alternative 7 (52% to 88% for the modeled drought period), and an increase from 1% to 2% (0% to 0% for the modeled drought period) for the 100 μg/L threshold. Changes in exceedance frequency of the 50 μg/L and 100 μg/L concentration thresholds at other assessment locations would be less considerable, with exception to Franks Tract. Although long-term average bromide concentrations were modeled to decrease at Franks Tract, exceedances of the 100 μg/L threshold would increase slightly, from 82% under Existing Conditions to 99% under Alternative 7 (78% to 97% for the modeled drought period). This comparison to Existing Conditions reflects changes in bromide due to both Alternative 7 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise.

Due to the relatively small differences between modeled Existing Conditions and No Action baselines, changes in long-term average bromide concentrations and changes in exceedance frequencies relative to the No Action Alternative would be generally of similar magnitude to those previously described for the Existing Conditions comparison (Appendix 8E, *Bromide*, Table 16). Modeled long-term average bromide concentration at Barker Slough is predicted to increase by 1% (34% for the modeled drought period) relative to the No Action Alternative. Modeled long-term average bromide concentration increases at Staten Island are predicted to increase by 31% (29% for the modeled drought period) relative to the No Action Alternative. However, unlike the Existing Conditions comparison, long-term average bromide concentrations at Buckley Cove would increase relative to the No Action Alternative, although the increases would be relatively small (≤9%). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in bromide due only to Alternative 7 operations.

At Barker Slough, modeled long-term average bromide concentrations for the two baseline conditions are very similar (Appendix 8E, *Bromide*, Table 16). Such similarity demonstrates that the modeled Alternative 7 change in bromide is almost entirely due to Alternative 7 operations, and not climate change/sea level rise. Therefore, operations are the primary driver of effects on bromide at Barker Slough, regardless whether Alternative 7 is compared to Existing Conditions, or compared to the No Action Alternative.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) differed somewhat from what is presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 17). For most locations, the frequency of exceedance of the 50 μg/L and 100 μg/L were similar. The greatest difference between the methods was predicted for Barker Slough. The increases in frequency of exceedance of the 100 μg/L threshold, relative to Existing Conditions and the No Action Alternative, were not as great using this alternative EC to chloride and chloride to bromide relationship modeling approach as compared to that presented above from the mass-balance modeling approach. Results indicate 2% exceedance over the modeled period under Alternative 7, as compared to 1% under Existing Conditions and 2% under the No Action Alternative. For the drought period, exceedance frequency increased from 0% under Existing Conditions and the No Action Alternative, to 7% under Alternative 7.Because the mass-balance approach predicts a greater level of impact at Barker Slough, determination of impacts was based on the mass-balance results.

While the increase in long-term average bromide concentrations at Barker Slough are relatively small when modeled over a representative 16-year hydrologic period, increases during the modeled drought period, principally the relative increase in 100 μg/L exceedance frequency, would represent a substantial change in source water quality during a season of drought. As discussed for Alternative 1A, drinking water treatment plants obtaining water via the North Bay Aqueduct utilize a variety of conventional and enhanced treatment technologies in order to achieve DBP drinking water criteria. While the implications of such a modeled drought period change in bromide concentrations at Barker Slough is difficult to predict, the substantial modeled increases could lead to adverse changes in the formation of disinfection byproducts such that considerable treatment plant upgrades may be necessary in order to achieve equivalent levels of health protection during seasons of drought. Increases at Staten Island are also considerable, although there are no existing or foreseeable municipal intakes in the immediate vicinity. Because many of the other modeled locations already frequently exceed the 100 μg/L threshold under Existing Conditions and the No Action Alternative, these locations likely already require treatment plant technologies to achieve equivalent levels of health protection, and thus no additional treatment technologies would be triggered by the small increases in the frequency of exceeding the 100 μg/L threshold. Hence, no further impact on the drinking water beneficial use would be expected at these locations.

The seasonal intakes at Mallard Slough and City of Antioch are infrequently used due to water quality constraints related to sea water intrusion. On a long-term average basis, bromide at these locations is in excess of 3,000 μg/L, but during seasonal periods of high Delta outflow can be <300 μg/L. Based on modeling using the mass-balance approach, use of the seasonal intakes at Mallard Slough and City of Antioch under Alternative 7 would experience a period average increase in bromide during the months when these intakes would most likely be utilized. For those wet and above normal water year types where mass balance modeling would predict water quality typically suitable for diversion, predicted long-term average bromide would increase from 103 μg/L to 152 μg/L (48% increase) at City of Antioch and would increase from 150 μg/L to 204 μg/L (36% increase) at Mallard Slough relative to Existing Conditions (Appendix 8E, *Bromide*, Table 25).

Increases would be similar for the No Action Alternative comparison. Modeling results using the EC to chloride and chloride to bromide relationships show increases during these months, but the relative magnitude of the increases is much lower (Appendix 8E, Table 26). Regardless of the differences in the data between the two modeling approaches, the decisions surrounding the use of these seasonal intakes is largely driven by acceptable water quality, and thus have historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at the City of Antioch and Mallard Slough intake would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

Based on modeling using the mass-balance approach, relative to existing and No Action Alternative conditions, Alternative 7 would lead to predicted improvements in long-term average bromide concentrations at Franks Tract, Rock Slough, and Contra Costa PP No. 1, in addition to Banks and Jones (discussed below). At these locations, long-term average bromide concentrations would be predicted to decrease by as much as 16–32%, depending on baseline comparison. Modeling results using the EC to chloride and chloride to bromide relationships generally do not show similar decreases for Rock Slough and Contra Costa PP No. 1, but rather, predict small increases. Based on the small magnitude of increases predicted, these increases would not adversely affect beneficial uses at those locations.

Important to the results presented above is the assumed habitat restoration footprint on both the temporal and spatial scales incorporated into the modeling. Modeling sensitivity analyses have indicated that habitat restoration (which are reflected in the modeling—see Section 8.3.1.3), not operations covered under CM1, are the driving factor in the modeled bromide increases. The timing, location, and specific design of habitat restoration will have effects on Delta hydrodynamics, and any deviations from modeled habitat restoration and implementation schedule will lead to different outcomes. Although habitat restoration near Barker Slough is an important factor contributing to modeled bromide concentrations at the North Bay Aqueduct, BDCP habitat restoration elsewhere in the Delta can also have large effects. Because of these uncertainties, and the possibility of adaptive management changes to BDCP restoration activities, including location, magnitude, and timing of restoration, the estimates are not predictive of the bromide levels that would actually occur in Barker Slough or elsewhere in the Delta.

SWP/CVP Export Service Areas

Under Alternative 7, improvement in long-term average bromide concentrations would occur at the Banks and Jones pumping plants. Long-term average bromide concentrations for the modeled 16-year hydrologic period at these locations would decrease by as much as 71% relative to Existing Conditions and 67% relative to the No Action Alternative (Appendix 8E, *Bromide*, Table 16). As a result, exceedances of the 50 μg/L and 100 μg/L assessment thresholds would be substantially reduced, resulting in considerable overall improvement in Export Service Areas water quality respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also be observed since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in bromide is difficult to predict, the relative decrease in overall loading of bromide to the Export Service Areas would likely alleviate or lessen any expected increase in bromide concentrations at Vernalis (see discussion of Upstream of the Delta) as well as locations in the Delta receiving a large fraction of San Joaquin River water, such as much of the south Delta.

The discussion above is based on results of the mass-balance modeling approach. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) were consistent with the discussion above, and assessment of bromide using these data results in the same conclusions as are presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 17).

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 7 would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, Alternative 7 operations and maintenance, relative to the No Action Alternative, would result in small increases (i.e., <1%) in long-term average bromide concentrations at Vernalis related to relatively small declines in long-term average flow on the San Joaquin River. However, Alternative 7 operation and maintenance activities would cause substantial degradation to water quality with respect to bromide at Barker Slough, source of the North Bay Aqueduct. Resultant substantial change in long-term average bromide at Barker Slough could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-5 is available to reduce these effects. Iimplementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 7 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 7 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. However, south of the Delta, the San Joaquin River is a substantial source of bromide, primarily due to the use of irrigation water imported from the southern Delta. Concentrations of bromide at Vernalis are inversely correlated to net river flow. Under Alternative 7, long-term average flows at Vernalis would decrease only slightly, resulting in less than substantial predicted increases in long-term average bromide of about 3% relative to Existing Conditions.

Relative to Existing Conditions, Alternative 7 would result in substantial increases in long-term average bromide concentration at Staten Island and Barker Slough (for the modeled drought period only). There are no existing or foreseeable municipal drinking water intakes in the vicinity of Staten Island, but Barker Slough is the source of the North Bay Aqueduct. While the increase in long-term average bromide concentrations at Barker Slough are predicted to be relatively small when modeled over a representative 16-year hydrologic period, increases during the modeled drought period would represent a substantial change in source water quality during a season of drought. These predicted drought season related increases in bromide at Barker Slough could lead to adverse changes in the formation of disinfection byproducts at drinking water treatment plants such that considerable water treatment plant upgrades would be necessary in order to achieve equivalent levels of drinking water health protection.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Under Alternative 7, substantial improvement would occur at the Banks and Jones pumping plants, where predicted long-term average bromide concentrations are predicted to decrease by as much as 71% relative to Existing Conditions. An overall improvement in bromide-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 7 operation and maintenance would not result in any substantial change in long-term average bromide concentration upstream of the Delta. Furthermore, under Alternative 7, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to bromide. Bromide is not bioaccumulative, therefore change in long-term average bromide concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, bromide is not a constituent related to any 303(d) listings. Alternative 7 operation and maintenance activities would not cause substantial long-term degradation to water quality respective to bromide with the exception of water quality at Barker Slough (drought period only) and at Staten Island in the eastern Delta. There are no existing or foreseeable municipal intakes in the vicinity of Staten Island, but Barker Slough is the source of the North Bay Aqueduct. At Barker Slough, modeled long-term annual average concentrations of bromide would increase by 34% during the modeled drought period. For the modeled 1 drought period the frequency of predicted bromide concentrations exceeding 100 μg/L would increase from 0% under Existing Conditions to 22% under Alternative 7. Substantial changes in long-term average bromide during seasons of drought could necessitate changes in treatment plant operation or require treatment plant upgrades in order to maintain DBP compliance. The model predicted change at Barker Slough during the drought period is substantial and, therefore, would represent a substantially increased risk for adverse effects on existing MUN beneficial uses should treatment upgrades not be undertaken. The impact is considered significant.

Implementation of Mitigation Measure WQ-5 along with a separate other commitment relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-5 is recommended to attempt to reduce the effect that increased bromide concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-5, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from bromide-related concentration effects on municipal water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementation of the North Bay Aqueduct AIP, acquiring alternative water supplies, or other actions to indirectly reduce the effects of elevated bromide and DOC in existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-5: Avoid, Minimize, or Offset, as Feasible, Adverse Water Quality Conditions

Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 7 would be similar to conservation measures under Alternative 1A, but 40 linear miles rather than 20 linear miles of channel margin habitat would be enhanced, and 20,000 acres rather than 10,000 acres of seasonally inundated floodplain would be restored. As discussed for Alternative 1A, implementation of the CM2–CM21 would not present new or substantially changed sources of bromide to the study area. Some conservation measures may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution is not expected to substantially increase or present new sources of bromide. CM2–CM21 would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

In summary, implementation of CM2–CM21 under Alternative 7, relative to the No Action Alternative, would have negligible, if any, effects on bromide concentrations. The effects on bromide from implementing CM2–CM21 are determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As discussed for Alternative 1A, implementation of CM2–CM21 would not present new or substantially changed sources of bromide to the study area. As such, effects on bromide resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 7 there would be no expected change to the sources of chloride in the Sacramento and eastside tributary watersheds. Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. The modeled long-term annual average flows on the lower San Joaquin River at Vernalis would decrease slightly compared to Existing Conditions and be similar compared to the No Action Alternative (as a result of climate change). The reduced flow would result in possible increases in long-term average chloride concentrations of about 2%, relative to the Existing Conditions and no change relative to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-62). Consequently, Alternative 7 would not be expected to cause exceedance of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to the Existing Conditions and No Action Alternative, Alternative 7 would result in similar or reduced long-term average chloride concentrations for the 16-year period modeled at most of the assessment locations, and, depending on modeling approach (see Section 8.3.1.3) increased concentrations at the Contra Costa Canal at Pumping Plant #1 (i.e., up to 29% compared to No Action Alternative), Rock Slough (i.e., up to 22% compared to No Action Alternative), and the SF Mokelumne at Staten Island (i.e., up to 28% compared to Existing Conditions and No Action Alternative) (Appendix 8G, *Chloride*, Table Cl-43 and Table Cl-44). Moreover, the direction and magnitude of predicted changes for Alternative 7 are similar between the alternatives, thus, the effects relative to Existing Conditions and the No Action Alternative are discussed together. Additionally, implementation of tidal habitat restoration under CM4 would increase the tidal exchange volume in the Delta, and thus may contribute to increased chloride concentrations in the Bay source water as a result of increased salinity intrusion. More discussion of this phenomenon is included in Section 8.3.1.3. Consequently, while uncertain, the magnitude of chloride increases may be greater than indicated herein and would affect the western Delta assessment locations the most which are influenced to the greatest extent by the Bay source water. The comparison to Existing Conditions reflects changes in chloride due to both Alternative 7 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes in chloride due only to operations. The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses

Estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at both the Antioch and Contra Costa Pumping Plant #1 locations. For Alternative 7, the modeled frequency of objective exceedance would increase from 7% of years under Existing Conditions and 0% under the No Action Alternative to 20% of years under Alternative 7 (Appendix 8G, *Chloride*, Table Cl-64).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 7, the modeled frequency of objective exceedance would decrease, from 6% of modeled days under Existing Conditions and 5% under the No Action Alternative to 1% of modeled days under Alternative 7 (Appendix 8G, *Chloride*, Table Cl-63).

Given the limitations inherent to estimating future chloride concentrations (see Section 8.3.1.3), estimation of chloride concentrations through both a mass balance approach and an EC-chloride relationship approach was used to evaluate the 250 mg/L Bay-Delta WQCP objectives in terms of both frequency of exceedance and use of assimilative capacity. When utilizing the mass balance approach to model monthly average chloride concentrations for the 16-year period, the predicted frequency of exceeding the 250 mg/L objective would decrease up to 12% (i.e., 24% for Existing Conditions to 12%) at the Contra Costa Canal at Pumping Plant #1 (Appendix 8G, *Chloride*, Table Cl-45 and Figure Cl-13). The frequency of exceedances would decrease at the San Joaquin River at Antioch (i.e., from 66% under Existing Conditions to 60%) with no substantial change predicted for Mallard Island (i.e., maximum increase of 1%) (Appendix 8G, Table Cl-45) and no substantial long-term degradation (Appendix 8G, Table Cl-47). However, relative to the No Action conditions, available assimilative capacity for chloride at the Contra Costa Canal at Pumping Plant #1 would be substantially reduced in August through October (i.e., reduction ranging from 35% to 74% for the 16 year period modeled, and 100% in August and September [i.e., eliminated]) (Appendix 8G, Table Cl-47), thus reflecting substantial degradation when concentrations would be near, or exceed, the objective.

In comparison, when utilizing the chloride-EC relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance generally agreed, but use of assimilative capacity were predicted to be larger at some locations (Appendix 8G, *Chloride*, Table Cl-46 and Table Cl-48). Specifically, while the model predicted exceedance frequency would decrease at the Contra Costa Canal at Pumping Plant #1 and Rock Slough locations, use of assimilative capacity would increase substantially for the months of February through June as well as September (i.e., maximum of 82% in March for the modeled drought period). Due to such seasonal long-term average water quality degradation at these locations, the potential exists for substantial adverse effects on the municipal and industrial beneficial uses through reduced opportunity for diversion of water with acceptable chloride levels. Moreover, due to the increased frequency of exceeding the 150 mg/L Bay-Delta WQCP objective, the potential exists for adverse effects on the municipal and industrial beneficial uses at Contra Costa Pumping Plant #1 and Antioch.

303(d) Listed Water Bodies

With respect to the 303(d) listing for chloride in Tom Paine Slough, the monthly average chloride concentrations for the 16-year period modeled at Old River at Tracy Road, which represents the nearest DSM2-modeled location to Tom Paine in the south Delta, would generally be similar compared to Existing Conditions and No Action Alternative, and thus, would not be further degraded on a long-term basis (Appendix 8G, Figure Cl-14).

With respect to Suisun Marsh, the monthly average chloride concentrations for the 16-year period modeled would generally increase compared to Existing Conditions and No Action Alternative in some months during October through May at the Sacramento River at Collinsville (Appendix 8G, Figure Cl-15), Mallard Island (Appendix 8G, Figure Cl-13), and increase substantially at Montezuma Slough at Beldon's Landing (i.e., over a doubling of concentration in December through February) (Appendix 8G, Figure Cl-16). Although modeling of Alternative 7 assumed no operation of the Montezuma Slough Salinity Control Gates, the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original

Alternative 4 modeling results for Suisun Marsh, but EC levels were still somewhat higher than EC levels under Existing Conditions for several locations and months. Although chloride was not specifically modeled in this sensitivity analysis, it is expected that chloride concentrations would be nearly proportional to EC levels in Suisun Marsh. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases in salinity are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term chloride increases in the Marsh. However, the chloride concentration increases at certain locations could be substantial, depending on siting and design of restoration areas. Thus, these increased chloride levels in Suisun Marsh are considered to contribute to additional, measureable long-term degradation that potentially would adversely affect the necessary actions to reduce chloride loading for any TMDL that is developed.

SWP/CVP Export Service Areas

Under Alternative 7, long-term average chloride concentrations based on the mass balance analysis of modeling results for the 16-year period modeled at the Banks and Jones pumping plants would decrease by as much as 70% relative to Existing Conditions and 66% compared to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-43). The modeled frequency of exceedances of applicable water quality objectives/criteria would decrease relative to Existing Conditions and No Action Alternative, for both the 16-year period and the drought period modeled (Appendix 8G, *Chloride*, Table Cl-45). Consequently, water exported into the SWP/CVP service area would generally be of similar or better quality with regards to chloride relative to Existing Conditions and the No Action Alternative conditions.

Results of the modeling approach which used relationships between EC and chloride (see Section 8.3.1.3) were consistent with the discussion above, and assessment of chloride using these data results in the same conclusions as are presented above for the mass-balance approach (Appendix 8G, *Chloride*, Table Cl-44 and Table Cl-46).

Commensurate with the reduced chloride concentrations in water exported to the service area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely alleviate or lessen any expected increase in chloride at Vernalis related to decreased annual average San Joaquin River flows (see discussion of Upstream of the Delta).

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative conditions, Alternative 7 would result in substantial increased water quality degradation relative to the 150 mg/L Bay-Delta WCCP objective at Contra Costa Pumping Plant #1 and Antioch, substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1 and Rock Slough, and potentially measureable water quality degradation relative to the 303(d) impairment in Suisun Marsh. The predicted chloride increases constitute an adverse effect on water quality (see Mitigation Measure WQ-7;

implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Additionally, the predicted changes relative to the No Action Alternative conditions indicate that in addition to the effects of climate change/sea level rise, implementation of CM1 and CM4 under Alternative 7 would contribute substantially to the adverse water quality effects.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 7, relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, the Alternative 7 would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, Alternative 7 operations would result in reduced chloride concentrations in the Delta such that exceedances of the 250 mg/L Bay-Delta WQCP objective at the San Joaquin River at Antioch and Mallard Slough would be reduced. Nevertheless, due to the predicted increased frequency of exceeding the 150 mg/L Bay-Delta WQCP objective at Contra Costa Pumping Plant #1 and Antioch as well as substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1 and Rock Slough, the potential exists for adverse effects on the municipal and industrial beneficial uses at Contra Costa Pumping Plant #1 and Antioch (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Moreover, the modeled increased chloride concentrations and degradation in the western Delta could further contribute, at measurable levels, to the existing 303(d) listed impairment due to chloride in Suisun Marsh for the protection of fish and wildlife.

Chloride concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under Alternative 7 would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 7 maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas. However, based on these findings, this impact is determined to be significant due to increased chloride concentrations and frequency of objective exceedance in the western Delta, as well as potential adverse effects on aquatic life beneficial uses in the interior Delta and fish and wildlife beneficial uses in Suisun Marsh.

While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-7 is recommended to attempt to reduce the effect that increased chloride concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-7, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from chloride concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when chloride concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-7: Conduct Additional Evaluation and Modeling of Increased Chloride Levels and Develop and Implement Phased Mitigation Actions

Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Under Alternative 7, the types and geographic extent of effects on chloride concentrations in the Delta as a result of implementation of the other conservation measures (i.e., CM2–CM21) would be similar to, and undistinguishable from, those effects previously described for Alternative 1A. The conservation measures would present no new direct sources of chloride to the affected environment. Moreover, some habitat restoration conservation measures (CM4–CM10) would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored tidal wetlands, floodplain, and related channel margin and off-channel habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement compared to Existing Conditions and No Action Alternative conditions.

In summary, based on the discussion above, the effects on chloride from implementing CM2–CM21 are considered to be not adverse.

CEQA Conclusion: Implementation of the CM2–CM21 for Alternative 7 would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP service area. Replacement of irrigated agricultural land uses in the Delta with habitat restoration conservation measures may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects: Effects of CM1 on DO under Alternative 7 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: Effects of CM1 on DO under Alternative 7 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Reservoir storage reductions that would occur under Alternative 7, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions that would occur would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state has begun to aggressively regulate the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters under Alternative 7, relative to Existing Conditions. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to ever increasing water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. This impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on DO under Alternative 7 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on DO resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, their associated reservoirs, and the San Joaquin River upstream of the Delta under Alternative 7 are not expected to be outside the ranges occurring under Existing Conditions or would occur under the No Action Alternative. Any minor changes in EC levels that could occur under Alternative 7 in water bodies upstream of the Delta would not be of sufficient magnitude, frequency and geographic extent that would cause adverse effects on beneficial uses or substantially degrade water quality with regard to EC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to Existing Conditions, Alternative 7 would result in an increase in the number of days the Bay-Delta WQCP EC objectives would be exceeded in the Sacramento River at Emmaton, and the San Joaquin River at San Andreas Landing, Prisoners Point, and Brandt Bridge (Appendix 8H, *Electrical Conductivity*, Table EC-7).

The percentage of days the Emmaton EC objective would be exceeded for the entire period modeled (1976–1991) would increase from 6% under Existing Conditions to 19% under Alternative 7, and the percent of days out of compliance would increase from 11% under Existing Conditions to 29% under Alternative 7.

The percentage of days the San Andreas Landing EC objective would be exceeded would increase from 1% under Existing Conditions to 4% under Alternative 7, and the percentage of days out of compliance with the EC objective would increase from 1% under Existing Conditions to 7% under Alternative 7. Sensitivity analyses were performed for Alternative 4 Scenario H3, and indicated that many similar exceedances were modeling artifacts, and the small number of remaining exceedances were small in magnitude, lasted only a few days, and could be addressed with real time operations of the SWP and CVP (see Section 8.3.1.1 for a description of real time operations of the SWP and CVP). Due to similarities in the nature of the exceedances between alternatives, the findings from these analyses can be extended to this alternative as well.

The percentage of days the Prisoners Point EC objective would be exceeded for the entire period modeled would increase from 6% under Existing Conditions to 40% under Alternative 7, and the percentage of days out of compliance with the EC objective would increase from 10% under Existing Conditions to 40% under Alternative 7. Sensitivity analyses conducted for Alternative 4 Scenario H3 indicated that removing all tidal restoration areas would reduce the number of exceedances, but there would still be substantially more exceedances than under Existing Conditions or the No Action Alternative. Results of the sensitivity analyses indicate that the exceedances are partially a function of the operations of the alternative itself, perhaps due to Head of Old River Barrier assumptions and south Delta export differences (see Appendix 8H, *Electrical Conductivity*, Attachment 1, for more discussion of these sensitivity analyses). Due to similarities in the nature of the exceedances between alternatives, the findings from these analyses can be extended to this alternative as well. Appendix 8H, Attachment 2, contains a more detailed assessment of the likelihood of these exceedances impacting aquatic life beneficial uses. Specifically, Appendix 8H, Attachment 2, discusses whether these exceedances might have indirect effects on striped bass spawning in the Delta, and concludes that the high level of uncertainty precludes making a definitive determination.

In the San Joaquin River at Brandt Bridge, the percentage of days exceeding the EC objective would increase from 3% under Existing Conditions to 4% under Alternative 7; the percentage of days out of compliance would increase from 8% under Existing Conditions to 9% under Alternative 7. These changes are minimal, and are not considered substantial in light of overall modeling uncertainty.

Average EC levels at the western and southern Delta compliance locations and San Joaquin River at San Andreas Landing (an interior Delta location) would decrease from 0–46% for the entire period modeled and 2–45% during the drought period modeled (1987–1991) (Appendix 8H, Table EC-18). In the S. Fork Mokelumne River at Terminous, average EC would increase 6% for the entire period modeled and 5% during the drought period modeled. Average EC in the S. Fork Mokelumne River at Terminous would increase during all months (Appendix 8H, Table EC-18). Average EC in the San Joaquin River at Prisoners Point would increase by 1% during the drought period (Appendix 8H, Table EC-18). Given that the western Delta is Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives under Alternative 7, relative to Existing Conditions, has the potential to contribute to additional impairment and potentially adversely affect beneficial uses. The comparison to Existing Conditions reflects changes in EC due to both Alternative 7 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise.

Relative to the No Action Alternative, the percentage of days exceeding EC objectives and percentage of days out of compliance would increase at: Sacramento River at Emmaton, San Joaquin River at Jersey Point, San Andreas Landing, Vernalis, Brandt Bridge, and Prisoners Point; and Old River near Middle River and at Tracy Bridge (Appendix 8H, *Electrical Conductivity*, Table EC-7). The increase in percentage of days exceeding the EC objective would be 39% at Prisoners Point and 5% or less at the remaining locations. The increase in percentage of days out of compliance would be 30% at Prisoners Point and 6% or less at the remaining locations. For the entire period modeled, average EC levels would increase at: S. Fork Mokelumne River (6%), Old River at Tracy Bridge (1%), and San Joaquin River at Prisoners Point (10%) (Appendix 8H, Table EC-18). During the drought period modeled, average EC would increase at: S. Fork Mokelumne River (6%), San Joaquin River at Brandt Bridge (1%) and Prisoners Point (8%), and Old River at Tracy Bridge (1%) (Appendix 8H, Table EC-18). Given that the western and southern Delta are Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives under Alternative 7, relative to the No Action Alternative, has the potential to contribute to additional impairment and potentially adversely affect beneficial uses. The comparison to the No Action Alternative reflects changes in EC due only to Alternative 7 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E).

For Suisun Marsh, October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Long-term average EC would increase under Alternative 7, relative to Existing Conditions, during the months of April and May by 0.2 mS/cm in the Sacramento River at Collinsville (Appendix 8H, *Electrical Conductivity*, Table EC-21). Long-term average EC would decrease relative to Existing Conditions in Montezuma Slough at National Steel during October–May (Appendix 8H, Table EC-22). The most substantial increase would occur near Beldon Landing, with long-term average EC levels increasing by 0.8–3.3 mS/cm, depending on the month, nearly doubling during some months the long-term average EC relative to Existing Conditions (Appendix 8H, Table EC-23). Sunrise Duck Club and Volanti Slough also would have long-term average EC increases of 0.1–1.6 mS/cm (Appendix 8H, Tables EC-24 and EC-25). Modeling of this alternative assumed no operation of the Montezuma Slough Salinity Control Gates, but the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 Scenario H3 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results, but EC levels were still somewhat higher than EC levels under Existing Conditions and the No Action Alternative for several locations and months. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions and the No Action Alternative, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term EC increases to be on the order of 1 mS/cm or less. Due to similarities in the nature of the EC increases between alternatives, the findings from these analyses can be extended to this alternative as well.

The degree to which the long-term average EC increases in Suisun Marsh would cause exceedance of Bay-Delta WQCP objectives is unknown, because these objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated “equivalent or better protection will be provided at the location” (State Water Resources Control Board 2006:14). The long-term average EC increase may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the marsh. However, the EC increases at certain locations could be substantial, depending on siting and design of restoration areas, and it is uncertain the degree to which current management plans for the Suisun Marsh would be able to address these substantially higher EC levels and protect beneficial uses. Thus, these increased EC levels in Suisun Marsh are considered to have a potentially adverse effect on marsh beneficial uses. Long-term average EC increases in Suisun Marsh under Alternative 7 relative to the No Action Alternative would be similar to the increases relative to Existing Conditions. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC concentrations could contribute to additional impairment.

SWP/CVP Export Service Areas

At the Banks and Jones pumping plants, Alternative 7 would result in no exceedances of the Bay-Delta WQCP’s 1,000 µmhos/cm EC objective for the entire period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-10). Thus, there would be no adverse effect on the beneficial uses in the SWP/CVP Export Service Areas using water pumped at this location under the Alternative 7.

At the Banks pumping plant, relative to Existing Conditions, average EC levels under Alternative 7 would decrease substantially: 47% for the entire period modeled and 51% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 43% for the entire period modeled and 46% during the drought period modeled (Appendix 8H, Table EC-18).

At the Jones pumping plant, relative to Existing Conditions, average EC levels under Alternative 7 would also decrease substantially: 52% for the entire period modeled and 59% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 50% for the entire period modeled and 57% during the drought period modeled. (Appendix 8H, Table EC-18)

Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 7 would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas; rather, Alternative 7 would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows (see EC impact discussion under the No Action Alternative).

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC. Alternative 7 would result in lower average EC levels relative to Existing Conditions and the No Action Alternative and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

NEPA Effects: In summary, the increased frequency of exceedance of EC objectives in the western Delta under Alternative 7, relative to the No Action Alternative, would contribute to adverse effects on the agricultural beneficial uses. In addition. the increased frequency of exceedance of the San Joaquin River at Prisoners Point EC objective and long-term and drought period average EC could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. Given that the western Delta is Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives in this portion of the Delta has the potential to contribute to additional beneficial use impairment. The increases in long-term average EC levels that could occur in Suisun Marsh would further degrade existing EC levels and could contribute to adverse effects on the fish and wildlife beneficial uses. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC levels could contribute to additional beneficial use impairment. These increases in EC constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects. Implementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential EC-related changes would reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the

effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

River flow rate and reservoir storage reductions that would occur under Alternative 7, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's aggressive regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 7 would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas. There would be no exceedance of the EC objective at the Jones and Banks pumping plants. Average EC levels for the entire period modeled would decrease at both plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

In the Plan Area, Alternative 7 would result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded in the Sacramento River at Emmaton (agricultural objective; 13% increase), and San Joaquin River at Prisoners Point (fish and wildlife objective; 34% increase) in the interior Delta for the entire period modeled (1976–1991). The increased frequency of exceedance of the fish and wildlife objective at Prisoners Point could contribute to adverse effects on aquatic life (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. The increased frequency of the EC exceedance at Emmaton could contribute to adverse effects on agricultural uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The western Delta is Clean Water Act section 303(d) listed for elevated EC and the increased frequency of exceedance of EC objectives that would occur in this portion of the Delta could make beneficial use impairment measurably worse. This impact is considered to be significant.

Further, relative to Existing Conditions, Alternative 7 could result in substantial increases in long-term average EC during the months of October through May in Suisun Marsh. The increases in long-term average EC levels that could occur in Suisun Marsh could further degrade existing EC levels and thus contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in wildlife. Suisun Marsh is Clean Water Act section 303(d) listed for elevated EC and the increases in long-term average EC that would occur in the marsh could make beneficial use impairment measurably worse. This impact is considered to be significant.

Implementation of Mitigation Measure WQ-11 along with a separate other commitment relating to the potential increased costs associated with EC-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-11 is recommended to attempt to reduce the effect that increased EC concentrations may have on Delta beneficial uses.

However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-11, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from EC concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when EC concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-11: Avoid, Minimize, or Offset, as Feasible, Reduced Water Quality Conditions

Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on EC under Alternative 7 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on EC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 7, the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries would be altered, relative to Existing Conditions and the No Action Alternative.

The Sacramento River at Freeport and San Joaquin River at Vernalis (as summarized for water quality average concentrations in Tables 8-48 and 8-49) were examined for flow/concentration relationships for mercury and methylmercury. No significant, predictive regression relationships were discovered for mercury or methylmercury, except for total mercury with flow at Freeport (monthly or annual) (Appendix 8I, Figures I-10 through I-13). Such a positive relationship between total mercury and flow is to be expected based on the association of mercury with suspended sediment and the mobilization of sediments during storm flows. However, the changes in flow in the Sacramento River under Alternative 7 relative to Existing Conditions and the No Action Alternative are not of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore mercury loading should not be substantially different due to changes in flow. In addition, even though it may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but will not change substantially relative to Existing Conditions or the No Action Alternative due to changes in flows under Alternative 7.

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

The water quality impacts of waterborne concentrations of mercury and methylmercury and fish tissue mercury concentrations were evaluated for 9 Delta locations. The analysis of percentage change in assimilative capacity of waterborne total mercury of Alternative 7 relative to the 25 ng/L ecological risk benchmark as compared to Existing Conditions showed a 7% reduction at Old River at Rock Slough and Contra Costa Pumping Plant, and a 6.6% reduction at those same locations relative to the No Action Alternative. These changes are not expected to result in adverse effects to beneficial use (Figures 8-53a and 8-54a). Similarly, changes in methylmercury concentration are expected to be relatively small. The greatest annual average methylmercury concentration for drought conditions was 0.164 ng/L for the San Joaquin River at Buckley Cove which was slightly higher than Existing Conditions (0.161 ng/L), and slightly lower than the No Action Alternative (0.167 ng/L) (Appendix 8I, *Mercury*, Table I-6). All modeled input concentrations exceeded the methylmercury TMDL guidance objective of 0.06 ng/L, therefore percentage change in assimilative capacity was not evaluated for methylmercury.

Fish tissue estimates show substantial percentage increases in concentration and exceedance quotients for mercury at some Delta locations. The greatest changes in exceedance quotients relative to Existing Conditions and the No Action Alternative are 30–39% at the Contra Costa Pumping Plant and 32–45% for Old River at Rock Slough (Figures 8-55a and 8-55b; Appendix 8I, Table I-14b). Because these increases are substantial, and it is evident that substantive increases are expected at numerous locations throughout the Delta, these changes may be measurable in the environment. See Appendix 8I for a discussion of the uncertainty associated with the fish tissue estimates.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 7 are projected to be lower than Existing Conditions and the No Action Alternative (Appendix 8I, *Mercury*, Figures I-8 and I-9). Therefore, mercury shows an increased assimilative capacity at these locations (Figures 8-53a and 8-54a).

The largest improvements in bass tissue mercury concentrations and exceedance quotients for Alternative 7, relative to Existing Conditions and the No Action Alternative at any location within the Delta are expected for the export pump locations (specifically, at Jones Pumping plant, 30% improvement relative to Existing Conditions, 32% relative to the No Action Alternative)(Figures 8-55a and 8-55b; Appendix 8I, Table I-14b).

NEPA Effects: Based on the above discussion, the effects of mercury and methylmercury in comparison of Alternative 7 to the No Action Alternative (as waterborne and bioaccumulated forms) are considered to be adverse for the case of fish tissue bioaccumulation at some locations.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 7, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta will not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. Monthly average waterborne concentrations of total and methylmercury, over the period of record, are very similar to Existing Conditions, but showed notable increases at some locations. Estimates of fish tissue mercury concentrations show substantial increases would occur for several sites for Alternative 7 as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP and CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 7 as compared to Existing Conditions.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. However, increases in fish tissue mercury concentrations are substantial, and changes in fish tissue mercury concentrations would make existing mercury-related impairment in the Delta measurably worse. In comparison to

Existing Conditions, Alternative 7 would increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. This impact is considered to be significant. Feasible or effective actions to reduce the effects on mercury resulting from CM1 are unknown. General mercury management measures through CM12, or actions taken by other entities or programs such as TMDL implementation, may minimize or reduce sources and inputs of mercury to the Delta and methylmercury formation. However, it is uncertain whether this impact would be reduced to a level that would be less than significant as a result of CM12 or other future actions. Therefore, the impact would be significant and unavoidable.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Some habitat restoration activities under Alternative 7 would occur on lands in the Delta formerly used for irrigated agriculture. Tidal and other restoration proposed under Alternative 7 have the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the restored habitat. Therefore, increases in mercury methylation in the habitat restoration areas is possible but uncertain depending on the specific restoration design implemented at a particular Delta location. Models to estimate the potential for methylmercury formation in restored areas are not currently available. However, DSM2 modeling for Alternative 7 operations does incorporate assumptions for certain habitat restoration activities proposed under CM2 and CM4 (see Section 8.3.1.3) that result in changes to Delta hydrodynamics compared to the No Action Alternative. These modeled restoration assumptions provide some insight into potential hydrodynamic changes that could be expected related to implementing CM2 and CM4 and are considered in the evaluation of the potential for increased mercury and methylmercury concentrations under Alternative 7.

CM12 addresses the potential for methylmercury bioaccumulation associated with restoration activities and acknowledges the uncertainties associated with mitigating or minimizing this potential effect. CM12 proposes project-specific mercury management plans for restoration actions that will incorporate relevant approaches recommended in Phase 1 Methylmercury TMDL control studies. Specific approaches recommended under CM12 that are intended to minimize or mitigate for potential increases in methylmercury bioaccumulation at future restoration sites include:

- Characterizing mercury, methylmercury, organic carbon, iron, and sulfate concentrations to better inform restoration design,
- Sequestering methylmercury at restoration sites using low intensity chemical dosing techniques,
- Minimizing microbial methylation associated with anoxic conditions by reducing the amount of organic material at a restoration site,
- Designing restoration sites to enhance photo degeneration that converts methylmercury into a biologically unavailable, inorganic form of mercury,
- Remediating restoration site soils with iron to reduce methylation in sulfide rich soils, and
- Considering capping mercury laden sediments, where possible to reduce methylation potential at a site.

Because of the uncertainties associated with site-specific estimates of methylmercury concentrations and the uncertainties in source modeling and tissue modeling, the effectiveness of methylmercury management proposed under CM12 to reduce methylmercury concentrations would need to be evaluated separately for each restoration effort, as part of design and implementation. Because of this uncertainty and the known potential for methylmercury creation in the Delta this potential effect of implementing CM2–CM21 is considered adverse.

***CEQA Conclusion*:** There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the CVP and SWP service areas due to implementation of CM2–CM21 relative to Existing Conditions. However, uptake of mercury from water and/or methylation of inorganic mercury may increase to an unquantified degree as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Methylmercury is 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites under Alternative 7 would be guided by CM12 which requires development of site specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time although the potential to reduce methylmercury concentrations exists based on current research. Although the BDCP will implement CM12 with the goal to reduce this potential effect the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant. No mitigation measures would be available until specific restoration actions are proposed. Therefore this programmatic impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 7 would have negligible, if any, impact on nitrate concentrations in the rivers and reservoirs upstream of the Delta in the Sacramento River watershed relative to Existing Conditions and the No Action Alternative.

Under Alternative 7, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by an estimated 6%, relative to Existing Conditions, and would remain virtually the same relative to the No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Given these relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River (see Appendix 8J, *Nitrate*, Figure 2), it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by changes in flow rates under Alternative 7.

Any negligible changes in nitrate-N concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to nitrate.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Results of the mixing calculations indicate that under Alternative 7, relative to Existing Conditions and the No Action Alternative, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Tables 25 and 26). Long-term average nitrate concentrations are anticipated to increase at most locations in the Delta. The increase would be greatest at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1 (all >85% increase). Long-term average concentrations were estimated to increase to 0.67, 1.04 and 1.10 mg/L-N for Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant#1, respectively, due primarily to increased San Joaquin River water percentage at these locations (see Appendix 8D, *Source Water Fingerprinting Results*). Although changes at specific Delta locations and for specific months may be substantial on a relative basis, the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds identified in Table 8-50. No additional exceedances of the MCL are anticipated at any location (Appendix 8J, *Nitrate*, Table 25). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, was up to approximately 13% at Old River at Rock Slough and Contra Costa Pumping Plant #1, and averaged approximately 6% on a long-term average basis (Appendix 8J, Table 27). Similarly, the use of available assimilative capacity at Franks Tract was up to approximately 6%, and averaged 3% over the long term. The concentrations estimated for these locations would not increase the likelihood of exceeding the 10 mg/L-N MCL, nor would they increase the risk for adverse effects to beneficial uses. At all other locations, use of assimilative capacity was negligible (<5%) (Appendix 8J, Table 27).

Nitrate concentrations will likely be higher than the modeling results indicate in certain locations. This includes in the Sacramento River between Freeport and Mallard Island and other areas in the Delta downstream of Freeport that are influenced by Sacramento River water. These increases are associated with ammonia and nitrate that are discharged from the SRWTP, which are not included in the modeling.

- Under Existing Conditions, most of the ammonia discharged from the SRWTP is converted to nitrate downstream of the facility’s discharge at Freeport, and thus, nitrate concentrations under Existing Conditions in these areas are expected to be higher than the modeling predicts, the increase becoming greater with increasing distance downstream. However, the increase in nitrate concentrations downstream of the SRWTP is expected to be small—the existing increase appears to be from approximately 0.1 mg/L-N to approximately 0.4–0.5 mg/L-N over this reach, due to approximately a 1:1 conversion of ammonia-N to nitrate-N (Central Valley Water Board 2010a:32).
- Under Alternative 7, the planned upgrades to the SRWTP, which include nitrification/partial denitrification, would substantially decrease ammonia concentrations in the discharge, but

would increase nitrate concentrations in the discharge up to 10 mg/L-N, which is substantially higher than under Existing Conditions.

- Overall, under Alternative 7, the nitrogen load from the SRWTP discharge is expected to decrease (by up to 50%), relative to Existing Conditions, due to nitrification/partial dentrification ugrades at the SRWTP facility. Thus, while concentrations of nitrate downstream of the facility are expected to be higher than modeling results indicate for both Existing Conditions and Alternative 7, the increase is expected to be greater under Existing Conditions than for Alternative 7 due to the upgrades that are assumed under Alternative 7.

The other areas in which nitrate concentrations will be higher than the modeling results indicate are immediately downstream of other wastewater treatment plants that practice nitrification, but not denitrification (e.g., City of Rio Vista Beach WWTF, Town of Discovery Bay WWTF, City of Stockton RWCF). For all such facilities in the Delta, the Regional Water Boards have issued NPDES permits that allow discharge of wastewater containing nitrate into the Delta, and under these permits, the State has determined that no beneficial uses are adversely affected by the discharge, and that the discharger's use of available assimilative capacity of the water body is acceptable. When dilution is necessary in order for the discharge to be in compliance with the Basin Plans (which incorporate the 10 mg/L-N MCL by reference), not all of the assimilative capacity of the receiving water is granted to the discharger. Thus, limited decreases in flows are not anticipated to result in systemic exceedances of the MCLs by these POTWs. Furthermore, NPDES permits are renewed on a 5-year basis, and thus, if under changes in flows, dilution was no longer sufficient to maintain nitrate below the MCL in the receiving water, the NPDES permit renewal process would address such cases.

Therefore, any increases in nitrate-N concentrations that may occur at certain locations within the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to nitrate.

SWP/CVP Export Service Areas

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N at the Banks and Jones pumping plants.

Results of the mixing calculations indicate that under Alternative 7, relative to Existing Conditions and the No Action Alternative, nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease on a long-term average annual basis (Appendix 8J, *Nitrate*, Tables 25 and 26). During the late summer, particularly in the drought period assessed, concentrations are expected to increase, but the absolute value of these changes (i.e., in mg/L-N) is small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Area, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.3 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP and CVP Export Service Area. No additional exceedances of the MCL are anticipated (Appendix 8J, Table 25). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the 10 mg/L-N MCL, was negligible for both Banks and Jones pumping plants (Appendix 8J, Table 27).

Any increases in nitrate-N concentrations that may occur in water exported via Banks and Jones pumping plants are not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regards to nitrate.

NEPA Effects: In summary, based on the discussion above, the effects on nitrate from implementing CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Nitrate-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate-N upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers). Although higher in the San Joaquin River watershed, nitrate-N concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 7, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mixing calculations indicate that under Alternative 7, relative to Existing Conditions, long-term average nitrate concentrations are anticipated to increase at most locations. The increase would be greatest at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1 (all >85% increase), due primarily to increased San Joaquin River water percentage at these locations. However, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives, and no additional exceedances of the MCL are anticipated at any location. Use of assimilative capacity at locations throughout the Delta (up to 13%) did not result in concentrations that would increase the likelihood of exceeding the 10 mg/L-N MCL, nor would they increase the risk for adverse effects to beneficial uses.

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N concentrations at the Banks and Jones pumping plants. Results of the mixing calculations indicate that under Alternative 7, relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease. No additional exceedances of the MCL are anticipated. Monthly average use of assimilative capacity available under Existing Conditions, relative to the MCL, for both Banks and Jones pumping plants in drought conditions was at times >50%, but the absolute value of these changes (i.e., in mg/L-N) was small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Area, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.3 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP and CVP Export Service Area.

Based on the above, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. No long-term water quality degradation is expected to occur such that exceedance of criteria is more likely or such that there is an increased risk of adverse impacts to beneficial uses. Nitrate is not 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on nitrate under Alternative 7 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on nitrate resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 7, there would be no substantial change to the sources of DOC within the watersheds upstream of the Delta. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows would not be expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Any negligible changes in DOC levels in water bodies upstream of the Delta under Alternative 7, relative to Existing Conditions and the No Action Alternative, would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to DOC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Under Alternative 7, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be similar to that previously described for Alternative 1A, although the magnitude of predicted long-term increase and relative frequency of concentration threshold exceedances would be substantially greater. Modeled effects would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1., where for the 16-year hydrologic period and the modeled drought period, long-term average concentration increases ranging from 0.7–1.1 mg/L would be predicted (≤30% net increase), resulting in long-term average DOC concentrations greater than 4 mg/L at Rock Slough and Contra Costa PP No. 1 (Appendix 8K, *Organic Carbon,* DOC Table 8). Increases in long-term average concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at Rock Slough and Contra Costa PP No. 1 locations. For Rock Slough, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 85% under the Alternative 7 (an increase from 47% to 82% for the drought period), and concentrations exceeding 4 mg/L would increase from 30% to 47% (32% to 57% for the drought period). For Contra Costa PP No. 1, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 85% under Alternative 7 (45% to 88% for the drought period), and concentrations exceeding 4 mg/L would increase from 32% to 52% (35% to 58% for the drought period). Relative change in frequency of threshold exceedance for other assessment locations would be similar or less. This comparison to Existing Conditions reflects changes in DOC due to both Alternative 7 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise.

In comparison, Alternative 7 relative to the No Action Alternative would generally result in a magnitude of change similar to that discussed for the comparison to Existing Conditions. Maximum increases of 0.7–1.0 mg/L DOC (i.e., ≤26%) would be predicted at Franks Tract, Rock Slough, and Contra Costa PP No. 1 relative to No Action Alternative) (Appendix 8K, *Organic Carbon,* DOC Table 8). Threshold concentration exceedance frequency trends would also be similar to those discussed for the Existing Conditions comparison, with exception to the predicted 4 mg/L exceedance frequency at Buckley Cove. In comparison to the No Action Alternative, the frequency which long-term average DOC concentrations exceeded 4 mg/L at Buckley Cove would increase from 27% to 33% (42% to 57% for the modeled drought period). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in DOC due only to Alternative 7 operations.

The increases in long-term average DOC concentrations estimated to occur at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are considered substantial and could potentially trigger significant changes in drinking water treatment plant design or operations. In particular, assessment locations at Rock Slough and Contra Costa PP No. 1 represent municipal intakes servicing existing drinking water treatment plants. Under Alternative 7, drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. While treatment technologies sufficient to achieve the necessary DOC removals exist, implementation of such technologies would likely require substantial investment in new or modified infrastructure.

Relative to existing and No Action Alternative conditions, Alternative 7 would lead to predicted improvements in long-term average DOC concentrations at Barker Slough, as well as Banks and Jones pumping plants (discussed below). Predicted long-term average DOC concentrations at Barker Slough would decrease <0.1–0.2 mg/L, depending on baseline conditions comparison and modeling period.

SWP/CVP Export Service Areas

Under Alternative 7, modeled long-term average DOC concentrations would decrease at Banks and Jones pumping plants for both the modeled 16-year hydrologic period and the modeled drought period. Modeled decreases would generally be similar between Existing Conditions and the No Action Alternative. Relative to Existing Conditions, long-term average DOC concentrations at Banks would be predicted to decrease by 1.1 mg/L (1.3 mg/L during drought period) (Appendix 8K, *Organic Carbon,* DOC Table 8). At Jones, long-term average DOC concentrations would be predicted to decrease by 1.0 mg/L (1.2 mg/L during drought period). Such substantial improvement in long-term average DOC concentrations would include fewer exceedances of concentration thresholds. Average DOC concentrations exceeding the 2 mg/L concentration threshold would decrease from 100% under Existing Conditions and the No Action Alternative to 67% at Banks and 61% at Jones under Alternative 7 (60% and 57%, respectively during the drought period), while concentrations exceeding 4 mg/L would nearly be eliminated (i.e., ≤15% exceedance frequency). Such modeled improvement would correspond to substantial improvement in Export Service Areas water quality, respective to DOC.

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 7 would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area. Maintenance activities would not be expected to cause any substantial change in long-term average DOC concentrations such that MUN beneficial uses, or any other beneficial use, would be adversely affected.

NEPA Effects: In summary, Alternative 7, relative to the No Action Alternative, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Long-term average DOC concentrations at Banks and Jones pumping plants are predicted to decrease by as much as 1.4 mg/L, while long-term average DOC concentrations for some Delta interior locations, including Franks Tract, Rock Slough and Contra Costa PP #1, are predicted to increase by as much as 1.0 mg/L. Resultant substantial changes in long-term average DOC at these Delta interior locations could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality and MUN beneficial uses. Mitigation Measure WQ-17 is available to reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

While greater water demands under the Alternative 7 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of DOC. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, Alternative 7 would result in substantial increases (i.e., 0.7–1.1 mg/L) in long-term average DOC concentrations at some Delta interior locations, and would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1. At these locations the predicted changes in DOC would substantially increase the frequency with which long-term average concentrations exceeds 2, 3, or 4 mg/L. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve

EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Such predicted magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial.

The assessment of Alternative 7 effects on DOC in the SWP/CVP Export Service Areas is based on assessment of changes in DOC concentrations at Banks and Jones pumping plants. Relative to Existing Conditions, long-term average DOC concentrations would decrease by as much as 1.3 mg/L at Banks and Jones pumping plants. The frequency with which long-term average DOC concentrations would exceed 2, 3, or 4 mg/L would be substantially reduced, where predicted exceedances of >4 mg/L would be nearly eliminated (i.e., ≤15% exceedance frequency). As a result, substantial improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 7 operation and maintenance would not result in any substantial change in long-term average DOC concentration upstream of the Delta. Furthermore, under Alternative 7, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to DOC. DOC is not bioaccumulative, therefore change in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, DOC is not a constituent related to any 303(d) listings. Nevertheless, new and modified conveyance facilities proposed under Alternative 7 would result in a substantial increase in long-term average DOC concentrations (i.e., 0.7–1.1 mg/L, equivalent to ≤30% relative increase) at Franks Tract, Rock Slough, and Contra Costa PP No.1. In particular, under Alternative 7, model predicted long-term average DOC concentrations would be greater than 4 mg/L at Rock Slough and Contra Costa PP No. 1 with commensurate substantial increases in the frequency with which average DOC concentrations exceed 2, 3, and 4 mg/L levels. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Therefore, such a magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial uses at Rock Slough and Contra Costa PP No. 1 should such treatment upgrades not be undertaken. The impact is considered significant and mitigation is required. While Mitigation Measure WQ-17 is available to partially reduce this impact of DOC, the feasibility and effectiveness of this mitigation measure is uncertain and implementation would not necessarily reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Mitigation Measure WQ-17: Consult with Delta Water Purveyors to Identify Means to Avoid, Minimize, or Offset Increases in Long-Term Average DOC Concentrations

Please see Mitigation Measure WQ-17 under Impact WQ-17 in the discussion of Alternative 6A.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** CM2–CM21 under Alternative 7 would be similar to conservation measures under Alternative 1A, but 40 linear miles rather than 20 linear miles of channel margin habitat would be enhanced, and 20,000 acres rather than 10,000 acres of seasonally inundated floodplain would be restored. Effects on DOC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A, except that the increased linear miles of channel margin habitat enhancement and increased acreage of seasonally inundated floodplain would increase the overall Alternative 7 DOC loading to the Delta. In total, CM4–CM7 and CM10 could contribute substantial amounts of DOC to raw drinking water supplies, largely depending on final design and operational criteria for the related restoration activities. Substantially increased long-term average DOC in raw water supplies could lead to a need for treatment plant upgrades in order to appropriately manage DBP formation in treated drinking water. This potential for future DOC increases would lead to substantially greater associated risk of long-term adverse effects on the MUN beneficial use.

In summary, the habitat restoration elements of CM4–CM7 and CM10 under Alternative 7 would present new localized sources of DOC to the study area, and in some circumstances would substitute for existing sources related to replaced agriculture. Depending on localized hydrodynamics and proximity to municipal drinking water intakes, such restoration activities could contribute substantial amounts of DOC to municipal raw water. Substantial increases in municipal raw water DOC could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-18 is available to reduce these effects.

CEQA Conclusion: Effects of CM4–CM7 and CM10 on DOC under Alternative 7 are similar to, and possibly greater than, those discussed for Alternative 1A. Similar to the discussion for Alternative 1A, this impact is considered to be significant. It is uncertain whether implementation of Mitigation Measure WQ-18 would reduce identified impacts to a less-than-significant level. Hence, this impact remains significant and unavoidable.

In addition to and to supplement Mitigation Measure WQ-18, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from DOC concentration effects on municipal and industrial water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementing treatment for DOC and/or DBPs or DOC source control strategies. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to DOC.

Mitigation Measure WQ-18: Design Wetland and Riparian Habitat Features to Minimize Effects on Municipal Intakes

Please see Mitigation Measure WQ-18 under Impact WQ-18 in the discussion of Alternative 1A.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects: Effects of CM1 on pathogens under Alternative 7 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: Effects of CM1 on pathogens under Alternative 7 would be the same as those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

River flow rate and reservoir storage reductions that would occur due to implementation of CM1 (water facilities and operations) under Alternative 7, relative to Existing Conditions, would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta, given the small magnitude of urban runoff contributions relative to the magnitude of river flows, that pathogen concentrations in the rivers have a minimal relationship to river flow rate, and the expected reduced pollutant loadings in response to NPDES stormwater-related regulations.

It is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens. This conclusion is based on the Pathogens Conceptual Model, which found that pathogen sources in close proximity to a Delta site appear to have the greatest influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative.

In the SWP/CVP Export Service Areas waters, relative to Existing Conditions, an increased proportion of water coming from the Sacramento River would not adversely affect beneficial uses in the SWP/CVP Export Service Areas. The pathogen levels in the Sacramento River are similar to or lower than the water diverted at the Delta export pumps. Further, it is localized sources of pathogens that appear to have the greatest influence on concentrations. Thus, an increased proportion of Sacramento River water diverted to the SWP/CVP Export Service Areas would result in minimal changes in pathogen levels in the SWP/CVP Export Service Areas waters.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is Clean Water Act section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on pathogens under Alternative 7 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on pathogens resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, under Alternative 7 no specific operations or maintenance activity of the SWP or CVP would substantially drive a change in pesticide use, and thus pesticide sources would remain unaffected upstream of the Delta. Nevertheless, changes in the timing and magnitude of reservoir releases could have an effect on available dilution capacity along river segments such as the Sacramento, Feather, American, and San Joaquin Rivers.

Under Alternative 7, winter (November–March) and summer (April–October) season average flow rates on the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis would change. Relative to existing condition and the No Action Alternative, seasonal average flow rates on the Sacramento would decrease no more than 3% during the summer and 4% during the winter (Appendix 8L, *Pesticides*, Tables 1–4). On the Feather River, average flow rates would decrease no more than 5% during the summer, but would increase as much as 7% in the winter. American River average flow rates would decrease by as much as 15% in the summer but would increase by as much as 6% in the winter. Seasonal average flow rates on the San Joaquin River would decrease by as much as 12% in the summer, but increase by as much as 1% in the winter. For the same reasons stated for the No Action Alternative, decreased seasonal average flow of ≤15% is not considered to be of sufficient magnitude to substantially increase pesticide concentrations or alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of water bodies upstream of the Delta.

Delta

Sources of diuron, OP and pyrethroid insecticides to the Plan Area include direct input of surface runoff from in-Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. Similar to Upstream of the Delta, CVP/SWP operations would not affect these sources.

Under Alternative 7, the distribution and mixing of Delta source waters would change. Percentage change in monthly average source water fraction were evaluated for the modeled 16-year (1976–1991) hydrologic period and a representative drought period (1987–1991), with special attention given to changes in San Joaquin River, Sacramento River and Delta Agriculture sources water fractions. Relative to Existing Conditions, under Alternative 7 modeled San Joaquin River fractions would increase greater than 10% at Franks Tract, Rock Slough, Contra Costa PP No. 1, and the San Joaquin River at Antioch (Appendix 8D, *Source Water Fingerprinting Results*). At Antioch, San Joaquin River source water fractions when modeled for the 16-year hydrologic period would increase by 11–14% from November through May (no increase >10% for the modeled drought period). While this change at Antioch is not considered substantial, changes in San Joaquin River source water fraction in the Delta interior would be considerable. At Franks Tract, San Joaquin River source water fractions would increase between 18–28% for October through June (12–25% for November through June of the modeled drought period). Changes at Rock Slough and Contra Costa PP No. 1 would be very similar, where modeled San Joaquin River source water fractions would increase from 27–71% (11–70% for the modeled drought period) for October through June. Relative to Existing Conditions, there would be no modeled increases in Sacramento River fractions greater than 16% (with exception to Banks and Jones which are discussed below) and Delta agricultural fractions greater than 6%. Increases in San Joaquin River source water fraction at Franks Tract, Rock Slough, and Contra Costa PP NO. 1 would primarily balance through decreases in Sacramento

River water, and as a result the San Joaquin River would account for greater than 50% of the total source water volume at Franks Tract between March through May (<50% for all months during the modeled drought period), and would be 50%, and as much as 81% during November through May at Rock Slough and Contra Costa PP No. 1 for both the modeled drought and 16-year hydrologic periods. While the source water and potential pesticide related toxicity co-occurrence predictions do not mean adverse effects would occur, such considerable modeled increases in early summer source water fraction at Franks Tract and winter and summer source water fractions at Rock Slough and Contra Costa PP No. 1 could substantially alter the long-term risk of pesticide-related toxicity to aquatic life, given the apparent greater incidence of pesticides in the San Joaquin River.

When compared to the No Action Alternative, changes in source water fractions would be similar in season, geographic extent, and magnitude to those discussed for Existing Conditions with exception to Buckley Cove during the modeled drought period. At Buckley Cove, modeled drought period San Joaquin River fractions would increase 15% in July and 14% in August when compared to No Action Alternative (Appendix 8D, *Source Water Fingerprinting Results*). These increases would primarily balance through decreases in Sacramento River water and eastside tributary waters. Nevertheless, the San Joaquin River at Buckley Cove during the modeled drought period would only account for 36% of the total source water volume in July and 26% in August. These changes at Buckley Cove are not considered substantial, however, as discussed for Existing Conditions, under the No Action Alternative the similar magnitude change at Franks Tract, Rock Slough, and Contra Costa PP No. 1 would be considered substantial and could substantially alter the long-term risk of pesticide-related toxicity to aquatic life.

These predicted adverse effects on pesticides relative to Existing Conditions and the No Action Alternative fundamentally assume that the present pattern of pesticide incidence in surface water will occur at similar levels into the future. In reality, however, the makeup and character of the pesticide use market in the late long-term (i.e., the year 2060) will not be exactly as it is today. Current use of chlorpyrifos and diazinon is on the decline with their replacement by pyrethroids on the rise, yet in this assessment it is the apparent greater incidence of diazinon and chlorpyrifos on the San Joaquin River that serves as the basis for concluding that substantially increased San Joaquin River source water fraction would correspond to an increased risk of pesticide-related toxicity to aquatic life. By 2060, however, alternative pesticides, such as neonicitinoids and biologicals, will likely be a more substantial contributing part of the existing mix of pesticides, and perhaps more prominent. The trend in the development of future-use pesticides is towards reduced risk pesticides, including more biopesticides, with greater targeted specificity, fewer residues, and lower overall non-target toxicity. By 2060 existing chlorpyrifos and diazinon TMDLs for the Sacramento and San Joaquin Rivers will have been in effect for more than 50 years. Moreover, it is reasonable to expect that CWA section 303(d) listings and future additional listings will have developed TMDLs by 2060. To the extent these existing and future TMDL's address current and future-use pesticides, a greater degree of pesticide related source control can be anticipated. Nevertheless, forecasting whether these various efforts will ultimately be successful at resolving current pesticide related impairments requires considerable speculation. While the fundamental assumptions that have guided this assessment of pesticides may be somewhat altered by 2060, these assumptions are informed by actual studies and monitoring data collected from the recent past and, therefore, judging project alternative effects in the future remain most accurate through use of these informed assumptions rather than based on assumptions founded upon future speculative conditions.

SWP/CVP Export Service Areas

Assessment of effects in SWP/CVP Export Service Areas is based on effects seen in the Plan Area at the Banks and Jones pumping plants. Under Alternative 7, Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants relative to Existing Conditions and the No Action Alternative (Appendix 8D, *Source Water Fingerprinting Results*). At Banks pumping plant, Sacramento source water fractions would generally increase from 27–79% for October through June (13–32% for December through March of the modeled drought period) and at Jones pumping plant Sacramento source water fractions would generally increase from 43–96% for October through June (37–89% for October through June of the modeled drought period). These increases in Sacramento source water fraction would primarily balance through equivalent decreases in San Joaquin River water. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of OP insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

***NEPA Effects*:** In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers, under Alternative 7 relative to the No Action Alternative, are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. However, modeled increases in San Joaquin River fraction at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are of sufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta. The effects on pesticides from operations and maintenance (CM1) are determined to be adverse and unavoidable.

***CEQA Conclusion*:** Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Sources of pesticides upstream of the Delta include direct input of pesticide containing surface runoff from agriculture and urbanized areas. Flows in rivers receiving these discharges dilute these pesticide inputs. Relative to Existing Conditions, however, modeled changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta.

In the Delta, sources of pesticides include direct input of surface runoff from Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. While facilities operations and maintenance activities would not affect these sources, changes in Delta source water fraction could change the relative risk associated with pesticide related toxicity to aquatic life. Under Alternative 7, modeled long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would increase considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase.

The assessment of Alternative 7 effects on pesticides in the SWP/CVP Export Service Areas is based on assessment of changes predicted at Banks and Jones pumping plants. Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants and would generally represent an improvement in export water quality respective to pesticides.

Based on the above, Alternative 7 would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions would not be expected to make any of these beneficial use impairments measurably worse, with principal exception to locations in the Delta that would receive a substantially greater fraction San Joaquin River water under Alternative 7. Long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would change considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase. Additionally, the potential for increased incidence of pesticide related toxicity could include pesticides such as chlorpyrifos and diazinon for which existing 303(d) listings exist for the Delta, and thus existing beneficial use impairment could be made discernibly worse. The impact is considered to be significant and unavoidable. There is no feasible mitigation available to reduce the effect of this significant impact.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 7 would be similar to conservation measures under Alternative 1A, but 40 linear miles rather than 20 linear miles of channel margin habitat would be enhanced, and 20,000 acres rather than 10,000 acres of seasonally inundated floodplain would be restored. Effects on pesticides resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. In summary, CM13 proposes the use of herbicides to control invasive aquatic vegetation around habitat restoration sites. Herbicides directly applied to water could include adverse effects on non-target aquatic life, such as aquatic invertebrates and beneficial aquatic plants. As such, aquatic life toxicity objectives could be exceeded with sufficient frequency and magnitude such that beneficial uses would be impacted, thus constituting an adverse effect on water quality.

In summary, based on the discussion above, the effects on pesticides from implementing CM2–CM21 are considered to be adverse. Mitigation Measure WQ-22 would be available to reduce this adverse effect.

CEQA Conclusion: Effects of CM2–CM21 on pesticides under Alternative 7 are similar to conservation measures discussed for Alternative 1A. Potential environmental effects related only to CM13 are considered to be significant. Mitigation is required. While Mitigation Measure WQ-22 is available to partially reduce this impact of pesticides, no feasible mitigation is available that would reduce it to a level that would be less than significant.

Mitigation Measure WQ-22: Implement Least Toxic Integrated Pest Management Strategies

Please see Mitigation Measure WQ-22 under Impact WQ-22 in the discussion of Alternative 1A.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects**:** Effects of water facilities and operations (CM1) on phosphorus levels in water bodies of the affected environment under Alternative 7 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels discussed in detail for Alternative 1A also adequately represent the effects under Alternative 7, which are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Because phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration upstream of the Delta are not anticipated for Alternative 7, relative to Existing Conditions.

Because phosphorus concentrations in the major source waters to the Delta are similar for much of the year, phosphorus concentrations in the Delta are not anticipated to change substantially on a long term-average basis under Alternative 7, relative to Existing Conditions. Algal growth rates are limited by availability of light in the Delta, and therefore any minor increases in phosphorus levels that may occur at some locations and times within the Delta would be expected to have little effect on primary productivity in the Delta.

The assessment of effects of phosphorus under Alternative 7 in the SWP and CVP Export Service Areas is based on effects on phosphorus at the Banks and Jones pumping plants. As noted above, phosphorus concentrations in the Delta (including Banks and Jones pumping plants) are not anticipated to change substantially on a long term-average basis.

Based on the above, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas under Alternative 7 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on phosphorus levels in water bodies of the affected environment under Alternative 7 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels from implementing CM2–CM21 discussed in detail for Alternative 1A also adequately represent the effects of these same actions under Alternative 7, which are considered to be not adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on phosphorus resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 7 would have negligible, if any, effect on selenium concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in selenium concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to selenium.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics. To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, such as additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See Section 8.3.1.3 for more information.

Selenium concentrations and threshold comparisons for each of the 11 modeled Delta assessment locations under Alternative 7, relative to Existing Conditions and the No Action Alternative, are presented in Appendix 8M, *Selenium*, Table M-9a for water, Tables M-17 and M-27 for most biota (whole-body fish [excluding sturgeon], bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, and Tables M-30 through M-32 for sturgeon at the two western Delta locations. Figures 8-59a and 8-60a present graphical distributions of predicted selenium concentration changes (shown as changes in available assimilative capacity based on 1.3 μg/L) in water at each modeled assessment location for all years. Appendix 8M, Figure M-24 provides more detail in the form of monthly patterns of selenium concentrations in water during the modeling period.

Alternative 7 would result in small to moderate changes in average selenium concentrations in water at all modeled Delta assessment locations relative to Existing Conditions and the No Action Alternative (Appendix 8M, *Selenium*, Table M-9a). Long-term average concentrations at some interior and western Delta locations would increase by 0.01–0.13 µg/L for the entire period modeled. The increases in selenium concentrations in water would result in reductions in available assimilative capacity for selenium of 1–12%, relative to the 1.3 µg/L USEPA draft water quality criterion (Figures 8-59a and 8-60a). The long-term average selenium concentrations in water under Alternative 7 (range 0.09–0.38 µg/L) would be similar to those for Existing Conditions (range 0.09–0.41 µg/L) and the No Action Alternative (range 0.09–0.38 µg/L), and all would be well below the USEPA draft water quality criterion of 1.3 µg/L (Appendix 8M, Table 9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 7 would generally result in small changes (less than 4%) in estimated selenium concentrations in most biota (whole-body fish (excluding sturgeon), bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, with little difference among locations (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-27). Despite the small changes in selenium concentrations in biota, Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0 (indicating low probability of adverse effects). Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years also are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by about 30% relative to Existing Conditions and to the No Action Alternative in all years (from about 4.7 to 6.1 mg/kg dry weight). Likewise, those for sturgeon in the Sacramento River at Mallard Island are predicted to increase by about 18% in all years (from about 4.4 to 5.2 mg/kg dry weight) (Appendix 8M, Tables M-30 and M-31). Selenium concentrations in sturgeon during drought years are expected to increase by 11–24% at those locations. Detection of changes in whole-body sturgeon such as those estimated for the western Delta may require large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at both locations (as they do for Existing Conditions and the No Action Alternative) and for all years at the San Joaquin River at Antioch, whereas Existing Conditions and the No Action Alternative do not (quotient increases from 0.94 to 1.2 at San Joaquin at Antioch) (Appendix 8M, Table M-32). High Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years in the San Joaquin River at Antioch, whereas Existing Conditions and the No Action Alternative do not (quotient increases from about 0.85 to 1.1) (Appendix 8M, Table M-32).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in the appendix, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. (There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium.) Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on "fixed" K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Increased water residence times could increase the bioaccumulation of selenium in biota, thereby potentially increasing fish tissue and bird egg concentrations of selenium (see residence time discussion in Appendix 8M, *Selenium*, and Presser and Luoma [2010b]). Thus, residence time was assessed for its relevance to selenium bioaccumulation. Table 8-60a shows the time for neutrally buoyant particles to move through the Delta (surrogate for flow and residence time). Although an increase in residence time throughout the Delta is expected under the No Action Alternative, relative to Existing Conditions (because of climate change and sea level rise), the change is fairly small in most areas of the Delta.

Relative to Existing Conditions and the No Action Alternative, increases in residence times for Alternative 7 would be greater in the South Delta and East Delta than in other sub-regions. Relative to Existing Conditions, annual average residence times for Alternative 7 in the South Delta are expected to increase by more than 35 days (Table 8-60a). and in the East Delta increase by more than 20 days. Increases in residence times for other sub-regions would be smaller, especially as compared to Existing Conditions and the No Action Alternative (which are longer than those modeled for the South Delta). As mentioned above, these results incorporate hydrodynamic effects of both CM1 and CM2 and CM4, and the effects of CM1 cannot be distinguished from the effects of CM2 and CM4. However, it is expected that CM2 and CM4 are substantial drivers of the increased residence time.

Presser and Luoma (2010b) summarized and discussed selenium uptake in the Bay-Delta (including hydrologic conditions [e.g., Delta outflow and residence time for water], K_ds [the ratio of selenium concentrations in particulates, as the lowest level of the food chain, relative to the water-borne concentration], and associated tissue concentrations [especially in clams and their consumers, such as sturgeon]). When the Delta Outflow Index (daily average flow per month) decreased by five-fold (73,732 cfs in June 1998 to 12,251 cfs in October 1998), residence time doubled (from 11 to 22 days) and the calculated mean K_d also doubled (from 3,198 to 6,501). However, when daily average Delta outflow in November 1999 was only 6,951 cfs (i.e., about one-half that in October 1998) and residence time was 70 days, the calculated mean K_d (7,614) did not increase proportionally.

Models are not available to quantitatively estimate the level of changes in selenium bioaccumulation as related to residence time, but the effects of residence time are incorporated in the bioaccumulation modeling for selenium that was based on higher K_d values for drought years in comparison to wet, normal, or all years; see Appendix 8M, *Selenium*. If increases in fish tissue or bird egg selenium were to occur, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. In consideration of this factor, although the Delta as a whole is a CWA Section 303(d)-listed water body for selenium, and although monitoring data of fish tissue or bird eggs in the Delta are sparse, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time from restoration areas would be a concern is the western Delta and Suisun Bay for sturgeon, as discussed above. As shown in Table 8-60a, the overall increase in residence time estimated in the western Delta is 3 days relative to Existing Conditions, and 1 day relative to the No Action Alternative. Given the available information, these increases are small enough that they are not expected to substantially affect selenium bioaccumulation in the western Delta. Because CM2 and CM4 are expected to be substantial drivers of the increased residence times, further discussion is included in Impact WQ-26 below.

In summary, relative to Existing Conditions and the No Action Alternative, Alternative 7 would result in small changes (less than 4%) in selenium concentrations throughout the Delta for most biota, although larger increases in selenium concentrations are predicted for sturgeon in the western Delta. The Low Toxicity Threshold Exceedance Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase from 0.94 for Existing Conditions and the No Action Alternative to 1.2, and from 0.88 to 1.0 at Sacramento River at Mallard Island. The High Toxicity Threshold Exceedance Quotient for selenium concentrations for sturgeon at Antioch would increase from 0.85 for Existing Conditions and 0.86 for the No Action Alternative to 1.1. Concentrations of selenium in sturgeon would exceed the higher benchmark for Antioch only in drought years, indicating a high potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall the predicted increase for Alternative 7 is high enough that it may represent a measureable increase in body burdens of sturgeon, which would constitute an adverse impact.

SWP/CVP Export Service Areas

Alternative 7 would result in moderate (0.09–0.15 µg/L) decreases in average selenium concentrations in water at the Banks and Jones pumping plants, relative to the Existing Conditions and the No Action Alternative, for the entire period modeled (Appendix 8M, *Selenium*, Table M-9a). These decreases in long-term average selenium concentrations in water would result increases in available assimilative capacity for selenium at these pumping plants of 9–16%, relative to the USEPA draft water quality criterion of 1.3 µg/L. Furthermore, the long-term average selenium concentrations in water for Alternative 7 (range 0.12–0.13 µg/L) would be well below the USEPA draft water quality criterion of 1.3 µg/L (Appendix 8M, Table 9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 7 would result in small changes (less than 3%) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) at Banks and Jones pumping plants (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-27). Concentrations in biota would not exceed any selenium benchmarks for Alternative 7 (Figures 8-61a through 8-64b).

NEPA Effects: Based on the discussion above, the effects on selenium from Alternative 7 are considered to be adverse. This determination is reached because selenium concentrations in whole-body sturgeon modeled at two western Delta locations would increase by an average of 21%, which may represent a measurable increase in the environment. These potentially measurable increases represent an adverse impact.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for selenium. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 7, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate that Alternative 7 would result in essentially no change in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. Relative to Existing Conditions, modeling estimates indicate that Alternative 7 would increase selenium concentrations in whole-body sturgeon modeled at two western Delta locations by an estimated 21%, which may represent a measurable increase in the environment. Because both low and high toxicity benchmarks are exceeded, these potentially measurable increases represent a potential impact to fish and wildlife beneficial uses.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 7 would cause no increase in the frequency with which applicable benchmarks would be exceeded, and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants.

Based on the above, although waterborne selenium concentrations would not exceed applicable water quality objectives/criteria; however, significant impacts on some beneficial uses of waters in the Delta could occur because high toxicity benchmarks would be exceeded (where they are not under Existing Conditions), and uptake of selenium from water to biota may measurably increase. In comparison to Existing Conditions, water quality conditions under this alternative would increase levels of selenium (a bioaccumulative pollutant) by frequency, magnitude, and geographic extent such that the affected environment may have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish); however, impacts to humans consuming those organisms are not expected to occur. Water quality conditions under this alternative with respect to selenium would cause long-term degradation of water quality in the western Delta. Except in the vicinity of the western Delta for sturgeon, water quality conditions under this alternative would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms. The greater level of selenium bioaccumulation in the western Delta would further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. This impact is considered significant. *AMM27 Selenium*

Management, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on selenium under Alternative 7 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on selenium resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 7 would result in negligible, and likely immeasurable, increases in trace metal concentrations in the rivers and reservoirs upstream of the Delta, relative to Existing Conditions and the No Action Alternative. Effects due to the operation and maintenance of the conveyance facilities are expected to be immeasurable, on an annual and long-term average basis. As such, Alternative 7 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to trace metals.

Delta

For the same reasons stated for the No Action Alternative, Alternative 7 would not result in substantial increases in trace metal concentrations in the Delta relative to Existing Conditions and the No Action Alternative. However, substantial changes in source water fraction would occur in the south Delta (Appendix 8D, *Source Water Fingerprinting Results*). Throughout much of the south Delta, San Joaquin River water would replace Sacramento River water, with the future trace metals profile largely reflecting that of the San Joaquin River. As discussed for the No Action Alternative, trace metal concentration profiles between the San Joaquin and Sacramento Rivers are very similar and currently meet Basin Plan objectives and CTR criteria. While the change in trace metal concentrations in the south Delta would likely be measurable, Alternative 7 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the Delta or substantially degrade the quality of Delta waters with regard to trace metals.

SWP/CVP Export Service Areas

For the same reasons stated for the No Action Alternative, Alternative 7 would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities. As such, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP export service area waters under Alternative 7, relative to Existing Conditions and the No Action Alternative. As such, Alternative 7 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment in the SWP and CVP Service Area or substantially degrade the quality of these water bodies, with regard to trace metals.

***NEPA Effects*:** In summary, Alternative 7, relative to the No Action Alternative, would not cause a substantial increase in long-term average trace metals concentrations within the affected environment, nor would it cause an increased frequency of water quality objective/criteria exceedances within the affected environment. The effect on trace metals is determined not to be adverse.

CEQA Conclusion: Effects of CM1 on trace metals under Alternative 7 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

While greater water demands under the Alternative 7 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based without a WER adjustment. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under the Alternative 7.

The assessment of the Alternative 7 effects on trace metals in the SWP/CVP Export Service Areas is based on assessment of changes in trace metal concentrations at Banks and Jones pumping plants. As just discussed regarding similarities in Delta source water trace metal concentrations, the Alternative 7 is not expected to result in substantial changes in trace metal concentrations in Delta waters, including Banks and Jones pumping plants, therefore effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

Based on the above, there would be no substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area waters under Alternative 7 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 7 would be similar to those under Alternative 1A, but 40 linear miles rather than 20 linear miles of channel margin habitat would be enhanced, and 20,000 acres rather than 10,000 acres of seasonally inundated floodplain would be restored. Effects on trace metals resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. As they pertain to trace metals, implementation of CM2–CM21 would not be expected to adversely affect beneficial uses of the affected environment or substantially degrade water quality with respect to trace metals.

In summary, implementation of CM2–CM21 under Alternative 7, relative to the No Action Alternative, would have negligible, if any, effect on trace metals concentrations. The effect on trace metals from implementing CM2–CM21 is determined not to be adverse.

CEQA Conclusion: Implementation of CM2–CM21 under Alternative 7 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects: Effects of CM1 on TSS and turbidity under Alternative 7 would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM1 is determined to not be adverse.

CEQA Conclusion: Effects of CM1 on TSS and turbidity under Alternative 7 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Changes river flow rate and reservoir storage that would occur under Alternative 7, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes would be site-specific and temporal, which would be regulated to limit both their short-term and long-term effects on TSS and turbidity levels to less than substantial levels.

Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the Delta region, relative to Existing Conditions.

There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative 7, relative to Existing Conditions, because as stated above, this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act section 303(d) listed constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on TSS and turbidity under Alternative 7 would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM2–CM21 is determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 7 would be similar to conservation measures proposed under Alternative 1A. As such, effects on TSS and turbidity resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

The conveyance features for CM1 under Alternative 7 would be very similar to those discussed for Alternative 1A. The primary difference between Alternative 7 and Alternative 1A is that under Alternative 7, there would be two fewer intakes and two fewer pumping plant locations, which would result in a reduced level of construction activity. Additional construction activity also would occur to restore channel margin and seasonally inundated floodplain habitats. However, construction techniques and locations of major features of the conveyance system within the Delta would be similar. The remainder of the facilities constructed under Alternative 7, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A. However, under Alternative 7, there would be up to 20,000 acres of inundated floodplain habitat restored (as opposed to 10,000 acres under the majority of the other alternatives), thus resulting in increased construction-related disturbances.

NEPA Effects**:** The types and magnitude of potential construction-related water quality effects associated with implementation of CM1–CM21 under Alternative 7 would be very similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. Nevertheless, the construction of CM1, and any individual components necessitated by CM2, and CM4–CM10, with the implementation of the BMPs specified in Appendix 3B*, Environmental Commitments, AMMs, and CMs,* and other agency permitted construction requirements would result in the potential water quality effects being largely avoided and minimized. The specific environmental commitments that would be implemented under Alternative 7 would be similar to those described for Alternative 1A. Consequently, relative to Existing Conditions, Alternative 7 would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP and CVP service area.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

CEQA Conclusion**:** Because environmental commitments would be implemented under Alternative 7 for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32. Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance (CM1)

Effects of facilities and operations (CM1) on *Microcystis* abundance, and thus microcystins concentrations, in water bodies of the affected environment under Alternative 7 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. This is because factors that affect *Microcystis* abundance in waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Services Areas under Alternative 1A would similarly change under Alternative 7, relative to Existing Conditions and the No Action Alternative. For the Delta in particular, there are differences in the direction and magnitude of water residence time changes during the *Microcystis* bloom period among the six Delta sub-regions under Alternative 7 compared to Alternative 1A, relative to Existing Conditions and No Action Alternative. However, under Alternative 7, relative to Existing Conditions and No Action Alternative, water residence times during the *Microcystis* bloom period in various

Delta sub-regions are expected to increase to a degree that could, similar to Alternative 1A, lead to an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms throughout the Delta.

Similar to Alternative 1A, elevated ambient water temperatures relative to Existing Conditions would occur in the Delta under Alternative 7, which could lead to earlier occurrences of *Microcystis* blooms in the Delta, and increase the overall duration and magnitude of blooms. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. While *Microcystis* blooms have not occurred in the Export Service Areas, conditions in the Export Service Areas under Alternative 7 may become more conducive to *Microcystis* bloom formation, relative to Existing Conditions, because water temperatures will increase in the Export Service Areas due to the expected increase in ambient air temperatures resulting from climate change.

NEPA Effects: Effects of water facilities and operations (CM1) on *Microcystis* in water bodies of the affected environment under Alternative 7 would be very similar to (i.e., nearly the same) to those discussed for Alternative 1A. In summary, Alternative 7 operations and maintenance, relative to the No Action Alternative, would result in long-term increases in hydraulic residence time of various Delta sub-regions during the summer and fall *Microcystis* bloom period. During this period, the increased residence time could result in a concurrent increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus microcystin levels, in affected areas of the Delta. As a result, Alternative 7 operation and maintenance activities would cause further degradation to water quality with respect to *Microcystis* in the Delta. Under Alternative 7, relative to No Action Alternative, water exported to the SWP/CVP Export Service Area will be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River, diverted at the north Delta intakes. It cannot be determined whether operations and maintenance under Alternative 7 will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants. Mitigation Measure WQ-32a and WQ-32b are available to reduce the effects of degraded water quality in the Delta. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 7, additional impacts from *Microcystis* in the reservoirs and watersheds upstream of the Delta are not expected, relative to Existing Conditions. Operations and maintenance occurring under Alternative 7 is not expected to change nutrient levels in upstream reservoirs or hydrodynamic conditions in upstream rivers and streams such that conditions would be more conductive to *Microcystis* production.

Relative to Existing Conditions, water temperatures and hydraulic residence times in the Delta are expected to increase under Alternative 7, resulting in an increase in the frequency, magnitude and geographic extent of *Microcystis* blooms in the Delta. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. Increases in Delta residence times are expected throughout the Delta during the summer and fall bloom period, due in small part to climate change and sea level rise, but due more proportionately to CM1 and the hydrodynamic impacts of restoration included in CM2 and CM4. The precise change in local residence times and *Microcystis* production expected within any Delta sub-region is unknown because conditions will vary across the complex networks of intertwining channels, shallow back water areas, and submerged islands that compose the Delta. Nonetheless, Delta residence times are, in general, expected to increase due to Alternative 7. Consequently, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 7 and the hydrodynamic impacts of restoration (CM2 and CM4).

The assessment of effects of *Microcystis* on SWP/CVP Export Service Areas is based on the assessment of changes in *Microcystis* levels in export source waters, as well as the effects of temperature and residence time changes within the Export Service Areas on *Microcystis* production. Under Alternative 7, relative to Existing Conditions, the potential for *Microcystis* to occur in the Export Service Area is expected to increase due to increasing water temperature, but this impact is driven entirely by climate change and not Alternative 7. Water exported from the Delta to the Export Service Area is expected to be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River. Because of this, it cannot be determined whether operations and maintenance under Alternative 7, relative to existing conditions, will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants.

Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, because it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 7 and the hydrodynamic impacts of restoration (CM2 and CM4), long-term water quality degradation may occur and, thus, significant impacts on beneficial uses could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in Microcystis occurrences due to climate change and sea level rise may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be significant.

Implementation of Mitigation Measure WQ-32a and WQ-32b may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of these mitigation measures to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Mitigation Measure WQ-32b: Investigate and Implement Operational Measures to Manage Water Residence Time

Please see Mitigation Measure WQ-32b under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-33. Effects on *Microcystis* Bloom Formation Resulting from Other Conservation Measures (CM2–CM21)

The effects of CM2–CM21 on *Microcystis* under Alternative 7 would be the same as those discussed for Alternative 1A. In summary, implementation of CM2 and CM4 could result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta, relative to Existing Conditions and the No Action Alternative, as a result of increased residence times for Delta waters. Because the hydrodynamic effects associated with implementing CM2 and CM4 were incorporated into the modeling used to assess CM1, a detailed assessment of the effects of implementing CM2 and CM4 on *Microcystis* blooms in the Delta via their effects on Delta water residence time is provided under CM1 (above). The effects of CM2 and CM4 on *Microcystis* may be reduced by implementation of Mitigation Measure WQ-32a. The effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain. CM3 and CM5–CM21 would not result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta.

NEPA Effects: Effects of CM2–CM21 on *Microcystis* under Alternative 7 would be the same as those discussed for Alternative 1A and are considered to be adverse.

CEQA Conclusion: Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. Because restoration actions implemented under CM2 and CM4 will increase residence time throughout the Delta and create local areas of warmer water during the bloom season, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus long-term water quality degradation and significant impacts on beneficial uses, could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in Microcystis occurrences due to climate change and sea level rise may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM2–CM21 are determined to be significant.

Implementation of Mitigation Measure WQ-32a may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance (CM1) and Implementation of CM2–CM21

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 7 would have a less than significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- DO
- Pathogens
- Pesticides
- Trace Metals
- Turbidity and TSS

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Thus, changes in boron, DO, pathogens, pesticides, and turbidity and TSS in Delta outflow are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay.

The effects of Alternative 7 on bromide, chloride, and DOC, in the Delta were determined to be significant/adverse. Increases in bromide, chloride, and DOC concentrations are of concern in drinking water supplies; however, as described previously, the San Francisco Bay does not have a designated MUN use. Thus, changes in bromide, chloride, and DOC in Delta outflow would not adversely effect any beneficial uses of San Francisco Bay.

Elevated EC, as assessed for this alternative, is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. As discussed above, San Francisco Bay does not have an AGR beneficial use designation. Further, as discussed for the No Action Alternative, changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow, which would be the primary driver of salinity changes, would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow.

Also, as discussed for the No Action Alternative, adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in San Francisco Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus have not been detected downstream of Suisun Bay.

While effects of Alternative 7 on the nutrients ammonia, nitrate, and phosphorus were determined to be less than significant/not adverse, these constituents are addressed further below because the response of the seaward bays to changed nutrient concentrations/loading may differ from the response of the Delta. Selenium and mercury are discussed further, because they are bioaccumulative constituents where changes in load due to both changes in Delta concentrations and exports are of concern.

Nutrients: Ammonia, Nitrate, and Phosphorus

Total nitrogen loads in Delta outflow to Suisun and San Pablo Bays under Alternative 7 would be dominated almost entirely by nitrate, because planned upgrades to the SRWTP will result in >95% removal of ammonia in its effluent. Total nitrogen loads to Suisun and San Pablo Bays would decrease by 13%, relative to Existing Conditions, and increase by 28%, relative to the No Action Alternative (Appendix 8O, *San Francisco Bay Analysis*, Table O-1). The change in nitrogen loading to Suisun and San Pablo Bays under Alternative 7 would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. To the extent that algal growth increases in relation to a change in ammonia concentration, this would have net positive benefits, because current algal levels in these embayments are low. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay.

The phosphorus load exported from the Delta to Suisun and San Pablo Bays for Alternative 7 is estimated to increase by 9%, relative to Existing Conditions, and increase by 4% relative to the No Action Alternative (Appendix 8O, Table O-1)). The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. Any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary (Senn and Novick 2014; Kimmerer and Thompson 2014). Therefore, the projected change in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay is not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Mercury

The estimated long-term average mercury and methylmercury loads in Delta exports are shown in Appendix 8O, Table O-2. Loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 7. Mercury load to the Bay is estimated to increase by 10 kg/year (4%), relative to Existing Conditions, and 7 kg/year (3%), relative to the No Action Alternative. Methylmercury load is estimated to increase by 0.29 kg/year (8%), relative to Existing Conditions, and increase by 0.20 kg/year (5%) relative to the No Action Alternative. The estimated total mercury load to the Bay is 270 kg/year, which would be less than the San Francisco Bay mercury TMDL WLA for the Delta of 330 kg/year. The estimated changes in mercury and methylmercury loads would be within the overall uncertainty associated with the estimates of long-term average net Delta outflow and the long-term average mercury and methylmercury concentrations in Delta source waters. The estimated changes in mercury load under the alternative would also be substantially less than the considerable differences among estimates in the current mercury load to San Francisco Bay (San Francisco Bay Regional Water Quality Control Board 2006; David et al. 2009).

Given that the estimated incremental increases of mercury and methylmercury loading to San Francisco Bay would fall within the uncertainty of current mercury and methylmercury load estimates, the estimated changes in mercury and methylmerucy loads in Delta exports to San Francisco Bay due to Alternative 7 are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to mercury, or make the existing CWA Section 303(d) impairment measurably worse.

Selenium

Changes in source water fraction and net Delta outflow under Alternative 7, relative to Existing Conditions, are projected to cause the total selenium load to the North Bay to increase by 20%, relative to Existing Conditions, and increase by 16%, relative to the No Action Alternative (Appendix 8O, Table O-3). Changes in long-term average selenium concentrations of the North Bay are assumed to be proportional to changes in North Bay selenium loads. Under Alternative 7, the long-term average total selenium concentration of the North Bay is estimated to be 0.15 µg/L and the dissolved selenium concentration is estimated to be 0.13 µg/L, which would be a 0.02 µg/L increase relative to Existing Conditions and the No Action Alternative (Appendix 8O, Table O-3). The dissolved selenium concentration would be below the target of 0.202 µg/L developed by Presser and Luoma (2013) to coincide with a white sturgeon whole-body fish tissue selenium concentration not greater than 8 mg/kg in the North Bay.

The incremental increase in dissolved selenium concentrations in water projected to occur under Alternative 7, relative to Existing Conditions and the No Action Alternative, would be higher than under Alternatives 1A–5, but still low (0.02 µg/L). The increased dissolved selenium concentration would be within the overall uncertainty of the analytical methods used to measure selenium in water column samples; however, it also would be within the uncertainty associated with estimating numeric water column selenium thresholds (Pressor and Luoma 2013). As described in Section 8.3.1.8, there have been improvements in selenium concentrations in the tissue of diving ducks and muscle of white sturgeon since the initial CWA Section 303(d) listing of the North Bay for selenium impairments, and selenium concentrations in white sturgeon muscle have also generally been below the USEPA's draft recommended fish muscle tissue concentration of 11.8 mg/kg dry weight (San Francisco Estuary Institute 2014). However, as described under Impact WQ-25, though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases for Alternative 7 are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Because the projected incremental increases in dissolved selenium could cause measurable changes in water column concentrations, and these incremental increases would be within the uncertainty in the target water column threshold for dissolved selenium for protection against adverse bioaccumulative effects in the North Bay ecosystem, and modeling predicts concentrations in the western Delta may represent a measurable increase in body burdens of sturgeon, there is potential that the incremental increase in dissolved selenium concentration projected to occur in the North Bay under Alternative 7 could result in adverse effects beneficial uses.

NEPA Effects: Based on the discussion above, Alternative 7, relative to the No Action Alternative, would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, based on the discussion above, effects on the San Francisco Bay from implementation of CM1–CM21 are considered to be not adverse with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS.

However, Alternative 7 could result in increases in selenium concentrations in the North San Francisco Bay that could result in adverse effects to fish and wildlife beneficial uses. This effect is considered to be adverse.

CEQA Conclusion: Based on the above, Alternative 7 would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Further, based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals or turbidity or TSS are anticipated in the Delta, relative to Existing Conditions, therefore, no substantial changes these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow. Adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in the Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus not have not been detected downstream of Suisun Bay. The 13% decrease in total nitrogen load and 9% increase in phosphorus load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. The estimated increase in mercury load (10 kg/year; 4%) and methylmercury load (0.29 kg/year; 8%), relative to Existing Conditions, is within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans.

In regard to selenium, the estimated increase in selenium load would be 20% and the estimated increase in dissolved selenium concentrations would be 0.02 μg/L. Though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Thus, the increase in selenium load may make the CWA section 303(d) selenium impairment measurably worse and cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish and wildlife. This impact is considered to be significant. *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

8.3.3.15 Alternative 8—Dual Conveyance with Pipeline/Tunnel, Intakes 2, 3, and 5, and Increased Delta Outflow (9,000 cfs; Operational Scenario F)

Alternative 8 would comprise physical/structural components similar to those under Alternative 1A with the principal exceptions that Alternative 8 would have only three intakes and intake pumping plants (i.e., Intakes 2, 3, and 5). Alternative 8 would convey up to 9,000 cfs of water from the north Delta to the south Delta through pipelines/tunnels from three screened intakes on the east bank of the Sacramento River between Clarksburg and Walnut Grove. A 750-acre intermediate forebay and pumping plant would be constructed near Hood. A new 600-acre Byron Tract Forebay, adjacent to and south of Clifton Court Forebay, would be constructed which would provide water to the south Delta pumping plants. Water supply and conveyance operations would follow the guidelines described as Scenario F, which includes Fall X2. The alternative would provide up to 1.5 MAF in increased Delta outflow. CM2–CM21 would be implemented under this alternative, and would be the same as those under Alternative 1A. See Chapter 3, *Description of Alternatives,* Section 3.5.15, for additional details on Alternative 8.

Effects of the Alternative on Delta Hydrodynamics

Under the No Action Alternative and Alternatives 1A–9, the following two primary factors can substantially affect water quality within the Delta:

- Within the south, west, and interior Delta, a decrease in the percentage of Sacramento River-sourced water and a concurrent increase in San Joaquin River-sourced water can increase the concentrations of numerous constituents (e.g., boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides, selenium). This source water replacement is caused by decreased exports of San Joaquin River water (due to increased Sacramento River water exports), or effects of climate change on timing of flows in the rivers. Changes in channel flows also can affect water residence time and many related physical, chemical, and biological variables.
- Particularly in the west Delta, sea water intrusion as a result of sea level rise or decreased Delta outflow can increase the concentration of salts (bromide, chloride) and levels of electrical conductivity. Conversely, increased Delta outflow (e.g., as a result of Fall X2 operations in wet and above normal water years) will decrease levels of these constituents, particularly in the west Delta.

Under Alternative 8, over the long term, average annual delta exports are anticipated to decrease by 2,046 TAF relative to Existing Conditions, and by 1,342 TAF relative to the No Action Alternative. Because, over the long-term, approximately 70% of the exported water would be from the new north Delta intakes, average monthly diversions at the south Delta intakes would be decreased because of the shift in diversions to the north Delta intakes (see Chapter 5, *Water Supply,* for more information). The result of this would be greatly increased San Joaquin River water influence throughout the south, west, and interior Delta, and a corresponding decrease in Sacramento River water influence. This can be seen, for example, in Appendix 8D, ALT 8–Old River at Rock Slough for ALL years (1976–1991), which shows increased San Joaquin River (SJR) percentage and decreased Sacramento River (SAC) percentage under the alternative, relative to Existing Conditions and the No Action Alternative.

Under Alternative 8, long-term average annual Delta outflow is anticipated to increase 2,195 TAF relative to Existing Conditions, due to both changes in operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario F) and climate change/sea level rise (see Chapter 5, *Water Supply*, for more information). The result of this is decreased sea water intrusion in the west Delta. The decrease of sea water intrusion in the west Delta under Alternative 8 is greater relative to the Existing Conditions because it does not include operations to meet Fall X2, whereas the No Action alternative and Alternative 8 do. Long-term average annual Delta outflow is anticipated to increase under Alternative 8 by 1,445 TAF relative to the No Action Alternative, due only to changes in operations. The decreases in sea water intrusion (represented by an decrease in San Francisco Bay (BAY) percentage) can be seen, for example, in Appendix 8D, ALT 8–Sacramento River at Mallard Island for ALL years (1976–1991).

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 8 would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

Assessment of effects of ammonia under Alternative 8 is the same as discussed under Alternative 1A, except that because flows in the Sacramento River at Freeport are different between the two alternatives, estimated monthly average and long term annual average predicted ammonia-N concentrations in the Sacramento River downstream of Freeport are different.

As Table 8-71 shows, estimated ammonia-N concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 8 and the No Action Alternative are expected to be similar. Minor increases in ammonia-N concentrations would occur during July through December, and remaining months would be unchanged or have a minor decrease. A minor increase in the annual average concentration would occur under Alternative 8, compared to the No Action Alternative. Moreover, the estimated concentrations downstream of Freeport under Alternative 8 would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 8, relative to the No Action Alternative, are not expected to substantially increase ammonia concentrations at any Delta locations.

Table 8-71. Estimated Ammonia-N (mg-L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative and Alternative 8

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative	0.074	0.084	0.069	0.060	0.057	0.060	0.058	0.064	0.067	0.060	0.067	0.064	0.065
Alternative 8	0.081	0.089	0.070	0.060	0.057	0.059	0.055	0.059	0.066	0.072	0.078	0.070	0.068

Any negligible increases in ammonia-N concentrations that could occur at certain locations in the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

SWP/CVP Export Service Areas

The assessment of effects on ammonia in the SWP/CVP Export Service Area is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. Similar to the discussion for Alternative 1A, under Alternative 8 for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease, relative to Existing Conditions (in association with less diversion of water influenced by the SRWTP). This decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in adverse effects on beneficial uses or substantially degrade water quality of exported water, with regards to ammonia.

Furthermore, as discussed above for the Plan Area, for all areas of the Delta, including Banks and Jones pumping plants, ammonia-N concentrations are not expected to be substantially different under Alternative 8, relative to the No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

NEPA Effects: In summary, based on the discussion above, effects on ammonia from implementation of CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Ammonia-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to the lack of substantial point and nonpoint sources of ammonia-N upstream of the SRWTP in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 8, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river ammonia-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

Ammonia-N concentrations in the Sacramento River downstream of the SRWTP would be substantially lower under Alternative 8, relative to Existing Conditions, due to upgrades to the SRWTP that are assumed to be in place, and thus, ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water are expected to decrease. At locations which are not influenced notably by Sacramento River water, concentrations are expected to remain relatively unchanged, due to the similarity in SJR and BAY concentrations and the lack of expected changes in either of these concentrations.

The assessment of effects on ammonia in the SWP/CVP Export Service Areas is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. As discussed above for the Plan Area, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 8, relative to Existing Conditions.

Based on the above, there would be no substantial, long-term increase in ammonia-N concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 8 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia-N is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on ammonia under Alternative 8 would be the same as those discussed for Alternative 1A and are considered to be not adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on ammonia resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Effects of CM1 on boron under Alternative 8 in areas upstream of the Delta would be very similar to the effects discussed for Alternative 1A. There would be no expected change to the sources of boron in the Sacramento and eastside tributary watersheds, and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled long-term annual average lower San Joaquin

River flow at Vernalis would decrease slightly compared to Existing Conditions (in association with project operations, climate change, and increased water demands) and the No Action Alternative considering only changes due to Alternative 8 operations. The reduced flow would result in possible increases in long-term average boron concentrations of up to about 3% relative to the Existing Conditions (Appendix 8F, *Boron*, Bo-24). The increased boron concentrations would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 8 would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Effects of CM1 on boron under Alternative 8 in the Delta would be similar to the effects discussed for Alternative 1A. Relative to the Existing Conditions and No Action Alternative, Alternative 8 would result in increased long-term average boron concentrations for the 16-year period modeled at interior Delta locations (by as much as 10% at the SF Mokelumne River at Staten Island, 35% at Franks Tract, 58% at Old River at Rock Slough) (Appendix 8F, *Boron*, Table Bo-20). The comparison to Existing Conditions reflects changes due to both Alternative 8 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes due only to operations.

Implementation of tidal habitat restoration under CM4 also may contribute to increased boron concentrations at western Delta assessment locations (more discussion of this phenomenon is included in Section 8.3.1.3), and thus would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations.

The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 μg/L human health advisory objective (i.e., for children) or 500 μg/L agricultural objective at any of the eleven Delta assessment locations, which represents no change from the Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-3A). The increased concentrations at interior Delta locations would result in moderate reductions in the long-term average assimilative capacity of up to 16% at Franks Tract and up to 34% at Old River at Rock Slough locations (Appendix 8F, Table Bo-21). However, because the absolute boron concentrations would still be well below the lowest 500 μg/L objective for the protection of the agricultural beneficial use under Alternative 8, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, Figure Bo-5).

SWP/CVP Export Service Areas

Effects of CM1 on boron under Alternative 8 in the Delta would be similar to the effects discussed for Alternative 1A. Under Alternative 8, long-term average boron concentrations would decrease by as much as 37% at the Banks Pumping Plant and by as much as 47% at Jones Pumping Plant relative to Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-20) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading.

Maintenance of SWP and CVP facilities under Alternative 8 would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment. Maintenance activities would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment.

***NEPA Effects*:** In summary, relative to the No Action Alternative conditions, Alternative 8 would result in relatively small long-term average increases in boron levels in the San Joaquin River and moderate increases in the interior and western Delta locations Delta. However, the predicted changes in the Delta would not be expected to result in exceedances of applicable objectives or further water quality degradation such that objectives would likely be exceeded or there would be substantially increased risk of adverse effects on water quality.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Boron is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 8, relative to Existing Conditions, would not be expected to result in a substantial adverse change in boron levels. Additionally, relative to Existing Conditions, Alternative 8 would not result in reductions in river flow rates (i.e., less dilution) or increased boron loading such that there would be any substantial increases in boron concentration upstream of the Delta in the San Joaquin River watershed.

Moderate increased boron levels (i.e., up to 58% increased concentration) and degradation predicted for interior and western Delta locations in response to a shift in the Delta source water percentages and tidal habitat restoration under this alternative would not be expected to cause exceedances of objectives. Alternative 8 maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 8 would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to Existing Conditions, Alternative 8 would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 8, while widespread in particular at interior Delta locations, would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Consequently, Alternative 8 would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on boron under Alternative 8 would be the same as those discussed for Alternative 1A and are determined to be not adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on boron resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 8 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 8 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. Consequently, Alternative 8 would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the eastside tributaries, or their associated reservoirs upstream of the Delta.

Under Alternative 8, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by 6%, relative to Existing Conditions, and would remain virtually the same relative to No Action Alternative (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). These decreases in flow would result in possible increases in long-term average bromide concentrations of about 3%, relative to Existing Conditions and less than <1% relative to the No Action Alternative (Appendix 8E, *Bromide*, Table 24). The small increases in lower San Joaquin River bromide levels that could occur under Alternative 8, relative to existing and No Action Alternative conditions would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the lower San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Using the mass-balance modeling approach for bromide (see Section 8.3.1.3), relative to Existing Conditions, Alternative 8 would result in increases in long-term average bromide concentrations at Staten Island and Barker Slough, while long-term average concentrations would decrease at the other assessment locations (Appendix 8E, *Bromide*, Table 18). At Barker Slough, predicted long-term average bromide concentrations would increase from 51 µg/L to 54 µg/L (4% relative increase) for the modeled 16-year hydrologic period, and would increase from 54 µg/L to 80 µg/L (50% relative increase) for the modeled drought period. At Barker Slough, the predicted 50 µg/L exceedance frequency would decrease from 49% under Existing Conditions to 34% under Alternative 8, but would increase slightly from 55% to 62% during the drought period. At Barker Slough, the predicted 100 µg/L exceedance frequency would increase from 0% under Existing Conditions to 10% under Alternative 8, and would increase from 0% to 27% during the drought period. At Staten Island, predicted long-term average bromide concentrations would increase from 50 µg/L to 64 µg/L (29% relative increase) for the modeled 16-year hydrologic period and would increase from 51 µg/L to 65 µg/L (26% relative increase) for the modeled drought period. At Staten Island, increases in average bromide concentrations would correspond to an increased frequency of 50 µg/l threshold exceedance, from 47% under Existing Conditions to 80% under Alternative 8 (52% to 87% for the modeled drought period), and an increase from 1% to 2% (0% to 0% for the modeled drought period) for the 100 µg/L threshold. Changes in exceedance frequency of the 50 µg/L and 100 µg/L concentration thresholds at other assessment locations would be less considerable, with exception to Franks Tract. Although long-term average bromide concentrations were modeled to decrease at Franks Tract, exceedances of the 100 µg/L threshold would increase slightly, from 82% under Existing Conditions to 98% under Alternative 8 (78% to 93% for the modeled drought period). This comparison to Existing Conditions reflects changes in bromide due to both Alternative 8 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario F) and climate change/sea level rise.

Due to the relatively small differences between modeled Existing Conditions and the No Action baseline, changes in long-term average bromide concentrations and changes in exceedance frequencies relative tithe No Action Alternative are generally of similar magnitude to those previously described for the Existing Conditions comparison (Appendix 8E, *Bromide*, Table 18). Modeled long-term average bromide concentration at Barker Slough is predicted to increase by 8% (50% for the modeled drought period) relative to the No Action Alternative. Modeled long-term average bromide concentration increases at Staten Island are predicted to increase by 33% (30% for the modeled drought period) relative to the No Action Alternative. However, unlike the Existing Conditions comparison, long-term average bromide concentrations at Buckley Cove would increase relative to the No Action Alternative, although the increases would be relatively small (≤2%). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in bromide due only to Alternative 8 operations.

At Barker Slough, modeled long-term average bromide concentrations for the two baseline conditions are very similar (Appendix 8E, Table 18). Such similarity demonstrates that the modeled Alternative 8 change in bromide is almost entirely due to Alternative 8 operations, and not climate change/sea level rise. Therefore, operations are the primary driver of effects on bromide at Barker Slough, regardless whether Alternative 8 is compared to Existing Conditions, or compared to the No Action Alternative.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) differed somewhat from what is presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 19). For most locations, the frequency of exceedance of the 50 μg/L and 100 μg/L were similar. The greatest difference between the methods was predicted for Barker Slough. The increases in frequency of exceedance of the 100 μg/L threshold, relative to Existing Conditions and the No Action Alternative, were not as great using this alternative EC to chloride and chloride to bromide relationship modeling approach as compared to that presented above from the mass-balance modeling approach. Results indicate 4% exceedance over the modeled period under Alternative 8, as compared to 1% under Existing Conditions and 2% under the No Action Alternative. For the drought period, exceedance frequency increased from 0% under Existing Conditions and the No Action Alternative, to 12% under Alternative 8.Because the mass-balance approach predicts a greater level of impact at Barker Slough, determination of impacts was based on the mass-balance results.

While the increase in long-term average bromide concentrations at Barker Slough are relatively small when modeled over a representative 16-year hydrologic period, increases during the modeled drought period, principally the relative increase in 100 μg/L exceedance frequency, would represent a substantial change in source water quality during a season of drought. As discussed for Alternative 1A, drinking water treatment plants obtaining water via the North Bay Aqueduct utilize a variety of conventional and enhanced treatment technologies in order to achieve DBP drinking water criteria. While the implications of such a modeled drought period change in bromide concentrations at Barker Slough is difficult to predict, the substantial modeled increases could lead to adverse changes in the formation of disinfection byproducts such that considerable treatment plant upgrades may be necessary in order to achieve equivalent levels of health protection during seasons of drought. Increases at Staten Island are also considerable, although there are no existing or foreseeable municipal intakes in the immediate vicinity. Because many of the other modeled locations already frequently exceed the 100 μg/L threshold under Existing Conditions and the No Action Alternative, these locations likely already require treatment plant technologies to achieve equivalent levels of health protection, and thus no additional treatment technologies would be triggered by the small increases in the frequency of exceeding the 100 μg/L threshold. Hence, no further impact on the drinking water beneficial use would be expected at these locations.

The seasonal intakes at Mallard Slough and City of Antioch are infrequently used due to water quality constraints related to sea water intrusion. On a long-term average basis, bromide at these locations is in excess of 3,000 μg/L, but during seasonal periods of high Delta outflow can be <300 μg/L. Based on modeling using the mass-balance approach, use of the seasonal intakes at Mallard Slough and City of Antioch under Alternative 8 would experience a period average increase in bromide during the months when these intakes would most likely be utilized. For those wet and above normal water year types where mass balance modeling would predict water quality typically suitable for diversion, predicted long-term average bromide would increase from 103 μg/L to 146 μg/L (42% increase) at City of Antioch and would increase from 150 μg/L to 193 μg/L (29% increase) at Mallard Slough relative to Existing Conditions (Appendix 8E, *Bromide*, Table 25).

Increases would be similar for the No Action Alternative comparison. Modeling results using the EC to chloride and chloride to bromide relationships show increases during these months, but the relative magnitude of the increases is much lower (Appendix 8E, Table 26). Regardless of the differences in the data between the two modeling approaches, the decisions surrounding the use of these seasonal intakes is largely driven by acceptable water quality, and thus have historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at the City of Antioch and Mallard Slough intake would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

Based on modeling using the mass-balance approach, relative to existing and No Action Alternative conditions, Alternative 8 would lead to predicted improvements in long-term average bromide concentrations at Franks Tract, Rock Slough, and Contra Costa PP No. 1, in addition to Banks and Jones (discussed below). At these locations, long-term average bromide concentrations would be predicted to decrease by as much as 11–37%, depending on baseline comparison. Modeling results using the EC to chloride and chloride to bromide relationships generally do not show similar decreases for Rock Slough and Contra Costa PP No. 1, but rather, predict small increases. Based on the small magnitude of increases predicted, these increases would not adversely affect beneficial uses at those locations.

Important to the results presented above is the assumed habitat restoration footprint on both the temporal and spatial scales incorporated into the modeling. Modeling sensitivity analyses have indicated that habitat restoration (which are reflected in the modeling—see Section 8.3.1.3), not operations covered under CM1, are the driving factor in the modeled bromide increases. The timing, location, and specific design of habitat restoration will have effects on Delta hydrodynamics, and any deviations from modeled habitat restoration and implementation schedule will lead to different outcomes. Although habitat restoration near Barker Slough is an important factor contributing to modeled bromide concentrations at the North Bay Aqueduct, BDCP habitat restoration elsewhere in the Delta can also have large effects. Because of these uncertainties, and the possibility of adaptive management changes to BDCP restoration activities, including location, magnitude, and timing of restoration, the estimates are not predictive of the bromide levels that would actually occur in Barker Slough or elsewhere in the Delta.

SWP/CVP Export Service Areas

Under Alternative 8, improvement in long-term average bromide concentrations would occur at the Banks and Jones pumping plants. Long-term average bromide concentrations for the modeled 16-year hydrologic period at these locations would decrease by as much as 75% relative to Existing Conditions and 69% relative to the No Action Alternative (Appendix 8E, *Bromide*, Table 18). As a result, exceedances of the 50 µg/L and 100 µg/L assessment thresholds would be substantially reduced, resulting in considerable overall improvement in Export Service Areas water quality respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also be observed since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in bromide is difficult to predict, the relative decrease in overall loading of bromide to the Export Service Areas would likely alleviate or lessen any expected increase in bromide concentrations at Vernalis (see discussion of Upstream of the Delta) as well as locations in the Delta receiving a large fraction of San Joaquin River water, such as much of the south Delta.

The discussion above is based on results of the mass-balance modeling approach. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) were consistent with the discussion above, and assessment of bromide using these data results in the same conclusions as are presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 19).

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 8 would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, Alternative 8 operations and maintenance, relative to the No Action Alternative, would result in small increases (i.e., <1%) in long-term average bromide concentrations at Vernalis related to relatively small declines in long-term average flow on the San Joaquin River. However, Alternative 8 operation and maintenance activities would cause substantial degradation to water quality with respect to bromide at Barker Slough, source of the North Bay Aqueduct. Resultant substantial change in long-term average bromide at Barker Slough could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-5 is available to reduce these effects. Implementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 8 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 8 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. However, south of the Delta, the San Joaquin River is a substantial source of bromide, primarily due to the use of irrigation water imported from the southern Delta. Concentrations of bromide at Vernalis are inversely correlated to net river flow. Under Alternative 8, long-term average flows at Vernalis would decrease only slightly, resulting in less than substantial predicted increases in long-term average bromide of about 3% relative to Existing Conditions.

Relative to Existing Conditions, Alternative 8 would result in increases in long-term average bromide concentration at Staten Island and Barker Slough. There are no existing or foreseeable municipal drinking water intakes in the vicinity of Staten Island, but Barker Slough is the source of the North Bay Aqueduct. While the increase in long-term average bromide concentrations at Barker Slough are predicted to be relatively small when modeled over a representative 16-year hydrologic period, increases during the modeled drought period would represent a substantial change in source water quality during a season of drought. These predicted drought season related increases in bromide at Barker Slough could lead to adverse changes in the formation of disinfection byproducts at drinking water treatment plants such that considerable water treatment plant upgrades would be necessary in order to achieve equivalent levels of drinking water health protection.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Under Alternative 8, substantial improvement would occur at the Banks and Jones pumping plants, where predicted long-term average bromide concentrations are predicted to decrease by as much as 75% relative to Existing Conditions. An overall improvement in bromide-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 8 operation and maintenance would not result in any substantial change in long-term average bromide concentration upstream of the Delta. Furthermore, under Alternative 8, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to bromide. Bromide is not bioaccumulative, therefore change in long-term average bromide concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, bromide is not a constituent related to any 303(d) listings. Alternative 8 operation and maintenance activities would not cause substantial long-term degradation to water quality respective to bromide with the exception of water quality at Barker Slough (drought period only) and at Staten Island in the eastern Delta. There are no existing or foreseeable municipal intakes in the vicinity of Staten Island, but Barker Slough is the source of the North Bay Aqueduct. At Barker Slough, modeled long-term annual average concentrations of bromide would increase by 50% during the modeled drought period. For the modeled drought period the frequency of predicted bromide concentrations exceeding 100 μg/L would increase from 0% under Existing Conditions to 27% under Alternative 8. Substantial changes in long-term average bromide during seasons of drought could necessitate changes in treatment plant operation or require treatment plant upgrades in order to maintain DBP compliance. The model predicted change at Barker Slough during the drought period is substantial and, therefore, would represent a substantially increased risk for adverse effects on existing MUN beneficial uses should treatment upgrades not be undertaken. The impact is considered significant.

Implementation of Mitigation Measure WQ-5 along with a separate other commitment relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-5 is recommended to attempt to reduce the effect that increased bromide concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-5, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from bromide-related concentration effects on municipal water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementation of the North Bay Aqueduct AIP, acquiring alternative water supplies, or other actions to indirectly reduce the effects of elevated bromide and DOC in existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-5: Avoid, Minimize, or Offset, as Feasible, Adverse Water Quality Conditions

Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 8 would be similar to conservation measures under Alternative 1A. As discussed for Alternative 1A, implementation of the CM2–CM21 would not present new or substantially changed sources of bromide to the study area. Some conservation measures may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution is not expected to substantially increase or present new sources of bromide. CM2–CM21 would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

In summary, implementation of CM2–CM21 under Alternative 8, relative to the No Action Alternative, would have negligible, if any, effects on bromide concentrations. The effects on bromide from implementing CM2–CM21 are determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As discussed for Alternative 1A, implementation of CM2–CM21 would not present new or substantially changed sources of bromide to the study area. As such, effects on bromide resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 8 there would be no expected change to the sources of chloride in the Sacramento and eastside tributary watersheds. Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. The modeled long-term annual average flows on the lower San Joaquin River at Vernalis would decrease slightly compared to Existing Conditions and be similar compared to the No Action Alternative (as a result of climate change). The reduced flow would result in possible increases in long-term average chloride concentrations of about 2%, relative to the Existing Conditions and no change relative to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-62). Consequently, Alternative 8 would not be expected to cause exceedance of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to the Existing Conditions and No Action Alternative, Alternative 8 would result in similar or reduced long-term average chloride concentrations for the 16-year period modeled at most of the assessment locations, and, depending on the modeling approach (see Section 8.3.1.3), increased concentrations at the North Bay Aqueduct at Barker Slough (i.e., up to 6% compared to No Action Alternative), Contra Costa Canal at Pumping Plant #1 (i.e., up to 24% compared to No Action Alternative), Rock Slough (i.e., up to 18% compared to No Action Alternative), and the SF Mokelumne at Staten Island (i.e., up to 29% compared to No Action Alternative) (Appendix 8G, *Chloride*, Table Cl-49 and Table Cl-50). Moreover, the direction and magnitude of predicted changes for Alternative 8 are similar between the alternatives, thus, the effects relative to Existing Conditions and the No Action Alternative are discussed together. Additionally, implementation of tidal habitat restoration under CM4 would increase the tidal exchange volume in the Delta, and thus may contribute to increased chloride concentrations in the Bay source water as a result of increased salinity intrusion. More discussion of this phenomenon is included in Section 8.3.1.3. Consequently, while uncertain, the magnitude of chloride increases may be greater than indicated herein and would affect the western Delta assessment locations the most which are influenced to the greatest extent by the Bay source water. The comparison to Existing Conditions reflects changes in chloride due to both Alternative 8 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario E) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes in chloride due only to operations. The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses

Estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at both the Antioch and Contra Costa Pumping Plant #1 locations. For Alternative 8, the modeled frequency of objective exceedance would increase from 7% of years under Existing Conditions and 0% under the No Action Alternative to 13% of years under Alternative 8 (Appendix 8G, *Chloride*, Table Cl-64).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 8, the modeled frequency of objective exceedance would decrease, from

6% of modeled days under Existing Conditions and 5% under the No Action Alternative to 1% of modeled days under Alternative 8 (Appendix 8G, *Chloride*, Table Cl-63).

Given the limitations inherent to estimating future chloride concentrations (see Section 8.3.1.3), estimation of chloride concentrations through both amass balance approach and an EC-chloride relationship approach was used to evaluate the 250 mg/L Bay-Delta WQCP objectives in terms of both frequency of exceedance and use of assimilative capacity. When utilizing the mass balance approach to model monthly average chloride concentrations for the 16-year period, the predicted frequency of exceeding the 250 mg/L objective would decrease up to 15% (i.e., 24% for Existing Conditions to 9%) at the Contra Costa Canal at Pumping Plant #1 (Appendix 8G, *Chloride*, Table Cl-51 and Figure Cl-13). The frequency of exceedances would decrease at the San Joaquin River at Antioch (i.e., from 66% under Existing Conditions to 58%) with no substantial change predicted for Mallard Island (i.e., maximum increase of 1%) (Appendix 8G, Table Cl-51) and no substantial long-term degradation (Appendix 8G, Table Cl-53). However, relative to the No Action conditions, available assimilative capacity for chloride at the Contra Costa Canal at Pumping Plant #1 would be substantially reduced in September and October (i.e., up to 100%, or eliminated, for the drought period modeled) (Appendix 8G, Table Cl-53), reflecting substantial degradation when concentrations would be near, or exceed, the objective.

In comparison, when utilizing the chloride-EC relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance generally agreed, but use of assimilative capacity were predicted to be larger at some locations (Appendix 8G, Table Cl-52 and Table Cl-54). Specifically, while the model predicted exceedance frequency would decrease at the Contra Costa Canal at Pumping Plant #1 and Rock Slough locations, use of assimilative capacity would increase substantially for the months of February through June as well as September (i.e., maximum of 82% in March for the modeled drought period). Due to such seasonal long-term average water quality degradation at these locations, the potential exists for substantial adverse effects on the municipal and industrial beneficial uses through reduced opportunity for diversion of water with acceptable chloride levels. Moreover, due to the increased frequency of exceeding the 150 mg/L Bay-Delta WQCP objective, the potential exists for adverse effects on the municipal and industrial beneficial uses at Contra Costa Pumping Plant #1 and Antioch.

303(d) Listed W*ater Bodies*

With respect to the 303(d) listing for chloride in Tom Paine Slough, the monthly average chloride concentrations for the 16-year period modeled at Old River at Tracy Road, which represents the nearest DSM2-modeled location to Tom Paine in the south Delta, would generally be similar compared to Existing Conditions and No Action Alternative, and thus, would not be further degraded on a long-term basis (Appendix 8G, Figure Cl-14).

With respect to Suisun Marsh, the monthly average chloride concentrations for the 16-year period modeled would generally be similar, or decrease, compared to Existing Conditions and No Action Alternative in some months during October through May at the Sacramento River at Collinsville (Appendix 8G, Figure Cl-15), Mallard Island (Appendix 8G, Figure Cl-13). However, chloride concentrations would increase substantially at Montezuma Slough at Beldon's Landing (i.e., over a doubling of concentration in December through February) (Appendix 8G, Figure Cl-16). Although modeling of Alternative 8 assumed no operation of the Montezuma Slough Salinity Control Gates, the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results for Suisun Marsh, but EC levels were still somewhat higher than EC levels under Existing Conditions for several locations and months. Although chloride was not specifically modeled in this sensitivity analysis, it is expected that chloride concentrations would be nearly proportional to EC levels in Suisun Marsh. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases in salinity are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term chloride increases in the Marsh. However, the chloride concentration increases at certain locations could be substantial, depending on siting and design of restoration areas. Thus, these increased chloride levels in Suisun Marsh are considered to contribute to additional, measureable long-term degradation that potentially would adversely affect the necessary actions to reduce chloride loading for any TMDL that is developed.

SWP/CVP Export Service Areas

Under Alternative 8, long-term average chloride concentrations based on the mass balance analysis of modeling results for the 16-year period modeled at the Banks and Jones pumping plants would decrease by as much as 73% relative to Existing Conditions and 70% compared to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-49). The modeled frequency of exceedances of applicable water quality objectives/criteria would decrease relative to Existing Conditions and No Action Alternative, for both the 16-year period and the drought period modeled (Appendix 8G, *Chloride*, Table Cl-51). Consequently, water exported into the SWP/CVP service area would generally be of similar or better quality with regards to chloride relative to Existing Conditions and the No Action Alternative conditions.

Results of the modeling approach which used relationships between EC and chloride (see Section 8.3.1.3) were consistent with the discussion above, and assessment of chloride using these data results in the same conclusions as are presented above for the mass-balance approach (Appendix 8G, Table Cl-50 and Table Cl-52).

Commensurate with the reduced chloride concentrations in water exported to the service area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely alleviate or lessen any expected increase in chloride at Vernalis related to decreased annual average San Joaquin River flows (see discussion of Upstream of the Delta).

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

***NEPA Effects*:** In summary, relative to the No Action Alternative conditions, Alternative 8 would result in substantial increased water quality degradation relative to the 150 mg/L Bay-Delta WCCP objective at Contra Costa Pumping Plant #1 and Antioch, substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1 and Rock Slough, and could contribute to measureable water quality degradation relative to the 303(d) impairment in Suisun Marsh. The predicted chloride increases constitute an adverse effect on water quality (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Additionally, the predicted changes relative to the No Action Alternative conditions indicate that in addition to the effects of climate change/sea level rise, implementation of CM1 and CM4 under Alternative 8 would contribute substantially to the adverse water quality effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 8, relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, the Alternative 8 would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, Alternative 8 operations would result in reduced chloride concentrations in the Delta such that exceedances of the 250 mg/L Bay-Delta WQCP objective at interior and western Delta locations would be reduced. Nevertheless, due to the predicted increased frequency of exceeding the 150 mg/L Bay-Delta WQCP objective at Contra Costa Pumping Plant #1 and Antioch as well as substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1, the potential exists for adverse effects on the municipal and industrial beneficial uses at Contra Costa Pumping Plant #1 and Antioch (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Moreover, the modeled increased chloride concentrations and degradation in the western Delta could further contribute, at measurable levels (i.e., over a doubling of concentration), to the existing 303(d) listed impairment due to chloride in Suisun Marsh for the protection of fish and wildlife.

Chloride concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under Alternative 8 would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 8 maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas. However, based on these findings, this impact is determined to be significant due to increased chloride concentrations and frequency of objective exceedance in the western Delta, as well as potential adverse effects on fish and wildlife beneficial uses in Suisun Marsh.

While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-7 is recommended to attempt to reduce the effect that increased chloride concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-7, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from chloride concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when chloride concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-7: Conduct Additional Evaluation and Modeling of Increased Chloride Levels and Develop and Implement Phased Mitigation Actions

Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Under Alternative 8, the types and geographic extent of effects on chloride concentrations in the Delta as a result of implementation of the other conservation measures (i.e., CM2–CM21) would be similar to, and undistinguishable from, those effects previously described for Alternative 1A. The conservation measures would present no new direct sources of chloride to the affected environment. Moreover, some habitat restoration conservation measures (CM4–10) would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored tidal wetlands, floodplain, and related channel margin and off-channel habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement compared to Existing Conditions and No Action Alternative conditions.

In summary, based on the discussion above, the effects on chloride from implementing CM2-CM21 are considered to be not adverse.

CEQA Conclusion: Implementation of the CM2–CM21 for Alternative 8 would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP service area. Replacement of irrigated agricultural land uses in the Delta with habitat restoration conservation measures may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance (CM1)

***NEPA Effects*:** Effects of CM1 on DO under Alternative 8 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

***CEQA Conclusion*:** Effects of CM1 on DO under Alternative 8 would be similar to conservation measures discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Reservoir storage reductions that would occur under Alternative 8, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions that would occur would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state has begun to aggressively regulate the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters under Alternative 8, relative to Existing Conditions. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to ever increasing water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. This impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on DO under Alternative 8 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on DO resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, their associated reservoirs, and the San Joaquin River upstream of the Delta under Alternative 8 are not expected to be outside the ranges occurring under Existing Conditions or would occur under the No Action Alternative. Any minor changes in EC levels that could occur under Alternative 8 in water bodies upstream of the Delta would not be of sufficient magnitude, frequency and geographic extent that would cause adverse effects on beneficial uses or substantially degrade water quality with regard to EC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to Existing Conditions, Alternative 8 would result in an increase in the number of days the Bay-Delta WQCP EC objectives would be exceeded in the Sacramento River at Emmaton, and the San Joaquin River at Vernalis, Prisoners Point, and Brandt Bridge, and in the Old River near Middle River (Appendix 8H, *Electrical Conductivity*, Table EC-8).

The percentage of days the Emmaton EC objective would be exceeded for the entire period modeled (1976–1991) would increase from 6% under Existing Conditions to 22% under Alternative 8, and the percentage of days out of compliance would increase from 11% under Existing Conditions to 34% under Alternative 7.

The increase in the percentage of days the Vernalis EC objective would be exceeded would be <1%, and the percentage of days out of compliance with the EC objective would increase from 7% under Existing Conditions to 8% under Alternative 8. These increases are minimal, and are not considered substantial, in light of the overall modeling uncertainty.

The percentage of days the Prisoners Point EC objective would be exceeded for the entire period modeled would increase from 6% under Existing Conditions to 38% under Alternative 8, and the percentage of days out of compliance with the EC objective would increase from 10% under Existing

Conditions to 38% under Alternative 8. Sensitivity analyses conducted for Alternative 4 Scenario H3 indicated that removing all tidal restoration areas would reduce the number of exceedances, but there would still be substantially more exceedances than under Existing Conditions or the No Action Alternative. Results of the sensitivity analyses indicate that the exceedances are partially a function of the operations of the alternative itself, perhaps due to Head of Old River Barrier assumptions and south Delta export differences (see Appendix 8H, *Electrical Conductivity*, Attachment 1, for more discussion of these sensitivity analyses). Due to similarities in the nature of the exceedances between alternatives, the findings from these analyses can be extended to this alternative as well. Appendix 8H, Attachment 2, contains a more detailed assessment of the likelihood of these exceedances impacting aquatic life beneficial uses. Specifically, Appendix 8H, Attachment 2, discusses whether these exceedances might have indirect effects on striped bass spawning in the Delta, and concludes that the high level of uncertainty precludes making a definitive determination.

In the San Joaquin River at Brandt Bridge, the percentage of days exceeding the EC objective would increase from 3% under Existing Conditions to 4% under Alternative 8; the percentage of days out of compliance would increase from 8% under Existing Conditions to 9% under Alternative 8. The increase in the percentage of days the Old River EC objective would be exceeded and out of compliance for the entire period modeled (1976–1991) would be <1%. These increases are minimal, and are not considered substantial, in light of the overall modeling uncertainty.

Average EC levels at the western and southern Delta compliance locations and San Joaquin River at San Andreas Landing (an interior Delta location) would decrease from 0–44% for the entire period modeled and 2–43% during the drought period modeled (1987–1991) (Appendix 8H, Table EC-19). In the S. Fork Mokelumne River at Terminous, average EC would increase 5% for the entire period modeled and drought period modeled. Average EC in the S. Fork Mokelumne River at Terminous would increase during all months (Appendix 8H, Table EC-19). Given that the western Delta is Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives under Alternative 8, relative to Existing Conditions has the potential to contribute to additional impairment and potentially adversely affect beneficial uses. The comparison to Existing Conditions reflects changes in EC due to both Alternative 8 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario F) and climate change/sea level rise.

Relative to the No Action Alternative, the change in percentage compliance with Bay-Delta WQCP EC objectives under Alternative 8 would be similar to that described above relative to Existing Conditions. The exception is that there would also be a slight increase (<1%) in the percentage of days the EC objective would be exceeded in the Old River at Tracy for the entire period modeled. Also, Old River at Tracy also would have an increase in the number of days out of compliance with the EC objectives. The percentage of days out of compliance with Tracy Bridge EC objectives would increase from 8% to 9% for the entire period modeled. For the entire period modeled, average EC levels would increase at all Delta compliance locations relative to the No Action Alternative, except in the San Joaquin River at San Andreas Landing and Jersey Point. The greatest average EC increase would occur in the San Joaquin River at Prisoners Point (7%); the increase at the other locations would be <1–6% (Appendix 8H, Table EC-19). Similarly, during the drought period modeled, average EC would increase at all locations, except the San Joaquin River at San Andreas Landing and Jersey Point. The greatest average EC increase during the drought period modeled would occur in the S. Fork Mokelumne River at Terminous (6%); the increases at the other locations would be 1–4% (Appendix 8H, Table EC-19). Given that the western and southern Delta are Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of

EC objectives under Alternative 7, relative to the No Action Alternative, has the potential to contribute to additional impairment and potentially adversely affect beneficial uses. The comparison to the No Action Alternative reflects changes in EC due only to Alternative 8 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario F).

For Suisun Marsh, October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Long-term average EC would decrease under Alternative 8, relative to Existing Conditions, during October–May in the Sacramento River at Collinsville and Montezuma Slough at National Steel (Appendix 8H, *Electrical Conductivity*, Tables EC-21 and EC-22). The most substantial increase would occur near Beldon Landing, with long-term average EC levels increasing by 0.1–3.5 mS/cm, depending on the month (Appendix 8H, Table EC-23). Sunrise Duck Club would have long-term average EC increases of 0.2–0.8 mS/cm (Appendix 8H, Table EC-24) and Volanti Slough would have long-term average EC increases of 0.1–1.1 mS/cm. The degree to which the long-term average EC increases would cause exceedance of Bay-Delta WQCP objectives is unknown, because objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated "equivalent or better protection will be provided at the location" (State Water Resources Control Board 2006:14). Modeling of this alternative assumed no operation of the Montezuma Slough Salinity Control Gates, but the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 Scenario H3 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results, but EC levels were still somewhat higher than EC levels under Existing Conditions and the No Action Alternative for several locations and months. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions and the No Action Alternative, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term EC increases to be on the order of 1 mS/cm or less. Due to similarities in the nature of the EC increases between alternatives, the findings from these analyses can be extended to this alternative as well.

The long-term average EC increase in Suisun Marsh may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the marsh. However, the EC increases at certain locations could be substantial and it is uncertain the degree to which current management plans for the Suisun Marsh would be able to address these substantially higher EC levels and protect beneficial uses. Thus, these increased EC levels in Suisun Marsh are considered to have a potentially adverse effect on marsh beneficial uses. Long-term average EC increases in Suisun Marsh under Alternative 8 relative to the No Action Alternative would be similar to the increases relative to Existing Conditions. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC concentrations could contribute to additional impairment relative to Existing Conditions and the No Action Alternative.

SWP/CVP Export Service Areas

At the Banks and Jones pumping plants, Alternative 8 would result in no exceedances of the Bay-Delta WQCP's 1,000 μmhos/cm EC objective for the entire period modeled (Appendix 8H, *Electrical*

Conductivity, Table EC-10). Thus, there would be no adverse effect on the beneficial uses in the SWP/CVP Export Service Areas using water pumped at this location under the Alternative 8.

At the Banks pumping plant, relative to Existing Conditions, average EC levels under Alternative 8 would decrease substantially: 49% for the entire period modeled and 53% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 45% for the entire period modeled and 50% during the drought period modeled (Appendix 8H, Table EC-19).

At the Jones pumping plant, relative to Existing Conditions, average EC levels under Alternative 8 would also decrease substantially: 53% for the entire period modeled and 62% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 51% for the entire period modeled and 60% during the drought period modeled. (Appendix 8H, Table EC-19)

Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 8 would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas; rather, Alternative 8 would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows (see EC impact discussion under the No Action Alternative).

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC. Alternative 8 would result in lower average EC levels relative to Existing Conditions and the No Action Alternative and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

***NEPA Effects*:** In summary, the increased frequency of exceedance of EC objectives in the western Delta under Alternative 8, relative to the No Action Alternative, would contribute to adverse effects on the agricultural beneficial uses. In addition. the increased frequency of exceedance of the San Joaquin River at Prisoners Point EC objective and long-term and drought period average EC could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. Given that the western Delta is Clean Water Act section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives in this portion of the Delta has the potential to contribute to additional beneficial use impairment. The increases in long-term average EC levels that could occur in Suisun Marsh would further degrade existing EC levels and could contribute additional to adverse effects on the fish and wildlife beneficial uses. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC levels could contribute to additional beneficial use impairment. These increases in EC constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects. Implementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential EC-related changes would reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

River flow rate and reservoir storage reductions that would occur under Alternative 8, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's aggressive regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 8 would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas. There would be no exceedance of the EC objective at the Jones and Banks pumping plants. Average EC levels for the entire period modeled would decrease at both plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

In the Plan Area, Alternative 8 would result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded in the Sacramento River at Emmaton (agricultural objective; 16% increase) and Prisoners Point (fish and wildlife objective; 32% increase) in the interior Delta for the entire period modeled (1976–1991). The increased frequency of exceedance of the fish and wildlife objective at Prisoners Point could contribute to adverse effects on aquatic life (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. The increased frequency of the EC exceedance at Emmaton could contribute to adverse effects on agricultural uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The western Delta is Clean Water Act section 303(d) listed for elevated EC and the increased frequency of exceedance of EC objectives that would occur in this portion of the Delta could make beneficial use impairment measurably worse. This impact is considered to be significant.

Further, relative to Existing Conditions, Alternative 8 could result in substantial increases in long-term average EC during the months of October through May in Suisun Marsh. The increases in long-term average EC levels that would occur in Suisun Marsh could further degrade existing EC levels and thus contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in wildlife. Suisun Marsh is Clean Water Act section 303(d) listed for elevated EC and the increases in long-term average EC that would occur in the marsh could make beneficial use impairment measurably worse. This impact is considered to be significant.

Implementation of Mitigation Measure WQ-11 along with a separate other commitment relating to the potential increased costs associated with EC-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-11 is recommended to attempt to reduce the effect that increased EC concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-11, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from EC concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when EC concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B, *Environmental Commitments, AMMs, and CMs*, for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-11: Avoid, Minimize, or Offset, as Feasible, Reduced Water Quality Conditions

Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on EC under Alternative 8 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on EC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 8, the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries would be altered, relative to Existing Conditions and the No Action Alternative.

The Sacramento River at Freeport and San Joaquin River at Vernalis (as summarized for water quality average concentrations in Tables 8-48 and 8-49) were examined for flow/concentration relationships for mercury and methylmercury. No significant, predictive regression relationships were discovered for mercury or methylmercury, except for total mercury with flow at Freeport (monthly or annual) (Appendix 8I, Figures I-10 through I-13). Such a positive relationship between total mercury and flow is to be expected based on the association of mercury with suspended sediment and the mobilization of sediments during storm flows. However, the changes in flow in the

Sacramento River under Alternative 8 relative to Existing Conditions and the No Action Alternative are not of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore mercury loading should not be substantially different due to changes in flow. In addition, even though it may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but will not change substantially relative to Existing Conditions or the No Action Alternative due to changes in flows under Alternative 8.

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

The water quality impacts of waterborne concentrations of mercury and methylmercury and fish tissue mercury concentrations were evaluated for 9 Delta locations. The analysis of percentage change in assimilative capacity of waterborne total mercury of Alternative 8 relative to the 25 ng/L ecological risk benchmark as compared to Existing Conditions showed the greatest decrease of 7% for the Contra Costa Pumping Plant, and 6.9% at the same location for the No Action Alternative (Figures 8-53a and 8-54a). Similarly, changes in methylmercury concentration are expected to be relatively small. The greatest annual average methylmercury concentration for drought conditions was 0.165 ng/L for the San Joaquin River at Buckley Cove, which was slightly higher than Existing Conditions and slightly lower than the No Action Alternative (Appendix 8I, Figure I-9). All modeled input concentrations exceeded the methylmercury TMDL guidance objective of 0.06 ng/L, therefore percentage change in assimilative capacity was not evaluated for methylmercury.

Fish tissue estimates show more substantial percentage increases in concentration and exceedance quotients for mercury at some Delta locations. The greatest changes in exceedance quotients relative to Existing Conditions and the No Action Alternative are 33–40% at the Contra Costa Pumping Plant and 34–46% for Old River at Rock Slough (Figures 8-55a and 8-55b; Appendix 8I, *Mercury*, Table I-15b). Because these increases are substantial, and it is evident that substantive increases are expected at numerous locations throughout the Delta, these changes may be measurable in the environment. See Appendix 8I for a discussion of the uncertainty associated with the fish tissue estimates.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 8 are projected to be lower than Existing Conditions and the No Action Alternative at the Jones and Banks pumping plants (Appendix 8I, Figures I-8 and I-9). Therefore, mercury shows an increased assimilative capacity at these locations (Figures 8-53a and 8-54a).

The largest improvements in bass tissue mercury concentrations and exceedance quotients for Alternative 8, relative to Existing Conditions and the No Action Alternative at any location within the Delta are expected for the export pump locations (specifically, at Jones Pumping plant, 27% improvement relative to Existing Conditions, 31% relative to the No Action Alternative) (Figures 8-55a and 8-55b; Appendix 8I, Table I-15b).

NEPA Effects: Based on the above discussion, the effects of mercury and methylmercury in comparison of Alternative 8 to the No Action Alternative (as waterborne and bioaccumulated forms) are considered to be adverse for the case of fish tissue bioaccumulation at some locations.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 8, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta will not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. Monthly average waterborne concentrations of total and methylmercury, over the period of record, are very similar to Existing Conditions, but showed notable increases at some locations. Estimates of fish tissue mercury concentrations show substantial increases would occur for several sites for Alternative 8, relative to Existing Conditions.

Assessment of effects of mercury in the SWP and CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 8 as compared to Existing Conditions.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. However, increases in fish tissue mercury concentrations are substantial, and changes in fish tissue mercury concentrations would make existing mercury-related impairment in the Delta measurably worse. In comparison to Existing Conditions, Alternative 8 would increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms.

This impact is considered to be significant. Feasible or effective actions to reduce the effects on mercury resulting from CM1 are unknown. General mercury management measures through CM12, or actions taken by other entities or programs such as TMDL implementation, may minimize or reduce sources and inputs of mercury to the Delta and methylmercury formation. However, it is uncertain whether this impact would be reduced to a level that would be less than significant as a result of CM12 or other future actions. Therefore, the impact would be significant and unavoidable.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Some habitat restoration activities under Alternative 8 would occur on lands in the Delta formerly used for irrigated agriculture. Tidal and other restoration proposed under Alternative 8 have the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the restored habitat. Therefore, increases in mercury methylation in the habitat restoration areas is possible but uncertain depending on the specific restoration design implemented at a particular Delta location. Models to estimate the potential for methylmercury formation in restored areas are not currently available. However, DSM2 modeling for Alternative 8 operations does incorporate assumptions for certain habitat restoration activities proposed under CM2 and CM4 (see Section 8.3.1.3) that result in changes to Delta hydrodynamics compared to the No Action Alternative. These modeled restoration assumptions provide some insight into potential hydrodynamic changes that could be expected related to implementing CM2 and CM4 and are considered in the evaluation of the potential for increased mercury and methylmercury concentrations under Alternative 8.

CM12 addresses the potential for methylmercury bioaccumulation associated with restoration activities and acknowledges the uncertainties associated with mitigating or minimizing this potential effect. CM12 proposes project-specific mercury management plans for restoration actions that will incorporate relevant approaches recommended in Phase 1 Methylmercury TMDL control studies. Specific approaches recommended under CM12 that are intended to minimize or mitigate for potential increases in methylmercury bioaccumulation at future restoration sites include:

- Characterizing mercury, methylmercury, organic carbon, iron, and sulfate concentrations to better inform restoration design,
- Sequestering methylmercury at restoration sites using low intensity chemical dosing techniques,
- Minimizing microbial methylation associated with anoxic conditions by reducing the amount of organic material at a restoration site,
- Designing restoration sites to enhance photo degeneration that converts methylmercury into a biologically unavailable, inorganic form of mercury,
- Remediating restoration site soils with iron to reduce methylation in sulfide rich soils, and

- Considering capping mercury laden sediments, where possible to reduce methylation potential at a site.

Because of the uncertainties associated with site-specific estimates of methylmercury concentrations and the uncertainties in source modeling and tissue modeling, the effectiveness of methylmercury management proposed under CM12 to reduce methylmercury concentrations would need to be evaluated separately for each restoration effort, as part of design and implementation. Because of this uncertainty and the known potential for methylmercury creation in the Delta this potential effect of implementing CM2–CM21 is considered adverse.

***CEQA Conclusion*:** There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the CVP and SWP service areas due to implementation of CM2–CM21 relative to Existing Conditions. However, uptake of mercury from water and/or methylation of inorganic mercury may increase to an unquantified degree as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Methylmercury is 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites under Alternative 8 would be guided by CM12 which requires development of site specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time although the potential to reduce methylmercury concentrations exists based on current research. Although the BDCP will implement CM12 with the goal to reduce this potential effect the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant. No mitigation measures would be available until specific restoration actions are proposed. Therefore this programmatic impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 8 would have negligible, if any, impact on nitrate concentrations in the rivers and reservoirs upstream of the Delta in the Sacramento River watershed relative to Existing Conditions and the No Action Alternative.

Under Alternative 8, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by an estimated 6%, relative to Existing Conditions, and would remain virtually the same relative to No Action (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Given these relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River (see Appendix 8J, *Nitrate*, Figure 2), it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by changes in flow rates under Alternative 8.

Any negligible changes in nitrate-N concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to nitrate.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Results of the mixing calculations indicate that under Alternative 8, relative to Existing Conditions and the No Action Alternative, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Tables 28 and 29). Long-term average nitrate concentrations are anticipated to increase at most locations in the Delta. The increase would be greatest at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1 (all >85% increase). Long-term average concentrations were estimated to increase to 0.68, 1.06 and 1.13 mg/L-N for Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant#1, respectively, due primarily to increased San Joaquin River water percentage at these locations (see Appendix 8D, *Source Water Fingerprinting Results*). Although changes at specific Delta locations and for specific months may be substantial on a relative basis, the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds identified in Table 8-50. No additional exceedances of the MCL are anticipated at any location (Appendix 8J, Table 28). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, was up to approximately 13% at Old River at Rock Slough and Contra Costa Pumping Plant #1, and averaged approximately 6% on a long-term average basis (Appendix 8J, Table 30). Similarly, the use of available assimilative capacity at Franks Tract was up to approximately 6%, and averaged 3% over the long term. The concentrations estimated for these locations would not increase the likelihood of exceeding the 10 mg/L-N MCL, nor would they increase the risk for adverse effects to beneficial uses. At all other locations, use of assimilative capacity was negligible (<5%) (Appendix 8J, Table 30).

Nitrate concentrations will likely be higher than the modeling results indicate in certain locations. This includes in the Sacramento River between Freeport and Mallard Island and other areas in the Delta downstream of Freeport that are influenced by Sacramento River water. These increases are associated with ammonia and nitrate that are discharged from the SRWTP, which are not included in the modeling.

- Under Existing Conditions, most of the ammonia discharged from the SRWTP is converted to nitrate downstream of the facility's discharge at Freeport, and thus, nitrate concentrations under Existing Conditions in these areas are expected to be higher than the modeling predicts, the increase becoming greater with increasing distance downstream. However, the increase in nitrate concentrations downstream of the SRWTP is expected to be small—the existing increase appears to be from approximately 0.1 mg/L-N to approximately 0.4–0.5 mg/L-N over this reach, due to approximately a 1:1 conversion of ammonia-N to nitrate-N (Central Valley Water Board 2010a:32).

- Under Alternative 8, the planned upgrades to the SRWTP, which include nitrification/partial denitrification, would substantially decrease ammonia concentrations in the discharge, but would increase nitrate concentrations in the discharge up to 10 mg/L-N, which is substantially higher than under Existing Conditions.
- Overall, under Alternative 8, the nitrogen load from the SRWTP discharge is expected to decrease (by up to 50%), relative to Existing Conditions, due to nitrification/partial dentrification ugrades at the SRWTP facility. Thus, while concentrations of nitrate downstream of the facility are expected to be higher than modeling results indicate for both Existing Conditions and Alternative 8, the increase is expected to be greater under Existing Conditions than for Alternative 8 due to the upgrades that are assumed under Alternative 8.

The other areas in which nitrate concentrations will be higher than the modeling results indicate are immediately downstream of other wastewater treatment plants that practice nitrification, but not denitrification (e.g., City of Rio Vista Beach WWTF, Town of Discovery Bay WWTF, City of Stockton RWCF). For all such facilities in the Delta, the Regional Water Boards have issued NPDES permits that allow discharge of wastewater containing nitrate into the Delta, and under these permits, the State has determined that no beneficial uses are adversely affected by the discharge, and that the discharger's use of available assimilative capacity of the water body is acceptable. When dilution is necessary in order for the discharge to be in compliance with the Basin Plans (which incorporate the 10 mg/L-N MCL by reference), not all of the assimilative capacity of the receiving water is granted to the discharger. Thus, limited decreases in flows are not anticipated to result in systemic exceedances of the MCLs by these POTWs. Furthermore, NPDES permits are renewed on a 5-year basis, and thus, if under changes in flows, dilution was no longer sufficient to maintain nitrate below the MCL in the receiving water, the NPDES permit renewal process would address such cases.

Therefore, any increases in nitrate-N concentrations that may occur at certain locations within the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to nitrate.

SWP/CVP Export Service Areas

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N at the Banks and Jones pumping plants.

Results of the mixing calculations indicate that under Alternative 8, relative to Existing Conditions and the No Action Alternative, nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease on a long-term average annual basis (Appendix 8J, *Nitrate*, Tables 28 and 29). During the late summer, particularly in the drought period assessed, concentrations are expected to increase, but the absolute value of these changes (i.e., in mg/L-N) is small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Area, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.5 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP and CVP Export Service Area. No additional exceedances of the MCL are anticipated (Appendix 8J, *Nitrate*, Table 28). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the 10 mg/L-N MCL, was negligible for both Banks and Jones pumping plants (Appendix 8J, Table 30).

Any increases in nitrate-N concentrations that may occur in water exported via Banks and Jones pumping plants are not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regards to nitrate.

NEPA Effects**:** In summary, based on the discussion above, the effects on nitrate from implementing CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Nitrate-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate-N upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers). Although higher in the San Joaquin River watershed, nitrate-N concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 8, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mixing calculations indicate that under Alternative 8, relative to Existing Conditions, long-term average nitrate concentrations are anticipated to increase at most locations. The increase would be greatest at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1 (all >85% increase), due primarily to increased San Joaquin River water percentage at these locations. However, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives, and no additional exceedances of the MCL are anticipated at any location. Use of assimilative capacity at locations throughout the Delta (up to 13%) did not result in concentrations that would increase the likelihood of exceeding the 10 mg/L-N MCL, nor would they increase the risk for adverse effects to beneficial uses.

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N concentrations at the Banks and Jones pumping plants. Results of the mixing calculations indicate that under Alternative 8, relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease. No additional exceedances of the MCL are anticipated. Monthly average use of assimilative capacity available under Existing Conditions, relative to the MCL, for both Banks and Jones pumping plants in drought conditions was at times >50%, but the absolute value of these changes (i.e., in mg/L-N) was small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Area, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.3 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP and CVP Export Service Area.

Based on the above, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. No long-term water quality degradation is expected to occur such that exceedance of criteria is more likely or such that there is an increased risk of adverse impacts to beneficial uses. Nitrate is not 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on nitrate under Alternative 8 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on nitrate resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 8, there would be no substantial change to the sources of DOC within the watersheds upstream of the Delta. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows would not be expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Any negligible changes in DOC levels in water bodies upstream of the Delta under Alternative 8, relative to Existing Conditions and the No Action Alternative, would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to DOC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Under Alternative 8 relative to Existing Conditions, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be similar to that previously described for

Alternative 1A, although the magnitude of predicted long-term increase and relative frequency of concentration threshold exceedances would be substantially greater. Modeled effects would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1., where for the 16-year hydrologic period and the modeled drought period, long-term average concentration increases ranging from 0.7–1.1 mg/L would be predicted (≤32% net increase), resulting in long-term average DOC concentrations greater than 4 mg/L at Rock Slough and Contra Costa PP No. 1 (Appendix 8K, *Organic Carbon,* DOC Table 9). Increases in long-term average concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at Rock Slough and Contra Costa PP No. 1 locations. For Rock Slough, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 90% under the Alternative 8 (an increase from 47% to 88% for the drought period), and concentrations exceeding 4 mg/L would increase from 30% to 48% (32% to 57% for the drought period). For Contra Costa PP No. 1, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 93% under Alternative 8 (45% to 95% for the drought period), and concentrations exceeding 4 mg/L would increase from 32% to 55% (35% to 60% for the drought period). Relative change in frequency of threshold exceedance for other assessment locations would be similar or less. This comparison to Existing Conditions reflects changes in DOC due to both Alternative 8 operations (including north Delta intake capacity of 9,000 cfs and numerous other components of Operational Scenario F) and climate change/sea level rise.

In comparison, Alternative 8 relative to the No Action Alternative would generally result in a magnitude of change similar to that discussed for the comparison to Existing Conditions. Maximum increases of 0.7–1.0 mg/L DOC (i.e., ≤27%) would be predicted at Franks Tract, Rock Slough, and Contra Costa PP No. 1 relative to No Action Alternative (Appendix 8K, *Organic Carbon,* DOC Table 9). Threshold concentration exceedance frequency trends would also be similar to those discussed for the Existing Conditions comparison, with exception to the predicted 4 mg/L exceedance frequency at Buckley Cove. In comparison to the No Action Alternative, the frequency which long-term average DOC concentrations exceeded 4 mg/L at Buckley Cove would increase from 27% to 32% (42% to 58% for the modeled drought period). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in DOC due only to Alternative 8 operations.

The increases in long-term average DOC concentrations estimated to occur at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are considered substantial and could potentially trigger significant changes in drinking water treatment plant design or operations. In particular, assessment locations at Rock Slough and Contra Costa PP No. 1 represent municipal intakes servicing existing drinking water treatment plants. Under Alternative 8, drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. While treatment technologies sufficient to achieve the necessary DOC removals exist, implementation of such technologies would likely require substantial investment in new or modified infrastructure.

Relative to existing and No Action Alternative conditions, Alternative 8 would lead to predicted improvements in long-term average DOC concentrations at Barker Slough, as well as Banks and Jones pumping plants (discussed below). Predicted long-term average DOC concentrations at Barker Slough would decrease ≤0.1 mg/L, depending on baseline conditions comparison and modeling period.

SWP/CVP Export Service Areas

Under Alternative 8, modeled long-term average DOC concentrations would decrease at Banks and Jones pumping plants for both the modeled 16-year hydrologic period and the modeled drought period. Modeled decreases would generally be similar between Existing Conditions and the No Action Alternative. Relative to Existing Conditions, long-term average DOC concentrations at Banks would be predicted to decrease by 1.0 mg/L (1.2 mg/L during drought period) (Appendix 8K, *Organic Carbon,* DOC Table 9). At Jones, long-term average DOC concentrations would be predicted to decrease by 1.0 mg/L (1.1 mg/L during drought period). Such substantial improvement in long-term average DOC concentrations would include fewer exceedances of concentration thresholds. Average DOC concentrations exceeding the 2 mg/L concentration threshold would decrease from 100% under Existing Conditions and the No Action Alternative to 63% at Banks and 61% at Jones under Alternative 8 (62% and 57%, respectively during the drought period), while concentrations exceeding 4 mg/L would nearly be eliminated (i.e., ≤17% exceedance frequency). Such modeled improvement would correspond to substantial improvement in Export Service Areas water quality, respective to DOC.

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 8 would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area. Maintenance activities would not be expected to cause any substantial change in long-term average DOC concentrations such that MUN beneficial uses, or any other beneficial use, would be adversely affected.

NEPA Effects: In summary, Alternative 8, relative to the No Action Alternative, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Long-term average DOC concentrations at Banks and Jones pumping plants are predicted to decrease by as much as 1.3 mg/L, while long-term average DOC concentrations for some Delta interior locations, including Franks Tract, Rock Slough and Contra Costa PP #1, are predicted to increase by as much as 1.0 mg/L. Resultant substantial changes in long-term average DOC at these Delta interior locations could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality and MUN beneficial uses. Mitigation Measure WQ-17 is available to reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

While greater water demands under the Alternative 8 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of DOC. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, Alternative 8 would result in substantial increases (i.e., 0.7–1.1 mg/L) in long-term average DOC concentrations at some Delta interior locations, and would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1. At these locations the predicted changes in DOC would substantially increase the frequency with which long-term average concentrations exceeds 2, 3, or 4 mg/L. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Such predicted magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial.

The assessment of Alternative 8 effects on DOC in the SWP/CVP Export Service Areas is based on assessment of changes in DOC concentrations at Banks and Jones pumping plants. Relative to Existing Conditions, long-term average DOC concentrations would decrease by as much as 1.2 mg/L at Banks and Jones pumping plants. The frequency with which long-term average DOC concentrations would exceed 2, 3, or 4 mg/L would be substantially reduced, where predicted exceedances of >4 mg/L would be nearly eliminated (i.e., ≤17% exceedance frequency). As a result, substantial improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 8 operation and maintenance would not result in any substantial change in long-term average DOC concentration upstream of the Delta. Furthermore, under Alternative 8, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to DOC. DOC is not bioaccumulative, therefore change in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, DOC is not a constituent related to any 303(d) listings. Nevertheless, new and modified conveyance facilities proposed under Alternative 8 would result in a substantial increase in long-term average DOC concentrations (i.e., 0.7–1.1 mg/L, equivalent to ≤32% relative increase) at Franks Tract, Rock Slough, and Contra Costa PP No.1. In particular, under Alternative 8, model predicted long-term average DOC concentrations would be greater than 4 mg/L at Rock Slough and Contra Costa PP No. 1 with commensurate substantial increases in the frequency with which average DOC concentrations exceed 2, 3, and 4 mg/L levels. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Therefore, such a magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial uses at Rock Slough and Contra Costa PP No. 1 should such treatment upgrades not be undertaken. The impact is considered significant and mitigation is required. While Mitigation Measure WQ-17 is available to partially reduce this impact of DOC, the feasibility and effectiveness of this mitigation measure is uncertain and implementation would not necessarily reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Mitigation Measure WQ-17: Consult with Delta Water Purveyors to Identify Means to Avoid, Minimize, or Offset Increases in Long-Term Average DOC Concentrations

Please see Mitigation Measure WQ-17 under Impact WQ-17 in the discussion of Alternative 6A.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 8 would be similar to conservation measures under Alternative 1A. Effects on DOC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. In total, CM4–CM7 and CM10 could contribute substantial amounts of DOC to raw drinking water supplies, largely depending on final design and operational criteria for the related restoration activities. Substantially increased long-term average DOC in raw water supplies could lead to a need for treatment plant upgrades in order to appropriately manage DBP formation in treated drinking water. This potential for future DOC increases would lead to substantially greater associated risk of long-term adverse effects on the MUN beneficial use.

In summary, the habitat restoration elements of CM4–CM7 and CM10 under Alternative 8 would present new localized sources of DOC to the study area, and in some circumstances would substitute for existing sources related to replaced agriculture. Depending on localized hydrodynamics and proximity to municipal drinking water intakes, such restoration activities could contribute substantial amounts of DOC to municipal raw water. Substantial increases in municipal raw water DOC could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-18 is available to reduce these effects.

CEQA Conclusion**:** Effects of CM4–CM7 and CM10 on DOC under Alternative 8 are similar to, and possibly greater than, those discussed for Alternative 1A. Similar to the discussion for Alternative 1A, this impact is considered to be significant. It is uncertain whether implementation of Mitigation Measure WQ-18 would reduce identified impacts to a less-than-significant level. Hence, this impact remains significant and unavoidable.

In addition to and to supplement Mitigation Measure WQ-18, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from DOC concentration effects on municipal and industrial water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementing treatment for DOC and/or DBPs or DOC source control strategies. Please refer to Appendix 3B, *Environmental Commitments, AMMs, and CMs*, for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to DOC.

Mitigation Measure WQ-18: Design Wetland and Riparian Habitat Features to Minimize Effects on Municipal Intakes

Please see Mitigation Measure WQ-18 under Impact WQ-18 in the discussion of Alternative 1A.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects**:** Effects of CM1 on pathogens under Alternative 8 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion**:** Effects of CM1 on pathogens under Alternative 8 would be the same as those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

River flow rate and reservoir storage reductions that would occur due to implementation of CM1 (water facilities and operations) under Alternative 8, relative to Existing Conditions, would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta, given the small magnitude of urban runoff contributions relative to the magnitude of river flows, that pathogen concentrations in the rivers have a minimal relationship to river flow rate, and the expected reduced pollutant loadings in response to NPDES stormwater-related regulations.

It is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens. This conclusion is based on the Pathogens Conceptual Model, which found that pathogen sources in close proximity to a Delta site appear to have the greatest influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative.

In the SWP/CVP Export Service Areas waters, relative to Existing Conditions, an increased proportion of water coming from the Sacramento River would not adversely affect beneficial uses in the SWP/CVP Export Service Areas. The pathogen levels in the Sacramento River are similar to or lower than the water diverted at the Delta export pumps. Further, it is localized sources of pathogens that appear to have the greatest influence on concentrations. Thus, an increased proportion of Sacramento River water diverted to the SWP/CVP Export Service Areas would result in minimal changes in pathogen levels in the SWP/CVP Export Service Areas waters.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is Clean Water Act section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on pathogens under Alternative 8 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on pathogens resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, under Alternative 8 no specific operations or maintenance activity of the SWP or CVP would substantially drive a change in pesticide use, and thus pesticide sources would remain unaffected upstream of the Delta. Nevertheless, changes in the timing and magnitude of reservoir releases could have an effect on available dilution capacity along river segments such as the Sacramento, Feather, American, and San Joaquin Rivers.

Under Alternative 8, winter (November–March) and summer (April–October) season average flow rates on the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis would change. Relative to existing condition and the No Action Alternative, seasonal average flow rates on the Sacramento would decrease no more than 8% during the summer and 1% during the winter (Appendix 8L, *Pesticides*, Tables 1–4). On the Feather River, average flow rates would decrease no more than 18% during the summer, but would increase as much as 30% in the winter. American River average flow rates would decrease by as much as 15% in the summer but would increase by as much as 5% in the winter. Seasonal average flow rates on the San Joaquin River would decrease by as much as 12% in the summer, but increase by as much as 1% in the winter. For the same reasons stated for the No Action Alternative, decreased seasonal average flow of ≤18% is not considered to be of sufficient magnitude to substantially increase pesticide concentrations or alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of water bodies upstream of the Delta.

Delta

Sources of diuron, OP and pyrethroid insecticides to the Plan Area include direct input of surface runoff from in-Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. Similar to Upstream of the Delta, CVP/SWP operations would not affect these sources.

Under Alternative 8, the distribution and mixing of Delta source waters would change. Percentage change in monthly average source water fraction was evaluated for the modeled 16-year (1976–1991) hydrologic period and a representative drought period (1987–1991), with special attention given to changes in San Joaquin River, Sacramento River and Delta Agriculture sources water fractions. Relative to Existing Conditions, under Alternative 8 modeled San Joaquin River fractions would increase greater than 10% at Franks Tract, Rock Slough, Contra Costa PP No. 1, and the San Joaquin River at Antioch (Appendix 8D, *Source Water Fingerprinting Results*). At Antioch, San Joaquin River source water fractions when modeled for the 16-year hydrologic period would increase by 11–14% from November through May (no increase >10% for the modeled drought period). While this change at Antioch is not considered substantial, changes in San Joaquin River source water fraction in the Delta interior would be considerable. At Franks Tract, San Joaquin River source water fractions would increase between 18–29% for October through June (11–25% for November through June of the modeled drought period). Changes at Rock Slough and Contra Costa PP No. 1 would be very similar, where modeled San Joaquin River source water fractions would increase from 28–72% (15–71% for the modeled drought period) for October through June. Relative to Existing Conditions, there would be no modeled increases in Sacramento River fractions greater than 15% (with exception to Banks and Jones which are discussed below) and Delta agricultural fractions greater than 8%. Increases in San Joaquin River source water fraction at Franks Tract, Rock Slough, and Contra Costa PP NO. 1 would primarily balance through decreases in Sacramento River water, and as a result the San Joaquin River would account for greater than 50% of the total source water volume at Franks Tract between March through May (<50% for all months during the modeled drought period), and would be ≥50%, and as much as 81% during November through May at Rock Slough and Contra Costa PP No. 1 for both the modeled drought and 16-year hydrologic periods. While the source water and potential pesticide related toxicity co-occurrence predictions do not mean adverse effects would occur, such considerable modeled increases in early summer source water fraction at Franks Tract and winter and summer source water fractions at Rock Slough and Contra Costa PP No. 1 could substantially alter the long-term risk of pesticide-related toxicity to aquatic life, given the apparent greater incidence of pesticides in the San Joaquin River.

When compared to the No Action Alternative, changes in source water fractions would be similar in season, geographic extent, and magnitude to those discussed for Existing Conditions with exception to Buckley Cove during the modeled drought period. At Buckley Cove, modeled drought period San Joaquin River fractions would increase 23% in July and 28% in August when compared to No Action Alternative (Appendix 8D, *Source Water Fingerprinting Results*). These increases would primarily balance through decreases in Sacramento River water and eastside tributary waters. Nevertheless, the San Joaquin River at Buckley Cove during the modeled drought period would only account for 44% of the total source water volume in July and 39% in August. These changes at Buckley Cove are not considered substantial, however, as discussed for Existing Conditions, under the No Action Alternative the similar magnitude change at Franks Tract, Rock Slough, and Contra Costa PP No. 1 would be considered substantial and could substantially alter the long-term risk of pesticide-related toxicity to aquatic life.

These predicted adverse effects on pesticides relative to Existing Conditions and the No Action Alternative fundamentally assume that the present pattern of pesticide incidence in surface water will occur at similar levels into the future. In reality, however, the makeup and character of the pesticide use market in the late long-term (i.e., the year 2060) will not be exactly as it is today. Current use of chlorpyrifos and diazinon is on the decline with their replacement by pyrethroids on the rise, yet in this assessment it is the apparent greater incidence of diazinon and chlorpyrifos on the San Joaquin River that serves as the basis for concluding that substantially increased San Joaquin River source water fraction would correspond to an increased risk of pesticide-related toxicity to aquatic life. By 2060, however, alternative pesticides, such as neonicitinoids and biologicals, will likely be a more substantial contributing part of the existing mix of pesticides, and perhaps more prominent. The trend in the development of future-use pesticides is towards reduced risk pesticides, including more biopesticides, with greater targeted specificity, fewer residues, and lower overall non-target toxicity. By 2060 existing chlorpyrifos and diazinon TMDLs for the Sacramento and San Joaquin Rivers will have been in effect for more than 50 years. Moreover, it is reasonable to expect that CWA section 303(d) listings and future additional listings will have developed TMDLs by 2060. To the extent these existing and future TMDL's address current and future-use pesticides, a greater degree of pesticide related source control can be anticipated. Nevertheless, forecasting whether these various efforts will ultimately be successful at resolving current pesticide related impairments requires considerable speculation. While the fundamental assumptions that have guided this assessment of pesticides may be somewhat altered by 2060, these assumptions are informed by actual studies and monitoring data collected from the recent past and, therefore, judging project alternative effects in the future remain most accurate through use of these informed assumptions rather than based on assumptions founded upon future speculative conditions.

SWP/CVP Export Service Areas

Assessment of effects in SWP/CVP Export Service Areas is based on effects seen in the Plan Area at the Banks and Jones pumping plants. Under Alternative 8, Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants relative to Existing Conditions and the No Action Alternative (Appendix 8D, *Source Water Fingerprinting Results*). At Banks pumping plant, Sacramento source water fractions would generally increase from 26–78% for October through June (6–45% for December through March of the modeled drought period) and at

Jones pumping plant Sacramento source water fractions would generally increase from 42–95% for October through June (37–88% for October through June of the modeled drought period). These increases in Sacramento source water fraction would primarily balance through equivalent decreases in San Joaquin River water. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of OP insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

NEPA Effects: In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers, under Alternative 8 relative to the No Action Alternative, are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. However, modeled increases in San Joaquin River fraction at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are of sufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta. The effects on pesticides from operations and maintenance (CM1) are determined to be adverse and unavoidable.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Sources of pesticides upstream of the Delta include direct input of pesticide containing surface runoff from agriculture and urbanized areas. Flows in rivers receiving these discharges dilute these pesticide inputs. Relative to Existing Conditions, however, modeled changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta.

In the Delta, sources of pesticides include direct input of surface runoff from Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. While facilities operations and maintenance activities would not affect these sources, changes in Delta source water fraction could change the relative risk associated with pesticide related toxicity to aquatic life. Under Alternative 8, modeled long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would increase considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase.

The assessment of Alternative 8 effects on pesticides in the SWP/CVP Export Service Areas is based on assessment of changes predicted at Banks and Jones pumping plants. Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants and would generally represent an improvement in export water quality respective to pesticides.

Based on the above, Alternative 8 would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions would not be expected to make any of these beneficial use impairments measurably worse, with principal exception to locations in the Delta that would receive a substantially greater fraction San Joaquin River water under Alternative 8. Long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would change considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase. Additionally, the potential for increased incidence of pesticide related toxicity could include pesticides such as chlorpyrifos and diazinon for which existing 303(d) listings exist for the Delta, and thus existing beneficial use impairment could be made discernibly worse. The impact is considered to be significant and unavoidable. There is no feasible mitigation available to reduce the effect of this significant impact.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** CM2–CM21 under Alternative 8 would be similar to conservation measures under Alternative 1A. Effects on pesticides resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. In summary, CM13 proposes the use of herbicides to control invasive aquatic vegetation around habitat restoration sites. Herbicides directly applied to water could include adverse effects on non-target aquatic life, such as aquatic invertebrates and beneficial aquatic plants. As such, aquatic life toxicity objectives could be exceeded with sufficient frequency and magnitude such that beneficial uses would be impacted, thus constituting an adverse effect on water quality.

In summary, based on the discussion above, the effects on pesticides from implementing CM2-CM21 are considered to be adverse. Mitigation Measure WQ-22 would be available to reduce this adverse effect.

***CEQA Conclusion*:** Effects of CM2–CM21 on pesticides under Alternative 8 are similar to those discussed for Alternative 1A. Potential environmental effects related only to CM13 are considered to be significant. Mitigation is required. While Mitigation Measure WQ-22 is available to partially reduce this impact of pesticides, no feasible mitigation is available that would reduce it to a level that would be less than significant.

Mitigation Measure WQ-22: Implement Least Toxic Integrated Pest Management Strategies

Please see Mitigation Measure WQ-22 under Impact WQ-22 in the discussion of Alternative 1A.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance (CM1)

***NEPA Effects*:** Effects of water facilities and operations (CM1) on phosphorus levels in water bodies of the affected environment under Alternative 8 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels discussed in detail for Alternative 1A also adequately represent the effects under Alternative 8, which are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Because phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration upstream of the Delta are not anticipated for Alternative 8, relative to Existing Conditions.

Because phosphorus concentrations in the major source waters to the Delta are similar for much of the year, phosphorus concentrations in the Delta are not anticipated to change substantially on a long term-average basis under Alternative 8, relative to Existing Conditions. Algal growth rates are limited by availability of light in the Delta, and therefore any minor increases in phosphorus levels that may occur at some locations and times within the Delta would be expected to have little effect on primary productivity in the Delta.

The assessment of effects of phosphorus under Alternative 8 in the SWP and CVP Export Service Areas is based on effects on phosphorus at the Banks and Jones pumping plants. As noted above, phosphorus concentrations in the Delta (including Banks and Jones pumping plants) are not anticipated to change substantially on a long term-average basis.

Based on the above, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas under Alternative 8 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on phosphorus levels in water bodies of the affected environment under Alternative 8 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels from implementing CM2–CM21 discussed in detail for Alternative 1A also adequately represent the effects of these same actions under Alternative 8, which are considered to be not adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on phosphorus resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 8 would have negligible, if any, effect on selenium concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in selenium concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to selenium.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics. To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, such as additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See Section 8.3.1.3 for more information.

Selenium concentrations and threshold comparisons for each of the 11 modeled Delta assessment locations under Alternative 8, relative to Existing Conditions and the No Action Alternative, are presented in Appendix 8M, *Selenium*, Table M-9a for water, Tables M-18 and M-28 for most biota (whole-body fish [excluding sturgeon], bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, and Tables M-30 through M-32 for sturgeon at the two western Delta locations. Figures 8-59a and 8-60a present graphical distributions of predicted selenium concentration changes (shown as changes in available assimilative capacity based on 1.3 µg/L) in water at each modeled assessment location for all years. Appendix 8M, Figure M-24 provides more detail in the form of monthly patterns of selenium concentrations in water during the modeling period.

Alternative 8 would result in small to moderate changes in average selenium concentrations in water at modeled Delta assessment locations relative to Existing Conditions and the No Action Alternative (Appendix 8M, *Selenium*, Table M-9a). Long-term average concentrations at some interior and western Delta locations would increase by 0.01–0.14 µg/L for the entire period modeled (1976–1991). These increases in selenium concentrations in water would result in reductions in available assimilative capacity for selenium of 1-13%, relative to the 1.3 µg/L USEPA draft water quality criterion (Figures 8-59a and 8-60a). The long-term average selenium concentrations in water for Alternative 8 (range 0.09–0.39 µg/L) would be similar to Existing Conditions (range 0.09–0.41 µg/L) and the No Action Alternative (range 0.09–0.38 µg/L), and all would be below the USEPA draft water quality criterion of 1.3 µg/L (Appendix 8M, Table 9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 8 would generally result in small changes (less than 4%) in estimated selenium concentrations in most biota (whole-body fish (excluding sturgeon), bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-28). Despite the small changes in selenium concentrations in biota, Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0 (indicating low probability of adverse effects). Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years also are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by about 31% relative to Existing Conditions and to the No Action Alternative in all years (from about 4.7 to 6.1 mg/kg dry weight). Likewise, those for sturgeon in the Sacramento River at Mallard Island are predicted to increase by about 17% in all years (from about 4.4 to 5.2 mg/kg dry weight) (Appendix 8M, Tables M-30 and M-31). Selenium concentrations in sturgeon during drought years are expected to increase by 23% at Antioch and 11% at Mallard Island. Detection of changes in whole-body sturgeon such as those estimated for the western Delta may require large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at both locations (as they do for Existing Conditions and the No Action Alternative) and for all years at Antioch, whereas Existing Conditions and the No Action Alternative do not (quotient increases from 0.94 to 1.2 at Antioch) (Appendix 8M, Table M-32). High Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at Antioch unlike Existing Conditions and the No Action Alternative (quotient increases from 0.85 to 1.1) (Appendix 8M, Table M-32).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in the appendix, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. (There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium.) Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on "fixed" K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Increased water residence times could increase the bioaccumulation of selenium in biota, thereby potentially increasing fish tissue and bird egg concentrations of selenium (see residence time discussion in Appendix 8M, *Selenium*, and Presser and Luoma [2010b]). Thus, residence time was assessed for its relevance to selenium bioaccumulation. Table 8-60a shows the time for neutrally buoyant particles to move through the Delta (surrogate for flow and residence time). Although an increase in residence time throughout the Delta is expected under the No Action Alternative, relative to Existing Conditions (because of climate change and sea level rise), the change is fairly small in most areas of the Delta.

Relative to Existing Conditions and the No Action Alternative, increases in residence times for Alternative 8 would be greater in the South Delta and East Delta than in other sub-regions. Relative to Existing Conditions, annual average residence times for Alternative 8 in the South Delta are expected to increase by more than 37 days (Table 8-60a). and in the East Delta increase by more than 23 days. Increases in residence times for other sub-regions would be smaller, especially as compared to Existing Conditions and the No Action Alternative (which are longer than those modeled for the South Delta). As mentioned above, these results incorporate hydrodynamic effects of both CM1 and CM2 and CM4, and the effects of CM1 cannot be distinguished from the effects of CM2 and CM4. However, it is expected that CM2 and CM4 are substantial drivers of the increased residence time.

Presser and Luoma (2010b) summarized and discussed selenium uptake in the Bay-Delta (including hydrologic conditions [e.g., Delta outflow and residence time for water], K_ds [the ratio of selenium concentrations in particulates, as the lowest level of the food chain, relative to the water-borne concentration], and associated tissue concentrations [especially in clams and their consumers, such as sturgeon]). When the Delta Outflow Index (daily average flow per month) decreased by five-fold (73,732 cfs in June 1998 to 12,251 cfs in October 1998), residence time doubled (from 11 to 22 days) and the calculated mean K_d also doubled (from 3,198 to 6,501). However, when daily average Delta outflow in November 1999 was only 6,951 cfs (i.e., about one-half that in October 1998) and residence time was 70 days, the calculated mean K_d (7,614) did not increase proportionally.

Models are not available to quantitatively estimate the level of changes in selenium bioaccumulation as related to residence time, but the effects of residence time are incorporated in the bioaccumulation modeling for selenium that was based on higher K_d values for drought years in comparison to wet, normal, or all years; see Appendix 8M, *Selenium*. If increases in fish tissue or bird egg selenium were to occur, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. In consideration of this factor, although the Delta as a whole is a CWA Section 303(d)-listed water body for selenium, and although monitoring data of fish tissue or bird eggs in the Delta are sparse, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time from restoration areas would be a concern is the western Delta and Suisun Bay for sturgeon, as discussed above. As shown in Table 8-60a, the overall increase in residence time estimated in the western Delta is 4 days relative to Existing Conditions, and 2 days relative to the No Action Alternative. Given the available information, these increases are small enough that they are not expected to substantially affect selenium bioaccumulation in the western Delta. Because CM2 and CM4 are expected to be substantial drivers of the increased residence times, further discussion is included in Impact WQ-26 below.

In summary, relative to Existing Conditions and the No Action Alternative, Alternative 8 would result in small changes in selenium concentrations throughout the Delta for most biota (less than 4%), although larger increases in selenium concentrations are predicted for sturgeon in the western Delta. Concentrations of selenium in sturgeon would exceed the lower benchmark for both western

Delta locations for all years and drought years, indicating a low potential for effects. Concentrations of selenium in sturgeon would exceed the higher benchmark for Antioch only in drought years, indicating a high potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, the predicted increases for Alternative 8 are high enough that they may represent a measureable increase in body burdens of sturgeon, which would constitute an adverse impact.

SWP/CVP Export Service Areas

Alternative 8 would result in moderate (0.08–0.15 μg/L) decreases in average selenium concentrations at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative, for the entire period modeled (Appendix 8M, *Selenium*, Table M-9a). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium at these pumping plants of 8–16%, relative to the 1.3 μg/L ecological benchmark (Figures 8-59a and 8-60a). Furthermore, the long-term average selenium concentrations in water for Alternative 8 (range 0.09–0.39 μg/L) would be well below the USEPA draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 8 would result in small changes (less than 4%) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) at SWP/CVP service areas (Figures 8-61a through 8-64b; Appendix 8M, *Selenium*, Table M-28). Concentrations in biota would not exceed any selenium benchmarks for Alternative 8 (Figures 8-61a through 8-64b).

NEPA Effects: Based on the discussion above, the effects on selenium from Alternative 8 are considered to be adverse. This determination is reached because selenium concentrations in whole-body sturgeon modeled at two western Delta locations would increase by an average of 30%, which may represent a measurable increase in the environment. These potentially measurable increases represent an adverse impact.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for selenium. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 8, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate that Alternative 8 would result in small changes in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. Relative to Existing Conditions, modeling estimates indicate that Alternative 8 would increase selenium concentrations in whole-body sturgeon modeled at two western Delta locations by an estimated 21%, which may represent a measureable increase in the environment. Because both low and high toxicity benchmarks are exceeded, these potentially measureable increases represent a potential impact on fish and wildlife beneficial uses.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 8 would cause no increase in the frequency with which applicable benchmarks would be exceeded, and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants locations.

Based on the above, although waterborne selenium concentrations would not exceed applicable water quality objectives/criteria; however, significant impacts on some beneficial uses of waters in the Delta could occur because uptake of selenium from water to biota may measurably increase such that high toxicity benchmarks may be exceeded. In comparison to Existing Conditions, water quality conditions under this alternative would increase levels of selenium (a bioaccumulative pollutant) by frequency, magnitude, and geographic extent such that the affected environment may have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish); however, impacts to humans consuming those organisms are not expected to occur. Water quality conditions under this alternative with respect to selenium would cause long-term degradation of water quality in the western Delta. Except in the vicinity of the western Delta for sturgeon, water quality conditions under this alternative would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms. The greater level of selenium bioaccumulation in the western Delta would further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. This impact is considered significant. *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on selenium under Alternative 8 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on selenium resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 8 would result in negligible, and likely immeasurable, increases in trace metal concentrations in the rivers and reservoirs upstream of the Delta, relative to Existing Conditions and the No Action Alternative. Effects due to the operation and maintenance of the conveyance facilities are expected to be immeasurable, on an annual and long-term average basis. As such, Alternative 8 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to trace metals.

Delta

For the same reasons stated for the No Action Alternative, Alternative 8 would not result in substantial increases in trace metal concentrations in the Delta relative to Existing Conditions and the No Action Alternative. However, substantial changes in source water fraction would occur in the south Delta (Appendix 8D, *Source Water Fingerprinting Results*). Throughout much of the south Delta, San Joaquin River water would replace Sacramento River water, with the future trace metals profile largely reflecting that of the San Joaquin River. As discussed for the No Action Alternative, trace metal concentration profiles between the San Joaquin and Sacramento Rivers are very similar and currently meet Basin Plan objectives and CTR criteria. While the change in trace metal concentrations in the south Delta would likely be measurable, Alternative 8 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the Delta or substantially degrade the quality of Delta waters with regard to trace metals.

SWP/CVP Export Service Areas

For the same reasons stated for the No Action Alternative, Alternative 8 would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities. As such, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP export service area waters under Alternative 8, relative to Existing Conditions and the No Action Alternative. As such, Alternative 8 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment in the SWP and CVP Service Area or substantially degrade the quality of these water bodies, with regard to trace metals.

NEPA Effects: In summary, Alternative 8, relative to the No Action Alternative, would not cause a substantial increase in long-term average trace metals concentrations within the affected environment, nor would it cause an increased frequency of water quality objective/criteria exceedances within the affected environment. The effect on trace metals is determined not to be adverse.

CEQA Conclusion: Effects of CM1 on trace metals under Alternative 8 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

While greater water demands under the Alternative 8 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based without a WER adjustment. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under the Alternative 8.

The assessment of the Alternative 8 effects on trace metals in the SWP/CVP Export Service Areas is based on assessment of changes in trace metal concentrations at Banks and Jones pumping plants. As just discussed regarding similarities in Delta source water trace metal concentrations, the Alternative 8 is not expected to result in substantial changes in trace metal concentrations in Delta waters, including Banks and Jones pumping plants, therefore effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

There would be no substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area waters under Alternative 8 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 8 would be similar to conservation measures under Alternative 1A. Effects on trace metals resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. As they pertain to trace metals, implementation of CM2–CM21 would not be expected to adversely affect beneficial uses of the affected environment or substantially degrade water quality with respect to trace metals.

In summary, implementation of CM2–CM21 under Alternative 8, relative to the No Action Alternative, would have negligible, if any, effect on trace metals concentrations. The effect on trace metals from implementing CM2–CM21 is determined not to be adverse.

CEQA Conclusion: Implementation of CM2–CM21 under Alternative 8 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance (CM1)

***NEPA Effects*:** Effects of CM1 on TSS and turbidity under Alternative 8 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

***CEQA Conclusion*:** Effects of CM1 on TSS and turbidity under Alternative 8 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Changes river flow rate and reservoir storage that would occur under Alternative 8, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes would be site-specific and temporal, which would be regulated to limit both their short-term and long-term effects on TSS and turbidity levels to less than substantial levels.

Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the Delta region, relative to Existing Conditions.

There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative 8, relative to Existing Conditions, because as stated above, this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act section 303(d) listed constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on TSS and turbidity under Alternative 8 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 8 would be similar to conservation measures proposed under Alternative 1A. As such, effects on TSS and turbidity resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

The conveyance features for CM1 under Alternative 8 would be very similar to those discussed for Alternative 1A. The primary difference between Alternative 8 and Alternative 1A is that under Alternative 8, there would be two fewer intakes and two fewer pumping plant locations, which would result in a reduced level of construction activity. Additional construction activity also would occur to restore channel margin and seasonally inundated floodplain habitats. However, construction techniques and locations of major features of the conveyance system within the Delta would be similar. The remainder of the facilities constructed under Alternative 8, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A. However, under Alternative 8, there would be up to 20,000 acres of inundated floodplain habitat restored (as opposed to 10,000 acres under the majority of the other alternatives), thus resulting in increased construction-related disturbances.

***NEPA Effects*:** The types and magnitude of potential construction-related water quality effects associated with implementation of CM1–CM21 under Alternative 8 would be very similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. Nevertheless, the construction of CM1, and any individual components necessitated by CM2, and CM4–CM10, with the implementation of the BMPs specified in Appendix 3B*, Environmental Commitments, AMMs, and CMs,* and other agency permitted construction requirements would result in the potential water quality effects being largely avoided and minimized. The specific environmental commitments that would be implemented under Alternative 8 would be similar to those described for Alternative 1A. Consequently, relative to Existing Conditions, Alternative 8 would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP and CVP service area.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

CEQA Conclusion**:** Because environmental commitments would be implemented under Alternative 8 for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32. Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance (CM1)

Effects of facilities and operations (CM1) on *Microcystis* abundance, and thus microcystins concentrations, in water bodies of the affected environment under Alternative 8 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. This is because factors that affect *Microcystis* abundance in waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Services Areas under Alternative 1A would similarly change under Alternative 8, relative to Existing Conditions and the No Action Alternative. For the Delta in particular, there are differences in the direction and magnitude of water residence time changes during the *Microcystis* bloom period among the six Delta sub-regions under Alternative 8 compared to Alternative 1A, relative to Existing Conditions and No Action Alternative. However, under Alternative 8, relative to Existing Conditions and No Action Alternative, water residence times during the *Microcystis* bloom period in various Delta sub-regions are expected to increase to a degree that could, similar to Alternative 1A, lead to an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms throughout the Delta.

Similar to Alternative 1A, elevated ambient water temperatures relative to Existing Conditions would occur in the Delta under Alternative 8, which could lead to earlier occurrences of *Microcystis* blooms in the Delta, and increase the overall duration and magnitude of blooms. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. While *Microcystis* blooms have not occurred in the Export Service Areas, conditions in the Export Service Areas under Alternative 8 may become more conducive to *Microcystis* bloom formation, relative to Existing Conditions, because water temperatures will increase in the Export Service Areas due to the expected increase in ambient air temperatures resulting from climate change.

NEPA Effects: Effects of water facilities and operations (CM1) on *Microcystis* in water bodies of the affected environment under Alternative 8 would be very similar to (i.e., nearly the same) to those discussed for Alternative 1A. In summary, Alternative 8 operations and maintenance, relative to the

No Action Alternative, would result in long-term increases in hydraulic residence time of various Delta sub-regions during the summer and fall *Microcystis* bloom period. During this period, the increased residence time could result in a concurrent increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus microcystin levels, in affected areas of the Delta. As a result, Alternative 8 operation and maintenance activities would cause further degradation to water quality with respect to *Microcystis* in the Delta. Under Alternative 8, relative to No Action Alternative, water exported to the SWP/CVP Export Service Area will be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River, diverted at the north Delta intakes. It cannot be determined whether operations and maintenance under Alternative 8 will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants. Mitigation Measure WQ-32a and WQ-32b are available to reduce the effects of degraded water quality in the Delta. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 8, additional impacts from *Microcystis* in the reservoirs and watersheds upstream of the Delta are not expected, relative to Existing Conditions. Operations and maintenance occurring under Alternative 8 is not expected to change nutrient levels in upstream reservoirs or hydrodynamic conditions in upstream rivers and streams such that conditions would be more conductive to *Microcystis* production.

Relative to Existing Conditions, water temperatures and hydraulic residence times in the Delta are expected to increase under Alternative 8, resulting in an increase in the frequency, magnitude and geographic extent of *Microcystis* blooms in the Delta. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. Increases in Delta residence times are expected throughout the Delta during the summer and fall bloom period, due in small part to climate change and sea level rise, but due more proportionately to CM1 and the hydrodynamic impacts of restoration included in CM2 and CM4. The precise change in local residence times and *Microcystis* production expected within any Delta sub-region is unknown because conditions will vary across the complex networks of intertwining channels, shallow back water areas, and submerged islands that compose the Delta. Nonetheless, Delta residence times are, in general, expected to increase due to Alternative 8. Consequently, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 8 and the hydrodynamic impacts of restoration (CM2 and CM4).

The assessment of effects of *Microcystis* on SWP/CVP Export Service Areas is based on the assessment of changes in *Microcystis* levels in export source waters, as well as the effects of temperature and residence time changes within the Export Service Areas on *Microcystis* production. Under Alternative 8, relative to Existing Conditions, the potential for *Microcystis* to occur in the Export Service Area is expected to increase due to increasing water temperature, but this impact is driven entirely by climate change and not Alternative 8. Water exported from the Delta to the Export Service Area is expected to be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River. Because of this, it cannot be determined whether operations and maintenance under Alternative 8, relative to existing conditions, will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants.

Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, because it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 8 and the hydrodynamic impacts of restoration (CM2 and CM4), long-term water quality degradation may occur and, thus, significant impacts on beneficial uses could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be significant.

Implementation of Mitigation Measure WQ-32a and WQ-32b may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of these mitigation measures to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Mitigation Measure WQ-32b: Investigate and Implement Operational Measures to Manage Water Residence Time

Please see Mitigation Measure WQ-32b under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-33. Effects on *Microcystis* Bloom Formation Resulting from Other Conservation Measures (CM2–CM21)

The effects of CM2–CM21 on *Microcystis* under Alternative 8 would be the same as those discussed for Alternative 1A. In summary, implementation of CM2 and CM4 could result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta, relative to Existing Conditions and the No Action Alternative, as a result of increased residence times for Delta waters from. Because the hydrodynamic effects associated with implementing CM2 and CM4 were incorporated into the modeling used to assess CM1, a detailed assessment of the effects of implementing CM2 and CM4 on *Microcystis* blooms in the Delta via their effects on Delta water residence time is provided under CM1 (above). The effects of CM2 and CM4 on *Microcystis* may be reduced by implementation of Mitigation Measures WQ-32a. The effectiveness of the mitigation measure to result in feasible measures for reducing water quality effects is uncertain. CM3 and

CM5–CM21 would not result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta.

Implementation of Mitigation Measure WQ-32a may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

NEPA Effects: Effects of CM2–CM21 on *Microcystis* under Alternative 8 would be the same as those discussed for Alternative 1A and are considered to be adverse.

CEQA Conclusion: Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. Because restoration actions implemented under CM2 and CM4 will increase residence time throughout the Delta and create local areas of warmer water during the bloom season, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus long-term water quality degradation and significant impacts on beneficial uses, could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM2–CM21 are determined to be significant.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance (CM1) and Implementation of CM2–CM21

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 8 would have a less than significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- DO
- Pathogens
- Pesticides
- Trace Metals
- Turbidity and TSS

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Thus, changes in boron, DO, pathogens, pesticides, and turbidity and TSS in Delta outflow are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay.

The effects of Alternative 8 on bromide, chloride, and DOC, in the Delta were determined to be significant/adverse. Increases in bromide, chloride, and DOC concentrations are of concern in drinking water supplies; however, as described previously, the San Francisco Bay does not have a designated MUN use. Thus, changes in bromide, chloride, and DOC in Delta outflow would not adversely effect any beneficial uses of San Francisco Bay.

Elevated EC, as assessed for this alternative, is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. As discussed above, San Francisco Bay does not have an AGR beneficial use designation. Further, as discussed for the No Action Alternative, changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow, which would be the primary driver of salinity changes, would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow.

Also, as discussed for the No Action Alternative, adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in San Francisco Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus have not been detected downstream of Suisun Bay.

While effects of Alternative 8 on the nutrients ammonia, nitrate, and phosphorus were determined to be less than significant/not adverse, these constituents are addressed further below because the response of the seaward bays to changed nutrient concentrations/loading may differ from the response of the Delta. Selenium and mercury are discussed further, because they are bioaccumulative constituents where changes in load due to both changes in Delta concentrations and exports are of concern.

Nutrients: Ammonia, Nitrate, and Phosphorus

Total nitrogen loads in Delta outflow to Suisun and San Pablo Bays under Alternative 8 would be dominated almost entirely by nitrate, because planned upgrades to the SRWTP will result in >95% removal of ammonia in its effluent. Total nitrogen loads to Suisun and San Pablo Bays would decrease by 9%, relative to Existing Conditions, and increase by 33%, relative to the No Action Alternative (Appendix 8O, *San Francisco Bay Analysis*, Table O-1). The change in nitrogen loading to Suisun and San Pablo Bays under Alternative 8 would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. To the extent that algal growth increases in relation to a change in ammonia concentration, this would have net positive benefits, because current algal levels in these embayments are low. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay.

The phosphorus load exported from the Delta to Suisun and San Pablo Bays for Alternative 8 is estimated to increase by 14%, relative to Existing Conditions, and increase by 9% relative to the No

Action Alternative (Appendix 8O, Table O-1). The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. Any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary (Senn and Novick 2014; Kimmerer and Thompson 2014). Therefore, the projected change in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay is not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Mercury

The estimated long-term average mercury and methylmercury loads in Delta exports are shown in Appendix 8O, Table O-2. Loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 8. Mercury load to the Bay is estimated to increase by 16 kg/year (6%), relative to Existing Conditions, and 13 kg/year (5%), relative to the No Action Alternative. Methylmercury load is estimated to increase by 0.40 kg/year (11%), relative to Existing Conditions, and increase by 0.31 kg/year (8%) relative to the No Action Alternative. The estimated total mercury load to the Bay is 276 kg/year, which would be less than the San Francisco Bay mercury TMDL WLA for the Delta of 330 kg/year. The estimated changes in mercury and methylmercury loads would be within the overall uncertainty associated with the estimates of long-term average net Delta outflow and the long-term average mercury and methylmercury concentrations in Delta source waters. The estimated changes in mercury load under the alternative would also be substantially less than the considerable differences among estimates in the current mercury load to San Francisco Bay (San Francisco Bay Regional Water Quality Control Board 2006; David et al. 2009).

Given that the estimated incremental increases of mercury and methylmercury loading to San Francisco Bay would fall within the uncertainty of current mercury and methylmercury load estimates, the estimated changes in mercury and methylmerucy loads in Delta exports to San Francisco Bay due to Alternative 8 are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to mercury, or make the existing CWA Section 303(d) impairment measurably worse.

Selenium

Changes in source water fraction and net Delta outflow under Alternative 8, relative to Existing Conditions, are projected to cause the total selenium load to the North Bay to increase by 24%, relative to Existing Conditions, and increase by 20%, relative to the No Action Alternative (Appendix 8O, Table O-3). Changes in long-term average selenium concentrations of the North Bay are assumed to be proportional to changes in North Bay selenium loads. Under Alternative 8, the long-term average total selenium concentration of the North Bay is estimated to be 0.16μg/L and the dissolved selenium concentration is estimated to be 0.14 μg/L, which would be a 0.03 μg/L increase relative to Existing Conditions and the No Action Alternative (Appendix 8O, Table O-3). The dissolved selenium concentration would be below the target of 0.202 μg/L developed by Presser and Luoma (2013) to coincide with a white sturgeon whole-body fish tissue selenium concentration not greater than 8 mg/kg in the North Bay.

The incremental increase in dissolved selenium concentrations projected to occur under Alternative 8, relative to Existing Conditions and the No Action Alternative, would be higher than under Alternatives 1A–5, but still low (0.03 µg/L). The increased dissolved selenium concentration would be within the overall uncertainty of the analytical methods used to measure selenium in water column samples; however, it also would be within the uncertainty associated with estimating numeric water column selenium thresholds (Pressor and Luoma 2013). As described in Section 8.3.1.8, there have been improvements in selenium concentrations in the tissue of diving ducks and muscle of white sturgeon since the initial CWA Section 303(d) listing of the North Bay for selenium impairments, and selenium concentrations in white sturgeon muscle have also generally been below the USEPA's draft recommended fish muscle tissue concentration of 11.8 mg/kg dry weight (San Francisco Estuary Institute 2014). However, as described under Impact WQ-25, though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases for Alternative 8 are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Because the projected incremental increases in dissolved selenium could cause measurable changes in water column concentrations, and these incremental increases would be within the uncertainty in the target water column threshold for dissolved selenium for protection against adverse bioaccumulative effects in the North Bay ecosystem, and modeling predicts concentrations in the western Delta may represent a measurable increase in body burdens of sturgeon, there is potential that the incremental increase in dissolved selenium concentration projected to occur in the North Bay under Alternative 8 could result in adverse effects beneficial uses.

NEPA Effects: Based on the discussion above, Alternative 8, relative to the No Action Alternative, would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, based on the discussion above, effects on the San Francisco Bay from implementation of CM1–CM21 are considered to be not adverse with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. However, Alternative 8 could result in increases in selenium concentrations in the North San Francisco Bay that could result in adverse effects to fish and wildlife beneficial uses. This effect is considered to be adverse.

CEQA Conclusion: Based on the above, Alternative 8 would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Further, based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals or turbidity or TSS are anticipated in the Delta, relative to Existing Conditions, therefore, no substantial changes these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow. Adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in the Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus not have not been detected downstream of Suisun Bay. The 9% decrease in total nitrogen load and 14% increase in phosphorus load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. The estimated increase in mercury load (16 kg/year; 6%) and methylmercury load (0.40 kg/year; 11), relative to Existing Conditions, is within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans.

In regard to selenium, the estimated increase in selenium load would be 24% and the estimated increase in dissolved selenium concentrations would be 0.03 μg/L. Though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Thus, the increase in selenium load may make the CWA section 303(d) selenium impairment measurably worse and cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish and wildlife. This impact is considered to be significant. *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

8.3.3.16 Alternative 9—Through Delta/Separate Corridors (15,000 cfs; Operational Scenario G)

Under Alternative 9, two fish-screened intakes would be constructed–one at the Delta Cross Channel and the other at Georgiana Slough. Water would be conveyed through a flow-collection channel and radial gates, eventually reaching the existing channel. Once in the channel, water would flow south through the Mokelumne River and San Joaquin River to Middle River and Victoria Canal, which would be dredged to accommodate increased flows. Along the way, diverted water would be guided by operable barriers. Water flowing through Victoria Canal would lead into two new canal segments and pass under two existing watercourses through culvert siphons, eventually reaching Clifton Court Forebay. From there, water would flow through existing SWP facilities, and a new canal would be constructed to connect the forebay to CVP facilities. Water supply and conveyance operational criteria under Alternative 9 would be guided by criteria identified in Scenario G. CM2–CM21 would be implemented under this alternative, and would be the same as those under Alternative 1A. See Chapter 3, *Description of Alternatives,* Section 3.5.16, for additional details on Alternative 9.

Effects of the Alternative on Delta Hydrodynamics

Under the No Action Alternative and Alternatives 1A–9, the following two primary factors can substantially affect water quality within the Delta:

- Within the south, west, and interior Delta, a decrease in the percentage of Sacramento River-sourced water and a concurrent increase in San Joaquin River-sourced water can increase the concentrations of numerous constituents (e.g., boron, bromide, chloride, electrical conductivity, nitrate, organic carbon, some pesticides, selenium). This source water replacement is caused by decreased exports of San Joaquin River water (due to increased Sacramento River water exports), or effects of climate change on timing of flows in the rivers. Changes in channel flows also can affect water residence time and many related physical, chemical, and biological variables.
- Particularly in the west Delta, sea water intrusion as a result of sea level rise or decreased Delta outflow can increase the concentration of salts (bromide, chloride) and levels of electrical conductivity. Conversely, increased Delta outflow (e.g., as a result of Fall X2 operations in wet and above normal water years) will decrease levels of these constituents, particularly in the west Delta.

Under Alternative 9, over the long term, average annual delta exports are anticipated to decrease by 766 TAF relative to Existing Conditions, and by 63 TAF relative to the No Action Alternative. Although all of the diversions are from the existing south Delta intakes, the operable barriers included under this alternative would result in the exported water containing a higher proportion of Sacramento River water as opposed to San Joaquin River water (see Chapter 5, *Water Supply*, for more information). The result of this would be greatly increased San Joaquin River water influence throughout the south, west, and interior Delta, and a corresponding decrease in Sacramento River water influence. This can be seen, for example, in Appendix 8D, *Source Water Fingerprinting Results*, Figure 271, which shows increased San Joaquin River (SJR) percentage and decreased Sacramento River (SAC) percentage under the alternative, relative to Existing Conditions and the No Action Alternative.

Under Alternative 9, long-term average annual Delta outflow is anticipated to increase 807 TAF relative to Existing Conditions, due to both changes in operations (including use of operable barriers and numerous other components of Operational Scenario G) and climate change/sea level rise (see Chapter 5, *Water Supply*, for more information). The result of this is decreased sea water intrusion in the west Delta. The decrease of sea water intrusion in the west Delta under Alternative 9 would be greater relative to the Existing Conditions because Existing Conditions do not include operations to meet Fall X2, whereas the No Action Alternative and Alternative 9 do. Long-term average annual Delta outflow is anticipated to increase under Alternative 9 by 57 TAF relative to the No Action Alternative, due only to changes in operations. The decreases in sea water intrusion (represented by an decrease in San Francisco Bay (BAY) percentage) can be seen, for example, in Appendix 8D, Figure 271.

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 9 would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to

Existing Conditions and the No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

Assessment of effects of ammonia under Alternative 9 is the same as discussed under Alternative 1A, except that because flows in the Sacramento River at Freeport are different between the two alternatives, estimated monthly average and long term annual average predicted ammonia-N concentrations in the Sacramento River downstream of Freeport are different.

As Table 8-72 shows, estimated ammonia-N concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 9 and the No Action Alternative are expected to be similar. Minor increases in ammonia-N concentrations would occur during January through March, July, October, and December, and remaining months would be unchanged or have a minor decrease. A minor increase in the annual average concentration would occur under Alternative 9, compared to the No Action Alternative. Moreover, the estimated concentrations downstream of Freeport under Alternative 9 would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 9, relative to the No Action Alternative, are not expected to substantially increase ammonia concentrations at any Delta locations.

Table 8-72. Estimated Ammonia-N (mg-L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative and Alternative 9

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative	0.074	0.084	0.069	0.060	0.057	0.060	0.058	0.064	0.067	0.060	0.067	0.064	0.065
Alternative 9	0.076	0.084	0.070	0.061	0.058	0.061	0.058	0.063	0.067	0.061	0.067	0.064	0.066

Any negligible increases in ammonia-N concentrations that could occur at certain locations in the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

SWP/CVP Export Service Areas

The assessment of effects on ammonia in the SWP/CVP Export Service Area is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. Similar to the discussion for Alternative 1A, under Alternative 9 for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease, relative to Existing Conditions (in association with less diversion of water influenced by the SRWTP). This decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in adverse effects on beneficial uses or substantially degrade water quality of exported water, with regards to ammonia.

Furthermore, as discussed above for the Plan Area, for all areas of the Delta, including Banks and Jones pumping plants, ammonia-N concentrations are not expected to be substantially different under Alternative 9, relative to No Action Alternative. Any negligible increases in ammonia-N concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to ammonia.

NEPA Effects: In summary, based on the discussion above, effects on ammonia from implementation of CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Ammonia-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to the lack of substantial point and nonpoint sources of ammonia-N upstream of the SRWTP in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 9, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river ammonia-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

Ammonia-N concentrations in the Sacramento River downstream of the SRWTP would be substantially lower under Alternative 9, relative to Existing Conditions, due to upgrades to the SRWTP that are assumed to be in place, and thus, ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water are expected to decrease. At locations which are not influenced notably by Sacramento River water, concentrations are expected to remain relatively unchanged, due to the similarity in SJR and BAY concentrations and the lack of expected changes in either of these concentrations.

The assessment of effects on ammonia in the SWP/CVP Export Service Areas is based on assessment of ammonia-N concentrations at Banks and Jones pumping plants. As discussed above for the Plan Area, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 9, relative to Existing Conditions.

Based on the above, there would be no substantial, long-term increase in ammonia-N concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 9 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia-N is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on ammonia under Alternative 9 would be the same as those discussed for Alternative 1A and are considered to be not adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on ammonia resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Effects of CM1 on boron under Alternative 9 in areas upstream of the Delta would be very similar to the effects discussed for Alternative 1A. There would be no expected change to the sources of boron in the Sacramento and eastside tributary watersheds, and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled long-term annual average lower San Joaquin River flow at Vernalis would decrease slightly compared to Existing Conditions (in association with changed operations, climate change, and increased water demands) and the No Action Alternative considering only changes due to Alternative 9 operations. The reduced flow would result in possible increases in long-term average boron concentrations of up to about 3% relative to the Existing Conditions (Appendix 8F, *Boron*, Table Bo-32). The increased boron concentrations would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 9 would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to the Existing Conditions and No Action Alternative, Alternative 9 would result in similar or reduced long-term average boron concentrations for the 16-year period modeled at northern and eastern Delta locations, with a substantial reduction in boron concentrations in the San Joaquin River at Buckley Cove. Long-term average boron concentrations would increase at interior and western Delta locations (by as much as 66% at Franks Tract, 80% at Old River at Rock Slough, and 9% at the Sacramento River at Emmaton) (Appendix 8F, *Boron*, Table Bo-22). The comparison to Existing Conditions reflects changes due to both Alternative 9 operations (including use of operable barriers and numerous other components of Operational Scenario G) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes due only to operations.

Implementation of tidal habitat restoration under CM4 also may contribute to increased boron concentrations at western Delta assessment locations (more discussion of this phenomenon is included in Section 8.3.1.3), and thus would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations. The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 µg/L human health advisory objective (i.e., for children) or 500 µg/L agricultural objective at any of the eleven Delta assessment locations, which represents no change from the Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-3A). The increased concentrations at interior Delta locations would result in moderate reductions in the long-term average assimilative capacity of up to 33% at Franks Tract and up to 46% at Old River at Rock Slough locations (Appendix 8F, Table Bo-23). However, because the absolute boron concentrations would still be well below the lowest 500 µg/L objective for the protection of the agricultural beneficial use under Alternative 9, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, Figure Bo-5).

SWP/CVP Export Service Areas

Effects of CM1 on boron under Alternative 9 in the Delta would be similar to the effects discussed for Alternative 1A. Under Alternative 9, long-term average boron concentrations would decrease by as much as 18% at the Banks Pumping Plant and by as much as 31% at Jones Pumping Plant relative to Existing Conditions and No Action Alternative (Appendix 8F, *Boron*, Table Bo-22) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading.

Maintenance of SWP and CVP facilities under Alternative 9 would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment. Maintenance activities would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative conditions, Alternative 9 would result in moderate increases in long-term average boron concentrations in the Delta and not appreciably change boron levels in the lower San Joaquin River. However, the predicted changes in the Delta would not be expected to result in exceedances of applicable objectives or further water quality degradation such that objectives would likely be exceeded or there would be substantially increased risk of adverse effect on water quality.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Boron is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 9, relative to Existing Conditions, would not be expected to result in a substantial adverse change in boron levels. Additionally, relative to Existing Conditions, Alternative 9 would not result in reductions in river flow rates (i.e., less dilution) or increased boron loading such that there would be any substantial increases in boron concentration upstream of the Delta in the San Joaquin River watershed.

Moderate increased boron levels (i.e., up to 82% increased concentration) and degradation predicted for interior and western Delta locations in response to a shift in the Delta source water percentages and tidal habitat restoration under this alternative would not be expected to cause exceedances of objectives. Alternative 9 maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 9 would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to Existing Conditions, Alternative 9 would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 9, while widespread in particular at interior Delta locations, would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Consequently, Alternative 9 would not be expected to cause any substantial increases in boron concentrations or degradation with respect to boron such that objectives would be exceeded more frequently, or any beneficial uses would be adversely affected anywhere in the affected environment. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on boron under Alternative 9 would be the same as those discussed for Alternative 1A and are determined to be not adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on boron resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 9 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 9 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. Consequently, Alternative 9 would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the eastside tributaries, or their associated reservoirs upstream of the Delta.

Under Alternative 9, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by 6%, relative to Existing Conditions and would remain virtually the same relative to the No Action Alternative (see Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). These decreases in flow would result in possible increases in long-term average bromide concentrations of about 3% relative to Existing Conditions and less than <1% relative to the No Action Alternative (Appendix 8E, *Bromide*, Table 24). The small increases in lower San Joaquin River bromide levels that could occur under Alternative 9, relative to existing and No Action Alternative conditions would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the lower San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Using the mass-balance modeling approach for bromide (see Section 8.3.1.3), relative to Existing Conditions, Alternative 9 would result in increases in long-term average bromide concentrations at Buckley Cove (for the modeled drought period only), Emmaton, and Barker Slough, while long-term average concentrations would decrease at the other assessment locations (Appendix 8E, *Bromide*, Table 20). With regard to bromide, Emmaton is a suitable source of raw drinking water on a seasonal basis. While the relative change in long-term average bromide concentration at Emmaton is considerable (≤32%), the increase in the average would be due to more frequent seasonal peak concentrations in excess of 1,000 μg/L relative to Existing Conditions, particularly during October through December (Appendix 8E, *Bromide*, Figure 2). At Emmaton the predicted 50 μg/L exceedance frequency would increase only slightly from 82% under Existing Conditions to 86% under Alternative 9 (98% to 100% for the modeled drought period), and the predicted 100 μg/L exceedance frequency would increase from 72% under Existing Conditions to 81% under Alternative 9 (93% to 97% for the modeled drought period), indicative of very small changes during seasonally suitable periods of potential use. At Barker Slough, predicted long-term average bromide concentrations would increase from 51 μg/L to 61 μg/L (19% relative increase) for the modeled 16-year hydrologic period and 54 μg/L to 100 μg/L (88% relative increase) for the modeled drought period. At Barker Slough, the predicted 50 μg/L exceedance frequency would decrease from 49%

under Existing Conditions to 41% under Alternative 9, but would increase from 55% to 80% during the drought period. At Barker Slough, the predicted 100 μg/L exceedance frequency would increase from 0% under Existing Conditions to 16% under Alternative 9, and would increase from 0% to 42% during the drought period. At Buckley Cove, predicted long-term average bromide concentrations would remain the same (i.e., 259 μg/L), but would increase from 272 μg/L to 330 μg/L (21% relative increase) for the modeled drought period. At Buckley Cove, the predicted 50 μg/L exceedance frequency would not change (i.e., 100% exceedance), but the modeled 100 μg/L exceedance frequency would decrease from 100% under Existing Conditions to 90% under Alternative 9 (100% to 87% for the modeled drought period). This comparison to Existing Conditions reflects changes in bromide due to both Alternative 9 operations (including use of operable barriers and numerous other components of Operational Scenario G) and climate change/sea level rise.

Due to the relatively small differences between modeled Existing Conditions and No Action baselines, changes in long-term average bromide concentrations and changes in exceedance frequencies relative to the No Action Alternative would be generally of similar magnitude to those previously described for the Existing Conditions comparison (Appendix 8E, *Bromide*, Table 20). Modeled long-term average bromide concentration at Emmaton would increase by as much as 36%, but change in 50 and 100 μg/L exceedance thresholds would be smaller than that described for the Existing Conditions comparison, indicative of very small changes during seasonally suitable periods of potential use. Modeled long-term average bromide concentration at Barker Slough is predicted to increase by 23% (87% for the modeled drought period) relative to the No Action Alternative. Modeled long-term average bromide concentration increases at Buckley Cove are predicted to increase by 7% (36% for the modeled drought period) relative to the No Action Alternative. Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in bromide due only to Alternative 9 operations.

At Barker Slough, modeled long-term average bromide concentrations for the various baseline conditions are very similar (≤4%) (Appendix 8E, *Bromide*, Table 20). Such similarity demonstrates that the modeled Alternative 9 change in bromide is almost entirely due to Alternative 9 operations, and not climate change/sea level rise. Therefore, operations are the primary driver of effects on bromide at Barker Slough, regardless whether Alternative 9 is compared to Existing Conditions, or compared to the No Action Alternative.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) differed somewhat from what is presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 21). For most locations, the frequency of exceedance of the 50 μg/L and 100 μg/L were similar. The greatest difference between the methods was predicted for Barker Slough. The increases in frequency of exceedance of the 100 μg/L threshold, relative to Existing Conditions and the No Action Alternative, were not as great using this alternative EC to chloride and chloride to bromide relationship modeling approach as compared to that presented above from the mass-balance modeling approach. However, there were still substantial increases, resulting in 9% exceedance over the modeled period under Alternative 9, as compared to 1% under Existing Conditions and 2% under the No Action Alternative. For the drought period, exceedance frequency increased from 0% under Existing Conditions and the No Action Alternative, to 23% under Alternative 9.Furthermore, concentrations predicted at Buckley Cove also differed. The EC to chloride and chloride to bromide relationship modeling approach predicted that concentrations at Buckley cove would decrease under Alternative 9 on both a long term basis and under the modeled drought period, relative to Existing Conditions and the No Action Alternative.

This is in contrast to the mass-balance approach presented above, which predicted an increase in concentrations under the drought period. Because the mass-balance approach predicts a greater level of impact at Barker Slough, determination of impacts was based on the mass-balance results.

While the increase in long-term average bromide concentrations at Buckley Cove are relatively small when modeled over a representative 16-year hydrologic period, increases during the modeled drought period, principally the long-term average bromide concentration greater than 300 µg/L, would represent a substantial change in source water quality to the City of Stockton during a season of drought. Additionally, the increase in long-term average bromide concentrations predicted at Barker Slough, principally the relative increase in 100 µg/L exceedance frequency, would result in a substantial change in source water quality for existing drinking water treatment plants drawing water from the North Bay Aqueduct. While the implications of such modeled changes in bromide concentrations at Buckley Cove and Barker Slough is difficult to predict, the substantial modeled increases could lead to adverse changes in the formation of disinfection byproducts such that considerable treatment plant upgrades may be necessary in order to achieve equivalent levels of health protection. Because many of the other modeled locations already frequently exceed the 100 µg/L threshold under Existing Conditions and the No Action Alternative, these locations likely already require treatment plant technologies to achieve equivalent levels of health protection, and thus no additional treatment technologies would be triggered by the small increases in the frequency of exceeding the 100 µg/L threshold. Hence, no further impact on the drinking water beneficial use would be expected at these locations.

The seasonal intakes at Mallard Slough and City of Antioch are infrequently used due to water quality constraints related to sea water intrusion. On a long-term average basis, bromide at these locations is in excess of 3,000 µg/L, but during seasonal periods of high Delta outflow can be <300 µg/L. Based on modeling using the mass-balance approach, use of the seasonal intakes at Mallard Slough and City of Antioch under Alternative 9 would experience a period average increase in bromide during the months when these intakes would most likely be utilized. For those wet and above normal water year types where mass balance modeling would predict water quality typically suitable for diversion, predicted long-term average bromide would increase from 103 µg/L to 140 µg/L (37% increase) at City of Antioch and would decrease from 150 µg/L to 146 µg/L (3% decrease) at Mallard Slough relative to Existing Conditions (Appendix 8E, *Bromide*, Table 25). Changes would be similar for the No Action Alternative comparison. Modeling results using the EC to chloride and chloride to bromide relationships show increases during these months, but the relative magnitude of the increases is much lower (Appendix 8E, *Bromide*, Table 26). Regardless of the differences in the data between the two modeling approaches, the decisions surrounding the use of these seasonal intakes is largely driven by acceptable water quality, and thus have historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at the City of Antioch and Mallard Slough intake would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

Based on modeling using the mass-balance approach, relative to existing and No Action Alternative conditions, Alternative 9 would lead to predicted improvements in long-term average bromide concentrations at Staten Island, Franks Tract, Rock Slough, and Contra Costa PP No. 1, in addition to Banks and Jones (discussed below). At Staten Island and Franks Tract, long-term average bromide concentrations would be predicted to decrease by 4–21% depending on baseline comparison, while at Rock Slough and Contra Costa PP No.1, long-term average bromide concentrations would be predicted to decrease by 40–45%, depending on baseline comparison. Modeling results using the EC to chloride and chloride to bromide relationships generally do not show similar decreases for Rock

Slough and Contra Costa PP No. 1, but rather, predict small increases. Based on the small magnitude of increases predicted, these increases would not adversely affect beneficial uses at those locations.

Important to the results presented above is the assumed habitat restoration footprint on both the temporal and spatial scales incorporated into the modeling. Modeling sensitivity analyses have indicated that habitat restoration (which are reflected in the modeling—see Section 8.3.1.3), not operations covered under CM1, are the driving factor in the modeled bromide increases. The timing, location, and specific design of habitat restoration will have effects on Delta hydrodynamics, and any deviations from modeled habitat restoration and implementation schedule will lead to different outcomes. Although habitat restoration near Barker Slough is an important factor contributing to modeled bromide concentrations at the North Bay Aqueduct, BDCP habitat restoration elsewhere in the Delta can also have large effects. Because of these uncertainties, and the possibility of adaptive management changes to BDCP restoration activities, including location, magnitude, and timing of restoration, the estimates are not predictive of the bromide levels that would actually occur in Barker Slough or elsewhere in the Delta.

SWP/CVP Export Service Areas

Under Alternative 9, improvement in long-term average bromide concentrations would occur at the Banks and Jones pumping plants, with exception to the modeled drought period when compared the No Action Alternative. Long-term average bromide concentrations for the modeled 16-year hydrologic period at these locations would decrease by as much as 21% relative to Existing Conditions and 9% relative to the No Action Alternative (Appendix 8E, *Bromide*, Table 20). However, during the modeled drought period, long-term average bromide concentrations would increase by as much as 12% relative to the No Action Alternative. Exceedances of the 50 µg/L assessment threshold would remain virtually the same for both Banks and Jones, but exceedance of the 100 µg/L assessment threshold would decrease, from 100% to 81% at Banks and from 100% to 80% at Jones (100% to 77% for the modeled drought period at both Banks and Jones). Lower long-term average bromide concentrations at Banks and Jones would result in overall improvement in Export Service Areas water quality respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also be observed since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in bromide is difficult to predict, the relative decrease in overall loading of bromide to the Export Service Areas would likely alleviate or lessen any expected increase in bromide concentrations at Vernalis (see discussion of Upstream of the Delta) as well as locations in the Delta receiving a large fraction of San Joaquin River water, such as much of the south Delta.

The discussion above is based on results of the mass-balance modeling approach. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide (see Section 8.3.1.3) were consistent with the discussion above, and assessment of bromide using these data results in the same conclusions as are presented above for the mass-balance approach (see Appendix 8E, *Bromide*, Table 21).

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 9 would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that

MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, Alternative 9 operations and maintenance, relative to the No Action Alternative, would result in small increases (i.e., <1%) in long-term average bromide concentrations at Vernalis related to relatively small declines in long-term average flow on the San Joaquin River. However, Alternative 9 operation and maintenance activities would cause substantial degradation to water quality with respect to bromide at Barker Slough, source of the North Bay Aqueduct. Resultant substantial change in long-term average bromide at Barker Slough could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-5 is available to reduce these effects (implementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects).

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 9 there would be no expected change to the sources of bromide in the Sacramento and eastside tributary watersheds. Bromide loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations under Alternative 9 would have negligible, if any, effects on the concentration of bromide in the rivers and reservoirs of these watersheds. However, south of the Delta, the San Joaquin River is a substantial source of bromide, primarily due to the use of irrigation water imported from the southern Delta. Concentrations of bromide at Vernalis are inversely correlated to net river flow. Under Alternative 9, long-term average flows at Vernalis would decrease only slightly, resulting in less than substantial predicted increases in long-term average bromide of about 3% relative to Existing Conditions.

Relative to Existing Conditions, Alternative 9 would result in modeled increases in long-term average bromide concentration at Buckley Cove (for the drought period only), Barker Slough, and Emmaton. While the relative change in long-term average bromide concentration at Emmaton is considerable (≤32%), the increase in the average would be due to more frequent seasonal peak concentrations in excess of 1,000 μg/L relative to Existing Conditions, rather than substantial increases during seasonally suitable periods of potential use. However, substantial increases in long-term average bromide at Barker Slough and Buckley Cove (i.e., vicinity of the City of Stockton's drinking water intake) during a season of drought could lead to adverse changes in the formation of disinfection byproducts at drinking water treatment plants such that considerable water treatment plant upgrades would be necessary in order to achieve equivalent levels of drinking water health protection.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Under Alternative 9, substantial improvement would occur at the Banks and Jones pumping plants, where predicted long-term average bromide concentrations are predicted to decrease by as much as 21% relative to

Existing Conditions. An overall improvement in bromide-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 9 operation and maintenance would not result in any substantial change in long-term average bromide concentration upstream of the Delta. Furthermore, under Alternative 9, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to bromide. Bromide is not bioaccumulative, therefore change in long-term average bromide concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, bromide is not a constituent related to any 303(d) listings. Alternative 9 operation and maintenance activities would not cause substantial long-term degradation to water quality respective to bromide with the exception of water quality at Buckley Cove (drought period only) and Barker Slough. At Buckley Cove, modeled long-term annual average concentrations of bromide would increase from 272 μg/L to 330 μg/L (21% relative increase) during the modeled drought period. At Barker Slough, modeled long-term annual average concentrations of bromide would increase from 54 μg/L to 100 μg/L (88% relative increase) for the modeled drought period. Furthermore, for Barker Slough the frequency of predicted bromide concentrations exceeding 100 μg/L would increase from 0% under Existing Conditions to 16% under Alternative 9 (0% to 42% for the modeled drought period). Substantial changes in long-term average bromide at these locations could necessitate changes in treatment plant operation or require treatment plant upgrades in order to maintain DBP compliance. The model predicted change at Buckley Cove during the drought period and at Barker Slough is substantial and, therefore, would represent a substantially increased risk for adverse effects on existing MUN beneficial uses should treatment upgrades not be undertaken. The impact is considered significant. However, there is no feasible mitigation available for identified impacts at Buckley Cove, which would remain significant and unavoidable during drought periods.

Implementation of Mitigation Measure WQ-5 along with a separate other commitment relating to the potential increased treatment costs associated with bromide-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-5 is recommended to attempt to reduce the effect that increased bromide concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-5, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate othercommitment to address the potential increased water treatment costs that could result from bromide-related concentration effects on municipal water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementation of the North Bay Aqueduct AIP, acquiring alternative water supplies, or other actions to indirectly reduce the effects of elevated bromide and DOC in existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-5: Avoid, Minimize, or Offset, as Feasible, Adverse Water Quality Conditions

Please see Mitigation Measure WQ-5 under Impact WQ-5 in the discussion of Alternative 1A.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 9 would be similar to conservation measures under Alternative 1A, but with changes in the south Delta to accommodate the modified corridors. As discussed for Alternative 1A, implementation of CM2–CM21 would not present new or substantially changed sources of bromide to the study area. Some conservation measures may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution is not expected to substantially increase or present new sources of bromide. CM2–CM21 would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

In summary, implementation of CM2–CM21 under Alternative 9, relative to the No Action Alternative, would have negligible, if any, effects on bromide concentrations. The effects on bromide from implementing CM2–CM21 are determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As discussed for Alternative 1A, implementation of CM2–CM21 would not present new or substantially changed sources of bromide to the study area. As such, effects on bromide resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 9 there would be no expected change to the sources of chloride in the Sacramento and eastside tributary watersheds. Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. The modeled long-term annual average flows on the lower San Joaquin River at Vernalis would decrease slightly compared to Existing Conditions and be similar compared to the No Action Alternative (as a result of climate change). The reduced flow would result in possible increases in long-term average chloride concentrations of about 2%, relative to the Existing Conditions and no change relative to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-62). Consequently, Alternative 9 would not be expected to cause exceedance of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are

included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to the Existing Conditions and No Action Alternative, Alternative 9 would result in similar or reduced long-term average chloride concentrations for the 16-year period modeled at some of the assessment locations, and, depending on the modeling approach (see Section 8.3.1.3), increased concentrations at the North Bay Aqueduct at Barker Slough (i.e., up to 20% compared to No Action Alternative), Contra Costa Canal at Pumping Plant #1 (i.e., up to 23% compared to No Action Alternative), Rock Slough (i.e., up to 20% compared to No Action Alternative), Franks Tract (i.e., up to 29% compared to No Action Alternative), Sacramento River at Emmaton (i.e., up to 25% compared to No Action Alternative), Sacramento River at Mallard Island (i.e., up to 6% compared to No Action Alternative), and North Bay Aqueduct at Barker Slough (i.e., up to 18% compared to No Action Alternative)(Appendix 8G, *Chloride*, Tables Cl-55 and Cl-56). Moreover, the direction and magnitude of predicted changes for Alternative 9 are similar between the alternatives, thus, the effects relative to Existing Conditions and the No Action Alternative are discussed together. Additionally, implementation of tidal habitat restoration under CM4 would increase the tidal exchange volume in the Delta, and thus may contribute to increased chloride concentrations in the Bay source water as a result of increased salinity intrusion. More discussion of this phenomenon is included in Section 8.3.1.3. Consequently, while uncertain, the magnitude of chloride increases may be greater than indicated herein and would affect the western Delta assessment locations the most which are influenced to the greatest extent by the Bay source water. The comparison to Existing Conditions reflects changes in chloride due to both Alternative 9 operations (including use of operable barriers and numerous other components of Operational Scenario G) and climate change/sea level rise. The comparison to the No Action Alternative reflects changes in chloride due only to operations. The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses

Estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at both the Antioch and Contra Costa Pumping Plant #1 locations. For Alternative 9, the modeled frequency of objective exceedance would increase from 7% of years under Existing Conditions and 0% under the No Action Alternative to 13% of years under Alternative 9 (Appendix 8G, *Chloride*, Table Cl-64).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 9, the modeled frequency of objective exceedance would decrease, from 6% of modeled days under Existing Conditions and 5% under the No Action Alternative to 1% of modeled days under Alternative 9 (Appendix 8G, *Chloride*, Table Cl-63).

Given the limitations inherent to estimating future chloride concentrations (see Section 8.3.1.3), estimation of chloride concentrations through both amass balance approach and an EC-chloride relationship approach was used to evaluate the 250 mg/L Bay-Delta WQCP objectives in terms of both frequency of exceedance and use of assimilative capacity. When utilizing the mass balance approach to model monthly average chloride concentrations for the 16-year period, the predicted frequency of exceeding the 250 mg/L objective would be eliminated at the Contra Costa Canal at Pumping Plant #1 (24% for Existing Conditions to 0% under Alternative 9), thus indicating complete compliance with this objective would be achieved (Appendix 8G, *Chloride*, Table Cl-57 and Figure Cl-13). Compared to Existing Conditions, the frequency of exceedances would not change substantially at the San Joaquin River at Antioch (i.e., increase of 2% from 66% to 68%) or at Mallard Island (i.e., increase6% from 77% to 83%) and would be similar, or decrease, compared to the No Action Alternative (Appendix 8G, Table Cl-57), and there would be no substantial long-term degradation (Appendix 8G, Table Cl-59).

In comparison, when utilizing the chloride-EC relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance generally agreed, but use of assimilative capacity were predicted to be larger at some locations (Appendix 8G, *Chloride*, Tables Cl-58 and Cl-60). Specifically, while the model predicted exceedance frequency would decrease at the Contra Costa Canal at Pumping Plant #1, Rock Slough, and Franks Tract locations, use of assimilative capacity would increase substantially for the months of February through July at Rock at the Contra Costa Canal at Pumping Plant #1 (i.e., maximum of 79% in March and April for the modeled drought period) and at the San Joaquin River in March and April (i.e., 13% and 14%, respectively). Due to such seasonal long-term average water quality degradation at these locations, the potential exists for substantial adverse effects on the municipal and industrial beneficial uses through reduced opportunity for diversion of water with acceptable chloride levels. Moreover, due to the increased frequency of exceeding the 150 mg/L Bay-Delta WQCP objective, the potential exists for adverse effects on the municipal and industrial beneficial uses at Contra Costa Pumping Plant #1 and Antioch.

303(d) Listed Water Bodies

With respect to the 303(d) listing for chloride in Tom Paine Slough, the monthly average chloride concentrations for the 16-year period modeled at Old River at Tracy Road, which represents the nearest DSM2-modeled location to Tom Paine in the south Delta, would generally be similar compared to Existing Conditions and No Action Alternative, and thus, would not be further degraded on a long-term basis (Appendix 8G, Figure Cl-14).

With respect to Suisun Marsh, the monthly average chloride concentrations for the 16-year period modeled would generally increase compared to Existing Conditions and No Action Alternative in some months during October through May at the Sacramento River at Collinsville (Appendix 8G, Figure Cl-15), Mallard Island (Appendix 8G, Figure Cl-13), and increase substantially at Montezuma Slough at Beldon's Landing (i.e., over a doubling of concentration in December through February) (Appendix 8G, Figure Cl-16). Although modeling of Alternative 9 assumed no operation of the Montezuma Slough Salinity Control Gates, the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results for Suisun Marsh, but EC levels were still somewhat higher than EC levels under Existing Conditions for several locations and months. Although chloride was not specifically modeled in this sensitivity analysis, it is expected that chloride concentrations would be nearly proportional to EC levels in Suisun Marsh. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to Existing Conditions, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases in salinity are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term chloride increases in the Marsh. However, the chloride concentration increases at certain locations could be substantial, depending on siting and design of restoration areas. Thus, these increased chloride levels in Suisun Marsh are considered to contribute to additional, measureable long-term degradation that potentially would adversely affect the necessary actions to reduce chloride loading for any TMDL that is developed.

SWP/CVP Export Service Areas

Under Alternative 9, long-term average chloride concentrations based on the mass balance analysis of modeling results for the 16-year period modeled at the Banks and Jones pumping plants would decrease by as much as 21% relative to Existing Conditions and 10% compared to No Action Alternative (Appendix 8G, *Chloride*, Table Cl-55). The modeled frequency of exceedances of applicable water quality objectives/criteria would decrease relative to Existing Conditions and No Action Alternative, for both the 16-year period and the drought period modeled (Appendix 8G, *Chloride*, Table Cl-57). Consequently, water exported into the SWP/CVP service area would generally be of similar or better quality with regards to chloride relative to Existing Conditions and the No Action Alternative conditions.

Results of the modeling approach which used relationships between EC and chloride (see Section 8.3.1.3) were consistent with the discussion above, and assessment of chloride using these data results in the same conclusions as are presented above for the mass-balance approach (Appendix 8G, Tables Cl-56 and Cl-58).

Commensurate with the reduced chloride concentrations in water exported to the service area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely alleviate or lessen any expected increase in chloride at Vernalis related to decreased annual average San Joaquin River flows (see discussion of Upstream of the Delta).

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

***NEPA Effects*:** In summary, relative to the No Action Alternative conditions, Alternative 9 would result in additional exceedances of the 150 mg/L Bay-Delta WCCP objective at Contra Costa Pumping Plant #1 and Antioch, substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1, Rock Slough and Franks Tract, and potentially measureable water quality degradation relative to the 303(d) impairment in Suisun Marsh. The predicted chloride increases constitute an adverse effect on water quality (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Additionally, the predicted changes relative to the No

Action Alternative conditions indicate that in addition to the effects of climate change/sea level rise, implementation of CM1 and CM4 under Alternative 9 would contribute substantially to the adverse water quality effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the Alternative 9, relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, the Alternative 9 would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, Alternative 9 operations would result in substantially reduced chloride concentrations in the Delta such that exceedances of the 250 mg/L Bay-Delta WQCP objective at the San Joaquin River at Antioch and Mallard Slough would be reduced. Nevertheless, due to the predicted increased frequency of exceeding the 150 mg/L Bay-Delta WQCP objective at Contra Costa Pumping Plant #1 and Antioch as well as substantial seasonal use of assimilative capacity at Contra Costa Pumping Plant #1and Antioch, the potential exists for adverse effects on the municipal and industrial beneficial uses (see Mitigation Measure WQ-7; implementation of this measure along with a separate other commitment relating to the potential increased chloride treatment costs would reduce these effects). Moreover, the modeled increased chloride concentrations and degradation in the western Delta could further contribute, at measurable levels, to the existing 303(d) listed impairment due to chloride in Suisun Marsh for the protection of fish and wildlife.

Chloride concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under Alternative 9 would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 9 maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas. However, based on these findings, this impact is determined to be significant due to increased chloride concentrations and frequency of objective exceedance in the western Delta, as well as potential adverse effects on fish and wildlife beneficial uses in Suisun Marsh.

While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-7 is recommended to attempt to reduce the effect that increased chloride concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-7, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from chloride concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when chloride concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-7: Conduct Additional Evaluation and Modeling of Increased Chloride Levels and Develop and Implement Phased Mitigation Actions

Please see Mitigation Measure WQ-7 under Impact WQ-7 in the discussion of Alternative 1A.

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Under Alternative 9, the types and geographic extent of effects on chloride concentrations in the Delta as a result of implementation of the other conservation measures (i.e., CM2–CM21) would be similar to, and undistinguishable from, those effects previously described for Alternative 1A. The conservation measures would present no new direct sources of chloride to the affected environment. Moreover, some habitat restoration conservation measures (CM4–10) would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored tidal wetlands, floodplain, and related channel margin and off-channel habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement compared to Existing Conditions and No Action Alternative conditions.

In summary, based on the discussion above, the effects on chloride from implementing CM2-CM21 are considered to be not adverse.

CEQA Conclusion**:** Implementation of the CM2–CM21 for Alternative 9 would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP service area. Replacement of irrigated agricultural land uses in the Delta with habitat restoration conservation measures may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects**:** Effects of CM1 on DO under Alternative 9 would be the same as those discussed for Alternative 1A and are determined to be not adverse.

CEQA Conclusion**:** Effects of CM1 on DO under Alternative 9 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Reservoir storage reductions that would occur under Alternative 9, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions that would occur would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state has begun to aggressively regulate the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters under Alternative 9, relative to Existing Conditions. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to ever increasing water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. This impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on DO under Alternative 9 would be the same as those discussed for Alternative 1A and are determined to be not adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on DO resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, their associated reservoirs, and the San Joaquin River upstream of the Delta under Alternative 9 are not expected to be outside the ranges occurring under Existing Conditions or would occur under the No Action Alternative. Any minor changes in EC levels that could occur under Alternative 9 in water bodies upstream of the Delta would not be of sufficient magnitude, frequency and geographic extent that would cause adverse effects on beneficial uses or substantially degrade water quality with regard to EC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Relative to Existing Conditions, Alternative 9 would result in an increase in the number of days the Bay-Delta WQCP EC objectives would be exceeded in the Sacramento River at Emmaton, and the San Joaquin River at San Andreas Landing and Jersey Point (Appendix 8H, *Electrical Conductivity*, Table EC-9).

The percentage of days the Emmaton EC objective would be exceeded for the entire period modeled (1976–1991) would increase from 6% under Existing Conditions to 18% under Alternative 9, and the percentage of days out of compliance would increase from 11% under Existing Conditions to 31% under Alternative 9.

The percentage of days the Jersey Point EC objective would be exceeded and the percentage of days out of compliance would increase from 0% under Existing Conditions to 2% under Alternative 9. The increase in percentage of days the San Andreas Landing EC objective would be exceeded and the percentage of days out of compliance would be <1%. These increases are minimal, and are not considered substantial, in light of overall modeling uncertainty.

Average EC levels at the western and southern Delta compliance locations, except at Emmaton in the western Delta, and S. Fork Mokelumne River at Terminous (an interior Delta location) would decrease from 1–33% for the entire period modeled and 2–33% during the drought period modeled (1987–1991) (Appendix 8H, *Electrical Conductivity*, Table EC-20). In the Sacramento River at Emmaton, average EC would increase 22% for the entire period modeled and 36% during the drought period modeled. In the San Joaquin River at San Andreas Landing, average EC would increase 16% for the entire period modeled and 33% during the drought period modeled. Average EC in the Sacramento River at Emmaton and San Joaquin River at San Andreas Landing would increase during all months (Appendix 8H, Table EC-20). In the San Joaquin River at Prisoners Point, average EC would increase 2% for the entire period modeled and 16% during the drought period modeled. Average EC at Prisoners Point would increase in September through December (Appendix

8H, Table EC-20). The western portion of the Delta—which is Clean Water Act section 303(d) listed as impaired due to elevated EC—would have an increased frequency of exceedance of the Bay-Delta WQCP objectives (Appendix 8H, Table EC-9) and long-term average EC levels at compliance locations in this region would increase relative to Existing Conditions (Appendix 8H, Table EC-20). Thus, Alternative 9 could contribute to additional impairment and potentially adversely affect beneficial uses for section 303(d) listed Delta waterways, relative to Existing Conditions. The comparison to Existing Conditions reflects changes in EC due to both Alternative 9 operations (including use of operable barriers and numerous other components of Operational Scenario G) and climate change/sea level rise.

Relative to the No Action Alternative, the change in percentage compliance with Bay-Delta WQCP EC objectives under Alternative 9 would be similar to that described above relative to Existing Conditions, except there would not be an increase in objective exceedance in the San Joaquin River at Jersey Point. For the entire period modeled, average EC levels would increase in the Sacramento River at Emmaton, and San Joaquin River at San Andreas Landing and Prisoners Point. The greatest average EC increase would occur in the San Joaquin River at San Andreas Landing (22%); the increase at Emmaton would be 21% and at Prisoners Point would be 12% (Appendix 8H, *Electrical Conductivity*, Table EC-20). Similarly, during the drought period modeled, average EC would increase at these locations. The greatest average EC increase during the drought period modeled also would occur in the San Joaquin River at San Andreas Landing (33%); the average EC increase at Emmaton would be 24% and at Prisoners Point would be 25% (Appendix 8H, Table EC-20). The western portion of the Delta–which is Clean Water Act section 303(d) listed as impaired due to elevated EC–would have an increased frequency of exceedance of the Bay-Delta WQCP objectives (Appendix 8H, Table EC-9) and long-term average EC levels at this compliance location would increase relative to the No Action Alternative (Appendix 8H, Table EC-20). Thus, Alternative 9 could contribute to additional impairment and potentially adversely affect beneficial uses for section 303(d) listed Delta waterways, relative to the No Action Alternative. The comparison to the No Action Alternative reflects changes in EC due only to Alternative 9 operations (including use of operable barriers and numerous other components of Operational Scenario G).

For Suisun Marsh, October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Long-term average EC would increase under Alternative 9, relative to Existing Conditions, during the months of December through May by 0.2–0.4 mS/cm in the Sacramento River at Collinsville (Appendix 8H, *Electrical Conductivity*, Table EC-21). In Montezuma Slough at National Steel during January and February, long-term average EC would increase 0.1–0.2 mS/cm (Appendix 8H, Table EC-22). The most substantial increase would occur near Beldon Landing, with long-term average EC levels increasing by 1.5–6.3 mS/cm, depending on the month, nearly doubling and tripling during some months the long-term average EC relative to Existing Conditions (Appendix 8H, Table EC-23). Sunrise Duck Club and Volanti Slough also would have long-term average EC increases during February–May of 1.5–3.9 mS/cm (Appendix 8H, Tables EC-24 and EC-25). Modeling of this alternative assumed no operation of the Montezuma Slough Salinity Control Gates, but the project description assumes continued operation of the Salinity Control Gates, consistent with assumptions included in the No Action Alternative. A sensitivity analysis modeling run conducted for Alternative 4 Scenario H3 with the gates operational consistent with the No Action Alternative resulted in substantially lower EC levels than indicated in the original Alternative 4 modeling results, but EC levels were still somewhat higher than EC levels under Existing Conditions and the No Action Alternative for several locations and months. Another modeling run with the gates operational and restoration areas removed resulted in EC levels nearly equivalent to

Existing Conditions and the No Action Alternative, indicating that design and siting of restoration areas has notable bearing on EC levels at different locations within Suisun Marsh (see Appendix 8H, Attachment 1, for more information on these sensitivity analyses). These analyses also indicate that increases are related primarily to the hydrodynamic effects of CM4, not operational components of CM1. Based on the sensitivity analyses, optimizing the design and siting of restoration areas may limit the magnitude of long-term EC increases to be on the order of 1 mS/cm or less. Due to similarities in the nature of the EC increases between alternatives, the findings from these analyses can be extended to this alternative as well.

The degree to which the long-term average EC increases in Suisun Marsh would cause exceedance of Bay-Delta WQCP objectives is unknown, because these objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated "equivalent or better protection will be provided at the location" (State Water Resources Control Board 2006:14). The long-term average EC increase may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the marsh. However, the EC increases at certain locations could be substantial, depending on siting and design of restoration areas, and it is uncertain the degree to which current management plans for the Suisun Marsh would be able to address these substantially higher EC levels and protect beneficial uses. Thus, these increased EC levels in Suisun Marsh are considered to have a potentially adverse effect on marsh beneficial uses. Long-term average EC increases in Suisun Marsh under Alternative 9 relative to the No Action Alternative would be similar to the increases relative to Existing Conditions. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC concentrations could contribute to additional impairment.

SWP/CVP Export Service Areas

At the Banks and Jones pumping plants, Alternative 9 would result in no exceedances of the Bay-Delta WQCP's 1,000 µmhos/cm EC objective for the entire period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-10). Thus, there would be no adverse effect on the beneficial uses in the SWP/CVP Export Service Areas using water pumped at this location under the Alternative 9.

At the Banks pumping plant, relative to Existing Conditions, average EC levels under Alternative 9 would decrease substantially on average: 56% for the entire period modeled and 62% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 53% for the entire period modeled and 60% during the drought period modeled (Appendix 8H, Table EC-20).

At the Jones pumping plant, relative to Existing Conditions, average EC levels under Alternative 9 would also decrease on average, but to a lesser degree: 22% for the entire period modeled and 18% during the drought period modeled. Relative to the No Action Alternative, average EC levels would decrease by 18% for the entire period modeled and 14% during the drought period modeled (Appendix 8H, Table EC-20).

Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 9 would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas; rather, Alternative 9 would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows (see EC impact discussion under the No Action Alternative).

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC. Alternative 9 would result in lower long-term average EC levels relative to Existing Conditions and the No Action Alternative and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

NEPA Effects: In summary, the increased long-term and drought period average EC levels that would occur in the San Joaquin River at San Andreas Landing (interior Delta), and the increased frequency of exceedance of EC objectives in the Sacramento River at Emmaton under Alternative 9, relative to the No Action Alternative, would contribute to adverse effects on the agricultural beneficial uses. Given that the western Delta is Clean Water Act section 303(d) listed as impaired due to elevated EC, the increased frequency of exceedance of the Bay-Delta WQCP objectives and long-term average EC levels at this compliance location could contribute to additional impairment and potentially adversely affect beneficial uses for section 303(d) listed Delta waterways, relative to the No Action Alternative. The increases in long-term average EC levels that could occur in Suisun Marsh would further degrade existing EC levels and could contribute additional to adverse effects on the fish and wildlife beneficial uses. Suisun Marsh is section 303(d) listed as impaired due to elevated EC, and the potential increases in long-term average EC levels could contribute to additional beneficial use impairment. These increases in EC constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects. Implementation of this measure along with a separate other commitment as set forth in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, relating to the potential EC-related changes would reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

River flow rate and reservoir storage reductions that would occur under Alternative 9, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's aggressive regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 9 would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas. There would be no exceedance of the

EC objective at the Jones and Banks pumping plants. Average EC levels for the entire period modeled would decrease at both plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

In the Plan Area, Alternative 9 would result in an12% increase in the frequency with which the Bay-Delta WQCP EC objectives are exceeded at Emmaton (western Delta), a 2% increase in the frequency with which fish and wildlife EC objectives are exceeded in the San Joaquin River at Jersey Point for the entire period modeled (1976–1991). Further, average EC levels at Emmaton would increase by 22% for the entire period modeled and 36% during the drought period modeled, and EC levels at San Andreas Landing would increase by 16% for the entire period modeled and 33% during the drought period modeled. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The interior Delta is not Clean Water Act section 303(d) listed for elevated EC, however, the western Delta is. The increases in long-term and drought period average EC levels and increased frequency of exceedance of EC objectives that would occur in the Sacramento River at Emmaton and San Joaquin River at San Andreas would potentially contribute to adverse effects on the agricultural beneficial uses in the interior Delta. This impact is considered to be significant.

Further, relative to Existing Conditions, Alternative 9 could result in substantial increases in long-term average EC during the months of October through May in Suisun Marsh. The increases in long-term average EC levels that would occur in Suisun Marsh could further degrade existing EC levels and thus contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in wildlife. Suisun Marsh is Clean Water Act section 303(d) listed for elevated EC and the increases in long-term average EC that would occur in the marsh could make beneficial use impairment measurably worse. This impact is considered to be significant.

Implementation of Mitigation Measure WQ-11 along with a separate other commitment relating to the potential increased costs associated with EC-related changes would reduce these effects. While mitigation measures to reduce these water quality effects in affected water bodies to less-than-significant levels are not available, implementation of Mitigation Measure WQ-11 is recommended to attempt to reduce the effect that increased EC concentrations may have on Delta beneficial uses. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable. Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

In addition to and to supplement Mitigation Measure WQ-11, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from EC concentration effects on municipal, industrial and agricultural water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards acquiring alternative water supplies or towards modifying existing operations when EC concentrations at a particular location reduce opportunities to operate existing water supply diversion facilities. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to chloride, electrical conductivity, and bromide.

Mitigation Measure WQ-11: Avoid, Minimize, or Offset, as Feasible, Reduced Water Quality Conditions

Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 1A.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on EC under Alternative 9 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on EC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 9, the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries would be altered, relative to Existing Conditions and the No Action Alternative.

The Sacramento River at Freeport and San Joaquin River at Vernalis (as summarized for water quality average concentrations in Tables 8-48 and 8-49) were examined for flow/concentration relationships for mercury and methylmercury. No significant, predictive regression relationships were discovered for mercury or methylmercury, except for total mercury with flow at Freeport (monthly or annual) (Appendix 8I, *Mercury*, Figures I-10 through I-13). Such a positive relationship between total mercury and flow is to be expected based on the association of mercury with suspended sediment and the mobilization of sediments during storm flows. However, the changes in flow in the Sacramento River under Alternative 9 relative to Existing Conditions and the No Action Alternative are not of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore mercury loading should not be substantially different due to changes in flow. In addition, even though it may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but will not change substantially relative to Existing Conditions or the No Action Alternative due to changes in flows under Alternative 9.

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

The water quality impacts of waterborne concentrations of mercury and methylmercury and fish tissue mercury concentrations were evaluated for 9 Delta locations. The analysis of percentage change in assimilative capacity of waterborne total mercury of Alternative 9 relative to the 25 ng/L ecological risk benchmark as compared to Existing Conditions showed the greatest decrease of 10.2% at Old River at Rock Slough, and a 10.1% reduction relative to the No Action Alternative at that location (Figures 8-53a and 8-54a). Similarly, increases in long term annual average methylmercury concentration are expected to be greatest (approximately 30%) at the Contra Costa Pumping Plant as compared to Existing Conditions and the No Action Alternative (Appendix 8I, *Mercury*, Figure I-9, Table I-6). The concentration of methylmercury is estimated to be 0.163 ng/L at that location, which is greater than Existing Conditions (0.121 ng/L) and the No Action Alternative (0.122 ng/L). All modeled input concentrations exceeded the methylmercury TMDL guidance objective of 0.06 ng/L, therefore percentage change in assimilative capacity was not evaluated for methylmercury.

Fish tissue estimates show some substantial percentage increases in concentration and exceedance quotients for mercury at some Delta locations. The greatest change in exceedance quotients are expected for Old River at Rock Slough with changes of 66% over Existing Conditions, and 59% over the No Action Alternative (Figures 8-55a and 8-55b; Appendix 8I, *Mercury*, Table I-16b). The Contra Costa Pumping Plant values shows a 62% increase in fish tissue concentrations over Existing Conditions, and 59% over the No Action Alternative (Appendix 8I, Table I-16b). Because these increases are substantial, and it is evident that substantive increases are expected at numerous locations throughout the Delta, these changes may be measurable in the environment. See Appendix 8I for a discussion of the uncertainty associated with the fish tissue estimates.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 9 are projected to be lower than Existing Conditions and the No Action Alternative at the Jones and Banks pumping plants (Appendix 8I, FiguresI-7 and I-9). Therefore, mercury shows an increased assimilative capacity at these locations (Figures 8-53a and 8-54a). Bass tissue mercury concentrations are also improved under Alternative 9, relative to Existing Conditions and the No Action Alternative (Figures 8-55a and 8-55b; Appendix 8I, Tables I-16a and I-16b).

NEPA Effects: Based on the above discussion, the effects of mercury and methylmercury in comparison of Alternative 9 to the No Action Alternative (as waterborne and bioaccumulated forms) are considered to be adverse for the case of fish tissue bioaccumulation at some locations.

***CEQA Conclusion*:** Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 9, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta will not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. Monthly average waterborne concentrations of total and methylmercury, over the period of record, are very similar to Existing Conditions, but showed notable increases at some locations. Estimates of fish tissue mercury concentrations show substantial increases would occur for several sites for Alternative 9 as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP and CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 9 as compared to Existing Conditions.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. However, increases in fish tissue mercury concentrations are substantial, and changes in fish tissue mercury concentrations would make existing mercury-related impairment in the Delta measurably worse. In comparison to Existing Conditions, Alternative 9 would increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. This impact is considered to be significant. Feasible or effective actions to reduce the effects on mercury resulting from CM1 are unknown. General mercury management measures through CM12, or actions taken by other entities or programs such as TMDL implementation, may minimize or reduce sources and inputs of mercury to the Delta and methylmercury formation. However, it is uncertain whether this impact would be reduced to a level that would be less than significant as a result of CM12 or other future actions. Therefore, the impact would be significant and unavoidable.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Some habitat restoration activities under Alternative 9 would occur on lands in the Delta formerly used for irrigated agriculture. Tidal and other restoration proposed under

Alternative 9 have the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the restored habitat. Therefore, increases in mercury methylation in the habitat restoration areas is possible but uncertain depending on the specific restoration design implemented at a particular Delta location. Models to estimate the potential for methylmercury formation in restored areas are not currently available. However, DSM2 modeling for Alternative 9 operations does incorporate assumptions for certain habitat restoration activities proposed under CM2 and CM4 (see Section 8.3.1.3) that result in changes to Delta hydrodynamics compared to the No Action Alternative. These modeled restoration assumptions provide some insight into potential hydrodynamic changes that could be expected related to implementing CM2 and CM4 and are considered in the evaluation of the potential for increased mercury and methylmercury concentrations under Alternative 9.

CM12 addresses the potential for methylmercury bioaccumulation associated with restoration activities and acknowledges the uncertainties associated with mitigating or minimizing this potential effect. CM12 proposes project-specific mercury management plans for restoration actions that will incorporate relevant approaches recommended in Phase 1 Methylmercury TMDL control studies. Specific approaches recommended under CM12 that are intended to minimize or mitigate for potential increases in methylmercury bioaccumulation at future restoration sites include:

- Characterizing mercury, methylmercury, organic carbon, iron, and sulfate concentrations to better inform restoration design,
- Sequestering methylmercury at restoration sites using low intensity chemical dosing techniques,
- Minimizing microbial methylation associated with anoxic conditions by reducing the amount of organic material at a restoration site,
- Designing restoration sites to enhance photo degeneration that converts methylmercury into a biologically unavailable, inorganic form of mercury,
- Remediating restoration site soils with iron to reduce methylation in sulfide rich soils, and
- Considering capping mercury laden sediments, where possible to reduce methylation potential at a site.

Because of the uncertainties associated with site-specific estimates of methylmercury concentrations and the uncertainties in source modeling and tissue modeling, the effectiveness of methylmercury management proposed under CM12 to reduce methylmercury concentrations would need to be evaluated separately for each restoration effort, as part of design and implementation. Because of this uncertainty and the known potential for methylmercury creation in the Delta this potential effect of implementing CM2-CM21 is considered adverse.

***CEQA Conclusion*:** There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the CVP and SWP service areas due to implementation of CM2–CM21 relative to Existing Conditions. However, uptake of mercury from water and/or methylation of inorganic mercury may increase to an unquantified degree as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Methylmercury is 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites under Alternative 9 would be guided by CM12 which requires development of site specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time although the potential to reduce methylmercury concentrations exists based on current research. Although the BDCP will implement CM12 with the goal to reduce this potential effect the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant. No mitigation measures would be available until specific restoration actions are proposed. Therefore this programmatic impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 9 would have negligible, if any, impact on nitrate concentrations in the rivers and reservoirs upstream of the Delta in the Sacramento River watershed relative to Existing Conditions and the No Action Alternative.

Under Alternative 9, modeling indicates that long-term annual average flows on the San Joaquin River would decrease by an estimated 6% relative to Existing Conditions, and would remain virtually the same relative to the No Action Alternative (see Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Given these relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River (see Appendix 8J, *Nitrate*, Figure 2), it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by changes in flow rates under Alternative 9.

Any negligible changes in nitrate-N concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to nitrate.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Results of the mixing calculations indicate that under Alternative 9, relative to Existing Conditions, and the No Action Alternative, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Tables 31 and 32). Long-term average nitrate concentrations are anticipated to increase at most locations in the Delta. The increase would be greatest at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1 (all >100% increase). Long-term average concentrations were estimated to increase to

0.96, 1.32, and 1.38 mg/L-N for Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant#1, respectively, due primarily to increased San Joaquin River water percentage at these locations (see Appendix 8D, *Source Water Fingerprinting Results*). Although changes at specific Delta locations and for specific months may be substantial on a relative basis, the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds identified in Table 8-50. No additional exceedances of the MCL are anticipated at any location (Appendix 8J, *Nitrate*, Table 31). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, was up to approximately 13% at Old River at Rock Slough and Contra Costa Pumping Plant #1, and averaged approximately 9% on a long-term average basis (Appendix 8J, Table 33). Similarly, the use of available assimilative capacity at Franks Tract was up to approximately 10%, and averaged approximately 6% over the long term. The concentrations estimated for these locations would not increase the likelihood of exceeding the 10 mg/L-N MCL, nor would they increase the risk for adverse effects to beneficial uses. At all other locations, use of assimilative capacity was negligible (<5%) (Appendix 8J, Table 33).

Nitrate concentrations will likely be higher than the modeling results indicate in certain locations. This includes in the Sacramento River between Freeport and Mallard Island and other areas in the Delta downstream of Freeport that are influenced by Sacramento River water. These increases are associated with ammonia and nitrate that are discharged from the SRWTP, which are not included in the modeling.

- Under Existing Conditions, most of the ammonia discharged from the SRWTP is converted to nitrate downstream of the facility's discharge at Freeport, and thus, nitrate concentrations under Existing Conditions in these areas are expected to be higher than the modeling predicts, the increase becoming greater with increasing distance downstream. However, the increase in nitrate concentrations downstream of the SRWTP is expected to be small—the existing increase appears to be from approximately 0.1 mg/L-N to approximately 0.4–0.5 mg/L-N over this reach, due to approximately a 1:1 conversion of ammonia-N to nitrate-N (Central Valley Water Board 2010a:32).
- Under Alternative 9, the planned upgrades to the SRWTP, which include nitrification/partial denitrification, would substantially decrease ammonia concentrations in the discharge, but would increase nitrate concentrations in the discharge up to 10 mg/L-N, which is substantially higher than under Existing Conditions.
- Overall, under Alternative 9, the nitrogen load from the SRWTP discharge is expected to decrease (by up to 50%), relative to Existing Conditions, due to nitrification/partial dentrification ugrades at the SRWTP facility. Thus, while concentrations of nitrate downstream of the facility are expected to be higher than modeling results indicate for both Existing Conditions and Alternative 9, the increase is expected to be greater under Existing Conditions than for Alternative 9 due to the upgrades that are assumed under Alternative 9.

The other areas in which nitrate concentrations will be higher than the modeling results indicate are immediately downstream of other wastewater treatment plants that practice nitrification, but not denitrification (e.g., City of Rio Vista Beach WWTF, Town of Discovery Bay WWTF, City of Stockton RWCF). For all such facilities in the Delta, the Regional Water Boards have issued NPDES permits that allow discharge of wastewater containing nitrate into the Delta, and under these permits, the State has determined that no beneficial uses are adversely affected by the discharge, and that the discharger's use of available assimilative capacity of the water body is acceptable. When dilution is necessary in order for the discharge to be in compliance with the Basin Plans (which incorporate the 10 mg/L-N MCL by reference), not all of the assimilative capacity of the receiving water is granted to the discharger. Thus, limited decreases in flows are not anticipated to result in systemic exceedances of the MCLs by these POTWs. Furthermore, NPDES permits are renewed on a 5-year basis, and thus, if under changes in flows, dilution was no longer sufficient to maintain nitrate below the MCL in the receiving water, the NPDES permit renewal process would address such cases.

Therefore, any increases in nitrate-N concentrations that may occur at certain locations within the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regards to nitrate.

SWP/CVP Export Service Areas

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N at the Banks and Jones pumping plants.

Results of the mixing calculations indicate that under Alternative 9, relative to Existing Conditions and the No Action Alternative, nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease on a long-term average annual basis (Appendix 8J, *Nitrate*, Table 31 and 32). No additional exceedances of the MCL are anticipated (Appendix 8J, Table 31). On a monthly average basis and on a long term annual average basis, for all modeled years and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions and the No Action Alternative, relative to the 10 mg/L-N MCL, was negligible for both Banks and Jones pumping plants (Appendix 8J, Table 33).

Therefore, implementation of this alternative is not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regards to nitrate.

NEPA Effects: In summary, based on the discussion above, the effects on nitrate from implementing CM1 are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Nitrate-N concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate-N upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers). Although higher in the San Joaquin River watershed, nitrate-N concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 9, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate-N concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mixing calculations indicate that under Alternative 9, relative to Existing Conditions, long-term average nitrate concentrations are anticipated to increase at most locations. The increase would be greatest at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping

Plant #1 (all >100% increase), due primarily to increased San Joaquin River water percentage at these locations. However, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives, and no additional exceedances of the MCL are anticipated at any location. Use of assimilative capacity at locations throughout the Delta (up to 13%) did not result in concentrations that would increase the likelihood of exceeding the 10 mg/L-N MCL, nor would they increase the risk for adverse effects to beneficial uses.

Assessment of effects of nitrate in the SWP and CVP Export Service Areas is based on effects on nitrate-N concentrations at the Banks and Jones pumping plants. Results of the mixing calculations indicate that under Alternative 9, relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to decrease. No additional exceedances of the MCL are anticipated, and use of assimilative capacity available under Existing Conditions, relative to the MCL, for both Banks and Jones pumping plants was negligible for all months.

Based on the above, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. No long-term water quality degradation is expected to occur such that exceedance of criteria is more likely or such that there is an increased risk of adverse impacts to beneficial uses. Nitrate is not 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on nitrate under Alternative 9 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on nitrate resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

Under Alternative 9, there would be no substantial change to the sources of DOC within the watersheds upstream of the Delta. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows would not be expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Any negligible changes in DOC levels in water bodies upstream of the Delta under Alternative 9, relative to Existing Conditions and the No Action Alternative, would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regards to DOC.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics, To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, for example, additional loading of a constituent to the Delta, are discussed within the impact header for CM2–CM21. See section 8.3.1.3 for more information.

Under Alternative 9, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be similar to that previously described for Alternative 1A, although the magnitude of predicted long-term increase and relative frequency of concentration threshold exceedances would be substantially greater. Modeled effects would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1., where for the 16-year hydrologic period and the modeled drought period, long-term average concentration increases ranging from 0.6–1.0 mg/L would be predicted (≤28% net increase), resulting in long-term average DOC concentrations greater than 4 mg/L at Rock Slough and Contra Costa PP No. 1 (Appendix 8K, *Organic Carbon,* DOC Table 10). Increases in long-term average concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at Rock Slough and Contra Costa PP No. 1 locations. For Rock Slough, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 99% under the Alternative 9 (an increase from 47% to 100% for the drought period), and concentrations exceeding 4 mg/L would increase from 30% to 44% (32% to 67% for the drought period). For Contra Costa PP No. 1, long-term average DOC concentrations exceeding 3 mg/L would increase from 52% under Existing Conditions to 100% under Alternative 9 (45% to 100% for the drought period), and concentrations exceeding 4 mg/L would increase from 32% to 45% (35% to 65% for the drought period). Relative change in frequency of threshold exceedance for other assessment locations would be similar or less. This comparison to Existing Conditions reflects changes in DOC due to both Alternative 9 operations (including use of operable barriers and numerous other components of Operational Scenario G) and climate change/sea level rise.

In comparison, Alternative 9 relative to the No Action Alternative would generally result in a magnitude of change similar to that discussed for the comparison to Existing Conditions. Maximum increases of 0.6–0.9 mg/L DOC (i.e., ≤24%) would be predicted at Franks Tract, Rock Slough, and Contra Costa PP No. 1 relative to No Action Alternative (Appendix 8K, *Organic Carbon,* DOC Table 10). Threshold concentration exceedance frequency trends would also be similar to those discussed for the Existing Conditions comparison, with exception to the predicted 4 mg/L exceedance frequency at Buckley Cove. In comparison to the No Action Alternative, the frequency which long-term average DOC concentrations exceeded 4 mg/L at Buckley Cove would increase from 27% to 39% (42% to 50% for the modeled drought period). Unlike the comparison to Existing Conditions, this comparison to the No Action Alternative reflects changes in DOC due only to Alternative 9 operations.

The increases in long-term average DOC concentrations estimated to occur at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are considered substantial and could potentially trigger significant changes in drinking water treatment plant design or operations. In particular, assessment locations at Rock Slough and Contra Costa PP No. 1 represent municipal intakes servicing existing drinking water treatment plants. Under Alternative 9, drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. While treatment technologies sufficient to achieve the necessary DOC removals exist, implementation of such technologies would likely require substantial investment in new or modified infrastructure.

Relative to existing and No Action Alternative conditions, Alternative 9 would lead to predicted improvements in long-term average DOC concentrations at Barker Slough and Staten Island, as well Banks and Jones pumping plants (discussed below). Predicted long-term average DOC concentrations at Barker Slough and Staten Island would decrease <0.1–0.2 mg/L, depending on baseline conditions comparison and modeling period.

SWP/CVP Export Service Areas

Under Alternative 9, modeled long-term average DOC concentrations would decrease at Banks and Jones pumping plants for both the modeled 16-year hydrologic period and the modeled drought period. Modeled decreases would generally be similar between Existing Conditions and the No Action Alternative. Relative to Existing Conditions, long-term average DOC concentrations at Banks would be predicted to decrease by 1.5 mg/L (1.8 mg/L during drought period) (Appendix 8K, *Organic Carbon,* DOC Table 10). At Jones, long-term average DOC concentrations would be predicted to decrease by 1.5 mg/L (1.7 mg/L during drought period). Such substantial improvement in long-term average DOC concentrations would include fewer exceedances of concentration thresholds. At both Banks and Jones, average DOC concentrations exceeding the 2 mg/L concentration threshold would decrease from 100% under Existing Conditions and the No Action Alternative to 39% under Alternative 9 (100% to 32% during the drought period), while concentrations exceeding 4 mg/L would nearly be eliminated (i.e., ≤10% exceedance frequency). Such modeled improvement would correspond to substantial improvement in Export Service Areas water quality, respective to DOC.

Similar to the discussion pertaining to the No Action Alternative, maintenance of SWP and CVP facilities under Alternative 9 would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area. Maintenance activities would not be expected to cause any substantial change in long-term average DOC concentrations such that MUN beneficial uses, or any other beneficial use, would be adversely affected.

NEPA Effects: In summary, Alternative 9, relative to the No Action Alternative, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta. Long-term average DOC concentrations at Banks and Jones pumping plants are predicted to decrease by as much as 1.9 mg/L, while long-term average DOC concentrations for some Delta interior locations, including Franks Tract, Rock Slough and Contra Costa PP #1, are predicted to increase by as much as 0.9 mg/L. Resultant substantial changes in long-term average DOC at these Delta interior locations could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality and MUN beneficial uses. Mitigation Measure WQ-17 is available to reduce these effects.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the

effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

While greater water demands under the Alternative 9 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of DOC. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, Alternative 9 would result in substantial increases (i.e., 0.6–1.0 mg/L) in long-term average DOC concentrations at some Delta interior locations, and would be greatest at Franks Tract, Rock Slough, and Contra Costa PP No. 1. At these locations the predicted changes in DOC would substantially increase the frequency with which long-term average concentrations exceeds 2, 3, or 4 mg/L. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Such predicted magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial.

The assessment of Alternative 9 effects on DOC in the SWP/CVP Export Service Areas is based on assessment of changes in DOC concentrations at Banks and Jones pumping plants. Relative to Existing Conditions, long-term average DOC concentrations would decrease by as much as 1.8 mg/L at Banks and Jones pumping plants. The frequency with which long-term average DOC concentrations would exceed 2, 3, or 4 mg/L would be substantially reduced, where predicted exceedances of >4 mg/L would be nearly eliminated (i.e., ≤10% exceedance frequency). As a result, substantial improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, Alternative 9 operation and maintenance would not result in any substantial change in long-term average DOC concentration upstream of the Delta. Furthermore, under Alternative 9, water exported from the Delta to the SWP/CVP service area would be substantially improved relative to DOC. DOC is not bioaccumulative, therefore change in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Additionally, DOC is not a constituent related to any 303(d) listings. Nevertheless, new and modified conveyance facilities proposed under Alternative 9 would result in a substantial increase in long-term average DOC concentrations (i.e., 0.6–1.0 mg/L, equivalent to ≤28% relative increase) at Franks Tract, Rock Slough, and Contra Costa PP No. 1. In particular, under Alternative 9, model predicted long-term average DOC concentrations would be greater than 4 mg/L at Rock Slough and Contra Costa PP No. 1 with commensurate substantial increases in the frequency with which average DOC concentrations exceed 2, 3, and 4 mg/L levels. Drinking water treatment plants obtaining water from these interior Delta locations would likely need to upgrade existing treatment systems in order to achieve EPA Stage 1 Disinfectants and Disinfection Byproduct Rule action thresholds. Therefore, such a magnitude change in long-term average DOC concentrations would represent a substantially increased risk for adverse effects on existing MUN beneficial uses at Rock Slough and Contra Costa PP No. 1 should such treatment upgrades not be undertaken. The impact is considered significant and mitigation is required. While Mitigation Measure WQ-17 is available to partially reduce this impact of DOC, the feasibility and effectiveness of this mitigation measure is uncertain and implementation would not necessarily reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Mitigation Measure WQ-17: Consult with Delta Water Purveyors to Identify Means to Avoid, Minimize, or Offset Increases in Long-Term Average DOC Concentrations

Please see Mitigation Measure WQ-17 under Impact WQ-17 in the Alternative 6A discussion.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 9 would be similar to conservation measures under Alternative 1A, but with changes in the south Delta to accommodate the modified corridors. Therefore, effects on DOC resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. In summary, CM4–CM7 and CM10 could contribute substantial amounts of DOC to raw drinking water supplies, largely depending on final design and operational criteria for the related wetland and riparian habitat restoration activities. Substantially increased long-term average DOC in raw water supplies could lead to a need for treatment plant upgrades in order to appropriately manage DBP formation in treated drinking water. This potential for future DOC increases would lead to substantially greater associated risk of long-term adverse effects on the MUN beneficial use.

In summary, the habitat restoration elements of CM4–CM7 and CM10 under Alternative 9 would present new localized sources of DOC to the study area, and in some circumstances would substitute for existing sources related to replaced agriculture. Depending on localized hydrodynamics and proximity to municipal drinking water intakes, such restoration activities could contribute substantial amounts of DOC to municipal raw water. Substantial increases in municipal raw water DOC could necessitate changes in water treatment plant operations or require treatment plant upgrades in order to maintain DBP compliance, and thus would constitute an adverse effect on water quality. Mitigation Measure WQ-18 is available to reduce these effects.

CEQA Conclusion: Effects of CM4–CM7 and CM10 on DOC under Alternative 9 are similar to those discussed for Alternative 1A. Similar to the discussion for Alternative 1A, this impact is considered to be significant. Mitigation is required. It is uncertain whether implementation of Mitigation Measure WQ-18 would reduce identified impacts to a less-than-significant level. Hence, this impact remains significant and unavoidable.

In addition to and to supplement Mitigation Measure WQ-18, the BDCP proponents have incorporated into the BDCP, as set forth in EIR/EIS Appendix 3B, *Environmental Commitments, AMMs, and CMs*, a separate other commitment to address the potential increased water treatment costs that could result from DOC concentration effects on municipal and industrial water purveyor operations. Potential options for making use of this financial commitment include funding or providing other assistance towards implementing treatment for DOC and/or DBPs or DOC source control strategies. Please refer to Appendix 3B for the full list of potential actions that could be taken pursuant to this commitment in order to reduce the water quality treatment costs associated with water quality effects relating to DOC.

Mitigation Measure WQ-18: Design Wetland and Riparian Habitat Features to Minimize Effects on Municipal Intakes

Please see Mitigation Measure WQ-18 under Impact WQ-18 in the discussion of Alternative 1A.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance (CM1)

***NEPA Effects*:** Effects of CM1 on pathogens under Alternative 9 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

***CEQA Conclusion*:** Effects of CM1 on pathogens under Alternative 9 would be the same as those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

River flow rate and reservoir storage reductions that would occur due to implementation of CM1 (water facilities and operations) under Alternative 9, relative to Existing Conditions, would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta, given the small magnitude of urban runoff contributions relative to the magnitude of river flows, that pathogen concentrations in the rivers have a minimal relationship to river flow rate, and the expected reduced pollutant loadings in response to NPDES stormwater-related regulations.

It is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens. This conclusion is based on the Pathogens Conceptual Model, which found that pathogen sources in close proximity to a Delta site appear to have the greatest influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative.

In the SWP/CVP Export Service Areas waters, relative to Existing Conditions, an increased proportion of water coming from the Sacramento River would not adversely affect beneficial uses in the SWP/CVP Export Service Areas. The pathogen levels in the Sacramento River are similar to or lower than the water diverted at the Delta export pumps. Further, it is localized sources of pathogens that appear to have the greatest influence on concentrations. Thus, an increased proportion of Sacramento River water diverted to the SWP/CVP Export Service Areas would result in minimal changes in pathogen levels in the SWP/CVP Export Service Areas waters.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is Clean Water Act section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of CM2–CM21

***NEPA Effects*:** Effects of CM2–CM21 on pathogens under Alternative 9 would be the same as those discussed for Alternative 1A and are considered to not be adverse.

***CEQA Conclusion*:** CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on pathogens resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, under Alternative 9 no specific operations or maintenance activity of the SWP or CVP would substantially drive a change in pesticide use, and thus pesticide sources would remain unaffected upstream of the Delta. Nevertheless, changes in the timing and magnitude of reservoir releases could have an effect on available dilution capacity along river segments such as the Sacramento, Feather, American, and San Joaquin Rivers.

Under Alternative 9, winter (November–March) and summer (April–October) season average flow rates on the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis would change. Relative to existing condition and the No Action Alternative, seasonal average flow rates on the Sacramento would decrease no more than 3% during the summer and winter (Appendix 8L, *Pesticides*, Tables 1–4). On the Feather River, average flow rates would increase by as much as 10% during the summer, but would decrease by as much as 5% in the winter. American River average flow rates would decrease by as much as 17% in the summer but would increase by as much as 7% in the winter. Seasonal average flow rates on the San Joaquin River would decrease by as much as 12% in the summer, but increase by as much as 1% in the winter. For the same reasons stated for the No Action Alternative, decreased seasonal average flow of ≤17% is not considered to be of sufficient magnitude to substantially increase pesticide concentrations or alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of water bodies upstream of the Delta.

Delta

Sources of diuron, OP and pyrethroid insecticides to the Plan Area include direct input of surface runoff from in-Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. Similar to Upstream of the Delta, CVP/SWP operations would not affect these sources.

Under Alternative 9, the distribution and mixing of Delta source waters would change. Percentage change in monthly average source water fraction was evaluated for the modeled 16-year (1976–1991) hydrologic period and a representative drought period (1987–1991), with special attention given to changes in San Joaquin River, Sacramento River and Delta Agriculture sources water fractions. Relative to Existing Conditions, under Alternative 9 modeled San Joaquin River fractions would increase greater than 10% at Franks Tract, Rock Slough, Contra Costa PP No. 1, and the San Joaquin River at Antioch (Appendix 8D, *Source Water Fingerprinting Results*). At Antioch, San

Joaquin River source water fractions would increase by 12–15% from October through May (11–14% from November through April for the modeled drought period). While this change at Antioch is not considered substantial, changes in San Joaquin River source water fraction in the Delta interior would be considerable. At Franks Tract, San Joaquin River source water fractions would increase between 25–57% for the entire calendar year of January through December (11–52% for October through July of the modeled drought period). Changes at Rock Slough and Contra Costa PP No. 1 would be very similar, where modeled San Joaquin River source water fractions would increase from 35–80% (25–78% for the modeled drought period) for the entire calendar year of January through December. In addition, Sacramento River fractions would increase greater than 10% at Staten Island and Buckley Cove (not including Banks and Jones). At Staten Island, Sacramento River fractions would increase by 16% in April and 20% in May (13–15% from February through April of the modeled drought period). These changes at Staten Island are not considered substantial. At Buckley Cove, however, Sacramento source water fraction would increase between 36–72% (46–73% for the drought period) for the entire calendar year of January through December. Although a considerable change, this change in source water fraction at Buckley Cove would balance through a nearly equivalent decrease in San Joaquin River water. Delta agricultural fractions would not increase greater than 8% at any assessment location.

Relative to Existing Conditions, increases in San Joaquin River source water fraction at Franks Tract, Rock Slough, and Contra Costa PP NO. 1 would primarily balance through decreases in Sacramento River water, and as a result the San Joaquin River would account for greater than 50% of the total source water volume at Franks Tract between October and June (>50% for November and December during the modeled drought period), and would be greater than 50%, and as much as 86% for the entire calendar year at Rock Slough and Contra Costa PP No. 1 (greater than 50% and as high as 80% for October through June of the modeled drought period). While the source water and potential pesticide related toxicity co-occurrence predictions do not mean adverse effects would occur, such considerable modeled increases in winter and early summer source water fraction at Franks Tract and winter and summer source water fractions at Rock Slough and Contra Costa PP No. 1 could substantially alter the long-term risk of pesticide-related toxicity to aquatic life, given the apparent greater incidence of pesticides in the San Joaquin River.

When compared to the No Action Alternative, changes in source water fractions would be similar in season, geographic extent, and magnitude to those discussed for Existing Conditions (Appendix 8D, *Source Water Fingerprinting Results*). Relative to the No Action Alternative the similar magnitude increase in San Joaquin River source water fraction at Franks Tract, Rock Slough, and Contra Costa PP No. 1 would be considered substantial and could substantially increase the long-term risk of pesticide-related toxicity to aquatic life.

These predicted adverse effects on pesticides relative to Existing Conditions and the No Action Alternative fundamentally assume that the present pattern of pesticide incidence in surface water will occur at similar levels into the future. In reality, however, the makeup and character of the pesticide use market in the late long-term (i.e., the year 2060) will not be exactly as it is today. Current use of chlorpyrifos and diazinon is on the decline with their replacement by pyrethroids on the rise, yet in this assessment it is the apparent greater incidence of diazinon and chlorpyrifos on the San Joaquin River that serves as the basis for concluding that substantially increased San Joaquin River source water fraction would correspond to an increased risk of pesticide-related toxicity to aquatic life. By 2060, however, alternative pesticides, such as neonicitinoids and biologicals, will likely be a more substantial contributing part of the existing mix of pesticides, and perhaps more prominent. The trend in the development of future-use pesticides is towards reduced risk pesticides, including more biopesticides, with greater targeted specificity, fewer residues, and lower overall non-target toxicity. By 2060 existing chlorpyrifos and diazinon TMDLs for the Sacramento and San Joaquin Rivers will have been in effect for more than 50 years. Moreover, it is reasonable to expect that CWA section 303(d) listings and future additional listings will have developed TMDLs by 2060. To the extent these existing and future TMDL's address current and future-use pesticides, a greater degree of pesticide related source control can be anticipated. Nevertheless, forecasting whether these various efforts will ultimately be successful at resolving current pesticide related impairments requires considerable speculation. While the fundamental assumptions that have guided this assessment of pesticides may be somewhat altered by 2060, these assumptions are informed by actual studies and monitoring data collected from the recent past and, therefore, judging project alternative effects in the future remain most accurate through use of these informed assumptions rather than based on assumptions founded upon future speculative conditions.

SWP/CVP Export Service Areas

Assessment of effects in SWP/CVP Export Service Areas is based on effects seen in the Plan Area at the Banks and Jones pumping plants. Under Alternative 9, Sacramento River source water fractions would increase at both Banks and Jones pumping plants relative to Existing Conditions and the No Action Alternative (Appendix 8D, *Source Water Fingerprinting Results*). At Banks pumping plant, Sacramento source water fractions would generally increase from 12–38% for February through June (12–37% for February through June of the modeled drought period) and at Jones pumping plant Sacramento source water fractions would generally increase from 7–54% for the entire calendar year (14–69% for September through June of the modeled drought period). These increases in Sacramento source water fraction would primarily balance through equivalent decreases in San Joaquin River water. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of OP insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

***NEPA Effects*:** In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers, under Alternative 9 relative to the No Action Alternative, are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. However, modeled increases in San Joaquin River fraction at Franks Tract, Rock Slough, and Contra Costa PP No. 1 are of sufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta. The effects on pesticides from operations and maintenance (CM1) are determined to be adverse and unavoidable.

***CEQA Conclusion*:** Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Sources of pesticides upstream of the Delta include direct input of pesticide containing surface runoff from agriculture and urbanized areas. Flows in rivers receiving these discharges dilute these pesticide inputs. Relative to Existing Conditions, however, modeled changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers are of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta.

In the Delta, sources of pesticides include direct input of surface runoff from Delta agriculture and Delta urbanized areas as well as inputs from rivers upstream of the Delta. While facilities operations and maintenance activities would not affect these sources, changes in Delta source water fraction could change the relative risk associated with pesticide related toxicity to aquatic life. Under Alternative 9, modeled long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would increase considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase.

The assessment of Alternative 9 effects on pesticides in the SWP/CVP Export Service Areas is based on assessment of changes predicted at Banks and Jones pumping plants. Sacramento River source water fractions would increase substantially at both Banks and Jones pumping plants and would generally represent an improvement in export water quality respective to pesticides.

Based on the above, Alternative 9 would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions would not be expected to make any of these beneficial use impairments measurably worse, with principal exception to locations in the Delta that would receive a substantially greater fraction San Joaquin River water under Alternative 9. Long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 locations would change considerably for the calendar year such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase. Additionally, the potential for increased incidence of pesticide related toxicity could include pesticides such as chlorpyrifos and diazinon for which existing 303(d) listings exist for the Delta, and thus existing beneficial use impairment could be made discernibly worse. The impact is considered to be significant and unavoidable. There is no feasible mitigation available to reduce the effect of this significant impact.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 9 would be similar to conservation measures under Alternative 1A, but with changes in the south Delta to accommodate the modified corridors. Effects on pesticides resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. In summary, CM13 proposes the use of herbicides to control invasive aquatic vegetation around habitat restoration sites. Herbicides directly applied to water could include adverse effects on non-target aquatic life, such as aquatic invertebrates and beneficial aquatic plants. As such, aquatic life toxicity objectives could be exceeded with sufficient frequency and magnitude such that beneficial uses would be impacted, thus constituting an adverse effect on water quality.

In summary, based on the discussion above, the effects on pesticides from implementing CM2–CM21 are considered to be adverse. Mitigation Measure WQ-22 would be available to reduce this adverse effect.

***CEQA Conclusion*:** Effects of CM2–CM21 on pesticides under Alternative 9 are similar to those discussed for Alternative 1A. Potential environmental effects related only to CM13 are considered to be significant. Mitigation is required. While Mitigation Measure WQ-22 is available to partially reduce this impact of pesticides, no feasible mitigation is available that would reduce it to a level that would be less than significant.

Mitigation Measure WQ-22: Implement Least Toxic Integrated Pest Management Strategies

Please see Mitigation Measure WQ-22 under Impact WQ-22 in the discussion of Alternative 1A.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance (CM1)

***NEPA Effects*:** Effects of water facilities and operations (CM1) on phosphorus levels in water bodies of the affected environment under Alternative 9 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels discussed in detail for Alternative 1A also adequately represent the effects under Alternative 9, which are considered to be not adverse.

CEQA Conclusion: Key findings discussed in the effects assessment relative to Existing Conditions is provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Because phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration upstream of the Delta are not anticipated for Alternative 9, relative to Existing Conditions.

Because phosphorus concentrations in the major source waters to the Delta are similar for much of the year, phosphorus concentrations in the Delta are not anticipated to change substantially on a long term-average basis under Alternative 9, relative to Existing Conditions. Algal growth rates are limited by availability of light in the Delta, and therefore any minor increases in phosphorus levels that may occur at some locations and times within the Delta would be expected to have little effect on primary productivity in the Delta.

The assessment of effects of phosphorus under Alternative 9 in the SWP and CVP Export Service Areas is based on effects on phosphorus at the Banks and Jones pumping plants. As noted above, phosphorus concentrations in the Delta (including Banks and Jones pumping plants) are not anticipated to change substantially on a long term-average basis.

Based on the above, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the CVP and SWP service areas under Alternative 9 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects**:** Effects of CM2–CM21 on phosphorus levels in water bodies of the affected environment under Alternative 9 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. Consequently, the environmental consequences to phosphorus levels from implementing CM2–CM21 discussed in detail for Alternative 1A also adequately represent the effects of these same actions under Alternative 9, which are considered to be not adverse.

CEQA Conclusion**:** CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on phosphorus resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 9 would have negligible, if any, effect on selenium concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative. Any negligible increases in selenium concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to selenium.

Delta

Modeling scenarios included assumptions regarding how certain habitat restoration activities (CM2 and CM4) would affect Delta hydrodynamics. To the extent that restoration actions alter hydrodynamics within the Delta region, which affects mixing of source waters, these effects are included in this assessment of operations-related water quality changes (i.e., CM1). Other effects of CM2–CM21 not attributable to hydrodynamics, such as additional loading of a constituent to the

Delta, are discussed within the impact header for CM2–CM21. See Section 8.3.1.3 for more information.

Selenium concentrations and threshold comparisons for each of the 11 modeled Delta assessment locations under Alternative 9, relative to Existing Conditions and the No Action Alternative, are presented in Appendix 8M, *Selenium*, Table M-9a for water, Tables M-19 and M-29 for most biota (whole-body fish [excluding sturgeon], bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) throughout the Delta, and Tables M-30 through M-32 for sturgeon at the two western Delta locations. Figures 8-59a and 8-60a present graphical distributions of predicted selenium concentration changes (shown as changes in available assimilative capacity based on 1.3 µg/L) in water at each modeled assessment location for all years. Appendix 8M, Figure M-24, provides more detail in the form of monthly patterns of selenium concentrations in water during the modeling period.

Alternative 9 would result in small to moderate changes in average selenium concentrations in water at modeled Delta assessment locations relative to Existing Conditions and the No Action Alternative (Appendix 8M, *Selenium*, Table M-9a). Long-term average concentrations at some interior and western Delta locations would increase by 0.01–0.21 µg/L for the entire period modeled (1976–1991). These increases in selenium concentrations in water would result in reductions in available assimilative capacity of 1–19%, relative to the 1.3 µg/L USEPA draft water quality criterion (Figures 8-59a and 8-60a). The long-term average selenium concentrations in water for Alternative 9 (range 0.09–0.37 µg/L) would be similar to Existing Conditions (range 0.09–0.41 µg/L) and the No Action Alternative (range 0.09–0.38 µg/L), and all would be below the USEPA draft water quality criterion of 1.3 µg/L Appendix 8M, Table M-9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 9 would generally result in small changes (less than 4%) in estimated selenium concentrations in most biota (whole-body fish (excluding sturgeon), bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) (Figures 8-61a through 8-64b; Appendix 8M, Table M-29). Despite the small changes in selenium concentrations in biota, Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0 (indicating low probability of adverse effects). Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years also are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by about 35% relative to Existing Conditions and to the No Action Alternative in all years (from about 4.7 to 6.4 mg/kg dry weight). Likewise, those for sturgeon in the Sacramento River at Mallard Island are predicted to increase by about 17% in all years (from about 4.4 to 5.2 mg/kg dry weight) (Appendix 8M, *Selenium*, Tables M-30 and M-31). Selenium concentrations in sturgeon during drought years are expected to increase by about 35% at Antioch and 17% at Mallard Island. Detection of changes in whole-body sturgeon such as those estimated for the western Delta may require large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at both locations (as they do for Existing Conditions and the No Action Alternative; Appendix 8M, Table M-32) and for all years at Antioch, whereas Existing Conditions and the No Action Alternative do not (quotient increases from 0.94 to 1.3 at Antioch) (Appendix 8M, Table M-32). High Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at Antioch (where quotient increases from 0.85 to 1.2), unlike Existing Conditions and the No Action Alternative (Appendix 8M, Table M-32).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota are attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in the appendix, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. (There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium.) Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on “fixed” K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Increased water residence times could increase the bioaccumulation of selenium in biota, thereby potentially increasing fish tissue and bird egg concentrations of selenium (see residence time discussion in Appendix 8M, *Selenium*, and Presser and Luoma [2010b]). Thus, residence time was assessed for its relevance to selenium bioaccumulation. Table 8-60a shows the time for neutrally buoyant particles to move through the Delta (surrogate for flow and residence time). Although an increase in residence time throughout the Delta is expected under the No Action Alternative, relative to Existing Conditions (because of climate change and sea level rise), the change is fairly small in most areas of the Delta.

Relative to Existing Conditions and the No Action Alternative, increases in residence times for Alternative 9 would be greater in the South Delta than in other sub-regions. Relative to Existing Conditions, annual average residence times for Alternative 9 in the South Delta are expected to increase by more than 18 days (Table 8-60a) and by more than 16 days relative to the No Action Alternative. Increases in residence times for other sub-regions would be smaller, especially as compared to Existing Conditions and the No Action Alternative As mentioned above, these results incorporate hydrodynamic effects of both CM1 and CM2 and CM4, and the effects of CM1 cannot be distinguished from the effects of CM2 and CM4. However, it is expected that CM2 and CM4 are substantial drivers of the increased residence time.

Presser and Luoma (2010b) summarized and discussed selenium uptake in the Bay-Delta (including hydrologic conditions [e.g., Delta outflow and residence time for water], K_ds [the ratio of selenium concentrations in particulates, as the lowest level of the food chain, relative to the water-borne concentration], and associated tissue concentrations [especially in clams and their consumers, such as sturgeon]). When the Delta Outflow Index (daily average flow per month) decreased by five-fold (73,732 cfs in June 1998 to 12,251 cfs in October 1998), residence time doubled (from 11 to 22 days) and the calculated mean K_d also doubled (from 3,198 to 6,501). However, when daily average Delta outflow in November 1999 was only 6,951 cfs (i.e., about one-half that in October 1998) and residence time was 70 days, the calculated mean K_d (7,614) did not increase proportionally.

Models are not available to quantitatively estimate the level of changes in selenium bioaccumulation as related to residence time, but the effects of residence time are incorporated in the bioaccumulation modeling for selenium that was based on higher K_d values for drought years in comparison to wet, normal, or all years (see Appendix 8M, *Selenium*). If increases in fish tissue or bird egg selenium were to occur, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. In consideration of this factor, although the Delta as a whole is a CWA Section 303(d)-listed water body for selenium, and although monitoring data of fish tissue or bird eggs in the Delta are sparse, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time from restoration areas would be a concern is the western Delta and Suisun Bay for sturgeon, as discussed above. As shown in Table 8-60a, the overall increase in residence time estimated in the western Delta is 3 days relative to Existing Conditions, and 1 day relative to the No Action Alternative. Given the available information, these increases are small enough that they are not expected to substantially affect selenium bioaccumulation in the western Delta. Because CM2 and CM4 are expected to be substantial drivers of the increased residence times, further discussion is included in Impact WQ-26 below.

In summary, relative to Existing Conditions and the No Action Alternative, Alternative 9 would result in small changes in selenium concentrations throughout the Delta for most biota (less than 4%), although larger increases in selenium concentrations are predicted for sturgeon in the western Delta. Concentrations of selenium in sturgeon would only exceed the lower benchmark for both western Delta locations for all years and drought years, indicating a low potential for effects. Concentrations of selenium in sturgeon would exceed the higher benchmark for Antioch only in drought years, indicating a high potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, the predicted increase for Alternative 9 are high enough that they may represent a measureable increase in body burdens of sturgeon, which would constitute an adverse impact.

SWP/CVP Export Service Areas

Alternative 9 would result in moderate decreases in average selenium concentrations in water at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative, for the entire period modeled (Appendix 8M, *Selenium*, Table M-9a). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium at these pumping plants of 5–12%, relative to the 1.3 µg/L USEPA draft water quality criterion (Figures 8-59a and 8-60a). Furthermore, the long-term average selenium concentrations in water for Alternative 9 (range 0.16–0.17 µg/L) would be well below the USEPA draft water quality criterion of 1.3 µg/L (Appendix 8M, Table M-9a).

Relative to Existing Conditions and the No Action Alternative, Alternative 9 would result in small changes (less than 3%) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) at export service areas (Figures 8-61a through 8-64b; Appendix 8M, Table M-29). Concentrations in biota would not exceed any selenium benchmarks for Alternative 9 (Figures 8-61a through 8-64b).

NEPA Effects: Based on the discussion above, the effects on selenium from Alternative 9 are considered to be adverse. This determination is reached because selenium concentrations in whole-body sturgeon modeled at two western Delta locations would increase by an average of 26%, which may represent a measurable increase in the environment. These potentially measurable increases represent an adverse impact.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for selenium. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Water Board 2010d) and State Water Board (2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 9, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate that Alternative 9 would result in small changes in selenium concentrations in water or most biota through the Delta, with no exceedances of benchmarks for biological effects. Relative to Existing Conditions, modeling estimates indicate that Alternative 9 would increase selenium concentrations in whole-body sturgeon modeled at two western Delta locations by an average of 26%, which may represent a measurable increase in the environment. Because both low and high toxicity benchmarks are exceeded, these potentially measurable increases represent a potential impact to fish and wildlife beneficial uses.

The assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 9 would cause no increase in the frequency with which applicable benchmarks would be exceeded, and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants.

Based on the above, although waterborne selenium concentrations would not exceed applicable water quality objectives/criteria; however, significant impacts on some beneficial uses of waters in the Delta could occur because uptake of selenium from water to biota would be expected to increase above potential effects levels at some locations, and in the western Delta where concentrations in sturgeon exceed both low and high toxicity benchmarks under Existing Conditions, uptake of selenium from water to sturgeon may measurably increase. In comparison to Existing Conditions, water quality conditions under this alternative would increase levels of selenium (a bioaccumulative pollutant) by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish); however, impacts to humans consuming those organisms are not expected to occur. Water quality conditions under this alternative with respect to selenium would cause long-term degradation of water quality in the western Delta. Except in the vicinity of the western Delta, water quality conditions under this alternative would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms. The greater level of selenium bioaccumulation in the western Delta would further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. This impact is considered significant. *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on selenium under Alternative 9 would be the same as those discussed for Alternative 1A and are considered not to be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on selenium resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance (CM1)

Upstream of the Delta

For the same reasons stated for the No Action Alternative, Alternative 9 would result in negligible, and likely immeasurable, increases in trace metal concentrations in the rivers and reservoirs upstream of the Delta, relative to Existing Conditions and the No Action Alternative. Effects due to the operation and maintenance of the conveyance facilities are expected to be immeasurable, on an annual and long-term average basis. As such, Alternative 9 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to trace metals.

Delta

For the same reasons stated for the No Action Alternative, Alternative 9 would not result in substantial increases in trace metal concentrations in the Delta relative to Existing Conditions and the No Action Alternative. However, substantial changes in source water fraction would occur in the south Delta (Appendix 8D, *Source Water Fingerprinting Results*). Throughout much of the south Delta, San Joaquin River water would replace Sacramento River water, with the future trace metals profile largely reflecting that of the San Joaquin River. As discussed for the No Action Alternative, trace metal concentration profiles between the San Joaquin and Sacramento Rivers are very similar and currently meet Basin Plan objectives and CTR criteria. While the change in trace metal concentrations in the south Delta would likely be measurable, Alternative 9 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the Delta or substantially degrade the quality of Delta waters with regard to trace metals.

SWP/CVP Export Service Areas

For the same reasons stated for the No Action Alternative, Alternative 9 would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities. As such, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP export service area waters under Alternative 9, relative to Existing Conditions and the No Action Alternative. As such, Alternative 9 would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment in the SWP and CVP Service Area or substantially degrade the quality of these water bodies, with regard to trace metals.

NEPA Effects: In summary, Alternative 9, relative to the No Action Alternative, would not cause a substantial increase in long-term average trace metals concentrations within the affected environment, nor would it cause an increased frequency of water quality objective/criteria exceedances within the affected environment. The effect on trace metals is determined not to be adverse.

CEQA Conclusion: Effects of CM1 on trace metals under Alternative 9 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

While greater water demands under the Alternative 9 would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based without a WER adjustment. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under the Alternative 9.

The assessment of the Alternative 9 effects on trace metals in the SWP/CVP Export Service Areas is based on assessment of changes in trace metal concentrations at Banks and Jones pumping plants. As just discussed regarding similarities in Delta source water trace metal concentrations, the Alternative 9 is not expected to result in substantial changes in trace metal concentrations in Delta waters, including Banks and Jones pumping plants, therefore effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

Based on the above, there would be no substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area waters under Alternative 9 relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of CM2–CM21

NEPA Effects: CM2–CM21 under Alternative 9 would be similar to conservation measures under Alternative 1A, but with changes in the south Delta to accommodate the modified corridors. Effects on trace metals resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. Implementation of CM2–CM21 would not be expected to adversely affect beneficial uses of the affected environment or substantially degrade water quality with respect to trace metals.

In summary, implementation of CM2–CM21under Alternative 9, relative to the No Action Alternative, would have negligible, if any, effect on trace metals concentrations. The effect on trace metals from implementing CM2–CM21 is determined not to be adverse.

CEQA Conclusion: Implementation of CM2–CM21 under Alternative 9 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP export service area. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance (CM1)

NEPA Effects: Effects of CM1 on TSS and turbidity under Alternative 9 would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM1 is determined to not be adverse.

CEQA Conclusion: Effects of CM1 on TSS and turbidity under Alternative 9 would be similar to those discussed for Alternative 1A, and are summarized here, then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion under Alternative 1A.

Changes river flow rate and reservoir storage that would occur under Alternative 9, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes would be site-specific and temporal, which would be regulated to limit both their short-term and long-term effects on TSS and turbidity levels to less than substantial levels.

Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. Consequently, this alternative is expected to have minimal effect on TSS concentrations and turbidity levels in the Delta region, relative to Existing Conditions.

There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative 9, relative to Existing Conditions, because as stated above, this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act section 303(d) listed constituents. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of CM2–CM21

NEPA Effects: Effects of CM2–CM21 on TSS and turbidity under Alternative 9 would be the same as those discussed for Alternative 1A. The effects on TSS and turbidity from implementing CM2–CM21 is determined to not be adverse.

CEQA Conclusion: CM2–CM21 proposed under Alternative 9 would be similar to conservation measures proposed under Alternative 1A. As such, effects on TSS and turbidity resulting from the implementation of CM2–CM21 would be similar to those previously discussed for Alternative 1A. This impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities (CM1–CM21)

The construction activities necessary to implement new conveyance features for CM1 under Alternative 9 would involve substantially different locations and types of construction activity to those discussed for Alternative 1A. In particular, the construction of permanent operable gates, locks, new levees, channel improvements and enlargement within Delta channels would involve considerable in-channel dredging and in-water facility construction activity. However, construction techniques for many features of the conveyance system within the Delta would be similar. Landside construction of water conveyance facilities under Alternative 9 would involve an array of intakes, pumping plants, pipelines, culvert siphons, canals, borrow areas, and other facilities. The remainder of the facilities constructed under Alternative 9, including CM2–CM21, would be very similar to, or the same as, those to be constructed for Alternative 1A.

NEPA Effects: he types of potential construction-related materials used, constituent discharges, and related water quality effects associated with implementation of CM1 under Alternative 9 would be similar to the effects discussed for Alternative 1A, and the effects anticipated with implementation of CM2–CM21 would be essentially identical. However, given the substantial differences in the conveyance features under CM1, there could be differences in the location, magnitude, duration, and frequency of construction activities and related water quality effects. In particular, relative to the Existing Conditions and No Action Alternative conditions, the extensive in-water dredging, and construction of channel enlargements, operable barriers, culvert siphons, and canal segments under Alternative 9 would result in potential direct turbidity discharges and sediment resuspension. Nevertheless, the construction of CM1, and any individual components necessitated by CM2, and CM4–CM10, with the implementation of the BMPs specified in Appendix 3B*, Environmental Commitments, AMMs, and CMs,* and other agency permitted construction requirements would result in the potential water quality effects being largely avoided and minimized. The specific environmental commitments that would be implemented under Alternative 9 would be similar to those described for Alternative 1A with the exception that Category "B" BMPs for RTM dewatering basin construction and operations, if necessary at all, would be much reduced. Consequently, relative to Existing Conditions, Alternative 9 would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP and CVP service area.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

***CEQA Conclusion*:** Because environmental commitments would be implemented under Alternative 9 for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP and CVP service area. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32. Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance (CM1)

Effects of facilities and operations (CM1) on *Microcystis* abundance, and thus microcystins concentrations, in water bodies of the affected environment under Alternative 9 would be very similar (i.e., nearly the same) to those discussed for Alternative 1A. This is because factors that affect *Microcystis* abundance in waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Services Areas under Alternative 1A would similarly change under Alternative 9, relative to Existing Conditions and the No Action Alternative. For the Delta in particular, there are differences in the direction and magnitude of water residence time changes during the *Microcystis* bloom period among the six Delta sub-regions under Alternative 9 compared to Alternative 1A, relative to Existing Conditions and No Action Alternative. However, under Alternative 9, relative to Existing Conditions and No Action Alternative, water residence times during the *Microcystis* bloom period in various Delta sub-regions are expected to increase to a degree that could, similar to Alternative 1A, lead to an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms throughout the Delta.

Similar to Alternative 1A, water exported from the Delta to the SWP/CVP Export Service Areas will consist of a mixture of water from the south Delta that is affected by *Microcystis* and Sacramento River water diverted from the north Delta that is unaffected by *Microcystis*. Sacramento River water will be conveyed through existing Delta channels under Alternative 9, in contrast to pipelines or tunnels which will be constructed to convey this water under Alternative 1A. Under Alternative 9, Delta channels, gates and barriers will be operated and maintained to convey Sacramento River water to the south Delta pump intakes in manner to maintain the water quality of this source water. Thus, it is expected that diverted Sacramento River water will remain relatively unaffected by *Microcystis* until it mixes with *Microcystis*-affected water from the south Delta at Banks and Jones pumping plants. For the same reasons described for Alternative 1A, it cannot be determined whether operations and maintenance under Alternative 9, relative to existing conditions, will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants.

Similar to Alternative 1A, elevated ambient water temperatures relative to Existing Conditions would occur in the Delta under Alternative 9, which could lead to earlier occurrences of *Microcystis* blooms in the Delta, and increase the overall duration and magnitude of blooms. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. While *Microcystis* blooms have not occurred in the Export Service Areas, conditions in the Export Service Areas under Alternative 9 may become more conducive to *Microcystis* bloom formation, relative to Existing Conditions, because water temperatures will increase in the Export Service Areas due to the expected increase in ambient air temperatures resulting from climate change.

NEPA Effects: Effects of water facilities and operations (CM1) on *Microcystis* in water bodies of the affected environment under Alternative 9 would be very similar to (i.e., nearly the same) to those discussed for Alternative 1A. In summary, Alternative 9 operations and maintenance, relative to the No Action Alternative, would result in long-term increases in hydraulic residence time of various Delta sub-regions during the summer and fall *Microcystis* bloom period. During this period, the increased residence time could result in a concurrent increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus microcystin levels, in affected areas of the Delta. As a result, Alternative 9 operation and maintenance activities would cause further degradation to water quality with respect to *Microcystis* in the Delta. Under Alternative 9, relative to No Action Alternative, water exported to the SWP/CVP Export Service Area will be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River, diverted at the north Delta intakes. It cannot be determined whether operations and maintenance under Alternative 9 will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants. Mitigation Measure WQ-32a and WQ-32b are available to reduce the effects of degraded water quality in the Delta. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be adverse.

CEQA Conclusion: Key findings discussed in the effects assessment provided above are summarized here, and are then compared to the CEQA thresholds of significance (defined in Section 8.3.2) for the purpose of making the CEQA impact determination for this constituent. For additional details on the effects assessment findings that support this CEQA impact determination, see the effects assessment discussion that immediately precedes this conclusion.

Under Alternative 9, additional impacts from *Microcystis* in the reservoirs and watersheds upstream of the Delta are not expected, relative to Existing Conditions. Operations and maintenance occurring under Alternative 9 is not expected to change nutrient levels in upstream reservoirs or hydrodynamic conditions in upstream rivers and streams such that conditions would be more conductive to *Microcystis* production.

Relative to Existing Conditions, water temperatures and hydraulic residence times in the Delta are expected to increase under Alternative 9, resulting in an increase in the frequency, magnitude and geographic extent of *Microcystis* blooms in the Delta. However, the degradation of water quality from *Microcystis* blooms due to the expected increases in Delta water temperatures is driven entirely by climate change, not effects of CM1. Increases in Delta residence times are expected throughout the Delta during the summer and fall bloom period, due in small part to climate change and sea level rise, but due more proportionately to CM1 and the hydrodynamic impacts of restoration included in CM2 and CM4. The precise change in local residence times and *Microcystis* production expected within any Delta sub-region is unknown because conditions will vary across the complex networks of intertwining channels, shallow back water areas, and submerged islands that compose the Delta. Nonetheless, Delta residence times are, in general, expected to increase due to Alternative 9. Consequently, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 9 and the hydrodynamic impacts of restoration (CM2 and CM4).

The assessment of effects of *Microcystis* on SWP/CVP Export Service Areas is based on the assessment of changes in *Microcystis* levels in export source waters, as well as the effects of temperature and residence time changes within the Export Service Areas on *Microcystis* production. Under Alternative 9, relative to Existing Conditions, the potential for *Microcystis* to occur in the Export Service Area is expected to increase due to increasing water temperature, but this impact is driven entirely by climate change and not Alternative 9. Water exported from the Delta to the Export Service Area is expected to be a mixture of *Microcystis*-affected source water from the south Delta intakes and unaffected source water from the Sacramento River. Because of this, it cannot be determined whether operations and maintenance under Alternative 9, relative to existing conditions, will result in increased or decreased levels of *Microcystis* and microcystins in the mixture of source waters exported from Banks and Jones pumping plants.

Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, because it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta will occur due to the operations and maintenance of Alternative 9 and the hydrodynamic impacts of restoration (CM2 and CM4), long-term water quality degradation may occur and, thus, significant impacts on beneficial uses could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM1 is determined to be significant.

Implementation of Mitigation Measure WQ-32a and WQ-32b may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of these mitigation measures to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Mitigation Measure WQ-32b: Investigate and Implement Operational Measures to Manage Water Residence Time

Please see Mitigation Measure WQ-32b under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-33. Effects on *Microcystis* Bloom Formation Resulting from Other Conservation Measures (CM2–CM21)

The effects of CM2–CM21 on *Microcystis* under Alternative 9 would be the same as those discussed for Alternative 1A. In summary, implementation of CM2 and CM4 could result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta, relative to Existing Conditions and the No Action Alternative, as a result of increased residence times for Delta waters. Because the hydrodynamic effects associated with implementing CM2 and CM4 were incorporated into the modeling used to assess CM1, a detailed assessment of the effects of implementing CM2 and CM4 on *Microcystis* blooms in the Delta via their effects on Delta water residence time is provided under CM1 (above). The effects of CM2 and CM4 on *Microcystis* may be reduced by implementation of Mitigation Measures WQ-32a. The effectiveness of the mitigation measure to result in feasible measures for reducing water quality effects is uncertain. CM3 and CM5–CM21 would not result in an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta.

NEPA Effects: Effects of CM2–CM21 on *Microcystis* under Alternative 9 would be the same as those discussed for Alternative 1A and are considered to be adverse.

CEQA Conclusion: Based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. Because restoration actions implemented under CM2 and CM4 will increase residence time throughout the Delta and create local areas of warmer water during the bloom season, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms, and thus long-term water quality degradation and significant impacts on beneficial uses, could occur. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans.Although there is considerable uncertainty regarding this impact, the effects on *Microcystis* from implementing CM2–CM21 are determined to be significant.

Implementation of Mitigation Measure WQ-32a may reduce degradation of Delta water quality due to *Microcystis*. However, because the effectiveness of this mitigation measure to result in feasible measures for reducing water quality effects is uncertain, this impact is considered to remain significant and unavoidable.

Mitigation Measure WQ-32a: Design Restoration Sites to Reduce Potential for Increased *Microcystis* Blooms

Please see Mitigation Measure WQ-32a under Impact WQ-32 in the discussion of Alternative 1A.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance (CM1) and Implementation of CM2–CM21

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 9 would have a less than significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- DO
- Pathogens
- Pesticides
- Trace Metals
- Turbidity and TSS

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Thus, changes in boron, DO, pathogens, pesticides, and turbidity and TSS in Delta outflow are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay.

The effects of Alternative 9 on bromide, chloride, and DOC, in the Delta were determined to be significant/adverse. Increases in bromide, chloride, and DOC concentrations are of concern in drinking water supplies; however, as described previously, the San Francisco Bay does not have a designated MUN use. Thus, changes in bromide, chloride, and DOC in Delta outflow would not adversely effect any beneficial uses of San Francisco Bay.

Elevated EC, as assessed for this alternative, is of concern for its effects on the AGR AGR and fish and wildlife beneficial uses. As discussed above, San Francisco Bay does not have an AGR beneficial use designation. Further, as discussed for the No Action Alternative, changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow, which would be the primary driver of salinity changes, would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow.

Also, as discussed for the No Action Alternative, adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in San Francisco Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus have not been detected downstream of Suisun Bay.

While effects of Alternative 9 on the nutrients ammonia, nitrate, and phosphorus were determined to be less than significant/not adverse, these constituents are addressed further below because the response of the seaward bays to changed nutrient concentrations/loading may differ from the response of the Delta. Selenium and mercury are discussed further, because they are bioaccumulative constituents where changes in load due to both changes in Delta concentrations and exports are of concern.

Nutrients: Ammonia, Nitrate, and Phosphorus

Total nitrogen loads in Delta outflow to Suisun and San Pablo Bays under Alternative 9 would be dominated almost entirely by nitrate, because planned upgrades to the SRWTP will result in >95% removal of ammonia in its effluent. Total nitrogen loads to Suisun and San Pablo Bays would decrease by 17%, relative to Existing Conditions, and increase by 21%, relative to the No Action Alternative (Appendix 8O, *San Francisco Bay Analysis*, Table O-1). The change in nitrogen loading to Suisun and San Pablo Bays under Alternative 9 would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. To the extent that algal growth increases in relation to a change in ammonia concentration, this would have net positive benefits, because current algal levels in these embayments are low. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay.

The phosphorus load exported from the Delta to Suisun and San Pablo Bays for Alternative 9 is estimated to increase by 5%, relative to Existing Conditions, and there would be no change relative to the No Action Alternative (Appendix 8O, Table O-1). The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. Any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary (Senn and Novick 2014; Kimmerer and Thompson 2014). Therefore, the projected change in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay is not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Mercury

The estimated long-term average mercury and methylmercury loads in Delta exports are shown in Appendix 8O, *San Francisco Bay Analysis*, Table O-2. Loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 9. Mercury load to the Bay is estimated to increase by 8 kg/year (3%), relative to Existing Conditions, and 5 kg/year (2%), relative to the No Action Alternative. Methylmercury load is estimated to increase by 0.14 kg/year (4%), relative to Existing Conditions, and increase by 0.05 kg/year (1%) relative to the No Action Alternative. The estimated total mercury load to the Bay is 268 kg/year, which would be less than the San Francisco Bay mercury TMDL WLA for the Delta of 330 kg/year. The estimated changes in mercury and methylmercury loads would be within the overall uncertainty associated with the estimates of long-term average net Delta outflow and the long-term average mercury and methylmercury concentrations in Delta source waters. The estimated changes in mercury load under the alternative would also be substantially less than the considerable differences among estimates in the current mercury load to San Francisco Bay (San Francisco Bay Regional Water Quality Control Board 2006; David et al. 2009).

Given that the estimated incremental increases of mercury and methylmercury loading to San Francisco Bay would fall within the uncertainty of current mercury and methylmercury load estimates, the estimated changes in mercury and methylmerucy loads in Delta exports to San Francisco Bay due to Alternative 9 are not expected to result in adverse effects to beneficial uses or substantially degrade the water quality with regard to mercury, or make the existing CWA Section 303(d) impairment measurably worse.

Selenium

Changes in source water fraction and net Delta outflow under Alternative 9, relative to Existing Conditions, are projected to cause the total selenium load to the North Bay to increase by 16%, relative to Existing Conditions, and increase by 13%, relative to the No Action Alternative (Appendix 8O, *San Francisco Bay Analysis*, Table O-3). Changes in long-term average selenium concentrations of the North Bay are assumed to be proportional to changes in North Bay selenium loads. Under Alternative 9, the long-term average total selenium concentration of the North Bay is estimated to be 0.15 μg/L and the dissolved selenium concentration is estimated to be 0.13 μg/L, which would be a 0.02 μg/L increase relative to Existing Conditions and the No Action Alternative (Appendix 8O, Table O-3). The dissolved selenium concentration would be below the target of 0.202 μg/L developed by Presser and Luoma (2013) to coincide with a white sturgeon whole-body fish tissue selenium concentration not greater than 8 mg/kg in the North Bay.

The incremental increase in dissolved selenium concentrations projected to occur under Alternative 9, relative to Existing Conditions and the No Action Alternative, would be higher than under Alternatives 1A–5, but still low (0.02 μg/L). The increased dissolved selenium concentration would be within the overall uncertainty of the analytical methods used to measure selenium in water column samples; however, it also would be within the uncertainty associated with estimating numeric water column selenium thresholds (Pressor and Luoma 2013). As described in Section 8.3.1.8, there have been improvements in selenium concentrations in the tissue of diving ducks and muscle of white sturgeon since the initial CWA Section 303(d) listing of the North Bay for selenium impairments, and selenium concentrations in white sturgeon muscle have also generally been below the USEPA's draft recommended fish muscle tissue concentration of 11.8 mg/kg dry weight (San Francisco Estuary Institute 2014). However, as described under Impact WQ-25, though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases for Alternative 9 are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Because the projected incremental increases in dissolved selenium could cause measurable changes in water column concentrations, and these incremental increases would be within the uncertainty in the target water column threshold for dissolved selenium for protection against adverse bioaccumulative effects in the North Bay ecosystem, and modeling predicts concentrations in the western Delta may represent a measurable increase in body burdens of sturgeon, there is potential that the incremental increase in dissolved selenium concentration projected to occur in the North Bay under Alternative 9 could result in adverse effects beneficial uses.

NEPA Effects: Based on the discussion above, Alternative 9, relative to the No Action Alternative, would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, based on the discussion above, effects on the San Francisco Bay from implementation of CM1–CM21 are considered to be not adverse with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. However, Alternative 9 could result in increases in selenium concentrations in the North San Francisco Bay that could result in adverse effects to fish and wildlife beneficial uses. This effect is considered to be adverse.

CEQA Conclusion: Based on the above, Alternative 9 would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Further, based on the above, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, nutrients (ammonia, nitrate, phosphorus), trace metals, or turbidity and TSS. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals or turbidity or TSS are anticipated in the Delta, relative to Existing Conditions, therefore, no substantial changes these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow. Adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in the

Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus not have not been detected downstream of Suisun Bay. The 17% decrease in total nitrogen load and 5% increase in phosphorus load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. The estimated increase in mercury load (8 kg/year; 3%) and methylmercury load (0.14 kg/year; 4%), relative to Existing Conditions, is within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans.

In regard to selenium, the estimated increase in selenium load would be 16% and the estimated increase in dissolved selenium concentrations would be 0.02 µg/L. Though there is some uncertainty in the estimate of sturgeon concentrations at western Delta locations, the predicted increases are high enough that they may represent measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish). Thus, the increase in selenium load may make the CWA section 303(d) selenium impairment measurably worse and cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish and wildlife. This impact is considered to be significant.*AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium. The effectiveness of AMM27 is uncertain and, therefore implementation may not reduce the identified impact to a level that would be less than significant, and therefore it is significant and unavoidable.

8.3.4 Effects and Mitigation Approaches—Alternatives 4A, 2D, and 5A

8.3.4.1 No Action Alternative Early Long-Term

Discussion of water quality impacts of the No Action Alternative (ELT) was first provided in the Partially Recirculated Draft Environmental Impact Report/Supplementatl Draft Environmental Impact Statement (RDEIR/SDEIS). The water quality assessments in the RDEIR/SDEIS for boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Services Areas utilized results from water quality modeling that assumed no implementation of Yolo Bypass improvements or tidal habitat restoration. The analysis of effects of the No Action Alternative (ELT) presented herein on boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Service Areas is based on revised modeling, which assumed implementation of Yolo Bypass improvements, but no tidal habitat restoration. The water quality impact conclusions for the No Action Alternative (ELT) in this Final EIR/EIS remain the same as those presented in the RDEIR/SDEIS. The revisions to the assessment are in the presentation of modeled changes in concentrations, water quality criteria/objective exceedances, and use of assimilative capacity.

As described in Section Chapter 3, Section 3.5.17, *No Action Alternative ELT*, 8,000 acres of tidal habitat restoration areas would be developed under the No Action Alternative (ELT). In general, the significance of this relative to the modeling results that do not reflect this restoration area is the assessment of bromide, chloride and EC for the No Action Alternative (ELT), relative to Existing Conditions, may underestimate increases in bromide, EC, and chloride that could occur, particularly in the west Delta. Nevertheless, there is some uncertainty in the results of all quantitative assessments that refer to modeling results, due to the differing assumptions used in the modeling and the description of the No Action Alternative (ELT).

Note that the numbering of water quality impacts for the No Action Alternative (ELT), presented below, is consistent with the numbering of impacts for Alternatives 4A, 2D, and 5A, For the project alternatives, two numbered impacts are provided for each constituent or constituent class, one for impacts due to water conveyance facilities operations and maintenance and the other for impacts due to Environmental Commitments. For the No Action Alternative (ELT), only discussion of impacts due to water conveyance facilities operations and maintenance is applicable. Therefore, only one numbered impact for each constituent or constituent-class is provided for the No Action Alternative (ELT), consistent with the numbering for Alternatives 4A, 2D, and 5A water conveyance facilities operations and maintenance impacts.

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on ammonia levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT) discussed in Section 8.3.3.1. This is because factors which affect ammonia levels in these areas would be similar at the ELT and LLT timeframes. The Sacramento Regional County Sanitation District will have completed modifications to the Sacramento Regional Wastewater Treatment Plant (SRWTP) in the ELT that will substantially reduce ammonia in the treated wastewater discharge and thus substantially lower concentrations of ammonia in the Sacramento River downstream of the SRWTP relative to Existing Conditions. A substantial decrease in Sacramento River ammonia concentrations is expected to decrease ammonia concentrations for all areas that are influenced by Sacramento River water, which includes various locations in the Delta and at Jones and Banks Pumping Plants where Delta water is exported to the SWP/CVP Export Service Areas. At locations which are not influenced notably by Sacramento River water, concentrations are expected to remain relatively unchanged relative to Existing Conditions. Based on these factors and for the reasons described for the No Action Alternative (LLT) in Section 8.3.3.1, the effects on ammonia from implementing the No Action Alternative (ELT) would not be adverse.

CEQA Conclusion: The effects of the No Action Alternative (ELT) on ammonia levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT). This is because factors that would directly affect ammonia levels in the surface waters of these areas are expected to be similar in the ELT and LLT. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Ammonia is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered less than significant.

Impact WQ-3: Effects on Boron Concentrations Resulting from Existing Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on boron concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for the No Action Alternative (LLT) in Section 8.3.3.1. There would be no expected change to the sources of boron in the Sacramento River and eastside tributary watersheds, and changes in the magnitude and timing of reservoir releases and river flows upstream of the Delta would have negligible, if any, effect on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly compared to Existing Conditions in association with climate change and increased water demands. The reduced flow would result in possible increases in long-term average boron concentrations of up to about 0.5% relative to the Existing Conditions (Appendix 8F, *Boron*, Table Bo-32). Consequently, the increases in lower San Joaquin River boron levels under the No Action Alternative (ELT), relative to Existing Conditions, would be small and not adversely affect any beneficial uses of the lower San Joaquin River.

Delta

Relative to Existing Conditions, the No Action Alternative (ELT) would result in similar or decreased long-term annual average boron concentrations at all of the Delta assessment locations for the 16-year period modeled (i.e., 1976–1991) (Appendix 8F, *Boron*, Table Bo-24). For the drought year period modeled (i.e., 1987–1991), the No Action Alternative (ELT) would result in increased annual average concentrations at Franks Tract (1% increase), Old River at Rock Slough (1% increase), and the Sacramento River at Emmaton (3% increase) relative to Existing Conditions.

With respect to the 2,000 μg/L EPA drinking water human health advisory objective (i.e., for children) and agricultural objective of 500 μg/L contained in the San Francisco Bay Water Board (Region 2) Basin Plan, the long-term annual average boron concentrations, for either the 16-year period or drought period modeled, are low and would not exceed these objectives at any of the eleven Delta assessment locations (Appendix 8F, *Boron*, Table Bo-3C). The maximum long-term average concentration of about 423 μg/L in the Sacramento River at Mallard Island under the No Action Alternative (ELT) represents a slight decrease from the Existing Conditions. Accordingly, the long-term assimilative capacity with respect to both objectives would not change substantially, thus boron levels that may occur under the No Action Alternative (ELT), relative to Existing Conditions, would not be expected to adversely affect municipal water supply beneficial uses of the Delta.

SWP/CVP Export Service Areas

Under the No Action Alternative (ELT), a relatively small increase would occur in the long-term average boron concentration at the Jones Pumping Plant, relative to the Existing Conditions (i.e., up to 1% for both the 16-year and drought period modeled) and a small decrease would occur at the Banks Pumping Plant (i.e., reduced 1%) (Appendix 8F, *Boron*, Table Bo-24). The small change in boron concentrations exported from the Delta would not be expected to measurably affect boron levels in the lower San Joaquin River at Vernalis or the existing CWA Section 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading.

In summary, the effects of additional future climate change/sea level rise under the No Action Alternative (ELT) condition would result in relatively small changes in long-term average boron concentrations in the lower San Joaquin River and several Delta locations. However, the predicted changes would not be expected to cause exceedances of applicable objectives or further measurable water quality degradation, and thus would not constitute an adverse effect on water quality. The changes to long-term and monthly average boron concentrations at locations upstream of the Delta, in the Delta, and the SWP/CVP Export Service areas under the No Action Alternative (ELT) would be similar or lower in magnitude relative to effects described for the No Action Alternative (LLT) in Section 8.3.3.1.

CEQA Conclusion: The effects of the No Action Alternative (ELT) on boron levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT). This is because factors that would directly affect boron levels in the surface waters of these areas are expected to be similar at the ELT and LLT timeframes. As such, the No Action Alternative (ELT) is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because boron concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Additionally, the changes in long-term average boron concentrations in exported water would not result in further degradation or the existing impairment and CWA Section 303(d) listing of boron in the lower San Joaquin River for the agricultural water supply beneficial use to be discernibly worse. Boron is not a bioaccumulative constituent, thus any increased concentrations under the No Action Alternative (ELT) would not result in adverse boron bioaccumulation effects to aquatic life or humans. Based on these findings, this impact is determined to be less than significant.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on bromide concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for the No Action Alternative (LLT) in Section 8.3.3.1, because factors affecting bromide concentrations in these water bodies would be the same in the ELT. There would be no expected change to the sources of bromide in the Sacramento River and eastside tributary watersheds, and changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of bromide in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions in association with climate change and increased water demands, but the associated change would less than in the LLT, and any associated bromide increase would not be substantial, as described for the LLT (Appendix 8E, *Bromide*, Table 24). Moreover, there are no existing municipal intakes on the lower San Joaquin River. Consequently, the No Action Alternative (ELT) would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the San Joaquin River, the eastside tributaries, or their associated reservoirs upstream of the Delta due to changes in bromide concentrations.

Delta

Estimates of bromide concentrations at Delta assessment locations were generated using a mass balance approach, and using relationships between EC and chloride and between chloride and bromide and DSM2 EC output. See Section 8.3.1.3 for more information regarding these modeling approaches. The assessment below identifies changes in bromide at Delta assessment locations based on both approaches.

Relative to Existing Conditions, the No Action Alternative (ELT) would result in small decreases or essentially no change in long-term average bromide concentrations at all modeled Delta assessment locations (Appendix 8E, *Bromide*, Tables 22 and 23). Long-term average concentrations of seawater-derived constituents generally decrease under the No Action Alternative (ELT) relative to Existing Conditions because the No Action Alternative (ELT) includes Fall X2 operations, while Existing Conditions does not (Appendices 3D, *Defining Existing Conditions, No Action Alternative, No Project Alternative, and Cumulative Impact Condition*, and 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Therefore, even though sea level rise is included in the No Action Alternative (ELT), and not in Existing Conditions, the effect of Fall X2 on bromide is generally greater than sea level rise.

The modeled frequency with which bromide concentrations would exceed bromide thresholds would change only slightly at Delta assessment locations (Appendix 8E, *Bromide*, Table 22). Small increases in exceedance of the CALFED Drinking Water Program long-term goal of 50 µg/L would occur at the Mokelumne River at Staten Island (4% increase), in the Sacramento River at Emmaton (2% increase) and in Old River at Rock Slough (1% increase). Small increases in exceedance of 100 µg/L, which is the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts, would occur at some Delta interior and western Delta assessment locations. In the Delta interior at Rock Slough and Franks Tract, the frequency of exceeding 100 µg/L would increase by up to 2%. In the western Delta, the frequency of exceeding 100 µg/L would increase by up to 5% at Emmaton, by up to 2% at Antioch and up to 1% at Mallard Island. As described for the No Action Alternative (LLT) in Section 8.3.3.1, the resulting bromide concentrations would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, particularly when considering the relatively small change in long-term annual average concentration.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide were consistent with the discussion above, and assessment of bromide using these data results in the same conclusions as are presented above for the mass-balance approach (Appendix 8E, *Bromide*, Table 23).

SWP/CVP Export Service Areas

Under the No Action Alternative (ELT), long-term average bromide concentrations at the Banks and Jones Pumping Plants would decrease by as much as 6% relative to Existing Conditions (Appendix 8E, *Bromide*, Table 22), based on the mass balance modeling results. The frequency with which bromide would exceed bromide concentration thresholds at the Banks and Jones Pumping Plants, relative to Existing Conditions, would remain unchanged (Appendix 8E, *Bromide*, Table 22). Consequently water exported into the SWP/CVP Export Service Areas through these south Delta pumps would be of similar or slightly better quality with regard to bromide under the No Action Alternative (ELT), relative to Existing Conditions. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide were consistent these results, and assessment of bromide using these modeling results leads to the same conclusions as presented for the mass balance approach (Appendix 8E, *Bromide*, Table 23).

In summary, the effects of additional future climate change/sea level rise under the No Action Alternative (ELT) condition would result in relatively small changes in long-term average bromide concentrations in the lower San Joaquin River and several Delta locations. However, the predicted changes would not be expected to cause exceedances of applicable objectives or further measurable water quality degradation, and thus would not constitute an adverse effect on water quality. The changes to long-term and monthly average boron concentrations at locations upstream of the Delta, in the Delta, and the SWP/CVP Export Service areas under the No Action Alternative (ELT) would be similar or lower in magnitude relative to effects described for the No Action Alternative (LLT) in Section 8.3.3.1.

Maintenance of SWP and CVP facilities under the No Action Alternative (ELT) would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

***CEQA Conclusion*:** While greater water demands under the No Action Alternative (ELT) would alter the magnitude and timing of reservoir releases north and east of the Delta, these activities would have negligible, if any, effect on the sources of bromide, and ultimately the concentration of bromide in the Sacramento River, the San Joaquin River, the eastside tributaries, and the various reservoirs of the related watersheds, as described for the No Action Alternative (LLT).

Relative to Existing Conditions, the No Action Alternative (ELT) would result in small decreases or essentially no change in average bromide concentrations at all modeled Delta assessment locations. Small increases in bromide threshold exceedances would occur at some Delta interior and western Delta assessment locations, including the Mokelumen River at Staten Island, Rock Slough, Franks Tract, Emmaton, Antioch and Mallard Island, but the resulting conditions would not be expected to adversely affect MUN beneficial uses, or any other beneficial use.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones Pumping Plants Average bromide concentrations at the Banks and Jones Pumping Plants are predicted to decrease by as much as 6% relative to Existing Conditions while exceedance of bromide concentration thresholds at the Banks and Jones Pumping Plants would remain unchanged.

Based on the above, the No Action Alternative (ELT) would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria because none exist for bromide. The No Action Alternative (ELT) would not result in any substantial change in long-term average bromide concentration or exceed 50 and 100 µg/L assessment threshold concentrations by frequency, magnitude, and geographic extent that would result in adverse effects on any beneficial uses within affected water bodies. Bromide is not a bioaccumulative constituent and thus concentrations under this alternative would not result in bromide bioaccumulating in aquatic organisms. Increases in exceedances of the 100 µg/L assessment threshold concentration would be 5% or less at all locations assessed, which is considered to be less-than substantial long-term degradation of water quality. The levels of bromide degradation that may occur under the No Action Alternative (ELT) would not be of sufficient magnitude to cause substantially increased risk for adverse effects on any beneficial uses of water bodies within the affected environment. Bromide is not CWA Section 303(d) listed and thus the minor increases in long-term average bromide concentrations would not affect existing beneficial use impairment because no such use impairment currently exists for bromide. Based on these findings, this impact is less than significant.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on chloride concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for the No Action Alternative in Section 8.3.3.1, because factors affecting chloride concentrations in these water bodies would be the same in the early long-term timeframe. There would be no expected change to the sources of chloride in the Sacramento River and eastside tributary watersheds, and changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of chloride in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions in association with climate change and increased water demands, but the associated change would less than under the LLT, and any associated chloride increase would be less than substantial, as described for the LLT. Moreover, there are no existing municipal intakes on the lower San Joaquin River. Consequently, the No Action Alternative (ELT) would not be expected to cause exceedance of chloride objectives or substantially degrade water quality with respect to chloride and thus would not adversely affect any beneficial uses of the Sacramento River, the San Joaquin River, the eastside tributaries, or their associated reservoirs upstream of the Delta.

Delta

Estimates of chloride concentrations at Delta assessment locations were generated using a mass balance approach and EC chloride relationships and DSM2 EC output. See Section 8.3.1.3 for more information regarding these modeling approaches. The assessment below identifies changes in chloride at Delta assessment locations based on both approaches.

Relative to Existing Conditions, the mass balance modeling predicts that the No Action Alternative (ELT) would result in similar, or in small decreases in, long-term average chloride concentrations for the 16-year period modeled (i.e., 1976–1991) at all Delta assessment locations except the Sacramento River at Emmaton (Appendix 8G, *Chloride*, Table Cl-65). In the Sacramento River at Emmaton, there would be a 2 mg/L (<1%) decrease in the long-term average chloride concentration, but a 45 mg/L (9%) increase in the drought period modeled (i.e., 1987–1991) chloride concentration. Long-term average concentrations of seawater-derived constituents would generally decrease under the No Action Alternative (ELT) relative to Existing Conditions because the No Action Alternative (ELT) includes Fall X2, while Existing Conditions does not (Appendices 3D, *Defining Existing Conditions, No Action Alternative, No Project Alternative, and Cumulative Impact Condition*, and 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Therefore, even though sea level rise is included in the No Action Alternative (ELT), and not in Existing Conditions, the effect of Fall X2 on chloride is generally greater than sea level rise.

The comparison to Existing Conditions reflects changes in chloride due to both increased demands and changed hydrology and Delta hydrodynamic conditions associated with climate change and sea level rise. The following outlines the modeled chloride changes relative to the applicable objectives and effects on beneficial uses in Delta waters.

Municipal and Industrial Beneficial Uses Relative to Existing Conditions

Estimates of chloride concentrations generated using EC chloride relationships were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective would be exceeded for the 16-year period modeled. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at Antioch or Contra Costa Pumping Plant #1. For the No Action Alternative (ELT), the frequency of objective exceedance would decrease relative to Existing Conditions. The frequency of exceedance of the 150 mg/L objective is predicted to be 7% of years under Existing Conditions and 0% under the No Action Alternative (Appendix 8G, *Chloride*, Table Cl-64).

Evaluation of the 250 mg/L Bay-Delta WQCP objective for chloride utilized results from both the mass balance approach and EC chloride relationships. The basis for the evaluation was the predicted number of days the objective would be exceeded for the modeled 16-year period.

Based on the mass-balance approach, there would be an increased frequency of exceedance of the 250 mg/L objective under the No Action Alternative (ELT), relative to Existing Conditions, in the Sacramento River at Emmaton, the San Joaquin River at Antioch, and the Sacramento River at Mallard Island. At Emmaton, the frequency of objective exceedance would increase from 55% under Existing Conditions to 60% under the alternative during the drought period; when the entire modeled period is considered, there would be a decrease in the frequency of objective exceedance. At Antioch, the frequency of objective exceedance would increase from 66% to 70% for the entire period modeled, and from 82% to 85% during the drought period modeled. In the Sacramento River at Mallard Island, the frequency of objective exceedance would increase from 85% to 86% for the entire period modeled (Appendix 8G, *Chloride*, Table Cl-81). These changes are small enough that they may be within the uncertainty of the modeling approach.

Estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For the No Action Alternative (ELT), the modeled frequency of objective exceedance would increase, from 6% of modeled days under Existing Conditions, to 8% of modeled days under the No Action Alternative (ELT) (Appendix 8G, *Chloride*, Table Cl-63).

The mass balance results also indicate reduced assimilative capacity with respect to the 250 mg/L objective during certain months and locations. At Franks Tract, Old River at Rock Slough, and Sacramento River at Emmaton, there would be a reduction in assimilative capacity in January of 48-100% during the drought period modeled. Use of assimilative capacity would be 67% over the 16 year period modeled in June in the Sacramento River at Emmaton. In the San Joaquin River at Antioch, there would be a reduction in assimilative capacity in March and April of up to 19% for the 16-year period modeled, and a 49% reduction during the drought period modeled (Appendix 8G, *Chloride*, Table Cl-67). Assimilative capacity at the Contra Costa Pumping Plant #1 also would be reduced, in February and March, by up to 13%, and by 75% during January of the drought period modeled.

When utilizing the EC-chloride relationship to model chloride concentrations for the 16-year period, trends in frequency of exceedance of the 250 mg/L objective and use of assimilative capacity are similar to those discussed above for the mass balance modeling approach (Appendix 8G, *Chloride*, Tables Cl-68 and Cl-82).

Based on the additional predicted seasonal and annual exceedances of Bay Delta WQCP objectives for chloride, and the associated long-term water quality degradation and use of assimilative capacity, the potential exists for adverse effects on the municipal and industrial beneficial uses in the western Delta, particularly at Antioch, through reduced opportunity for diversion of water with acceptable chloride levels.

CWA Section 303(d) Listed Water Bodies–Relative to Existing Conditions

Tom Paine Slough in the southern Delta is on the state's CWA Section 303(d) list for chloride with respect to the secondary MCL of 250 mg/L. Monthly average chloride concentrations at the Old River at Tracy Road for the 16-year period modeled, which represents the nearest DSM2-modeled location to Tom Paine Slough, would be well below the MCL and generally would be similar to Existing Conditions (Appendix 8G, *Chloride*, Figure Cl-17).

Suisun Marsh also is on the state's CWA Section 303(d) list for chloride in association with the Bay-Delta WQCP objectives for maximum allowable salinity during the months of October through May, which establish appropriate seasonal salinity conditions for fish and wildlife beneficial uses. The Sacramento River at Mallard Island, Sacramento River at Collinsville, and Montezuma Slough at Beldon's Landing within the marsh are DSM2-modeled locations representative of source water quality conditions for the marsh that is supported by inflowing flood tide waters from the west, and ebb tide flows of Sacramento River water into Montezuma Slough through the Suisun Marsh Salinity Control Gates located near Collinsville. Long-term average chloride concentrations at the Sacramento River at the Mallard Island for the 16-year period modeled would decrease by 100 mg/L (4%) relative to Existing Conditions (Appendix 8G, *Chloride*, Table Cl-65). The plots of monthly average chloride concentrations for the Sacramento River at Collinsville (Appendix 8G, *Chloride*, Figure Cl-19) and Montezuma Slough at Beldon's Landing (Appendix 8G, *Chloride*, Figure Cl-20) for the 16-year period modeled indicate that, relative to Existing Conditions, chloride concentrations would be similar or lower during the months of October through May. Consequently, chloride concentrations at Tom Paine Slough and Suisun Marsh would not be further degraded on a long-term basis or adversely affect necessary actions to reduce chloride loading for any TMDLs developed.

SWP/CVP Export Service Areas

Under the No Action Alternative (ELT), long-term average chloride concentrations at the Banks and Jones Pumping Plants would decrease by 6% and 5%, respectively, relative to Existing Conditions for the 16-year period modeled, based on mass-balance modeling results (Appendix 8G, *Chloride*, Table Cl-65). However, the frequency of objective exceedance would increase at both pumping plants, relative to Existing Conditions, for both the 16-year period and the drought period modeled (Appendix 8G, *Chloride*, Table Cl-81). Results of the modeling approach which utilized a EC chloride relationship are consistent these results, and assessment of chloride using these modeling output results in the same conclusions as for the mass-balance approach (Appendix 8G, *Chloride*, Tables Cl-66 and Cl-82).

Maintenance of SWP and CVP facilities under the No Action Alternative (ELT) would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any beneficial uses would be adversely affected anywhere in the affected environment.

***CEQA Conclusion*:** Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under the No Action Alternative (ELT), relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, the No Action Alternative (ELT) would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

It is expected there would be changes in Delta chloride levels in response to a shift in the Delta source water percentages under the No Action Alternative (ELT) or some degradation of these water bodies. There would be an increase in the frequency of exceedance of the daily average 250 mg/L chloride objective applicable at Contra Costa Pumping Plant #1 from 6% of modeled days to under Existing Conditions to 8% of modeled days under the No Action Alternative (ELT). Relative to Existing Conditions, the No Action Alternative (ELT) also would result in increased chloride concentrations such that frequency of exceedance of the 250 mg/L Bay-Delta WQCP objective would increase in the San Joaquin River at Antioch (by 4%) and in the Sacramento River at Mallard Island (by 1%), and long-term degradation may occur, that may result in adverse effects on the municipal and industrial water supply beneficial use. With respect to CWA Section 303(d) listings, the similar average chloride concentrations would not cause further degradation on a long-term basis that would adversely affect necessary actions to reduce chloride loading for any TMDLs developed for Tom Paine Slough and Suisun Marsh.

Long-term average chloride concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under the No Action Alternative (ELT) would not result in adverse chloride bioaccumulation effects to aquatic life or humans.

Based on these findings, this impact is determined to be significant due to increased chloride concentrations and objective exceedances, and additional long-term degradation, in the western Delta and associated effects on the municipal and industrial water supply beneficial uses.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on DO levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT) in Section 8.3.3.1. This is because the factors that would affect DO levels in the surface waters of these areas would be the same in the ELT as in the LLT. For the reasons described for the No Action Alternative (LLT) in Section 8.3.3.1, the effects on DO from implementing the No Action Alternative (ELT) is determined to not be adverse.

CEQA Conclusion: The effects of the No Action Alternative (ELT) on DO levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT). This is because the factors that would affect DO levels in the surface waters of these areas would be similar in the ELT and LLT. There would be no substantial, and likely no measurable, long-term change in DO levels Upstream of the Delta, in the Plan Area, or the SWP/CVP Export Service Areas under the No Action Alternative relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would adversely affect beneficial uses. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected, and, thus, beneficial uses would not be expected to be adversely affected. Various Delta waterways are CWA Section 303(d)-listed for low DO, but because no substantial decreases in DO levels are expected, greater degradation and impairment of these areas is not expected to occur. Based on these findings, this impact is considered less than significant.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on EC levels in reservoirs and rivers upstream of the Delta would be similar to those effects described for the No Action Alternative in Section 8.3.3.1. The extent of new urban growth would be less in the early long-term, thus discharges of EC-elevating parameters in runoff and wastewater discharges to water bodies upstream of the Delta would be expected to be less than in the LLT. However, the state is regulating point source discharges of EC-related parameters and implementing a program to further loading of EC-related parameters to tributaries. Based on these considerations, and those described in Section 8.3.3.1, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, or their associated reservoirs upstream of the Delta would not be expected to be outside the ranges occurring under Existing Conditions.

For the San Joaquin River, increases in EC levels under the No Action Alternative (ELT) could occur, but would be slightly less than those described for No Action Alternative (LLT) in Section 8.3.3.1. This is because the effects of climate change on flows, which could affect dilution of high EC discharges, would be less in the early long-term. The implementation of the adopted TMDL for the San Joaquin River at Vernalis and the ongoing development of the TMDL for the San Joaquin River upstream of Vernalis are expected to contribute to improved EC levels. Based on these considerations, substantial changes in EC levels in the San Joaquin River relative to Existing Conditions would not be expected of sufficient magnitude and geographic extent that would result in adverse effects on any beneficial uses, or substantially degrade the quality of these water bodies, with regard to EC.

Delta

Similar to the No Action Alternative (LLT), the No Action Alternative (ELT) would result in a fewer number of days when interior and southern Bay-Delta WQCP compliance locations would exceed EC objectives or be out of compliance with the EC objectives (Appendix 8H, *Electrical Conductivity*, Table EC-26). However, western Delta locations—Sacramento River at Emmaton (agricultural objective) and San Joaquin River at Jersey Point (fish and wildlife objective)—would experience an increased frequency of exceedance of EC objectives, where sea level rise and increased water demands would combine to cause increases in EC, relative to Existing Conditions (Appendix 8H, *Electrical Conductivity*, Table EC-26). The number of days the EC levels would exceed objectives and be out of compliance at these locations would be less at the ELT than the LLT. Further, average EC levels at western, interior, and southern Delta compliance locations, other than the Sacramento River at Emmaton, would decrease relative to Existing Conditions. The increase in exceedances at Jersey Point would be from 0% under Existing Conditions to 3% under No Action Alternative (ELT), which represents a very small increase for this objective. Further discussion of EC increases relative to this objective can be found in Appendix 8H, *Electrical Conductivity*, Attachment 2. Average EC at Emmaton would increase by 1% for the entire modeled period (1976–1991) and 10% for the drought period modeled (1987–1991), relative to Existing Conditions (Appendix 8H, *Electrical Conductivity*, Table EC-28), similar to increases that would occur in the LLT. Given that the western Delta is CWA Section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives and average EC levels at Emmaton during the drought period has the potential to contribute to additional impairment and adversely affect beneficial uses.

Also similar to the No Action Alternative (LLT), relative to Existing Conditions, the No Action Alternative (ELT) would result in increased average EC in Suisun Marsh during the months of February through May. The average EC increases would be lower in magnitude than in the LLT, ranging from 0.1–0.4 mS/cm, depending on the location and month (Appendix 8H, *Electrical Conductivity*, Tables EC-32 through EC-36). For the reasons described for the No Action Alternative in Section 8.3.3.1, the small increase in EC relative to Existing Conditions would not be expected to adversely affect beneficial uses of Suisun Marsh under the No Action Alternative (ELT). While Suisun Marsh is CWA Section 303(d) listed as impaired because of elevated EC, the potential increases in long-term average EC concentrations, relative to Existing Conditions, would not be expected to contribute to additional impairment, because the increase would be so small (<1 mS/cm) relative to the substantial fluctuations in daily EC in the marsh channels as to not be measurable, and beneficial uses would not be adversely affected.

SWP/CVP Export Service Areas

The frequency of exceedance of EC objectives at the Banks and Jones Pumping Plants under the No Action Alternative (ELT) would be slightly higher than that described for the No Action Alternative (LLT) in Section 8.3.3.1 (Appendix 8H, *Electrical Conductivity*, Table EC-27). The frequency of exceedance of the Bay-Delta WQCP 1,000 µmhos/cm objective would increase from 1% to 3% at Banks Pumping Plant and from 0% to 1% at Jones Pumping Plant. However, similar to the No Action Alternative (LLT), average EC levels for the entire period modeled would decrease slightly at the Banks and Jones Pumping Plants relative to Existing Conditions in the ELT time period (Appendix 8H, *Electrical Conductivity*, Table EC-28). For the reasons described for the No Action Alternative in Chapter 8, *Water Quality*, Section 8.3.3.1, the slight increase in frequency of exceedance of the EC objective under the No Action Alternative (ELT) would not be expected to adversely affect agricultural beneficial uses of this water. Further, the No Action Alternative (ELT) would not cause long-term degradation of EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions or contribute to additional CWA Section 303(d) impairment related to elevated EC in the SWP CVP Export Service Areas waters, because long-term average EC levels would be lower in the exported water. The lower average EC in the exported water would be expected to result in an improvement in lower San Joaquin River EC levels, as these levels are related, in part, by the irrigation deliveries from the Delta.

In summary, the increased frequency of exceedance of EC objectives and increased drought period average EC levels that would occur in the western Delta under the No Action Alternative (ELT) would contribute to adverse effects on the agricultural beneficial uses. Given that the western Delta is Clean Water Act Section 303(d) listed as impaired due to elevated EC, the increase in the incidence of exceedance of EC objectives and increases in drought period average EC in the western Delta under the No Action Alternative has the potential to contribute to additional beneficial use impairment. These increases in EC constitute an adverse effect on water quality.

CEQA Conclusion: River flow rate and reservoir storage reductions that would occur under the No Action Alternative (ELT), relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's current regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, the No Action Alternative (ELT) would not result in any substantial increases in long-term average EC levels in the SWP CVP Export Service Areas. At the Jones and Banks Pumping Plants there would be only a, respective, 1–2% increase in exceedance of the EC objective when the entire period modeled is considered. Average EC levels for the entire period modeled would decrease at both plants. Because the EC objective is for agricultural beneficial use protection, for which longer-term crop exposure to elevated EC waters is a concern, the minimal increase in the frequency of exceedance of the EC objective at the pumping plants for the entire period modeled coupled with the long-term average decrease in EC levels at the pumping plants would not adversely affect this beneficial use.

In the Plan Area, the No Action Alternative (ELT) would result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded in the Sacramento River at Emmaton. Further, long-term average EC levels would increase by 1% for the entire period modeled and 10% during the drought period modeled at Emmaton. The increases in drought period average EC levels that would occur in the Sacramento River at Emmaton would further degrade existing EC levels and thus contribute additionally to adverse effects on the agricultural beneficial use. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The western Delta is CWA Section 303(d) listed for elevated EC and the increases in long-term average EC and increased frequency of exceedance of EC objectives that would occur in the Sacramento River at Emmaton could make beneficial use impairment measurably worse. This impact is considered significant.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on mercury levels in surface waters upstream of the Delta relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT) in Section 8.3.3.1. This is because factors that affect mercury concentrations in surface waters upstream of the Delta are similar in the ELT and LLT under the No Action Alternative.

For the reasons stated for the No Action Alternative (LLT) in Section 8.3.3.1, any modified reservoir operations and subsequent changes in river flows at the ELT, relative to Existing Conditions, are expected to have negligible, if any, effects on average reservoir and river mercury concentrations in the Sacramento River watershed upstream of the Delta. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but will not change substantially relative to Existing Conditions due to changes in flows under the No Action Alternative (ELT).

Delta

Similar to the No Action Alternative (LLT), the No Action Alternative (ELT) would have very little effect on mercury or methylmercury concentrations in the Delta (Appendix 8I, *Mercury*, Tables I-17 and I-18), to the extent that these changes would likely not be measurable. Because of this, use of assimilative capacity for mercury would be negligible. Any small changes would not be expected to result in adverse effects to beneficial uses.

Similarly, estimates of fish tissue mercury concentrations and exceedance quotients show almost no differences would occur among sites for the No Action Alternative (ELT) as compared to Existing Conditions for the Delta sites (Appendix 8I, *Mercury*, Tables I-19a and I-19b). Peak exceedance quotients for drought conditions are all at the San Joaquin River at Buckley Cove (4.3 for Existing Conditions; 4.6 for the No Action Alternative (ELT); Eq2 model, Appendix 8I, *Mercury*, Table I-19b). These small differences of less than 7% are not expected to further degrade water quality, with regards to mercury, by measurable levels, and thus beneficial use impairment would not be made discernibly worse. Similar to waterborne concentrations of methylmercury (Appendix 8I, *Mercury*, Table I-18), the fish tissue concentrations and exceedance quotients would be highest at the San Joaquin River, Buckley Cove site during drought years. All modeled fish tissue mercury concentrations exceed tissue guidelines, with exceedance quotients greater than 1 (Appendix 8I, *Mercury*, Tables I-19a and I-19b).

Because the increases are relatively small, and it is not evident that substantive increases are expected at numerous locations throughout the Delta, these changes are expected to be within the uncertainty inherent in the modeling approach, and would likely not be measurable in the environment. See Appendix 8I, *Mercury*, for a complete discussion of the uncertainty associated with the fish tissue estimates. Briefly, the bioaccumulation models contain multiple sources of uncertainty associated with their development. These are related to: analytical variability; temporal and/or seasonal variability in Delta source water concentrations of methylmercury; interconversion of mercury species (i.e., the non-conservative nature of methylmercury as a modeled constituent); and limited sample size (both in number of fish and time span over which the measurements were made), among others. Although there is considerable uncertainty in the models used, the results serve as a reasonable approximations of a very complex process. Considering the uncertainty, small (i.e., <20–25%) increases or decreases in modeled fish tissue mercury concentrations at a low number of Delta locations (i.e., 2–3) should be interpreted to be within the uncertainty of the overall approach, and not predictive of actual adverse effects. Larger increases, or increases evident throughout the Delta, can be interpreted as more reliable indicators of potential adverse effects.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones Pumping Plants. Concentrations changes at these locations are expected to be very small, and likely not measurable. Thus, any change in use of assimilative capacity is also expected to be small and not measurable. Any increases in mercury concentrations that may occur in water exported via Banks and Jones Pumping Plants are not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regards to mercury.

Relative to Existing Conditions, the No Action Alternative (ELT) would result in small changes (less than 3%) in estimated methylmercury concentrations in largemouth bass. All modeled methylmercury concentrations in largemouth bass exceed fish tissue guidelines (Appendix 8I, *Mercury*, Tables I-19a and I-19b).

***CEQA Conclusion*:** Under the No Action Alternative (ELT), greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta will not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta for Existing Conditions and no assimilative capacity exists. However, monthly average waterborne concentrations of total and methylmercury, over the period of record under the No Action Alternative (ELT) would be very similar to Existing Conditions. Similarly, estimates of fish tissue mercury concentrations show almost no differences would occur among sites for the No Action Alternative (ELT) as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP and CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones Pumping Plants. The Banks and Jones Pumping Plants are expected to show very small water concentration changes and very small changes in fish tissue concentration of mercury for the No Action Alternative (ELT) as compared to Existing Conditions.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to Existing Conditions, the No Action Alternative (ELT) would not increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Based on these findings, this impact is considered less than significant.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on nitrate levels in surface waters upstream of the Delta relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT) in Section 8.3.3.1. This is because factors which affect nitrate concentrations in surface waters upstream of the Delta are similar in the ELT and LLT under the No Action Alternative. For the reasons stated for the No Action Alternative (LLT) in Section 8.3.3.1, any modified reservoir operations and subsequent changes in river flows at the ELT, relative to Existing Conditions, are expected to have negligible, if any, effects on average reservoir and river nitrate concentrations in the Sacramento River watershed upstream of the Delta. In the San Joaquin River watershed, nitrate concentrations are higher than in the Sacramento watershed, owing to use of nitrate-based fertilizers throughout the lower watershed. The correlation between historical water year average nitrate concentrations and water year average flow in the San Joaquin River at Vernalis is a weak inverse relationship—that is, generally higher flows result in lower nitrate concentrations, while low flows result in higher nitrate concentrations (linear regression r^2=0.49; Figure 2 in Appendix 8J, *Nitrate*). Under the No Action Alternative (ELT), average flows at Vernalis would decrease an estimated 1% relative to Existing Conditions, which is less than the 6% decrease in average flows estimated to occur at the LLT. Given these relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River, it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under the No Action Alternative (ELT).

Delta

Results of the mass balance calculations indicate that under the No Action Alternative (ELT), relative to Existing Conditions, nitrate concentrations throughout the Delta would remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Table 34). Although changes at specific Delta locations and for specific months may be substantial on a relative basis (Appendix 8J, *Nitrate*, Table 35), the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other relevant nitrate thresholds. Long-term average nitrate concentrations are anticipated to remain below 1 mg/L-N at all 11 Delta assessment locations except the San Joaquin River at Buckley Cove, where early long-term average concentrations would be somewhat above 1 mg/L-N. Nevertheless, at this location, early long-term average nitrate concentration would be somewhat reduced under the No Action Alternative (ELT), relative to Existing Conditions. No additional exceedances of the MCL are anticipated at any location (Appendix 8J, *Nitrate*, Table 34). On a monthly average basis and a long-term annual average basis, for all modeled years (1976–1991) and for the drought period (1987–1991) only, use of assimilative capacity available under Existing Conditions, relative to the drinking water MCL of 10 mg/L-N, would be low or negligible (i.e., <1%) for all locations and months (Appendix 8J, *Nitrate*, Table 36). Nitrate concentrations, change in nitrate concentrations relative to existing conditions, and use of assimilative capacity with regard to nitrate at various locations throughout the Delta under the No Action Alternative (ELT) would be approximately the same as would occur in the LLT.

As described in for the No Action Alternative for the LLT in Section 8.3.3.1, actual nitrate on concentrations would likely be higher than the modeling results indicate at certain locations under the No Action Alternative (ELT). This is because the mass balance modeling does not account for contributions from the SRWTP, which would be implementing nitrification/partial denitrification, or Delta wastewater treatment plant dischargers that practice nitrification, but not denitrification. However, for the reasons described for the No Action Alternative (LLT), additional nitrate contributions and resulting concentrations that may occur at certain locations within the Delta at the ELT would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regard to nitrate.

SWP/CVP Export Service Areas

Assessment of effects of the No Action Alternative (ELT) on nitrate in the SWP/CVP Export Service Areas is based on effects on nitrate at the Banks and Jones Pumping Plants.

Results of the mass balance calculations indicate that under the No Action Alternative (ELT), relative to Existing Conditions, early long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to change negligibly (Appendix 8J, *Nitrate*, Table 35), as is also expected for the LLT (see Section 8.3.3.1). No exceedances of the 10 mg/L MCL would occur (Appendix 8J, *Nitrate*, Table 34). On a monthly average basis and on a long-term annual average basis, for all modeled years and for the drought period only, use of assimilative capacity available under Existing Conditions relative to the MCL would be negligible (i.e., <1%) for both Banks and Jones Pumping Plants (Appendix 8J, *Nitrate*, Table 36). As discussed above, in the Delta region, nitrate concentrations would be higher than indicated in the modeling results for areas receiving Sacramento River water, including Banks and Jones pumping plants. However, long-term average nitrate concentrations would be expected to decrease under the No Action Alternative (ELT), relative to Existing Conditions. Resultant nitrate concentrations in water exported via Banks and Jones pumping plants under the No Action Alternative (ELT) are not expected to result in adverse effects to beneficial uses of exported water or substantially degrade the quality of exported water, with regard to nitrate.

In summary, based on the discussion above, effects on nitrate of facilities operation and maintenance are considered not adverse.

CEQA Conclusion: For the same reasons described for the LLT in Section 8.3.3.1, any modified reservoir operations and subsequent changes in river flows under the No Action Alternative (ELT), relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mass balance calculations indicate that under the No Action Alternative (ELT), relative to Existing Conditions, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the 10 mg/L MCL are anticipated at any location, and use of assimilative capacity available under Existing Conditions, relative to the drinking water MCL of 10 mg/L-N, would be low or negligible (i.e., <1%) for all locations and months.

Results of the mass balance calculations indicate that under the No Action Alternative (ELT), relative to Existing Conditions, average nitrate concentrations at Banks and Jones pumping plants are anticipated to change negligibly. No additional exceedances of the MCL are anticipated, and use of assimilative capacity available under Existing Conditions, relative to the MCL would be negligible (i.e., <1%) for both Banks and Jones pumping plants for all months.

Based on the above, there would be no substantial, long-term increase in nitrate concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the SWP/CVP Export Service Areas under the No Action Alternative (ELT), relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment from nitrate. Because nitrate concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered less than significant.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

While increased water demands and climate change under the No Action Alternative (ELT) would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of DOC. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta. Consequently, long-term average DOC concentrations under the No Action Alternative (ELT) would not be expected to change by frequency, magnitude and geographic extent, relative to Existing Conditions and, and thus, would not adversely affect the MUN beneficial use, or any other beneficial uses, in water bodies of the affected environment located upstream of the Delta.

Delta

Relative to the Existing Conditions, the No Action Alternative (ELT) would result in no changes, or a 0.1 mg/L decrease, in the long-term average DOC concentrations at the 11 assessment locations for the modeled 16-year period. However, the average DOC concentrations would increase slightly (i.e., up to 0.1 mg/L) in the modeled drought period (1987–1991) only at the Jones pumping plant location (Appendix 8K, *Organic Carbon*, Table DOC-11). At all 11 assessment locations, the range of frequency with which average DOC concentrations would exceed the 2 mg/L threshold concentration under the No Action Alternative (ELT) would be similar to Existing Conditions (i.e., 93–100%) for the modeled 16-year period and the drought period. The frequency with which DOC concentration would exceed the 3 mg/L and 4 mg/L thresholds also would be similar at most of the assessment locations, with exception of predicted changes at both the Banks and Jones pumping plants (discussed further below). While the No Action Alternative (ELT) would generally lead to similar or slightly higher long-term average DOC concentration in the western and interior Delta locations, the predicted changes would not be expected to be of magnitude that would adversely affect MUN beneficial uses, or any other beneficial use, particularly when considering the relatively small change in long-term annual average concentration (i.e., ≤0.1 mg/L).

SWP/CVP Export Service Areas

With respect to the potential for effects of the No Action Alternative (ELT), the long-term average DOC concentrations in water exported at the Banks and Jones pumping plants would not change measurably relative to Existing Conditions (i.e., up to 0.1 mg/L at Jones pumping plant for the modeled drought period) (Appendix 8K, *Organic Carbon*, Table DOC-11). At the Banks pumping plant, the frequency with which DOC concentrations would exceed 3 mg/L would increase from 64% under Existing Conditions to 69% under the No Action Alternative (ELT) for the 16-year period, and from 57% to 70% during the drought year period (Appendix 8K, *Organic Carbon*, Table DOC-11). The frequencies of exceedance of 3 mg/L at the Jones pumping plant would increase from 71% to 79% for the modeled 16-year and from 72% to 88% for the modeled drought period. The relative increase in the frequency with which DOC concentrations would exceed 4 mg/L at both the Banks and Jones pumping plants would be minimal (i.e., up to a 3% increased frequency at the Jones pumping plant). However, the predicted changes in long-term average DOC concentrations would not be expected to be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial use, within the SWP/CVP Export Service Areas. Long-term average DOC concentrations, and frequency of exceedance of threshold concentrations, would decrease slightly at Barker Slough under the No Action Alternative (ELT) relative to Existing Conditions.

In summary, the potential operations- and maintenance-related changes to DOC concentrations under the No Action Alternative (ELT) at locations upstream of the Delta, in the Delta, and the SWP/CVP Export Service Areas would generally be similar to, or of lower magnitude, than the effects described for the No Action Alternative (LLT) in Section 8.3.3.1. This is because the effects of climate change on hydrology and sea level rise would be less in the ELT compared to the LLT, and thus factors affecting DOC concentrations, would be lower in these water bodies in the ELT.

Maintenance of SWP and CVP facilities under the No Action Alternative (ELT) would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected environment.

CEQA Conclusion: The effects of the No Action Alternative (ELT) on DOC concentrations in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar, or of lower magnitude, than the effects described for the No Action Alternative (LLT). While greater water demands and climate change under the No Action Alternative (ELT) would alter the magnitude and timing of reservoir releases north, south and east of the Delta, these activities would have no substantial effect on the various watershed sources of DOC. Based on the above, the No Action Alternative (ELT) would not result in any substantial increase in the frequency with which long-term average DOC concentrations exceed the 2, 3, or 4 mg/L levels at any of the 11 assessment locations relative to Existing Conditions. The predicted change in long-term average DOC concentrations, relative to Existing Conditions, would not be expected to be of sufficient magnitude to adversely affect MUN beneficial uses, nor would there be any long-term water quality degradation with respect to DOC. DOC is not bioaccumulative and thus would not directly cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not CWA Section 303(d) listed for any water body within the affected environment. Because long-term average DOC concentrations would not be expected to increase substantially, no significant impacts on beneficial uses would occur. Based on these findings, this impact would be less than significant.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative (LLT) in Section 8.3.3.1. This is because the factors that would affect pathogen levels in the surface waters of these areas would be similar in the ELT and LLT. The difference in reservoir storage, river flows, and associated changes in Delta source water fractions due to climate change and sea level rise would not alter the pathogen sources in these waters. Thus, for the reasons described for the No Action Alternative in Section 8.3.3.1, the effects on pathogens from implementing the No Action Alternative (ELT) is determined to not be adverse.

CEQA Conclusion: The effects of the No Action Alternative (ELT) on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative. This is because the factors that would affect pathogen levels in the surface waters of these areas would be similar in the ELT and LLT. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is Clean Water Act Section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. This impact is considered less than significant.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on pesticide levels in surface waters upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to or less than those expected to occur at the LLT, described in Section 8.3.3.1. This is because at the ELT, the primary factor that will influence pesticide concentrations in surface waters upstream of the Delta, the effect of timing and magnitude of reservoir releases on dilution capacity, is expected to change to a similar or less degree than under the No Action Alternative (LLT). Changes in average winter and summer flow rates at the ELT relative to Existing Conditions are expected to be similar to or less than changes in flow rates expected at the LLT in the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis (Appendix 8L, *Pesticides,* Tables 1 through 4). Similarly, at the ELT, the primary factor that will influence pesticide concentrations in surface waters of the Delta and in the SWP/CVP Export Service areas (i.e., changes in San Joaquin River, Sacramento River and Delta agriculture source water fractions at various Delta locations, including Banks and Jones pumping plants) is expected to change by a similar or less degree than at the LLT. The percentage change in monthly average source water fractions at the ELT are similar to or less than changes expected at the LLT (Appendix 8D, *Source Water Fingerprinting Results*).

Development of 8,000 acres of tidal habitat under the No Action Alternative (ELT) could result in a limited reduction in pesticide use throughout the Delta through the potential repurposing of active or fallow agricultural land for natural habitat purposes. In the short-term, the repurposing of agricultural land associated with these measures may expose water used for habitat restoration to pesticide residues. Moreover, the fisheries enhancements to the Yolo Bypass that would occur under the No Action Alternative (ELT) could be managed alongside continuing agriculture, where pesticides may be used on a seasonal basis and where water during flood events may come in contact with residues of these pesticides. However, rapid dissipation would be expected, particularly in the large volumes of water involved in flooding, such that aquatic life toxicity objectives would not be exceeded by frequency, magnitude, and geographic extent whereby adverse effects on beneficial uses would be expected.

***CEQA Conclusion*:** As discussed above, the effects of the No Action Alternative (ELT) on pesticide levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative in Section 8.3.3.1. As such, the No Action Alternative (ELT) would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta, at the 11 assessment locations analyzed for the Delta, or the SWP CVP Export Service Areas. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous CWA Section 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions would not be expected to make any of these beneficial use impairments measurably worse. Because long-term average pesticide concentrations are not expected to increase substantially, no long-term water quality degradation with respect to pesticides is expected to occur and, thus, no adverse effects on beneficial uses would occur. This impact is considered less than significant.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on phosphorus levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to or less than those described for the No Action Alternative (LLT) in Section 8.3.3.1. This is because factors which affect phosphorus levels in surface waters of these areas would be similar at the ELT and LLT under the No Action Alternative. Phosphorus concentrations may increase during January through March at locations in the Delta where the source fraction of San Joaquin River water increases, due to the higher concentration of phosphorus in the San Joaquin River during these months compared to Sacramento River water or San Francisco Bay water. However, based on the DSM2 fingerprinting results (see Figures 288–308 in Appendix 8D, *Source Water Fingerprinting Results*), together with source water concentrations (presented in Figure 8-56), the magnitude of increases during these months is expected to be negligible (i.e., <0.01 mg/L) at all Delta locations. Thus, phosphorus levels in the Delta and waters exported from Banks and Jones pumping plants to the SWP/CVP Export Service Areas are expected to change less at the ELT compared to the LLT. For the reasons described for the No Action Alternative in Section 8.3.3.1 and those described above, the effects on phosphorus from implementing the No Action Alternative (ELT) is determined to not be adverse.

***CEQA Conclusion*:** The effects of the No Action Alternative (ELT) on phosphorus levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative in Section 8.3.3.1. This is because factors that would directly affect phosphorus levels in the surface waters of these areas are expected to be the same or change to a lesser degree than at the LLT. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered less than significant.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on selenium concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for the No Action Alternative (LLT) in Section 8.3.3.1. There would be no expected change to the sources of selenium in the Sacramento River and eastside tributary watersheds, and changes in the magnitude and timing of reservoir releases and river flows upstream of the Delta would have negligible, if any, effect on the concentration of selenium in the rivers and reservoirs of these watersheds.

Selenium concentrations in the San Joaquin River upstream of the Delta comply with NTR criteria and Basin Plan objectives at Vernalis under Existing Conditions, and they are expected to do so under the No Action Alternative (ELT). This is because a TMDL has been developed by the Central Valley Water Board (2001), the Grassland Bypass Project has established limits that will result in reduced inputs of selenium to the Delta, and the Central Valley Water Board (2010a) and State Water Board (2010d, 2010e) have established Basin Plan objectives that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta, Further, modeling of flows for the San Joaquin River at Vernalis indicates that average annual flows under the No Action Alternative (ELT) will vary by less than 10% from Existing Conditions (Appendix 5A, *BDCP/California WaterFix FEIR/FEIS Modeling Technical Appendix*). Given these relatively small decreases in flows and the considerable variability in the relationship between selenium concentrations and flows in the San Joaquin River, it is expected that selenium concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under the No Action Alternative (ELT).

In summary, any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Delta

Relative to Existing Conditions, the No Action Alternative (ELT) would result in little to no change in average selenium concentrations in water at all modeled Delta assessment locations. Long-term average concentrations would be the same or lower, with the exception of Old River at Rock Slough during the drought (1987–1991) period modeled, the Sacramento River at Emmaton and North Bay Aqueduct Pumping Plant for the entire and drought periods modeled, and Contra Costa Pumping Plant No. 1 for the entire (1976–1991) period modeled (Appendix 8M, *Selenium*, Table M-33). Long-term average concentrations at these locations would increase negligibly (by 0.01μg/L). The long-term average selenium concentrations in water under the No Action Alternative (ELT) would range from 0.09–0.39 μg/L (Appendix 8M, *Selenium*, Table M-33), which would be well below the EPA draft water quality criterion of 1.3 μg/L. Thus, the No Action Alternative (ELT) would not result in selenium concentration increases in water that would substantially degrade water quality.

Relative to Existing Conditions, the No Action Alternative (ELT) would result in little to no change in estimated selenium concentrations in most biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets), with the largest increase being 0.01 mg/kg dry weight (Appendix 8M, *Selenium*, Table M-34). During the drought period, concentrations of selenium in sturgeon in the western Delta would increase slightly, with about a 0.19 mg/kg dry weight (<3%) increase for the San Joaquin River at Antioch (Appendix 8M, *Selenium*, Tables M-41 and M-42).

All Toxicity Threshold Exceedance Quotients for whole fish, bird eggs, and fish fillets are less than 1.0, indicating low probability of adverse effects (Appendix 8M, *Selenium*, Table M-37). Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon from the western Delta exceed 1.0 for the drought period, indicating a higher probability for adverse effects for drought years (Appendix 8M, *Selenium*, Table M-43). Relative to Existing Conditions, Exceedance Quotients would increase by 0.00–0.02, indicating that there would be essentially no increased risk of toxicity associated with selenium concentrations under the No Action Alternative (ELT).

In summary, relative to Existing Conditions, the No Action Alternative (ELT) would result in essentially no change in selenium concentrations throughout the Delta. The No Action Alternative (ELT) would not be expected to substantially increase the frequency with which the applicable water quality criterion or toxicity or level of concern thresholds would be exceeded in the Delta or to substantially degrade the quality of water in the Delta, with regard to selenium.

SWP/CVP Export Service Areas

Relative to Existing Conditions, the No Action Alternative (ELT) would result in little to no change in average selenium concentrations in water at the south Delta pumping plants. At the Banks pumping plant, there would be no change in long-term average concentrations for the entire period modeled or the drought period modeled (Appendix 8M, *Selenium*, Table M-33). At the Jones pumping plant, selenium concentrations would increase by 0.01 μg/L for the entire period modeled (Appendix 8M, *Selenium*, Table M-33). Furthermore, the modeled selenium concentrations in water for the No Action Alternative (ELT) would range from 0.21–0.29 μg/L, well below the USEPA water quality criterion of 1.3 μg/L (Appendix 8M, *Selenium*, Table M-33).

Similarly, the No Action Alternative (ELT) would result in little to no change in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets), and concentrations of selenium in biota would not be expected to exceed any toxicity or level of concern benchmarks for biota (Appendix 8M, *Selenium*, Tables M-34 and Se-37).

Residence time of water in the Delta is not expected to change substantially under the No Action Alternative (ELT) relative to Existing Conditions. Thus, any minor residence time changes would not be expected to affect selenium bioaccumulation or fish tissue and bird egg concentrations of selenium.

In summary, relative to Existing Conditions, the No Action Alternative (ELT) would result in essentially no change in selenium concentrations in the SWP/CVP Export Service Areas, because there would essentially be no change in selenium concentrations at the Bank and Jones pumping plants. Thus, the No Action Alternative (ELT) would not be expected to substantially increase the frequency with which applicable water quality criteria, or toxicity and level of concern benchmarks would be exceeded in the Export Service Areas or substantially degrade the quality of water in the Export Service Areas, with regard to selenium.

CEQA Conclusion: There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010d, 2010e) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under the No Action Alternative (ELT), relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate that the No Action Alternative (ELT) would result in essentially no change in selenium concentrations throughout the Delta, with all changes on the order of 0.01 μg/L or less. Furthermore, there would not be an increased risk of exceeding toxicity and level of concern benchmarks for biota.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, the No Action Alternative (ELT) would result in no change in long-term average selenium concentrations at the Bank pumping plant, and very little increase (0.01 μg/L) at the Jones pumping plant.

Based on the above, selenium concentrations that would occur in water under this alternative would not cause additional exceedances of applicable state or federal numeric or narrative water quality objectives/criteria, or other relevant water quality effects thresholds identified for this assessment by frequency, magnitude, and geographic extent that would result in adverse effects to one or more beneficial uses within affected water bodies. In comparison to Existing Conditions, water quality conditions under this alternative would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Water quality conditions under this alternative with respect to selenium would not cause long-term degradation of water quality in the affected environment, and therefore would not result in use of available assimilative capacity such that exceedances of water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. This alternative would not further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. This impact is considered less than significant.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on trace metal concentrations in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative in Section 8.3.3.1. This is because the factors that would affect trace metal concentrations in the surface waters of these areas would be the same in the ELT as in the LLT. For the reasons described for the No Action Alternative in Section 8.3.3.1, the effects on trace metal concentrations from implementing the No Action Alternative (ELT) is determined to not be adverse.

CEQA Conclusion: The effects of the No Action Alternative (ELT) on trace metal concentrations in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative. This is because the factors that would affect trace metal concentrations in the surface waters of these areas would be similar in the ELT and LLT. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, negligible change in long-term trace metal concentrations throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. This impact is considered less than significant.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on TSS and turbidity levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative in Section 8.3.3.1. This is because the factors that would affect TSS and turbidity levels in the surface waters of these areas would be the same in the ELT as in the LLT. For the reasons described for the No Action Alternative (LLT) in Section 8.3.3.1, the effects on TSS and turbidity from implementing the No Action Alternative (ELT) is determined to not be adverse.

CEQA Conclusion: The effects of the No Action Alternative (ELT) on TSS and turbidity levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the No Action Alternative. This is because the factors that would affect TSS and turbidity levels in the surface waters of these areas would be similar in the ELT and LLT. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different from Existing Conditions, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor Clean Water Act section 303(d) listed constituents. This impact is considered less than significant.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities

The effects of construction-related activities and potential water quality effects that would occur under the No Action Alternative (ELT) in association with projects other than Alternative 4A would be similar to those described for the No Action Alternative in Section 8.3.3.1. This is because many construction-related activities that could affect the surface waters in the project area are ongoing (e.g., urban development), or recurring (e.g., maintenance activities for channels and levees, sediment dredging), and thus are expected to result in generally similar effects in the ELT and LLT. While the timing of construction of planned projects, described under the No Action Alternative (ELT) (e.g., restoration projects), is uncertain relative to the Existing Conditions, the potential construction-related contaminant discharges that may occur under the No Action Alternative (ELT) would be avoided and minimized upon implementation of BMPs and adherence to permit terms and conditions. Consequently, construction-related activities would not be expected to cause constituent discharges of sufficient magnitude to result in a substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas.

CEQA Conclusion: Alternative 4A construction-related contaminant discharges under the No Action Alternative (ELT) would not occur. Other reasonably foreseeable projects that are independent from Alternative 4A would result in construction-related impacts that are temporary and intermittent in nature and would involve negligible, if any, discharges of bioaccumulative or CWA Section 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would therefore not contribute to bioaccumulation of contaminants in organisms or humans or cause Section 303(d) impairments to be discernibly worse. Relative to Existing Conditions, the construction-related effects of other projects in the Delta would not be expected to cause or contribute to a substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality on a long-term average basis with respect to the constituents of concern, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas. Based on these findings, this impact is determined to be less than significant.

Impact WQ-32: Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the No Action Alternative (ELT) on *Microcystis* levels, and thus microcystin concentrations, in surface waters upstream of the Delta relative to Existing Conditions would be similar to those described for the No Action Alternative in Section 8.3.3.1. This is because factors that would affect *Microcystis* levels in these areas would be the same in the ELT and the LLT. In the rivers and streams of the Sacramento River watershed, watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), and the San Joaquin River upstream of the Delta, under Existing Conditions, bloom development is limited by high water velocity and low residence times. These conditions are not expected to change under the No Action Alternative (ELT).

Delta

In the Delta, enhancements to the Yolo Bypass and 8,000 acres of tidal habitat would be developed under the No Action Alternative (ELT). The hydrodynamic effects of these actions could lead to increased residence times in the affected Delta sub-regions relative to Existing Conditions. As described in Section 8.3.3.1, climate change and sea level rise are also expected to cause slight increases in water residence times throughout the Delta at the LLT. At the ELT the incremental contribution of climate change and sea level rise to increased water residence times would be less than that at the LLT.

Due to the assumed effects of climate change, Delta water temperatures are expected to increase relative to Existing Conditions under the No Action Alternative (ELT), although the magnitude of increase would be less at the ELT (1.3–2.5°F) compared to the LLT (2.9–4.9°F). Increasing water temperatures could lead to earlier attainment of the water temperature threshold of 19°C required to initiate *Microcystis* bloom formation, and thus earlier occurrences of *Microcystis* blooms in the Delta, relative to Existing Conditions. Elevated ambient water temperatures in the Delta, and thus an increase in *Microcystis* bloom duration and magnitude, are expected under the No Action Alternative (ELT), relative to Existing Conditions. However, the effects of elevated ambient water temperatures on *Microcystis* at the ELT are expected to be less than would occur at the LLT.

The combination of increased water residence times in the Delta, due to assumed restoration activities, and increased water temperatures, due to climate change, could lead to measurable increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms throughout the Delta at the ELT, relative to Existing Conditions. It is not expected that the effects on *Microcystis* in the Delta that could occur at the ELT would be significantly different than those that could occur at LLT.

SWP/CVP Export Service Area

The effects of the No Action Alternative (ELT) on *Microcystis* levels, and thus microcystin concentrations, in SWP/CVP Export Service Areas, relative to Existing Conditions, would be similar to or slightly less than those described for the No Action Alternative (LLT) in Section 8.3.3.1. This is for two reasons. First, the assessment of effects on *Microcystis* in the SWP/CVP Export Service Areas is based on the assessment of *Microcystis* production in source waters to Banks and Jones pumping plants, and the effects on *Microcystis* at Banks and Jones pumping plants is not expected to be different at the ELT and LLT for the reason discussed for the "Delta" above. Second, changes in ambient air temperatures due to climate change are expected to be less at the ELT compared to the LLT, as described for the "Delta" above. Thus, effects of climate change on the potential for environmental conditions in the SWP/CVP Export Service Areas to become more conducive for *Microcystis* growth, relative to Existing Conditions, are expected to be less at the ELT than at the LLT.

CEQA Conclusion: For the reasons described above, the effects of the No Action Alternative (ELT) on *Microcystis* levels, and thus microcystin concentrations, in surface waters upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to or less than those described for the No Action Alternative (LLT) in Section 8.3.3.1. As such, the No Action Alternative (ELT) would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not CWA Section 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. Because *Microcystis* and microcystins are not bioaccumulative, increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. However, because it is possible that under the No Action Alternative (ELT) increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta would occur due to both increased water temperatures from climate change, as well as increased water residence times related to restoration activities, long-term water quality degradation may occur in the Delta and water exported from the Delta to the SWP/CVP Export Service Areas. Thus, impacts on beneficial uses could occur. This impact is considered significant.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance

The effects of the No Action Alternative (ELT) on San Francisco Bay water quality would be similar to those described for the No Action Alternative (LLT) (see Section 8.3.3.1 and Appendix 8O, *San Francisco Bay Analysis*). The primary difference in the ELT is that the effects of climate change on upstream hydrology and sea level rise in the Delta and Bay would be less. However, for the same reasons described for the LLT, upstream constituent concentrations and Delta outflow would not be altered sufficiently by these differences to cause substantial water degradation or contribute to adverse effects to beneficial uses in San Francisco Bay.

CEQA Conclusion: The No Action Alternative (ELT) would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. Further, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals or turbidity or TSS are anticipated in the Delta, relative to Existing Conditions, therefore, no substantial changes in these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow and thus, have minimal influence on salinity changes. Adverse changes in *Microcystis* levels that could occur in the Delta would not cause adverse *Microcystis* blooms in the Bay, because *Microcystis* are intolerant of the Bay's high salinity and, thus have not been detected downstream of Suisun Bay. The reduction in total nitrogen load (associated with the SRWTP improvements) and changes in phosphorus load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. As with the LLT, the change in mercury and methylmercury load (which is based on source water and Delta outflow), relative to Existing Conditions, would be within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Similarly, based on LLT estimates, the increase in selenium load would be minimal, and total and dissolved selenium concentrations would be expected to be the same as Existing Conditions, and less than the target associated with white sturgeon whole-body fish tissue levels for the North Bay. Thus, the change in selenium load is not expected to contribute to water quality degradation, or make the CWA section 303(d) selenium impairment measurably worse or cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. This impact is considered less than significant.

8.3.4.2 Alternative 4A—Dual Conveyance with Modified Pipeline/Tunnel and Intakes 2, 3, and 5 (9,000 cfs; Operational Scenario H)

Discussion of water quality impacts of Alternative 4A was first provided in the Bay Delta Conservation Plan/California WaterFix RDEIR/SDEIS. The water quality assessments in the RDEIR/SDEIS for boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Services Areas utilized results from water quality modeling performed for Alternative 4 in the ELT, which included Yolo Bypass improvements, 25,000 acres of tidal habitat restoration, and the EC compliance location at Emmaton relocated to Threemile Slough. The analysis of effects of Alternative 4A, presented herein, on boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Service Areas is based on revised modeling, which assumed implementation of Yolo Bypass improvements, the EC compliance location remaining at Emmaton, and no tidal habitat restoration. Also, whereas the RDEIR/SDEIS Alternative 4A included two operational scenarios (H3 and H4), modeling for Alternative 4A was conducted at Operational Scenario H3+, a point that generally falls between Scenario H3 and H4 operations, as the initial conveyance facilities operational scenario. As specified in Chapter 3, *Description of Alternatives*, Section 3.6.4, the Delta outflow criteria under Scenario H for Alternative 4A would be determined by the Endangered Species Act and California Endangered Species Act Section 2081 permits, and operations to obtain such outflow would likely occur between Scenarios H3 and H4. Modeling results for Scenarios H3 and H4 using the 2015 CALSIM II model are shown in Appendix 5E, *Supplemental Modeling Requested by the State Water Resources Control Board Related to Increased Delta Outflows*, Attachment 1. In addition, following the initial operations, the adaptive management and monitoring program could be used to make long-term changes in initial operations criteria to address uncertainties about spring outflow for longfin smelt and fall outflow for delta smelt, among other species.

Future conveyance facilities operational changes may also be made as a result of adaptive management to respond to advances in science and understanding of how operations affect species. Conveyance facilities would be operated under an adaptive management range represented by Boundary 1 and Boundary 2 (See Section 5E.2 of Appendix 5E for additional information on Boundary 1 and Boundary 2). Impacts as a result of operations within this range would be consistent with the impacts discussed for the range of alternatives considered in this EIR/EIS. As shown in Appendix 5F, water supply modeling results for H3+ are within the range of results for Scenarios H3 and H4, and are consistent with the impacts discussed in the RDEIR/SDEIS. The following analysis of Alternative 4A impacts reflects modeling results of Operational Scenario H3+.

Because the modeling of Alternative 4A and the No Action Alternative (ELT) included Yolo Bypass Improvements, but no tidal habitat restoration, comparison of modeling results for Alternative 4A to No Action Alternative (ELT) results in the impact discussions below allows for isolating and identifying effects solely due to implementation of Alternative 4A in the ELT.

As described in Chapter 3, *Description of Alternatives*, actions associated with Alternative 4 that are not proposed to be implemented under Alternative 4A would continue to be pursued as part of existing, but separate, projects and programs associated with the 2008 USFWS and 2009 NMFS BiOps, California EcoRestore, and the 2014 California Water Action Plan. Due to the reduced suite of Environmental Commitments in Alternative 4A compared to Alternative 4 (in particular, significantly less tidal habitat restoration), the impacts to water quality due to Alternative 4A are substantially less compared to Alternative 4, particularly in the Delta.

The water quality impact conclusions for Alternative 4A remain the same as those presented in the RDEIR/SDEIS. The revisions to the assessment are in the presentation of modeled changes in concentrations, water quality criteria/objective exceedances, and use of assimilative capacity, and refinements to mitigation measures for EC.

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), substantial point and non-point sources of ammonia-N do not exist upstream of the SRWTP at Freeport in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Thus, like Alternative 4, operation of the water conveyance facilities under Alternative 4A would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative (ELT and LLT). Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

As described for Alternative 4 (Section 8.3.3.9), a substantial decrease in Sacramento River ammonia concentrations is expected under Alternative 4A relative to Existing Conditions, due to planned lowering of ammonia in the SRWTP effluent discharge, and this is expected to decrease ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water.

Concentrations of ammonia at locations not influenced notably by Sacramento River water would change little relative to Existing Conditions, due to the similarity in San Joaquin River and San Francisco Bay concentrations and the lack of expected changes in either of these concentrations. Thus, Alternative 4A would not result in substantial increases in ammonia concentrations in the Plan Area, relative to Existing Conditions.

Relative to the No Action Alternative (ELT and LLT), the primary mechanism that could potentially alter ammonia concentrations under Alternative 4A is decreased flows in the Sacramento River, which would lower dilution available to the SRWTP discharge. This flow change would be attributable only to operations of the water conveyance facilities, since the same assumptions regarding SRWTP discharge ammonia concentrations, water demands, climate change, and sea level rise apply to both Alternative 4A and the No Action Alternative (ELT and LLT). A simple mass balance calculation was performed to calculate ammonia concentrations downstream of the SRWTP discharge (i.e., downstream of Freeport) under Alternative 4A and the No Action Alternative (ELT) to assess the effects of the flow changes. Monthly average CALSIM II flows at Freeport and the upstream ammonia concentration (0.04 mg/L-N; Central Valley Water Board 2010a:5) were used, together with the SRWTP permitted average dry weather flow (181 mgd) and seasonal ammonia limitations (1.5 mg/L-N in Apr–Oct, 2.4 mg/L-N in Nov–Mar), to estimate the average change in ammonia concentrations downstream of the SRWTP. Table 8-73 shows monthly average and long-term annual average predicted concentrations under the alternative. As Table 8-73 shows, average monthly ammonia concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 4A and the No Action Alternative (ELT) are expected to be similar. In comparison to the No Action Alternative (ELT), minor increases in monthly average ammonia concentrations would occur during July through September, and during November. Minor decreases in ammonia concentrations are expected for January through April, June, and October. The annual average concentration under Alternative 4A would be the same as that under the No Action Alternative (ELT). Relative to the No Action Alternative (LLT), Alternative 4A (LLT) is expected to result in similar minor increases in Sacramento River ammonia concentration, because the increased water demands, climate change, and sea level rise in the LLT would occur under both alternatives, and neither would affect ammonia sources or loading. The estimated ammonia concentrations in the Sacramento River downstream of Freeport under Alternative 4A would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 4A, relative to the No Action Alternative (ELT and LLT), are not expected to substantially increase ammonia concentrations at any Delta locations.

Ammonia concentrations downstream of Freeport in the Sacramento River under Alternative 4A would be similar to those under Alternative 4 (see Table 8-67 in Section 8.3.3.9). As stated for Alternative 4, any negligible increases in ammonia concentrations that could occur at certain locations in the Delta under Alternative 4A would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regard to ammonia.

Table 8-73. Estimated Ammonia (mg/L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative Early Long-Term (ELT) and Alternative 4A

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative (ELT)	0.076	0.082	0.069	0.062	0.059	0.062	0.059	0.062	0.067	0.060	0.067	0.064	0.066
Alternative 4A ELT	0.075	0.086	0.069	0.061	0.058	0.061	0.058	0.062	0.063	0.061	0.069	0.066	0.066

SWP/CVP Export Service Areas

As discussed above, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 4A, relative to Existing Conditions (in association with less diversion of water influenced by the SRWTP). Like Alternative 4, this decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in an adverse effect on beneficial uses or substantially degrade water quality of exported water, with regard to ammonia. Furthermore, as discussed above, for all areas of the Delta, including Banks and Jones pumping plants, ammonia concentrations are not expected to be substantially different under Alternative 4A (ELT) relative to the No Action Alternative (ELT), and Alternative 4A (LLT) relative to the No Action Alternative (LLT). Thus, any negligible increases in ammonia concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade water quality at these locations, with regard to ammonia.

NEPA Effects: In summary, ammonia concentrations in water bodies upstream of the Delta, in the Plan Area, and the waters exported to the SWP/CVP Export Service Areas are not expected to be substantially different under Alternative 4A relative to the No Action Alternative (ELT and LLT). Thus, effects of the water conveyance facilities on ammonia are considered to be not adverse.

CEQA Conclusion: The magnitude and direction of changes in ammonia concentrations in water bodies upstream of the Delta, in the Plan Area, or the waters exported to the SWP/CVP Export Service Areas would be approximately the same as expected under Alternative 4, relative to Existing Conditions. There would be no substantial, long-term increase in ammonia concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 4A relative to Existing Conditions. As such, Alternative 4A is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not CWA Section 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Some habitat restoration activities included in Environmental Commitments 3, 4, and 6–11 would occur on lands in the Delta formerly used for irrigated agriculture. Although this may decrease ammonia loading to the Delta from agriculture, increased biota in those areas as a result of restored habitat may increase ammonia loading originating from flora and fauna. Ammonia loaded from organisms is expected to be converted rapidly to nitrate by established microbial communities. Thus, these land use changes would not be expected to substantially increase ammonia concentrations in the Delta. Implementation of Environmental Commitments 12, 15, and 16 do not include actions that would affect ammonia sources or loading. Based on these findings, the effects on ammonia from the implementation Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A are determined to not be adverse.

***CEQA Conclusion*:** Land use changes that would result from the Environmental Commitments are not expected to substantially increase ammonia concentrations, because the amount of area to be converted would be small relative to existing habitat, and any resulting ammonia would likely be rapidly converted to nitrate. Thus, it is expected there would be no substantial, long-term increase in ammonia concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 relative to Existing Conditions. As such, implementation of these Environmental Commitments would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Because ammonia concentrations would not be expected to increase substantially from implementation of these Environmental Commitments, no long-term water quality degradation would be expected to occur and, thus, no significant impact on beneficial uses would occur. Ammonia is not CWA Section 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), under Alternative 4A there would be no expected change to the sources of boron in the Sacramento River and eastside tributary watersheds and, thus, resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease by 1%, relative to Existing Conditions (in association with the different operational components of Alternative 4A in the ELT, climate change, and increased water demands) (Appendix 8F, *Boron*, Table Bo-32). The reduced flow relative to Existing Conditions would result in possible increases in long-term average boron concentrations of up to about 0.5% relative to the Existing Conditions. Flows would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial boron increases relative to the No Action Alternative (ELT). The increased boron concentrations, relative to Existing Conditions, under Alternative 4A in the ELT would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 4A in the ELT would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Effects of Alternative 4A in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect boron sources in these areas.

Delta

Effects of water conveyance facilities on boron under Alternative 4A in the Delta would be similar to the effects discussed for Alternative 4.

The effects of Alternative 4A relative to Existing Conditions and the No Action Alternative (ELT) are discussed together because the direction and magnitude of predicted change are similar. Relative to the Existing Conditions and No Action Alternative (ELT), Alternative 4A would result in increased long-term average boron concentrations for the 16-year period modeled at most of the interior Delta locations (increases up to 2% at the S. Fork Mokelumne River at Staten Island, 8% at Franks Tract, and 10% at Old River at Rock Slough) (Appendix 8F, *Boron*, Table Bo-26). The long-term average boron concentrations at most of the western Delta assessment locations would not change measurably. The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 μg/L human health advisory objective (i.e., for children) or the 500 μg/L agricultural objective at the majority of assessment locations, which represents no change from the Existing Conditions and No Action Alternative (ELT) (Appendix 8F, *Boron*, Table Bo-3C). A small increase in the frequency of exceedances 500 μg/L agricultural objective at the Sacramento River at Mallard Island (i.e., as much as 3% in the drought period relative to the No Action Alternative [ELT]) would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations. Minor reductions in long-term average assimilative capacity of up to 6% at interior Delta locations (i.e., Old River at Rock Slough) would occur with respect to the 500 μg/L agricultural objective (Appendix 8F, *Boron*, Table Bo-27). However, because the absolute boron concentrations would still be well below the lowest 500 μg/L objective for the protection of the agricultural beneficial use under Alternative 4A, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, *Boron*, Figure Bo-6).

Effects of Alternative 4A in the Delta in the LLT, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to those described above for the ELT. Boron concentrations may be higher at western Delta locations due to greater effects of climate change on sea level rise that would occur in the LLT; however, these effects are independent of the alternative.

Further, boron is of concern in waters diverted for agricultural use, which primarily occurs in the interior Delta, and based on Delta source water characteristics (see Table 8-42 in Section 8.3.1.7, *Construction-Specific Considerations Used in the Assessment*), boron concentrations in the interior Delta would be expected to remain suitable for agricultural use.

SWP/CVP Export Service Areas

Under Alternative 4A, long-term average boron concentrations would decrease at the Banks pumping plant (20%) and at Jones pumping plant (23%) relative to Existing Conditions, and the reductions would be similar compared to No Action Alternative (ELT) (Appendix 8F, *Boron*, Table Bo-26) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing CWA Section 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading. These same effects on boron at the Banks and Jones pumping plants would be expected in the LLT, because the primary effect of climate change on sea level rise and boron concentrations is expected in the western Delta.

Maintenance of SWP and CVP facilities under Alternative 4A would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative (ELT and LLT), Alternative 4A would result in relatively small increases in long-term average boron concentrations in the Delta, not measurably increase boron levels in the lower San Joaquin River, and reduce boron levels in water exported to the SWP/CVP export service areas. However, the predicted changes would not be expected to cause exceedances of applicable objectives or further measurable water quality degradation, and thus would not constitute an adverse effect on water quality.

CEQA Conclusion: Based on the above assessment, any modified reservoir operations and subsequent changes in river flows under Alternative 4A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in boron levels upstream of the Delta. Small increases in boron levels predicted for interior Delta locations in response to a shift in the Delta source water percentages would not be expected to cause exceedances of objectives, or substantial degradation of these water bodies. Alternative 4A maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 4A would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to Existing Conditions, Alternative 4A would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 4A would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing CWA Section 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 for Alternative 4A would present no new direct sources of boron to the affected environment, including areas upstream of the Delta, within the Delta region, and in the SWP/CVP Export Service Areas. Habitat restoration activities in the Delta, while involving increased land and water interaction within these habitats, would not be anticipated to contribute boron which is primarily associated with source water inflows to the Delta (i.e., San Joaquin River, agricultural drainage, and Bay source water). Moreover, some habitat restoration would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated boron concentrations, which would be considered an improvement compared to the No Action Alternative (ELT and LLT). Consequently, as they pertain to boron, implementation of the Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 for Alternative 4A would not present new or substantially changed sources of boron to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP Export Service Areas. As such, their implementation would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or other criteria would be exceeded in water bodies of the affected environment located upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas or substantially degrade the quality of these water bodies, with regard to boron. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), under Alternative 4A in the ELT there would be no expected change to the sources of bromide in the Sacramento River and eastside tributary watersheds. Thus, changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of bromide in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions and would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial bromide increases (Appendix 8E, *Bromide*, Table 24). Moreover, there are no existing municipal intakes on the lower San Joaquin River, which is the beneficial use most sensitive to elevated bromide concentrations. Consequently, Alternative 4A in the ELT would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the San Joaquin River, the eastside tributaries, or their associated reservoirs upstream of the Delta due to changes in bromide concentrations.

Effects of Alternative 4A in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect bromide sources in these areas.

Delta

Estimates of bromide concentrations at Delta assessment locations were generated using a mass balance approach, and using relationships between EC and chloride and between chloride and bromide and DSM2 EC output. See Section 8.3.1.3, *Plan Area*, for more information regarding these modeling approaches. The assessment below identifies changes in bromide at Delta assessment locations based on both approaches.

Based on the mass balance modeling approach for bromide, relative to Existing Conditions, Alternative 4A long-term average bromide concentrations would increase in the S. Fork Mokelumne River at Staten Island, and decrease at all other assessment locations (Appendix 8E, *Bromide*, Table 22). Average bromide concentrations at Staten Island would increase from 50 µg/L under Existing Conditions to 54 µg/L (8% increase) for the modeled 16-year hydrologic period (1976–1991). However, multiple interior and western Delta assessment locations would have an increased frequency of exceedance of 50 µg/L, which is the CALFED Drinking Water Program goal for bromide as a long-term average applied to drinking water intakes (Appendix 8E, *Bromide*, Table 22). These locations are the S. Fork Mokelumne River at Staten Island, Franks Tract, Old River at Rock Slough, Sacramento River at Emmaton, San Joaquin River at Antioch, and Sacramento River at Mallard Island. The greatest increase in frequency of exceedance of the CALFED Drinking Water Program long-term goal of 50 µg/L would occur in the S. Fork Mokelumne River (7% increase) and Sacramento River at Emmaton (4% increase). The increase in frequency of exceedance of the 50 µg/L threshold at the other locations would be 2% or less. Similarly, these locations and the Contra Costa Pumping Plant #1 would have an increased frequency of exceedance of 100 µg/L, which is the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts (Appendix 8E, *Bromide*, Table 22). The greatest increase in frequency of exceedance of 100 µg/L would occur at Sacramento River at Emmaton (5% increase) and San Joaquin River at Antioch and Franks Tract (4% increase). The increase in frequency of exceedance of the 100 µg/L threshold at the other locations would be 3% or less.

Changes in long-term average bromide concentrations and changes in threshold exceedance frequencies relative to the No Action Alternative (ELT) are generally of similar magnitude to those previously described relative to Existing Conditions (Appendix 8E, *Bromide*, Table 22). However, unlike the Existing Conditions comparison, relative to the No Action Alternative (ELT), long-term average bromide concentrations in the San Joaquin River at Buckley Cove and the North Bay Aqueduct at Barker Slough would increase under Alternative 4A, although the increases would be relatively small (<1%). Further, at the North Bay Aqueduct, the frequency of exceedance of 50 µg/L would increase from 35% to 40%; there would be no increased exceedance of the 100 µg/L threshold. The increase in the frequency of exceedance of the 50 µg/L threshold at the other locations would be 3% or less, The frequency of exceedance of the 100 µg/L at the other locations would increase relative to the No Action Alternative (ELT) by 2% or less in the Mokelumne River at Staten Island, Franks Tract, in Old River at Rock Slough, in the San Joaquin River at Antioch, in the Sacramento River at Mallard Island, and at Contra Costa. There would not be an increased exceedance of the 100 µg/L threshold at Emmaton.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide were consistent with the discussion above, and assessment of bromide using these modeling results leads to the same conclusions as are presented above for the mass balance approach (Appendix 8E, *Bromide*, Table 23).

The magnitude of bromide concentration increases at Mallard Slough and in the San Joaquin River at Antioch during their historical months of use, relative to Existing Conditions and the No Action Alternative (ELT) would be generally similar to those described for Alternative 4 (Appendix 8E, *Bromide*, Table 25), and the frequency of exceedance of bromide thresholds would be similar (Appendix 8E, *Bromide*, Table 22). As described for Alternative 4, the use of seasonal intakes at these locations is largely driven by acceptable water quality, and thus has historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at Antioch and Mallard Slough would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

The effects of Alternative 4A in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to that described above. There may be higher bromide concentrations in the LLT in the western Delta, but this would be associated with sea level rise, not the project alternative, because the primary source of bromide to the Delta is sea water intrusion.

SWP/CVP Export Service Areas

Under Alternative 4A, long-term average bromide concentrations at the Banks and Jones pumping plants, based on the mass balance modeling approach, would decrease. Long-term average bromide concentrations for the modeled 16-year hydrologic period at the pumping plants would decrease by as much as 46% relative to Existing Conditions and 43% relative to the No Action Alternative (ELT) (Appendix 8E, *Bromide*, Table 22). As a result, less frequent exceedances of the 50 μg/L and 100 μg/L assessment thresholds would occur and an overall improvement in SWP/CVP Export Service Areas water quality would occur respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also occur since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide are consistent with the mass balance results, and assessment of bromide using these modeling results leads to the same conclusions as are presented for the mass balance approach (Appendix 8E, *Bromide*, Table 23).

The effects of Alternative 4A in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to that described above, because the sea level rise that could occur in the LLT would not be expected to result in substantial bromide contributions to the water exported at Banks and Jones pumping plants.

Maintenance of SWP and CVP facilities under Alternative 4A would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

NEPA Effects**:** In summary, the operations and maintenance activities under Alternative 4A, relative to the No Action Alternative (ELT and LLT) would result in an increased frequency of exceedance of both the 50 μg/L and 100 μg/L bromide thresholds for protecting against the formation of disinfection byproducts in treated drinking water at the S. Fork Mokelumne River at Staten Island, Franks Tract,San Joaquin River at Antioch, and Sacramento River at Mallard Island. In addition, there would be an increased frequency of exceedance of the 50 μg/L threshold at Emmaton and the North Bay Aqueduct at Barker Slough, and an increased frequency of exceedance of the 100 μg/L threshold in the Old River at Rock Slough and at Contra Costa Pumping Plant #1. However, long-term average bromide concentrations would increase only in the S. Fork Mokelumne River at Staten Island, the San Joaquin River at Buckley Cove, and the North Bay Aqueduct at Barker Slough; there would be decreases in long-term average bromide concentrations at the other assessment locations. The long-term bromide concentration in the S. Fork Mokelumne River at Staten Island would be less than the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts, and the increase in the San Joaquin River at Buckley Cove and the North Bay Aqueduct at Barker Slough would be minimal (<2%). Thus, these increased bromide concentrations are not expected to result in adverse effects to MUN beneficial uses, or any other beneficial use, at these locations. Based on these findings, this effect is determined to not be adverse.

***CEQA Conclusion*:** While greater water demands under Alternative 4A would alter the magnitude and timing of reservoir releases north and east of the Delta, these activities would have negligible, if any, effect on the sources of bromide, and ultimately the concentration of bromide in the Sacramento River, the San Joaquin River, the eastside tributaries, and the various reservoirs of the related watersheds, as described for Alternative 4 (see Section 8.3.3.9).

Under Alternative 4A there would be an increased frequency of exceedance of both the 50 μg/L and 100 μg/L bromide thresholds for protecting against the formation of disinfection byproducts in treated drinking water at the S. Fork Mokelumne River at Staten Island, Franks Tract, Old River at Rock Slough, Sacramento River at Emmaton, San Joaquin River at Antioch, and Sacramento River at Mallard Island. Also, there would be an increased frequency of exceedance of the 100 μg/L threshold at the Contra Costa Pumping Plant #1. However, long-term average bromide concentrations would increase only in the S. Fork Mokelumne River at Staten Island and decrease at all other assessment locations. The long-term bromide concentration in the S. Fork Mokelumne River at Staten Island (54 μg/L) would be less than the 100 μg/L believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts. Further, as described for Alternative 4 (see Section 8.3.3.9), the use of seasonal intakes at Antioch and Mallard Island is largely driven by acceptable water quality, and thus has historically been opportunistic and opportunity to use these intakes would remain. Thus, these increased bromide concentrations would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Long-term average bromide concentrations at the Banks and Jones pumping plants are predicted to decrease by as much as 46% relative to Existing Conditions and there would be less frequent exceedance of bromide concentration thresholds.

Based on the above, Alternative 4A would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria because none exist for bromide. Alternative 4A would not result in any substantial change in long-term average bromide concentration or exceed 50 and 100 μg/L assessment threshold concentrations by frequency, magnitude, and geographic extent that would result in adverse effects on any beneficial uses within affected water bodies. Bromide is not a bioaccumulative constituent and thus concentrations under this alternative would not result in bromide bioaccumulating in aquatic organisms. Increases in exceedances of the 100 µg/L assessment threshold concentration would be 5% or less at all locations assessed, which is considered to be less than substantial long-term degradation of water quality. The levels of bromide degradation that may occur under the Alternative 4A would not be of sufficient magnitude to cause substantially increased risk for adverse effects on any beneficial uses of water bodies within the affected environment. Bromide is not CWA Section 303(d) listed and thus the minor increases in long-term average bromide concentrations would not affect existing beneficial use impairment because no such use impairment currently exists for bromide. Based on these findings, this impact is less than significant. No mitigation is required.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would present no new sources of bromide to the affected environment, including areas Upstream of the Delta, within the Plan Area, and the SWP/CVP Export Service Areas. Some habitat restoration activities would occur on lands in the Delta formerly used for irrigated agriculture. Such replacement or substitution of land use activity would not be expected to result in new or increased sources of bromide to the Delta. Therefore, as they pertain to bromide, implementation of these Environmental Commitments would not be expected to adversely affect MUN beneficial use, or any other beneficial uses, of the affected environment.

Environmental Commitment 4 would result in some tidal habitat restoration, however, the areal extent would be small relative to the existing and No Action Alternative tidal area and, thus not expected to appreciably affect the magnitude of daily tidal water exchange at the restoration areas or alter other hydrodynamic conditions in adjacent Delta channels that would result in measurable bromide concentration changes.

In summary, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A relative to the No Action Alternative (ELT and LLT), would have negligible, if any, effects on bromide concentrations. Therefore, the effects on bromide from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

***CEQA Conclusion*:** Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A would not present new or substantially changed sources of bromide to the affected environment. Some Environmental Commitments may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution would not be expected to substantially increase or present new sources of bromide. Thus, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would have negligible, if any, effects on bromide concentrations throughout the affected environment, would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria because none exist for bromide, and would not cause changes in bromide concentrations that would result in significant impacts on any beneficial uses within affected water bodies. Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause significant long-term water quality degradation such that there would be greater risk of significant impacts on beneficial uses, would not cause greater bioaccumulation of bromide, and would not further impair any beneficial uses due to bromide concentrations because no uses are currently impaired due to bromide levels. Based on these findings, this impact is considered less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 4A on chloride concentrations in reservoirs and rivers upstream of the Delta would be the similar to those effects described for Alternative 4 (see Section 8.3.3.9). Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. There would be no expected change to the sources of chloride in the Sacramento River and eastside tributary watersheds, and changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of chloride in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions and would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial chloride increases. Moreover, there are no existing municipal intakes on the lower San Joaquin River. Consequently, Alternative 4A in the ELT would not be expected to cause exceedances of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Effects of Alternative 4A in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect chloride sources in these areas.

Delta

Estimates of chloride concentrations at Delta assessment locations were generated using a mass balance approach and EC-chloride relationships and DSM2 EC output. See Section 8.3.1.3, *Plan Area*, for more information regarding these modeling approaches. The assessment below identifies changes in chloride at Delta assessment locations based on both approaches.

Modeling of chloride using both the mass balance approach and EC-chloride relationship predicts that Alternative 4A in the ELT would result in reduced long-term average chloride concentrations, relative to Existing Conditions, for the 16-year period modeled at all assessment locations except for the S. Fork Mokelumne River at Staten Island. The increase in long-term average chloride concentration at Staten Island would be 1 mg/L (7%) based on the mass balance modeling and <1 mg/L (3%) based on the EC-chloride relationship (Appendix 8G, *Chloride*, Tables Cl-69 and Cl-70). These increases are extremely small in absolute terms and relative to applicable water quality objectives, and are within the estimated modeling uncertainty. The results differ from Alternative 4, under which there would be increased long-term average chloride concentrations also at the North Bay Aqueduct at Barker Slough. The change in long-term average chloride concentrations relative to the No Action Alternative (ELT) would be similar to those relative to Existing Conditions.

The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses Relative to Existing Conditions

Estimates of chloride concentrations generated using EC-chloride relationships were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at Antioch and Contra Costa Pumping Plant #1. For Alternative 4A, the modeled frequency of objective exceedance would decrease at the Contra Costa Pumping Plant #1 from 7% of years under Existing Conditions, to 0% of years (Appendix 8G, *Chloride*, Table Cl-64).

Evaluation of the 250 mg/L Bay-Delta WQCP objective for chloride utilized results from both the mass balance approach and EC-chloride relationship. The basis for the evaluation was the predicted number of days the objective would be exceeded for the modeled 16-year period.

Based on the mass balance approach, there would be a decreased frequency of exceedance of the 250 mg/L objective under Alternative 4A, relative to Existing Conditions, at all locations except in the Sacramento River at Mallard Island and Emmaton, and San Joaquin River at Antioch. In the Sacramento River at Mallard Island, the frequency of objective exceedance would increase from 85% under Existing Conditions to 86% under Alternative 4A for the entire period modeled (Appendix 8G, *Chloride*, Table Cl-81). At Emmaton, there would be an increase in chloride objective exceedance during the drought period modeled, from 55% to 58%. In the San Joaquin River at Antioch, there would be an increase in the chloride objective exceedance during the drought period modeled from 82% to 83%. These changes are within the uncertainty of the modeling approach.

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 4A, the modeled frequency of objective exceedance would decrease, from 6% of modeled days under Existing Conditions, to 4% of modeled days under Alternative 4A (Appendix 8G, *Chloride*, Table Cl-63).

The mass balance results also indicate reduced assimilative capacity with respect to the 250 mg/L objective during certain months and at certain locations. In the San Joaquin River at Antioch, there would be a reduction in assimilative capacity in March and April of up to 21% for the 16-year period modeled, and 71% for the drought period modeled (Appendix 8G, *Chloride*, Table Cl-71). Assimilative capacity at the Contra Costa Pumping Plant #1 would be reduced in March, April, and June by up to 4% for the entire period modeled and in April, May and June by up to 4% for the drought period modeled. These estimates include the effect of climate change and sea level rise, as well as the alternative. Comparisons to the No Action Alternative (ELT) below provide an assessment of the effect of the alternative alone.

When utilizing the EC-chloride relationship to model chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity would be similar to those discussed when utilizing the mass balance modeling approach (Appendix 8G, *Chloride*, Tables Cl-72 and Cl-82). However, the EC-chloride relationships predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, *Plan Area*, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

CWA Section 303(d) Listed Water Bodies–Relative to Existing Conditions

Tom Paine Slough in the southern Delta is on the state's CWA Section 303(d) list for chloride with respect to the secondary MCL of 250 mg/L. Monthly average chloride concentrations at the Old River at Tracy Road for the 16-year period modeled, which represents the nearest DSM2-modeled location to Tom Paine Slough, would be generally similar under Alternative 4A in the ELT relative to Existing Conditions, and thus, would not be further degraded on a long-term basis and Alternative 4A in the ELT would thus not make this impairment discernibly worse (Appendix 8G, *Chloride*, Figure Cl-17).

Suisun Marsh also is on the state's CWA Section 303(d) list for chloride in association with the Bay-Delta WQCP objectives for maximum allowable salinity during the months of October through May, which establish appropriate seasonal salinity conditions for fish and wildlife beneficial uses. In the Sacramento River at Mallard Island, monthly average chloride concentrations for the 16-year period modeled would generally decrease under Alternative 4A in the ELT relative to Existing Conditions in October through February by 2–18%, and increase in March through May by 1–17% (Appendix 8G, *Chloride*, Figure Cl-18). In the Sacramento River at Collinsville monthly average chloride concentrations for the 16-year period modeled would similarly decrease under Alternative 4A in the ELT relative to Existing Conditions in October through February by 3–22% and increase in March and April by 11–21% (Appendix 8G, *Chloride*, Figure Cl-19). In Montezuma Slough at Beldon's Landing monthly average chloride concentrations for the 16-year period modeled would similarly decrease under Alternative 4A in the ELT relative to Existing Conditions in October through February by 1–15% and increase in March through May by 2–12% (Appendix 8G, *Chloride*, Figure Cl-20). Chloride levels in Suisun Marsh are highly dynamic on a sub-daily basis as a result of tidal influences. The changes identified above are small relative to normal day-to-day variability in chloride in Suisun Marsh. For these reasons, any changes in chloride in Suisun Marsh are expected to have no adverse effect on marsh beneficial uses. These changes reflect the effect of climate change and sea level rise, as well as the alternative. Comparisons to the No Action Alternative (ELT) below provide an assessment of the effect of the alternative alone.

Municipal Beneficial Uses Relative to No Action Alternative (ELT)

Similar to the assessment conducted for Existing Conditions, estimates of chloride concentrations generated from EC-chloride relationships were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses. For Alternative 4A in the ELT, the modeled frequency of objective exceedance would not change at the Contra Costa Pumping Plant #1—both the No Action Alternative (ELT) and Alternative 4A would have no exceedances (Appendix 8G, *Chloride*, Table Cl-64).

Based on the mass balance approach, the frequency of exceedance of the 250 mg/L objective under Alternative 4A in the ELT would be the same, or would decrease, at all locations relative to the No Action Alternative (ELT) (Appendix 8G, *Chloride*, Table Cl-81).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 4A, the modeled frequency of objective exceedance would decrease, from 8% of modeled days under the No Action Alternative (ELT), to 4% of modeled days under Alternative 4A (Appendix 8G, *Chloride*, Table Cl-63).

Estimates of long-term use of assimilative capacity using the mass balance results indicated the potential for reduced assimilative capacity with respect to the 250 mg/L objective for certain months and locations. Calculations using the long-term monthly average concentrations showed that in the San Joaquin River at Antioch, there would be a reduction in assimilative capacity in April of 5% for the entire period modeled and 48% for the drought period modeled (Appendix 8G, *Chloride*, Table Cl-71). However, this approach used long-term average chloride concentrations, which can be heavily influenced by changes in a small number of years when chloride concentrations would already be very high. Additionally, when long term averages are just below the objective, very small changes in chloride that are within the modeling uncertainty can result in very high estimates of use of assimilative capacity. To further investigate the potential for water quality degradation with respect to chloride, the concentrations of chloride during individual water years was examined.

This further examination was limited to the mass balance approach, since when utilizing the EC-chloride relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity were similar to those discussed for the mass balance modeling approach (Appendix 8G, *Chloride*, Tables Cl-82 and Cl-72). However, utilizing the EC-chloride relationships predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, *Plan Area*, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

Figure Cl-21 in Appendix 8G, *Chloride* shows chloride concentrations in April during the 5-year drought period (1987–1991) at Antioch, where Table Cl-71 in Appendix 8G, *Chloride* indicated up to 48% use of assimilative capacity. The figure shows that during 2 of the 5 years, chloride concentrations increased relative to the No Action Alternative (ELT) and decreased in the other 3 years. The absolute differences estimated are fairly small and may be within modeling uncertainty. Figures Cl-22 and Cl-23 in Appendix 8G show a box and whisker plot and exceedance plot for April at Antioch for all dry and critical water years modeled (not just the 1987–1991 drought period). These graphs show that while the median chloride concentration is increased relative to the No Action Alternative (ELT), the maximums, 25th percentile, and 75th percentile values are either similar or decreased. Based on this analysis, long-term degradation is not expected at Antioch in April during drought years.

Based on the low level of water quality degradation estimated for the western Delta, and the lack of exceedance of water quality objectives, Alternative 4A is not expected to have substantial adverse effects on municipal and industrial beneficial uses in the western Delta.

CWA Section 303(d) Listed Water Bodies–Relative to No Action Alternative (ELT)

With respect to the state's CWA Section 303(d) listing for chloride, monthly average chloride concentrations at Tom Paine Slough would not be further degraded on a long-term basis, based on the overall small changes that would occur in Old River at Tracy Road (Appendix 8G, *Chloride*, Figure Cl-17). In the Sacramento River at Mallard Island, monthly average chloride concentrations for the 16-year period modeled would increase slightly under Alternative 4A in the ELT relative to the No Action Alternative (ELT) in March and April by 1–4%, and decrease in May and October through February by up to 12% (Appendix 8G, *Chloride*, Figure Cl-18). In the Sacramento River at Collinsville monthly average chloride concentrations for the 16-year period modeled would similarly increase in March and April by 3%, and decrease in May and October through February by up to 18% (Appendix 8G, *Chloride*, Figure Cl-19). In Montezuma Slough at Beldon's Landing monthly average chloride concentrations for the 16-year period modeled would increase in December, March and April by 1–2%, and decrease in May, October, November, January and February by 6–10%(Appendix 8G, *Chloride*, Figure Cl-20). Chloride levels in Suisun Marsh are highly dynamic on a sub-daily basis as a result of tidal influences. The changes identified above are small relative to normal day-to-day variability in chloride in Suisun Marsh. For these reasons, any changes in chloride in Suisun Marsh are expected to have no adverse effect on marsh beneficial uses.

The effects of Alternative 4A in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to effects in the ELT. With greater climate change and sea level rise, additional outflow may be required at certain times to prevent increases in chloride in the west Delta. Small increases in chloride concentrations may occur in some areas, but it is not expected that these increases would cause exceedance of Bay-Delta WQCP objectives of cause substantial long-term degradation that would impact municipal and industrial beneficial uses.

SWP/CVP Export Service Areas

Under Alternative 4A in the ELT, long-term average chloride concentrations at the Banks and Jones pumping plants, based on the mass balance analysis of modeling results for the 16-year period, would decrease relative to Existing Conditions. Chloride concentrations would be reduced by 45% at Banks pumping plant (Appendix 8G, *Chloride*, Table Cl-69). At Jones pumping plant, chloride concentrations would be reduced 43% (Appendix 8G, *Chloride*, Table Cl-69). The frequency of exceedances of applicable water quality objectives would decrease relative to Existing Conditions, for both the 16-year period and the drought period modeled (Appendix 8G, *Chloride*, Table Cl-81). The chloride concentration changes relative to the No Action Alternative (ELT) would be similar. Consequently, water exported into the SWP/CVP Export Service Areas would generally be of similar or better quality with regard to chloride relative to Existing Conditions and the No Action Alternative (ELT). Results of the modeling approach which utilized a EC-chloride relationship are consistent these results, and assessment of chloride using these modeling output results in the same conclusions as for the mass balance approach (Appendix 8G, *Chloride*, Tables Cl-70 and Cl-82).

Commensurate with the reduced chloride concentrations in water exported to the SWP/CVP Export Service Area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely reduce chloride concentrations at Vernalis.

The effects of Alternative 4A in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be very similar to effects in the ELT. The difference in these timeframes that could contribute to EC differences between the ELT and LLT is climate change and sea level rise, and thus would not be due to the alternative.

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative (ELT and LLT), Alternative 4A would not result in substantially increased chloride concentrations upstream of the Delta, in the

Delta, or in the SWP/CVP Export Service Area on a long-term average basis that would result in adverse effects on the municipal and industrial water supply beneficial use, or any other beneficial use. Additional exceedance of the 150 mg/L and 250 mg/L objectives is not expected, and substantial long-term degradation is not expected that would result in adverse effects on the municipal and industrial water supply beneficial use, or any other beneficial use. Based on these findings, this effect is determined to not be adverse.

CEQA Conclusion**:** Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta; therefore, river flow rate and reservoir storage reductions that would occur under Alternative 4A relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, Alternative 4A would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, Alternative 4A would not result in substantially increased chloride concentrations in the Delta on a long-term average basis that would result in adverse effects on the municipal and industrial water supply beneficial use. Additional exceedance of the 150 mg/L and 250 mg/L objectives is not expected, and substantial long-term degradation is not expected that would result in adverse effects on the municipal and industrial water supply beneficial use.

Chloride concentrations would be reduced under Alternative 4A in water exported from the Delta to the SWP/CVP Export Service Areas thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under the Alternative 4A would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 4A maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas

Based on these findings, this impact is determined to be less than significant. No mitigation is required. Despite the fact that no mitigation is required, DWR proposed to further reduce any impacts by implementing Mitigation Measure WQ-7e.

Mitigation Measure WQ-7e: Implement Terms of the Contra Costa Water District Settlement Agreement

DWR and Contra Costa Water District (CCWD) entered into a settlement agreement (Agreement) for reducing potential impacts to CCWD water supply in the Delta related to construction and operation of the BDCP/California WaterFix. This mitigation measure includes conveyance of water to CCWD that meets specified water quality requirements, in quantities and on a schedule defined in the Agreement. The Agreement ensures that the quality of the water CCWD delivers to its customers is not impacted as a result of the BDCP/California WaterFix. The Agreement does not increase the total amount of water that CCWD would otherwise be entitled to divert.

DWR would convey mitigation water to CCWD in one of two ways: 1) the primary method of conveying the water would be through the existing Freeport Regional Water Authority Intake (Freeport Intake) and the existing interconnection between EBMUD’s Mokelumne Aqueduct and CCWD’s Los Vaqueros Pipeline; and 2) the secondary method of conveying the water would be through the BDCP/California WaterFix’s northern intakes and new Interconnection Facilities between the water conveyance facilities and existing CCWD facilities. Two different options for the new Interconnection Facilities are being considered: one on Victoria Island between the water conveyance facilities and the existing CCWD Middle River pipeline; and one at Clifton Court Forebay between the Clifton Court Forebay and the CCWD Los Vaqueros pipeline. No new facilities are required for the EBMUD/Freeport Intake conveyance method. DWR would be responsible for design and construction of the Victoria Island or Clifton Court Forebay facilities.

The Agreement requires an initial conveyance to CCWD of 30 TAF of water. For each year after the initial conveyance, a specified amount of water based on the prior year's operations would be conveyed in arrears. Under the Agreement, CCWD would take the same quantity of water that it would take absent the agreement, but the location and timing of diversions would change. Annual average diversions of mitigation water would be on the order of 30 TAF, and the rate of diversion of the mitigation water would be 150 cfs, with a maximum rate of diversion of 250 cfs upon mutual agreement between DWR and CCWD.

Additional description of the Agreement actions and analysis of the potential effects of this mitigation measures are provided in Appendix 31B. Terms of the Agreement are presented in Attachment 1 to Appendix 31B.

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A would present no new direct sources of chloride to the affected environment, including areas Upstream of the Delta, within the Plan Area, and the SWP/CVP Export Service Areas. Consequently, as they pertain to chloride, implementation of these Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment. Moreover, some habitat restoration activities would occur on lands within the Delta currently used for irrigated agriculture. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement relative to the No Action Alternative (ELT and LLT). Therefore, the effects on chloride from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

***CEQA Conclusion*:** Implementation of the Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP Export Service Areas. Replacement of irrigated agricultural land uses in the Delta with habitat restoration may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance

As described in detail for Alternative 4 (see Section 8.3.3.9), DO levels are primarily affected by water temperature, flow velocity, turbulence, amounts of oxygen demanding substances present (e.g., ammonia, organics), and rates of photosynthesis (which is influenced by nutrient levels), respiration, and decomposition. Water temperature and salinity affect the maximum DO saturation level (i.e., the highest amount of oxygen the water can dissolve). Flow velocity affects the turbulence and re-aeration of the water (i.e., the rate at which oxygen from the atmosphere can be dissolved in water). High nutrient content can support aquatic plant and algae growth, which in turn generates oxygen through photosynthesis and consumes oxygen through respiration and decomposition.

As described for Alternative 4, amounts of oxygen demanding substances present (e.g., ammonia, organics) in the reservoirs and rivers upstream of the Delta, rates of photosynthesis (which is influenced by nutrient levels/loading), and respiration and decomposition of aquatic life is not expected to change sufficiently under Alternative 4A (ELT and LLT) to substantially alter DO levels relative to Existing Conditions or the No Action Alternative (ELT and LLT). Further, the rivers upstream of the Delta are well oxygenated and experience periods of supersaturation (i.e., when DO level exceeds the saturation concentration). Because these are large, turbulent rivers, any reduced DO saturation level that would be caused by an increase in temperature under Alternative 4A would not be expected to cause DO levels to be outside of the range seen historically. Flow changes that would occur under Alternative 4A would not be expected to have substantial effects on river DO levels; likely, the changes would be immeasurable. This is because sufficient turbulence and interaction of river water with the atmosphere would continue to occur to maintain water saturation levels (due to these factors) at levels similar to that of Existing Conditions and the No Action Alternative (ELT and LLT).

Also as described for Alternative 4, salinity changes would generally have relatively minor effects on Delta DO levels. Further, the relative degree of tidal exchange of flows and turbulence, which contributes to exposure of Delta waters to the atmosphere for reaeration, would not be expected to substantially change relative to Existing Conditions or the No Action Alternative (ELT and LLT), such that these factors would reduce Delta DO levels below objectives or levels that protect beneficial uses. Similarly, increased temperature under Alternative 4A (ELT and LLT), which would be due to climate change, would generally have relatively minor effects on Delta DO levels, relative to Existing Conditions.

Similar to Alternative 4, flows in the San Joaquin River at Stockton were evaluated for Alternative 4A and are shown in Figure 8-65b. The figure shows that while flows would change somewhat, they would generally be within the range of flows seen under Existing Conditions and the No Action Alternative. Reports indicate that the aeration facility performs adequately under the range of flows from 250–1,000 cfs (ICF International 2010). Based on the above, the expected changes in flows in the San Joaquin River at Stockton are not expected to substantially move the point of minimum DO, and therefore the aeration facility would likely still be located appropriately to keep DO levels above Basin Plan objectives. Overall, assuming continued operation of the aerators, the alternative is not expected to have a substantial adverse effect on DO in the Deep Water Ship Channel. It is expected that DO levels in the Deep Water Ship Channel, which is CWA Section 303(d) listed as impaired due to low DO, would remain similar to those under Existing Conditions and the No Action Alternative (ELT and LLT) or improve as TMDL-required studies are completed and actions are implemented to improve DO levels. DO levels in other Clean Water Act Section 303(d)-listed waterways would not be expected to change relative to Existing Conditions or the No Action Alternative (ELT and LLT), as the circulation of flows, tidal flow exchange, and re-aeration would continue to occur.

In the SWP/CVP Export Service Areas, the primary factor that would affect DO in the conveyance channels and ultimately the receiving reservoirs would be changes in the levels of nutrients and oxygen-demanding substances and DO levels in the exported water. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions or the No Action Alternative (ELT and LLT) due to water quality regulations, canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

NEPA Effects: Because DO levels are not expected to change substantially relative to the No Action Alternative (ELT and LLT), the effects on DO from implementing Alternative 4A (ELT and LLT) are determined to not be adverse.

CEQA Conclusion: The effects of Alternative 4A on DO levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for Alternative 4 (see Section 8.3.3.9). Reservoir storage reductions that would occur under Alternative 4A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state regulates the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters, relative to Existing Conditions. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are CWA Section 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. Based on these findings, this impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Environmental Commitments 3, 4, and 6–11 would involve habitat restoration actions. The increased habitat provided by these Environmental Commitments could contribute to an increased biochemical or sediment demand, through contribution of organic carbon and plants decaying, though the areal extent of the effects would be less than under Alternative 4, because less land would be converted under Alternative 4A. The areal extent of new habitat implemented for the Environmental Commitments would be small relative to the existing and No Action Alternative tidal area, and similar habitat exists currently in the Delta and is not identified as contributing to adverse DO conditions. Although additional DOC loading to the Delta may occur (see impact WQ-18), the amount expected would be minimal and only a fraction of the DOC is available to microorganisms that would consume oxygen as part of the decay and mineralization process. Since decreases in dissolved organic carbon are not typically observed in Delta waterways due to these processes, any increase in DOC is unlikely to contribute to adverse DO levels in the Delta.

CM14, which under Alternative 4 would fund improvements to the oxygen aeration facility in the Stockton Deep Water Ship Channel to meet TMDL objectives established by the Central Valley Water Board, would not be implemented under Alternative 4A. However, the existing aeration facility would continue to be operated to enhance DO levels in the channel. Thus, DO levels would be expected similar those under the No Action Alternative (ELT and LLT).

CM19, which under Alternative 4 would fund projects to contribute to reducing pollutant discharges in stormwater, also would not be implemented under Alternative 4A. Thus, the potential for reduced biochemical oxygen demand load described for Alternative 4 would not occur in the near-term and loading of these constituents and, thus DO levels, would be expected to be similar to that which would occur under the No Action Alternative (ELT and LLT).

The remaining Environmental Commitments would not affect DO levels because they are actions that do not affect the presence of oxygen-demanding substances.

Based on the above findings, the effects on DO from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A are determined to not be adverse.

***CEQA Conclusion*:** It is expected that DO levels in the Upstream of the Delta Region, in the Plan Area, or in the SWP/CVP Export Service Areas following implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A would not be substantially different from existing DO conditions, because these would contribute to a minimal, localized change in oxygen-demanding substances associated with habitat restoration, if at all. Therefore, these Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels would be expected, long-term water quality degradation would not be expected, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are CWA Section 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and impairment of these areas would not be expected. Based on these findings, this impact would be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 4A on EC levels in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 (see Section 8.3.3.9). The extent of new urban growth would be less in the ELT, thus discharges of EC-elevating parameters in runoff and wastewater discharges to water bodies upstream of the Delta would be expected to be less than in the LLT. However, the state is regulating point source discharges of EC-related parameters and implementing a program to further decrease loading of EC-related parameters to tributaries. Based on these considerations, and those described in Section 8.3.3.9, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, or their associated reservoirs upstream of the Delta would not be expected to be outside the ranges occurring under Existing Conditions.

For the San Joaquin River, increases in EC levels under Alternative 4A could occur, but would be slightly less than those described for Alternative 4 (see Section 8.3.3.9). This is because the effects of climate change on flows, which could affect dilution of high EC discharges, would be less in the ELT. The implementation of the adopted TMDL for the San Joaquin River at Vernalis and the ongoing development of the TMDL for the San Joaquin River upstream of Vernalis are expected to contribute to improved EC levels. Based on these considerations, substantial changes in EC levels in the San Joaquin River relative to Existing Conditions would not be expected to be of sufficient magnitude and geographic extent that would result in adverse effects on any beneficial uses, or substantially degrade the quality of these water bodies, with regard to EC.

Delta

Relative to Existing Conditions and the No Action Alternative (ELT), initial review of modeling results indicated that Alternative 4A would potentially result in an increase in the number of days the Bay-Delta WQCP EC objectives would be exceeded in the Sacramento River at Emmaton and San Joaquin River at Prisoners Point (Appendix 8H, *Electrical Conductivity*, Table EC-26). To understand and interpret these results, considerations must be made regarding uncertainty in the modeling and results from sensitivity analyses. In addition, modeling results indicate there would be small increases in long-term monthly average EC at modeled Suisun Marsh locations relative to Existing Conditions. These locations are addressed in detail below. At all other locations, the level of exceedance and modeled average EC levels under the alternative were approximately equivalent or lower than under Existing Conditions and the No Action Alternative (ELT).

Sacramento River at Emmaton

Modeling results indicated that the Emmaton EC objective would be exceeded more often under Alternative 4A than under Existing Conditions and the No Action Alternative (ELT), and that increases in EC could cause substantial water quality degradation in summer months of below normal, dry and critical water years. However, these increases in exceedance of the objective and degradation are expected to be addressed via real-time operations, including real time management of the north Delta and south Delta intakes, as well as Delta Cross Channel operation. Further discussion is provided below.

Modeling results indicated that the percentage of days the Emmaton EC objective would be exceeded for the entire period modeled (1976–1991) would increase from 6% under Existing Conditions, or 12% under the No Action Alternative (ELT), to 16%, and the percentage of days out of compliance would increase from 11% under Existing Conditions, or 21% under the No Action Alternative (ELT), to 27% (Appendix 8H, *Electrical Conductivity*, Table EC-26).

Sensitivity analyses were performed that modeled Alternative 4 Scenario H3 at the LLT with Emmaton as the compliance point. These sensitivity analyses were only run at the LLT, but it is expected that the findings can generally be extended to the ELT, because the factors affecting salinity findings in the sensitivity analysis (e.g., modeling assumptions, physical hydrodynamic mechanisms) are similar between the ELT and LLT (see Appendix 8H, *Electrical Conductivity*, Attachment 1). Table 2 of Appendix 8H, *Electrical Conductivity*, Attachment 1, indicates that most of these exceedances are a result of modeling artifacts, but some exceedances are due to deadpool conditions that occurred under Alternative 4 and not under the No Action Alternative. As discussed in Chapter 5, *Water Supply*, Section 5.3.1, *Methods for Analysis*, under extreme hydrologic and operational conditions where there is not enough water supply to meet all requirements, CALSIM II uses a series of operating rules to reach a solution that is a simplified version of the very complex decision processes that SWP and CVP operators would use in actual extreme conditions. Thus, it is unlikely that the Emmaton objective would actually be exceeded due to dead pool conditions. However, these results indicate that water supply could be either under greater stress or under stress earlier in the year.

The results of the EC modeling indicate there would be months with substantial degradation relative to the No Action Alternative (ELT), particularly during the drought period modeled. Long-term monthly average EC levels at Emmaton would increase in the months of April, and July through September by 3–30% for the entire period modeled (1976–1991) and 6–41% during the drought period modeled (1987–1991), relative to the No Action Alternative (ELT) (Appendix 8H, *Electrical Conductivity*, Table EC-29). The largest increases in EC would occur in below normal, dry and critical water year types. However, as stated above, these periods of degradation are expected to be addressed via real-time operations. The level to which modeling output depicts degradation of water quality with respect to EC is primarily a function of the modeling not being able to fully capture how the system would be operated in real-time to minimize or avoid such degradation.

Discussions with SWP operators indicated that real-time operations would ensure that the Bay-Delta WQCP EC objectives at Emmaton, applicable from April 1 through August 15, would be met. In latter August and September, the Threemile Slough standard in the North Delta Water Agency Agreement and the Bay-Delta WQCP municipal and industrial objective at Rock Slough are in effect. During this period of the year, the coordinated operations of the SWP/CVP system strives to meet both standards in the most water-efficient method available to the CVP and SWP. Real-time operation would result in less EC degradation than depicted by modeling output because in order to comply with Bay-Delta WQCP objectives and the the North Delta Water Agency Agreement during the summer period, operators could, for example, increase upstream reservoir releases for necessary periods of time, reduce North Delta diversions, and/or close (short-term) the Delta Cross Channel. These options as well as real-time and forecasted tides, winds and barometric pressure are considered when the projects schedule daily operations, which the modeling does not fully capture.

Alternaltive 4A does not change the Bay-Delta WQCP objectives or the the North Delta Water Agency Agreement which are primary drivers of operations and resulting water quality in the Sacramento River at at Emmaton during late August and September. Therefore, the EC degradation at Emmaton that would occur upon implementation of Alternative 4A would be lesser than that shown by the modeling and would not be expected to differ substantially from that which would occur under the No Project Alternative because the compliance targets are not changing due to Alternative 4A during these months and real-time operations would achieve the compliance targets.

The modeling results also show that in the remaining months there would be decreases in EC relative to the No Action Alternative (ELT) of 3–21% for the entire period modeled and 2–28% for the drought period modeled. These decreases would contribute to the long-term average EC levels decreasing by 1% for the entire period modeled and drought period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-29).

San Joaquin River at Prisoners Point

Modeling results indicated that the EC objective that applies to the San Joaquin River between Jersey Point and Prisoners Point would be exceeded at Prisoners Point more often under Alternative 4A than under Existing Conditions and the No Action Alternative (ELT). However, these exceedances also are expected to be able to be addressed via real-time operations, including real time management of the north Delta and south Delta intakes, as well as Head of Old River Barrier management. Further discussion is provided below.

Modeling results estimated that the percentage of days the Prisoners Point EC objective would be exceeded would increase from 6% under Existing Conditions, or 2% under the No Action Alternative (ELT), to 12%, and the percentage of days out of compliance with the EC objective would increase from 10% under Existing Conditions, or 2% under the No Action Alternative (ELT), to 13% (Appendix 8H, *Electrical Conductivity*, Table EC-26). The magnitude of the exceedances is estimated to be very small—the objective is 440 µmhos/cm, and the EC during times of exceedance was between 440 and 600 µmhos/cm—and the exceedances generally occurred in drier water years (4 of the 5 years in which there were exceedances were dry water year type), when flows would be lower (Appendix 8H, *Electrical Conductivity*, Figures EC-1 through EC-5). During these times, the EC in the San Joaquin River at Vernalis is greater than in the Sacramento River entering the Delta, and is high enough on its own to cause an exceedance of the Prisoners Point EC objective.

There are two main drivers of the increase in exceedances under the alternative: an increase in San Joaquin River flow at Prisoners Point during April and May under the alternative, relative to Existing Conditions and the No Action Alternative (ELT), and a reduction in the amount of Sacramento River water moving past Prisoners Point under the alternative. The result is increased San Joaquin River water at Prisoners Point, and a reduction in the dilution that the Sacramento River provides the higher EC San Joaquin River. The increase in San Joaquin River flow at Prisoners Point is due to a reduction in pumping from the south Delta under the alternative, as well as due to the presence of the Head of Old River Barrier, which increases flow in the San Joaquin River downstream of Old River by preventing flow from entering Old River. The reduction in Sacramento River water influence is due to less pumping at the south Delta pumping plants (i.e., greater pumping draws more Sacramento River water through the Delta).

Sensitivity analyses conducted for Alternative 4 Scenario H3 at the LLT indicated that if the Head of Old River Barrier was open in April and May, exceedances would be reduced by about 5 percentage points. These sensitivity analyses were only run at the LLT, but it is expected that the findings can generally be extended to the ELT. Results of the sensitivity analyses indicate that the exceedances are partly due also to operations of the alternative itself, due to Head of Old River Barrier assumptions, and south Delta export differences (see Appendix 8H, Attachment 1, for more discussion of these sensitivity analyses). Appendix 8H, Attachment 2, contains a more detailed assessment of the likelihood of exceedances estimated via modeling adversely affecting aquatic life beneficial uses. Specifically, Appendix 8H, Attachment 2, discusses whether these exceedances might have indirect effects on striped bass spawning in the Delta, and concludes that the high level of uncertainty precludes making a definitive determination for those alternatives. Additionally, by adaptively managing the Head of Old River Barrier and the fraction of south Delta versus north Delta diversions, EC levels at Prisoners Point would likely be decreased to a level that would not adversely affect aquatic life beneficial uses.

Suisun Marsh

For Suisun Marsh October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Modeling results indicate that average EC for the entire period modeled would increase in the Sacramento River at Collinsville during the months of March and April relative to Existing Conditions, by 0.1–0.2 mS/cm (Appendix 8H, *Electrical Conductivity*, Table EC-32). In Montezuma Slough at National Steel, average EC levels would increase in March through May by 0.2 mS/cm (Appendix 8H, Table EC-33). There would be similarly small increases in long-term average EC in the months of March through May in Montezuma Slough near Beldon's Landing, Chadbourne Slough near Sunrise Duck Club, and Suisun Slough near Volanti Slough, ranging 0.1–0.4 mS/cm depending on month and location (Appendix 8H, Tables EC-34 through EC-36). Relative to the No Action Alternative (ELT), the modeled long-term average EC under the alternative would be similar or lower from October through May for these locations (Appendix 8H, Tables EC-32 through EC-36).

The Suisun Marsh EC objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated "equivalent or better protection will be provided at the location" (State Water Resources Control Board 2006:14). Long-term average EC increases relative to Existing Conditions may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the Marsh. Given the Bay-Delta WQCP narrative objective regarding "equivalent or better protection" in lieu of meeting specific numeric objectives, the small increases in EC under Alternative 4A, relative to Existing Conditions, would not be expected to adversely affect beneficial uses of Suisun Marsh. While Suisun Marsh is CWA Section 303(d) listed as impaired because of elevated EC, the potential increases in long-term average EC concentrations, relative to Existing Conditions, would not be expected to contribute to additional impairment, because the increase would be so small (<1 mS/cm) relative to the daily fluctuations in EC levels as to not be measurable and beneficial uses would not be adversely affected.

Further, the EC changes in Suisun Marsh relative to Existing Conditions reflect the influence of both operations of the alternative and sea level rise due to climate change, whereas the changes relative to the No Action Alternative (ELT) are due solely to operations of the alternative. As described above, there would be no increase in the long-term average EC at modeled Suisun Marsh locations, and for some locations long-term average EC would decrease. Therefore, it is expected that this alternative would not contribute to exceedances of EC objectives or additional impairment of beneficial uses, as affected by EC or other salinity-related parameters.

The effects of Alternative 4A in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to effects in the ELT. With greater climate change and sea level rise, additional outflow may be required at certain times to prevent increases in EC in the west Delta, but this requirement would not be due to the alternative.

SWP/CVP Export Service Areas

Under Alternative 4A, at the Banks pumping plant, the frequency of exceedance of the EC objective would be 1% for the entire period modeled and 2% for the drought period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-27). Relative to Existing Conditions, average EC levels under

Alternative 4A would decrease 25% for the entire period modeled and 20% during the drought period modeled (Appendix 8H, Table EC-29). Relative to the No Action Alternative (ELT), average EC levels would similarly decrease, by 22% for the entire period modeled and 18% during the drought period modeled (Appendix 8H, Table EC-29).

At the Jones pumping plant, the frequency of exceedance of the EC objective would be 0% for the entire period modeled and the drought period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-27). Relative to Existing Conditions, average EC levels under Alternative 4A would decrease 26% for the entire period modeled and 24% during the drought period modeled (Appendix 8H, Table EC-29). Relative to the No Action Alternative (ELT), average EC levels would similarly decrease, by 23% for the entire period modeled and 21% during the drought period modeled (Appendix 8H, Table EC-29).

Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 4A would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas. Rather, Alternative 4A would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows.

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC. Alternative 4A would result in lower average EC levels relative to Existing Conditions and the No Action Alternative (ELT) and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

The effects of Alternative 4A in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be very similar to effects in the ELT. The difference in these timeframes that could contribute to EC differences between the ELT and LLT is climate change and sea level rise, and thus would not be due to the alternative.

NEPA Effects: In summary, based on the results of the modeling and sensitivity analyses conducted, it is unlikely that there would be increased frequency of exceedance of agricultural EC objectives in the western, interior, or southern Delta. However, modeling results indicate that there could be increased long-term and drought period average EC levels during the summer months that would occur in the western Delta (i.e., in the Sacramento River at Emmaton) under Alternative 4A relative to the No Action Alternative (ELT), that could contribute to adverse effects on the agricultural beneficial uses. In addition, the increased frequency of exceedance of the San Joaquin River at Prisoners Point EC objective could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. Suisun Marsh is CWA Section 303(d) listed as impaired due to elevated EC, but EC levels are not expected to increase under Alternative 4A, relative to the No Action Alternative (ELT), and thus it is not expected to contribute to additional beneficial use impairment. The increases in EC in the Sacramento River at Emmaton, particularly during summer months of below normal, dry and critical water years, and the additional exceedances of water quality objectives in the San Joaquin River at Prisoners Point constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects so that they are not adverse.

CEQA Conclusion**:** River flow rate and reservoir storage reductions that would occur under Alternative 4A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 4A would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas, and exceedance of the Bay-Delta WQCP EC objective would be infrequent. Average EC levels for the entire period modeled would decrease at both the Banks and Jones pumping plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

Further, relative to Existing Conditions, Alternative 4A would not result in substantial increases in long-term average EC in Suisun Marsh. Thus, EC levels in Suisun Marsh are not expected to further degrade existing EC levels and thus would not contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, any changes in long-term average EC levels would not directly cause bioaccumulative problems in fish and wildlife. Suisun Marsh is CWA Section 303(d) listed as impaired due to elevated EC, but EC levels are not expected to change substantially under Alternative 4A, relative to Existing Conditions, and thus it is not expected that they would contribute to additional beneficial use impairment.

In the Plan Area, Alternative 4A is not expected to result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded, except for at the San Joaquin River at Prisoners Point (fish and wildlife objective; 6% increase). The increased frequency of exceedance of the fish and wildlife objective at Prisoners Point could contribute to adverse effects on aquatic life (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. However, by adaptively managing the Head of Old River Barrier and the fraction of south Delta versus north Delta diversions, EC levels at Prisoners Point would likely be decreased to a level that would not adversely affect aquatic life beneficial uses.

Average EC levels at Emmaton were modeled to increase by 9% during the drought period. The largest monthly average increases in EC would occur during the summer months of the drought period, and more generally in below normal, dry and critical water year types. The increases in drought period average EC levels modeled could cause substantial water quality degradation that would potentially contribute to adverse effects on the agricultural beneficial uses in the western Delta. The comparison to Existing Conditions reflects changes in EC due to both Alternative 4A operations and climate change/sea level rise. The adverse effects expected to occur at Emmaton would be due in part to the effects of climate change/sea level rise, and in part due to Alternative 4A operations. This is evidenced by the increases in EC in the No Action Alternative (ELT) at Emmaton relative to Existing Conditions, as well as the fact that a lesser level of adverse effects is expected at

Emmaton under Alternative 4A relative to the No Action Alternative (ELT). During summer of below normal, dry and critical water years, additional flow in the Sacramento River at Emmaton would reduce or eliminate increases in EC. It is expected that for July–September of below normal, dry and critical water years, real-time operations that would include more precise management of upstream reservoir realeases on a daily basis and less pumping from the north Delta intakes and greater reliance on south Delta intakes than that modeled would allow for enough flow in the Sacramento River at Emmaton to reduce water quality degradation to levels closer to the No Action Alternative that would not be expected to adversely affect beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The western Delta is CWA Section 303(d) listed for elevated EC and the increased EC degradation that was modeled in the western Delta could make beneficial use impairment measurably worse.

Based on these findings, this impact in the Plan Area is considered to be significant. Implementation of Mitigation Measure WQ-11 would be expected to reduce these effects to a less-than-significant level.

Mitigation Measure WQ-11: Avoid or Minimize Reduced Water Quality Conditions

The implementation of mitigation actions shall be focused on avoiding or minimizing those incremental effects attributable to implementation of Alternative 4A operations only. Mitigation actions to avoid or minimize the incremental EC effects attributable to climate change/sea level rise are not required because these changed conditions would occur with or without implementation of Alternative 4A. The goal of specific actions is to reduce/avoid additional exceedances of Delta EC objectives and reduce long-term average EC concentration increases to levels that would not adversely affect beneficial uses within the Delta, and would not make beneficial use impairment measurably worse. Implementation of Mitigation Measure WQ-11 would be expected to reduce effects on EC to a less-than-significant level.

Mitigation Measure WQ-11e: Implement Real-time Operations, Including Adaptively Managing Diversions at the North and South Delta Intakes, to Reduce or Eliminate Water Quality Degradation in the Western Delta

Modeling results for Alternative 4A indicate water quality degradation for EC in the Sacramento River at Emmaton in the months of July through September of below normal, dry and critical water year types, relative to the No Action Alternative (ELT). This mitigation measure establishes performance standards to address the modeled exceedances of Bay-Delta WQCP EC objectives and EC degradation such that impacts to beneficial uses affected by remaining degradation, following mitigation, would be less than significant.

The Bay-Delta WQCP establishes water quality objectives for EC at Emmaton applicable from April 1 through August 15 for the protection of agricultural beneficial uses. To address exceedances of Bay-Delta WQCP EC objectives and EC degradation at Emmaton that has been modeled to occur in July and the first half of August of below normal, dry, and critical water years, the project proponents shall rely upon real-time operations (which cannot be fully captured in the modeling) to ensure that Bay-Delta WQCP Emmaton EC objectives are met. As a component of real-time operations, the project proponents shall ensure adequate releases from upstream reservoirs on a daily time-step and adaptively manage the split between north and south Delta diversions to achieve the Bay-Delta WQCP EC objectives at Emmaton. The project proponents are required to operate to meet these objectives under Existing Conditions, and would be required to operate to these objectives under the No Action Alternative. Thus, operation of the project alternative to achieve the Bay-Delta WQCP EC objectives would be consistent with Existing Conditions and the No Action Alternative and result in a minimization of EC degradation at Emmaton during July and and the first half of August of below normal, dry, and critical water year types. Hence, the performance standard for July and the first half of August shall be the Bay-Delta WQCP Emmaton EC objectives.

The Bay-Delta WQCP does not establish an EC objective at Emmaton for the latter half of August or September. To address EC degradation at Emmaton that has been modeled to occur during this period of the year with the project alternative, the project proponents shall manage upstream reservoir releases on a daily basis and adaptively manage the split between north and south Delta diversions of below normal, dry and critical water years. The performance standard for late August and September shall be compliance with the Threemile Slough standard in the North Delta Water Agency Agreement and the Bay-Delta WQCP municipal and industrial objective at Rock Slough as implemented within Decision 1641 or as modified in the future. Allowing sufficient flow in the Sacramento River at Emmaton, through real-time operations, would contribute to reduced EC levels at this location, relative to that modeled for the project alternative, and would reduce EC degradation at Emmaton in late August and September to less-than-significant levels.

This mitigation measure is consistent with the adaptive management and real-time operations that would be utilized to minimize the project alternative's water quality effects to *Microcystis* in the summer months (discussed in Impact WQ-32). This mitigation measure also is consistent with the Other (Non-Environmental) Commitment to address reverse flows in the Sacramento River at Freeport that may occur with the project alternative, which are most likely to occur in low flow months of dry and critical years.

Mitigation Measure WQ-11f: Adaptively Manage Head of Old River Barrier and Diversions at the North and South Delta Intakes to Reduce or Eliminate Exceedances of the Bay-Delta WQCP Objective at Prisoners Point

Modeling results for Alternative 4A indicated additional exceedances of the Bay-Delta WQCP objective for protection of striped bass between Jersey Point and Prisoners Point, at Prisoners Point. It is expected that by adaptively managing the Head of Old River Barrier and the fraction of south Delta versus north Delta diversions, exceedances of the EC objective at Prisoners Point could be avoided, and EC levels at Prisoners Point would be decreased to a level that would not adversely affect aquatic life beneficial uses. The project proponents shall adaptively manage the Head of Old River Barrier and the split between north and south Delta diversions during April-May to avoid exceedances of the objective at Prisoners Point. These actions would not be required in critical water years, when the objective does not apply. The project proponents will consult with CDFW, USFWS, NMFS, and Reclamation to ensure that such actions are warranted to avoid adverse impacts of salinity on striped bass spawning in the San Joaquin River between Jersey Point and Prisoners Point, and to minimize adverse effects these mitigation actions may have on other species. As such, the mitigation performance standard for April and May shall be compliance with the Bay-Delta WQCP EC objective at Prisoners Point.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15 and 16

NEPA Effects: The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would present no new direct sources of EC to the affected environment, including areas upstream of the Delta, within the Delta region, and in the SWP/CVP Export Service Areas. As they pertain to EC, implementation of these Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment. Moreover, some habitat restoration activities would occur on lands within the Delta currently used for irrigated agriculture. Such replacement or substitution of land use activity is not expected to result in new or increased sources of EC to the Delta and, in fact, could decrease EC through elimination of high EC agricultural runoff.

Environmental Commitment 4 would result in some tidal habitat restoration; however, the areal extent would be small relative to the existing and No Action Alternative tidal area and, thus not expected to appreciably affect the magnitude of daily tidal water exchange at the restoration areas or alter other hydrodynamic conditions in adjacent Delta channels that would result in measurable EC changes.

In summary, implementation of the Environmental Commitments would not be expected to adversely affect EC levels in the affected environment and thus would not adversely affect beneficial uses or substantially degrade water quality with regard to EC within the affected environment. Therefore, the effects on EC from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A would not present new or substantially changed sources of EC to the affected environment. Some Environmental Commitments may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution is not expected to substantially increase or present new sources of EC, and could actually decrease EC loads to Delta waters, because agricultural drainage can be a source of elevated EC. Thus, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would have negligible, if any, adverse effects on EC levels throughout the affected environment and would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria that would result in adverse effects on any beneficial uses within affected water bodies. Further, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause significant long-term water quality degradation such that there would be greater risk of adverse effects on beneficial uses. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the Alternative 4A on mercury levels in surface waters upstream of the Delta relative to Existing Conditions and the No Action Alternative (ELT) would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because factors that affect mercury concentrations in surface waters upstream of the Delta are similar under Alternatives 4 and 4A. The changes in flow in the Sacramento River under Alternative 4A relative to Existing Conditions and the No Action Alternative (ELT) would not be of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore, mercury loading should not be substantially different due to changes in flow. In addition, even though they may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but would not change substantially because the anticipated changes in flow are not expected to substantially change mercury loading relative to Existing Conditions or the No Action Alternative (ELT).

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

Delta

The effects of Alternative 4A on waterborne concentrations of mercury (Appendix 8I, *Mercury*, Table I-17) and methylmercury (Appendix 8I, Table I-18), and fish tissue mercury concentrations for largemouth bass fillet (Appendix 8I, Tables I-20a and I-20b) were evaluated for nine Delta locations.

Increases in long-term average mercury concentrations relative to Existing Conditions and the No Action Alternative (ELT) would be very small, 0.3 ng/L or less. Also, use of assimilative capacity for mercury relative to the 25 ng/L ecological threshold under Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT), would be very low, about 2% or less, as a long-term average, for all Delta locations (Appendix 8I, *Mercury*, Table I-23). These concentration changes and small changes in assimilative capacity for mercury are not expected to result in adverse (or positive) effects to beneficial uses.

Changes in methylmercury concentrations in water also are expected to be very small. The greatest annual average methylmercury concentration under Alternative 4A would be 0.166 ng/L for the San Joaquin River at Buckley Cove, for the drought period modeled, which would be slightly higher than Existing Conditions (0.161 ng/L) and slightly lower than the No Action Alternative (ELT) (0.168 ng/L) (Appendix 8I, *Mercury*, Table I-18). All methylmercury concentrations in water were estimated to exceed the TMDL guidance objective of 0.06 ng/L under Existing Conditions and, therefore, no assimilative capacity exists.

Fish tissue estimates for largemouth bass fillet show small or no increases in mercury concentrations under Alternative 4A relative to Existing Conditions and the No Action Alternative (ELT) based on long-term annual average concentrations for mercury at the Delta locations (Appendix 8I, *Mercury*, Tables I-20a and I-20b). Concentrations expected for Alternative 4A with Equation 1 show increases of 6% or less relative to Existing Conditions and the No Action Alternative (ELT) (Appendix 8I, Table I-20a). Concentrations expected for Alternative 4A with

Equation 2 show increases of 8% or less relative to Existing Conditions and the No Action Alternative (ELT) (Appendix 8I, Table I-20b). Concentrations expected for Alternative 4A with Equation 1 show decreases of 1% relative to Existing Conditions at the North Bay Aqueduct at Barker Slough Pumping Plant in all years and 1% relative to the No Action Alternative at San Joaquin River at Buckley Cove in all years and the drought period (Appendix 8I, *Mercury*, Table I-20a). Concentrations expected for Alternative 4A with Equation 2 show decreases in the North Bay Aqueduct at Barker Slough relative to Existing Conditions in all years of 1%, and a decrease of 2% relative to the No Action Alternative (ELT) in all years and the drought period (Appendix 8I, Table I-20b).

Because the increases are relatively small, and it is not evident that substantive increases are expected at numerous locations throughout the Delta, these changes are expected to be within the uncertainty inherent in the modeling approach, and would likely not be measurable in the environment. See Appendix 8I, *Mercury*, for a complete discussion of the uncertainty associated with the fish tissue estimates. Briefly, the bioaccumulation models contain multiple sources of uncertainty associated with their development. These are related to analytical variability; temporal and/or seasonal variability in Delta source water concentrations of methylmercury; interconversion of mercury species (i.e., the non-conservative nature of methylmercury as a modeled constituent); and limited sample size (both in number of fish and time span over which the measurements were made), among others. Although there is considerable uncertainty in the models used, the results serve as reasonable approximations of a very complex process. Considering the uncertainty, small (i.e., < 20–25%) increases or decreases in modeled fish tissue mercury concentrations at a few Delta locations (i.e., 2–3) should be interpreted to be within the uncertainty of the overall approach, and not predictive of actual adverse effects. Larger increases, or increases evident throughout the Delta, can be interpreted as more reliable indicators of potential adverse effects.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 4A at the Jones and Banks pumping plants, would be lower than Existing Conditions and the No Action Alternative (ELT) (Appendix 8I, *Mercury*, Tables I-17 and I-18). Therefore, mercury shows an increased assimilative capacity at these locations (Appendix 8I, Table I-23).

The largest improvements in bass tissue mercury concentrations and exceedance quotients ([EQs]; modeled tissue divided by TMDL guidance concentration) for Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT) at any location within the Delta, are expected for the Banks and Jones pumping plant export pump locations. Concentrations expected for Alternative 4A at the export pump locations with Equation 1 in all years show decreases relative to Existing Conditions (8% to 10%) and relative to the No Action Alternative (ELT) (9% to 11%) (Appendix 8I, *Mercury*, Table I-20a). Concentrations expected for Alternative 4A with Equation 2 in all years show decreases at Banks and Jones pumping plants relative to Existing Conditions (11% to 14%) and the No Action Alternative (ELT) (13% to 15%) (Appendix 8I, Table I-20b).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

NEPA Effects: Based on the above discussion, Alternative 4A would not cause concentrations of mercury and methylmercury in water and fish tissue in the affected environment to be substantially different from the No Action Alternative (ELT and LLT) and, thus, would not cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to the No Action Alternative (ELT and LLT), Alternative 4A would not be expected to increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Based on these findings, the effects of Alternative 4A on mercury in the affected environment are considered to be not adverse.

CEQA Conclusion: Under Alternative 4A, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta would not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. However, monthly average waterborne concentrations of total and methylmercury over the period of record under Alternative 4A would be very similar to Existing Conditions. Similarly, estimates of fish tissue mercury concentrations show that small differences would occur among sites for Alternative 4A as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP/CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 4A, as compared to Existing Conditions.

As such, Alternative 4A is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to Existing Conditions, Alternative 4A would not increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: The potential types of effects on mercury resulting from implementation of the Environmental Commitments under Alternative 4A would be generally similar to those described under Alternative 4 (see Section 8.3.3.9). However, the magnitude of effects on mercury and methylmercury at locations upstream of the Delta, in the Delta, and the SWP/CVP Export Service Areas related to habitat restoration would be considerably lower than described for Alternative 4. This is because the amount of habitat restoration to be implemented under Alternative 4A would be very low compared to the total proposed restoration area that would be implemented under Alternative 4. The small amount of habitat restoration to be implemented under Alternative 4A may occur on lands in the Delta formerly used for irrigated agriculture. Habitat restoration proposed under Alternative 4A has the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the vicinity of the restored habitat areas. Design of restoration sites would be guided by Environmental Commitment 12, which requires development of site-specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time, although the potential to reduce methylmercury concentrations exists based on current research. Although Environmental Commitment 12 would be implemented with the goal to reduce this potential effect, there remain uncertainties related to site-specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta in the vicinity of the restored areas. Therefore, the effect of Environmental Commitments 3, 4, 6–12, 15, and 16 on mercury and methylmercury is considered to be adverse.

CEQA Conclusion: There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 relative to Existing Conditions. However, in the Delta, due to the small amount of tidal restoration areas proposed, relative to Existing Conditions, uptake of mercury from water and/or methylation of inorganic mercury may increase in localized areas as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Although not quantifiable, on a local level, increases in methylmercury concentrations may be measurable. Methylmercury is CWA Section 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites would be guided by Environmental Commitment 12, which requires development of site-specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time, although the potential to reduce methylmercury concentrations exists based on current research. Although Environmental Commitment 12 would be implemented with the goal to reduce this potential effect, the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant because, as described above, any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. No mitigation measures would be available until specific restoration actions are proposed. Therefore, this impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (in Section 8.3.3.9), nitrate levels in the major rivers (Sacramento, Feather, American) are low, generally due to ample dilution available in the reservoirs and rivers relative to the magnitude of the point and non-point source discharges, and there is no correlation between historical water year average nitrate concentrations and water year average flow in the Sacramento River at Freeport. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 4A, relative to Existing Conditions or the No Action Alternative (ELT), are expected to have negligible, if any, effects on average reservoir and river nitrate-N concentrations in the Sacramento River watershed upstream of the Delta.

In the San Joaquin River watershed, nitrate concentrations are higher than in the Sacramento River watershed, owing to use of nitrate based fertilizers throughout the lower watershed. The correlation between historical water year average nitrate concentrations and water year average flow in the San Joaquin River at Vernalis is a weak inverse relationship—that is, generally higher flows result in lower nitrate concentrations, while low flows result in higher nitrate concentrations (linear regression r^2=0.49; Figure 2 in Appendix 8J, *Nitrate*). Under Alternative 4A, long-term average flows at Vernalis would decrease an estimated 1% relative to Existing Conditions and would remain virtually the same relative to the No Action Alternative (ELT). Given the relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River, it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under the No Action Alternative (ELT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

Any negligible changes in nitrate concentrations that may occur under Alternative 4A in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to nitrate.

Delta

Mass balance calculations indicate that under Alternative 4A relative to Existing Conditions and the No Action Alternative (ELT), nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Table 34). Although changes at specific Delta locations and for specific months may be substantial on a relative basis (Appendix

8J, Table 37), the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds (see *Nitrate* under Section 8.3.1.7, *Constituent-Specific Considerations Used in the Assessment*). Long-term average nitrate concentrations are anticipated to remain below 1 mg/L-N at all 11 Delta assessment locations except the San Joaquin River at Buckley Cove, where long-term average concentrations would be somewhat above 1 mg/L-N. Nevertheless, at this location, long-term average nitrate concentrations would be somewhat reduced under Alternative 4A relative to Existing Conditions, and slightly increased relative to the No Action Alternative (ELT). No additional exceedances of the MCL are anticipated at any location under Alternative 4A (Appendix 8J, Table 34).

Use of assimilative capacity relative to the drinking water MCL of 10 mg/L-N under Alternative 4A would be low or negligible (i.e., <4%) in comparison to both Existing Conditions and the No Action Alternative (ELT), for all locations and months, for all modeled years (1976–1991), and for the drought period (1987–1991) (Appendix 8J, *Nitrate*, Table 38).

As described for Alternative 4, actual nitrate concentrations would likely be higher than the modeling results indicate in certain locations under Alternative 4A. This is the mass balance modeling does not account for contributions from the SRWTP, which would be implementing nitrification/partial denitrification, or Delta wastewater treatment plant dischargers that practice nitrification, but not denitrification. However, as described for Alternative 4, any increases in nitrate concentrations that may occur at certain locations within the Delta under Alternative 4A would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regard to nitrate.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

Assessment of effects of Alternative 4A on nitrate in the SWP/CVP Export Service Areas is based on effects on nitrate at the Banks and Jones pumping plants. Relative to Existing Conditions and the No Action Alternative (ELT), nitrate concentrations at Banks and Jones pumping plants under Alternative 4A are anticipated to decrease on a long-term average annual basis by 27% at the Banks pumping plant and 29% at the Jones pumping plant (Appendix 8J, *Nitrate*, Table 37). During the late summer, particularly in the drought period assessed, concentrations are expected to increase, but the absolute value of these changes (i.e., in mg/L-N) would be small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Areas, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.2 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP/CVP Export Service Areas. No additional exceedances of the MCL are anticipated under Alternative 4A relative to Existing Conditions and the No Action Alternative (ELT) (Appendix 8J, *Nitrate*, Table 34). On a monthly average basis and on a long-term annual average basis, for all modeled years and for the drought period only, use of assimilative capacity available under Existing Conditions and the No Action Alternative (ELT), relative to the 10 mg/L-N MCL, would be negligible (<2%) for both Banks and Jones pumping plants (Appendix 8J, Table 38).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

Any increases in nitrate concentrations that may occur in water exported via Banks and Jones pumping plants are not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regard to nitrate.

NEPA Effects: Modified reservoir operations and subsequent changes in river flows under Alternative 4A, relative to the No Action Alternative (ELT and LLT), are expected to have negligible, if any, effects on reservoir and river nitrate concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed. In the Delta, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the 10 mg/L-N MCL are anticipated at any Delta location, and use of assimilative capacity available under the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, would be low. Long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to differ negligibly relative to the No Action Alternative (ELT and LLT) and no additional exceedances of the 10 mg/L-N MCL are anticipated. Therefore, the effects on nitrate from implementing water conveyance facilities are considered to be not adverse.

CEQA Conclusion: Nitrate concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers).Although higher in the San Joaquin River watershed, nitrate concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 4A, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mass balance calculations indicate that under Alternative 4A, relative to Existing Conditions, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the 10 mg/L-N MCL are anticipated at any location, and use of assimilative capacity available under Existing Conditions, relative to the drinking water MCL of 10 mg/L-N, would be low or negligible (i.e., <4%) for all for virtually all locations and months.

Assessment of effects of nitrate in the SWP/CVP Export Service Areas is based on effects on nitrate concentrations at the Banks and Jones pumping plants. Results of the mass balance calculations indicate that under Alternative 4A relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to change negligibly. No additional exceedances of the 10 mg/L-N MCL are anticipated, and use of assimilative capacity available under Existing Conditions, relative to the MCL would be negligible (i.e., <2%) for both Banks and Jones pumping plants for all months.

Based on the above, there would be no substantial, long-term increase in nitrate concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the SWP/CVP Export Service Areas under Alternative 4A relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because nitrate concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not CWA Section 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Some habitat restoration activities included in Environmental Commitments 3, 4, and 6–11 would occur on lands within the Delta formerly used for agriculture. As discussed for Impact WQ-2, increased biota that may result in those areas may increase ammonia, which in turn may be converted to nitrate by established microbial communities. However, the areal extent of new habitat implemented for the Environmental Commitments would be less than the existing and No Action Alternative habitat areas, and similar habitat exists currently in the Delta and is not identified as contributing to adverse nitrate conditions. Thus, these land use changes would not be expected to substantially increase nitrate concentrations in the Delta. Implementation of Environmental Commitments 12, 15, and 16 do not include actions that would affect nitrate sources or loading. Based on these findings, the effects on nitrate from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

***CEQA Conclusion*:** Land use changes that would occur from the Environmental Commitments are not expected to substantially increase nitrate concentrations, because the amount of area to be converted would be small relative to existing habitat, and existing habitats are not known for contributing to adverse nitrate conditions. Thus, it is expected that implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because nitrate concentrations are not expected to increase substantially due to these Environmental Commitments, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 4A on DOC concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 because factors affecting DOC concentrations (e.g., source and non-point source inputs) in these water bodies would be similar. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows under Alternative 4A would not be expected to cause substantial long-term changes in DOC concentrations in the water bodies upstream of the Delta. Any changes in DOC levels in water bodies upstream of the Delta under Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies.

Delta

Under Alternative 4A, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be similar to that described for Alternative 4, although the magnitude of predicted long-term change and relative frequency of concentration threshold exceedances would be lower. The effects of Alternative 4A relative to Existing Conditions and the No Action Alternative (ELT) are discussed together because the direction and magnitude of predicted change are similar. Relative to the Existing Conditions and No Action Alternative (ELT), Alternative 4A would result in small increases in long-term average DOC concentrations for both the modeled 16-year period (1976–1991) and drought period (1987–1991) at several interior Delta locations (increases up to 0.2 mg/L at the S. Fork Mokelumne River at Staten Island, Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1) (Appendix 8K, *Organic Carbon*, Table DOC-11). The increases in average DOC concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at the Contra Costa Pumping Plant #1 location exceeding the 3 mg/L threshold (i.e., increase from 52% under Existing Conditions to 64% under Alternative 4A for the modeled 16-year period). The change in frequency of threshold concentration exceedances at other assessment locations would be similar or lower.

While Alternative 4A would lead to slightly higher long-term average DOC concentrations at some municipal water intakes and Delta interior locations, the predicted change would not be expected to adversely affect MUN beneficial uses, or any other beneficial use. As discussed for Alternative 4, substantial changes in ambient DOC concentrations would need to occur before significant changes in drinking water treatment plant design or operations are triggered. The increases in long-term average DOC concentrations estimated to occur at various Delta locations under Alternative 4A are of sufficiently small magnitude that they would not require existing drinking water treatment plants to substantially upgrade treatment for DOC removal above levels currently employed.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on DOC in the LLT are expected to be similar to those described above.

Relative to Existing Conditions and the No Action Alternative (ELT and LLT), Alternative 4A would lead to predicted improvements in long-term average DOC concentrations at Barker Slough, as well as Banks and Jones pumping plants (discussed below).

SWP/CVP Export Service Areas

Under the Alternative 4A, long-term average DOC concentrations would decrease at Barker Slough by 0.1 mg/L, and at both the Banks and Jones pumping plants by 0.4 mg/L, relative to Existing Conditions. Reductions would be similar compared to No Action Alternative (ELT) (Appendix 8K, *Organic Carbon*, Table DOC-11). Decreases in long-term average DOC would result in generally lower exceedance frequencies for concentration thresholds, although the frequency of exceedances of the 3 mg/L threshold during the modeled drought period would increase at the Banks and Jones pumping plants. Relative to Existing Conditions, exceedance of the 3 mg/L threshold would increase from 57% to 72% at Banks pumping plant and from 72% to 88% at Jones pumping plant. There would be little to no increase in exceedance of the 3 mg/L threshold relative to the No Action Alternative (ELT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on DOC in the LLT are expected to be similar to those described above.

Maintenance of SWP and CVP facilities under Alternative 4A would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area.

NEPA Effects: In summary, the operations and maintenance activities under Alternative 4A, relative to the No Action Alternative (ELT and LLT), would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. The long-term average DOC concentrations at Banks and Jones pumping plants are predicted to decrease by 0.4 mg/L, while long-term average DOC concentrations for some Delta interior locations are predicted to increase by as much as 0.2 mg/L. However, the increase in long-term average DOC concentration that could occur within the Delta interior would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters. Based on these findings, the effect of operations and maintenance activities on DOC under Alternative 4A is determined to be not adverse.

CEQA Conclusion: For the same reasons described for Alternative 4, the operations and maintenance activities under Alternative 4A, relative to the Existing Conditions, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. Any modified reservoir operations and subsequent changes in river flows under Alternative 4A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DOC levels upstream of the Delta. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, the Alternative 4A would result in relatively small increases (i.e., ≤0.2 mg/L) in long-term average DOC concentrations at some interior Delta locations. The predicted increases would not substantially increase the frequency with which long-term average DOC concentrations exceeds 2, 3, or 4 mg/L. Because this alternative would lead to only slightly higher long-term average DOC concentrations at the interior Delta locations and some municipal water intakes, the predicted changes would not be expected to adversely affect MUN beneficial uses, or any other beneficial use.

Relative to Existing Conditions, the Alternative 4A would result in reduced long-term average DOC concentrations at the Banks and Jones pumping plants and Barker Slough. However, Alternative 4A would result in slightly greater frequency of exceedance of the 3 mg/L DOC concentration threshold during the modeled drought period. Nevertheless, an overall improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, the operations and maintenance activities of Alternative 4A would not result in any substantial change in long-term average DOC concentration. The increases in long-term average DOC concentration that could occur within the Delta would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters or waters of the SWP/CVP Service Area. Because DOC is not bioaccumulative, the increases in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not CWA Section 303(d) listed for any water body within the affected environment. Because long-term average DOC concentrations are not expected to increase substantially, no long-term water quality degradation with respect to DOC is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

The potential types of effects on DOC resulting from implementation of the Environmental Commitments under Alternative 4A would be generally similar to those described under Alternative 4 (see Section 8.3.3.9). However, the magnitude of effects on DOC at locations upstream of the Delta, in the Delta, and the SWP/CVP export service areas would be considerably lower than described for Alternative 4.

As described for Alternative 4, Environmental Commitments 3, 9, 11, 12, 15, and 16 would present no major sources of DOC to the affected environment, including areas Upstream of the Delta, within the Plan Area, and the SWP/CVP Export Service Area that would adversely affect beneficial uses. Environmental Commitments 4, 6, 7, and 10 include habitat restoration activities known to be sources of DOC. However, the amount of new habitat restoration to be implemented would be very small compared to the areal extent of existing habitat and that proposed for the No Action Alternative. Based on the amount of habitat restoration proposed, DOC loading from these areas would be very low in these water bodies. Consequently, relative to the Existing Conditions and No Action Alternative (ELT and LLT), the potential DOC loading to the Delta would be minimal, and thus not contribute substantially to the amounts of DOC in raw drinking water supplies.

NEPA Effects: Relative to existing habitat and that to be developed under the No Action Alternative (ELT and LLT), the area of new habitat restoration implemented for the Environmental Commitments would be very small. Implementation of non-habitat restoration Environmental Commitments would not be expected to have substantial, if even measurable, effect on DOC concentrations upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas, because they would present no major sources of DOC to the affected environment. Consequently, any increases in average DOC levels in the affected environment are not expected to be of sufficient frequency, magnitude and geographic extent that would adversely affect the MUN beneficial use, or any other beneficial uses, of the affected environment, nor would potential increases substantially degrade water quality with regard to DOC. Based on these findings, the effect of the Environmental Commitments on DOC is determined to be not adverse.

CEQA Conclusion: Implementation of habitat restoration Environmental Commitments is not expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas, relative to the Existing Conditions, because the land area proposed for restoration would be relatively small compared to existing land area and sources of DOC. Implementation of other Environmental Commitments also would not be expected to have substantial, if even measurable, effect on DOC concentrations upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas, because they would present no major sources of DOC to the affected environment. Consequently, increases in average DOC levels in the affected environment are not expected to be of sufficient frequency, magnitude and geographic extent that would adversely affect the MUN beneficial use, or any other beneficial uses, of the affected environment, nor would potential increases substantially degrade water quality with regard to DOC. Furthermore, DOC is not bioaccumulative, therefore changes in DOC concentrations would not cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not CWA Section 303(d) listed for any water body within the affected environment. Because long-term average DOC concentrations are not expected to increase substantially, no long-term water quality degradation with respect to DOC is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance

The effects of operation of the water conveyance facilities under Alternative 4A on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those effects described for Alternative 4 (see Section 8.3.3.9). As described for Alternative 4, pathogen concentrations in the Sacramento and San Joaquin Rivers have a minimal relationship to flow rate in these rivers. Further, urban runoff contributions during the dry season would be expected to be a relatively small fraction of the rivers' total flow rates. During wet weather events, when urban runoff contributions would be higher, the flows in the rivers also would be higher. Given the small magnitude of urban runoff contributions relative to the magnitude of river flows and that pathogen concentrations in the rivers have a minimal relationship to river flow rate, river flow rate and reservoir storage reductions that would occur under Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta.

The effects of Alternative 4A relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be changes in the relative percentage of water throughout the Delta being comprised of various source waters (i.e., water from the Sacramento River, San Joaquin River, Bay water, eastside tributaries, and agricultural return flow), due to potential changes in inflows particularly from the Sacramento River watershed. However, as described for Alternative 4, it is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens, because it is expected that pathogen sources in close proximity to Delta sites would have a greater influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative. As such, there is not expected to be substantial, if even measurable, changes in pathogen concentrations in the SWP/CVP Export Service Area waters.

As such, Alternative 4A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or U.S. EPA-recommended pathogen criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to pathogens.

NEPA Effects: Because pathogen levels are expected to be minimally affected relative to the No Action Alternative (ELT and LLT), the effects on pathogens from implementing Alternative 4A are determined to be not adverse.

CEQA Conclusion: The effects of Alternative 4A on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because the factors that would affect pathogen levels in the surface waters of these areas would be similar. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is CWA Section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Environmental Commitments 3, 4, and 6–11 would involve habitat restoration actions. Tidal wetlands are known to be sources of coliforms originating from aquatic, terrestrial, and avian wildlife that inhabit these areas (Desmarais et al. 2001, Grant et al. 2001, Evanson and Ambrose 2006, Tetra Tech 2007). Specific locations of restoration areas for this alternative have not yet been established. However, most low-lying land suitable for restoration is unsuitable for livestock. Therefore, it is likely that the majority of land to be converted to wetlands would be crop-based agriculture or fallow/idle land. Because of a great deal of scientific uncertainty in the loading of coliforms from these various sources, the resulting change in coliform loading is uncertain, but it is anticipated that coliform loading to Delta waters would increase. Based on findings from the Pathogens Conceptual Model that pathogen concentrations are greatly influenced by the proximity to the source, this could result in localized increases in wildlife-related coliforms relative to the No Action Alternative (ELT and LLT). The geographic extent of the potential increases would be less than under Alternative 4, because less land would be converted under Alternative 4A. The Delta currently supports similar habitat types and, with the exception of the CWA Section 303(d) listing for the Stockton Deep Water Ship Channel, is not recognized as exhibiting pathogen concentrations that rise to the level of adversely affecting beneficial uses. As such, the potential increase in wildlife-related coliform concentrations due to tidal habitat creation is not expected to adversely affect beneficial uses.

The remaining Environmental Commitments would not be expected to affect pathogen levels, because they are actions that do not affect the presence of pathogen sources.

Based on these findings, the effects on pathogens from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

***CEQA Conclusion*:** Based on findings from the Pathogens Conceptual Model that pathogen concentrations are greatly influenced by the proximity to the source, implementation of Environmental Commitments 3, 4, and 6–11 could result in localized increases in wildlife-related coliforms relative to Existing Conditions. The geographic extent of the increase would be less than under Alternative 4, because less land would be converted under Alternative 4A. The Delta currently supports similar habitat types and, with the exception of the CWA Section 303(d) listing for the Stockton Deep Water Ship Channel, is not recognized as exhibiting pathogen concentrations that rise to the level of adversely affecting beneficial uses. As such, the potential increase in wildlife-related coliform concentrations due to tidal habitat creation is not expected to adversely affect beneficial uses. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is CWA Section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance

The effects of Alternative 4A operations and maintenance on pesticide levels in surface waters upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT), would be similar to those expected to occur under Alternative 4 (see Section 8.3.3.9). This is because under Alternative 4A, the primary factor that would influence pesticide concentrations in surface waters upstream of the Delta—the effect of timing and magnitude of reservoir releases on dilution capacity—is expected to change by a similar degree. Changes in average winter and summer flow rates, relative to Existing Conditions and the No Action Alternative (ELT), are expected to be similar to or less than changes in flow rates expected under Alternative 4 in the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis (Appendix 8L, *Pesticides,* Tables 1 through 4). Similarly, the primary factor that would influence pesticide concentrations in surface waters of the Delta and in the SWP/CVP Export Service Areas (i.e., changes in San Joaquin River, Sacramento River and Delta agriculture source water fractions at various Delta locations, including Banks and Jones pumping plants) is expected to change by a similar degree. The percentage change in monthly average source water fractions would be similar to changes expected under Alternative 4 (Appendix 8D, *Source Water Fingerprinting Results*).

It was concluded for Alternative 4, and thus for Alternative 4A based on similar flow changes, that the potential average summer flow reductions would not be of sufficient magnitude to substantially increase in-river pesticide concentrations or alter the long-term risk of pesticide-related effects on aquatic life beneficial uses upstream of the Delta. Greater long-term average flow reductions, and corresponding reductions in dilution/assimilative capacity, would be necessary before long-term risk of pesticide related effects on aquatic life beneficial uses would be adversely altered. Similarly, the modeled changes in the source water fractions of Sacramento River, San Joaquin River, and Delta agriculture water under Alternative 4A would not be of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of organophosphate insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

The flow changes in the LLT would be expected in the ranges of that described above for Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT), and that described for Alternative 4 relative to the No Action Alternative (LLT) in Section 8.3.3.9. Thus, similar to above and Alternative 4, the flow changes that would occur in the LLT under Alternative 4A, relative to Existing Conditions and the No Action Alternative (LLT), would not be expected to result in changes in dilution of pesticides of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses upstream of the Delta, in the Delta, or the SWP/CVP Export Service Areas.

NEPA Effects: In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers under Alternative 4A relative to the No Action Alternative (ELT and LLT) would be of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. Similarly, changes in source water fractions to the Delta would be of insufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta or CVP/SWP Export Service Areas. Therefore, the effects on pesticides from the water conveyance facilities are determined not to be adverse.

***CEQA Conclusion*:** Based on the discussion above, the effects of Alternative 4A on pesticide levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to or slightly less than those described for the Alternative 4. Alternative 4A would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta, at the 11 assessment locations analyzed for the Delta, or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous CWA Section 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions under

Alternative 4A would not be expected to make any of these beneficial use impairments measurably worse. Because long-term average pesticide concentrations are not expected to increase substantially, no long-term water quality degradation with respect to pesticides is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

As described for Alternative 4 (see Section 8.3.3.9), Environmental Commitments 3, 4, and 6–11 could involve the conversion of active or fallow agricultural lands to natural landscapes, such as wetlands, grasslands, floodplains, and vernal pools. In the long-term, conversion of agricultural land to natural landscapes could possibly result in a limited reduction in pesticide use throughout the Delta. In the short-term, tidal and non-tidal wetland restoration over former agricultural lands may include the contamination of water with pesticide residues contained in the soils. Present use pesticides typically degrade fairly rapidly, and in such cases where pesticide containing soils are flooded, dissipation of those pesticides would be expected to occur rapidly. Environmental Commitments 12, 15, and 16 do not include actions that would affect pesticide sources or loading. Unlike under Alternative 4, *CM13 Invasive Aquatic Vegetation Control* and *CM19 Urban Stormwater Treatment* would not be implemented. Because of this, benefits to water quality from treatment measures that would reduce pesticide loading from urban land uses, as well as adverse impacts to water quality from application of herbicides directly to waters in the plan area that would occur under Alternative 4 would not occur under Alternative 4A.

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of pesticides, and the potential short-term loading from former agricultural lands would be expected to degrade and dissipate rapidly. Therefore, relative to the No Action Alternative (ELT and LLT), the effects on pesticides from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of pesticides, and the potential short-term loading from former agricultural lands would be expected to degrade and dissipate rapidly, such that pesticide levels would differ little from Existing Conditions. Therefore, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause substantial long-term increases in pesticide concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP Export Service Areas. As such, these Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pesticide concentrations are not expected to increase substantially, no long-term water quality degradation for pesticides is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term pesticide concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. Environmental Commitments 3, 4, 6–12, 15, 16 do not include the use of pesticides known to be bioaccumulative in animals or humans, nor do the Environmental Commitments propose the use of any pesticide currently named in a CWA Section 303(d) listing of the affected environment. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance

The effects of Alternative 4A on phosphorus concentrations in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because factors which affect phosphorus concentrations in surface waters of these areas are the same under Alternative 4 and Alternative 4A. As described for Alternative 4, phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration are not anticipated under Alternative 4A, relative to Existing Conditions or the No Action Alternative (ELT), upstream of the Delta. Phosphorus concentrations may increase during January through March at locations in the Delta where the source fraction of San Joaquin River water increases, due to the higher concentration of phosphorus in the San Joaquin River during these months compared to Sacramento River water or San Francisco Bay water. However, based on the DSM2 fingerprinting results (Figures 309 through 330 in Appendix 8D, *Source Water Fingerprinting Results*), together with source water concentrations (in Figure 8-56), the magnitude of increases during these months is expected to be negligible to low (i.e., <0.02 mg/L) at all Delta locations relative to Existing Conditions and the No Action Alternative (ELT). Thus, phosphorus concentrations in the Delta and waters exported from Banks and Jones pumping plants to the SWP/CVP Export Service Areas are expected to be similar to Existing Conditions and the No Action Alternative (ELT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on phosphorus in the LLT are expected to be similar to those described above.

NEPA Effects: In summary, operation of the water conveyance facilities would have little to no effect on phosphorus concentrations in water bodies upstream of the Delta, in the Plan Area, and the waters exported to the SWP/CVP Export Service Areas, relative to the No Action Alternative (ELT and LLT). Thus, effects of the water conveyance facilities on phosphorus are considered to be not adverse.

***CEQA Conclusion*:** The effects of Alternative 4A on phosphorus levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the Alternative 4. There would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 4A relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

As described for Alternative 4 (see Section 8.3.3.9) Environmental Commitments 3, 4, and 6–11 would include activities that create additional aquatic habitat, which may affect phosphorus dynamics and speciation in localized areas where the restoration would occur, but would not contribute to additional phosphorus loading. Therefore, phosphorus concentrations are not expected to change substantially in the affected environment as a result of these restoration activities. Unlike under Alternative 4, *CM19 Urban Stormwater Treatment* would not be implemented under Alternative 4A. Because urban stormwater is a potential source of phosphorus in the affected environment, the slight decreases in phosphorus loading expected to occur as a result of implementation of CM19 under Alternative 4, relative to Existing Conditions and the No Action Alternative, would not occur under Alternative 4A. Environmental Commitments 12, 15, and 16 do not include actions that would affect phosphorus sources or loading.

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of phosphorus. Therefore, relative to the No Action Alternative (ELT and LLT), the effects on phosphorus from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of phosphorus. Therefore, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the SWP/CVP Export Service Areas due to implementation of these Environmental Commitments relative to Existing Conditions. Because phosphorus concentrations are not expected to increase substantially due to these Environmental Commitments, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not CWA Section 303(d) listed within the affected environment and, thus, the Environmental Commitments would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, any increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 4A on selenium concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 (see Section 8.3.3.9), because factors affecting selenium concentrations in these water bodies would be similar. Substantial point sources of selenium do not exist upstream in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Nonpoint sources of selenium within the watersheds of the Sacramento River and the eastern tributaries also are relatively low, resulting in generally low selenium concentrations in the reservoirs and rivers of those watersheds. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 4A, relative to Existing Conditions or the No Action Alternative (ELT and LLT), are expected to have negligible, if any, effects on reservoir and river selenium concentrations upstream of Freeport in the Sacramento River watershed or in the eastern tributaries upstream of the Delta. Similarly, it is expected that selenium concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under Alternative 4A, given the relatively small decreases in flows and the considerable variability in the relationship between selenium concentrations and flows in the San Joaquin River. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Delta

Alternative 4A would result in small changes in average selenium concentrations in water relative to Existing Conditions and No Action Alternative (ELT) at all modeled Delta assessment locations (Appendix 8M, *Selenium,* Table M-33). Long-term average concentrations at some interior and western Delta locations would increase by 0.01–0.03 μg/L for the entire period modeled (1976–1991). These small increases in selenium concentrations in water would result in small reductions (3% or less) in long-term average available assimilative capacity for selenium, relative to USEPA's draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-44). The long-term average selenium concentrations in water under Alternative 4A (range 0.09–0.40 μg/L) would be similar to Existing Conditions (range 0.09–0.41 μg/L) and the No Action Alternative (ELT) (range 0.09–0.39 μg/L), and would be below the draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-33).

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 4A would result in small changes (less than 1%) in estimated selenium concentrations in most biota (whole-body fish, bird eggs [invertebrate diet or fish diet], and fish fillets) throughout the Delta, with little difference among locations (Appendix 8M, *Selenium,* Tables M-34, and M-38). Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0, indicating low probability of adverse effects. Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by about 15% relative to Existing Conditions and to the No Action Alternative (ELT) in all years (from about 4.7 to about 5.4 mg/kg dry weight), and those for sturgeon in the Sacramento River at Mallard Island are predicted to increase by about 9–12% in all years (from about 4.4 to 4.9 mg/kg dry weight) (Appendix 8M, *Selenium,* Tables M-41 and M-42). Selenium concentrations in sturgeon during drought years are expected to increase by about 27% at those locations (Appendix 8M, Tables M-41 and M-42). Detection of small changes in whole-body sturgeon such as those estimated for the western Delta would require very large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at both locations (as they do for Existing Conditions and the No Action Alternative (ELT) and for all years in the San Joaquin River at Antioch (where quotient increases from 0.94 to 1.1) (Appendix 8M, Table M-43). The High Toxicity Threshold Quotient would be less than 1.0 at both locations for all years and drought years (Appendix 8M, Table M-43).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in Appendix 8M, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium. Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on "fixed" K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Residence time of water in the Delta is expected to increase relative to Existing Conditions primarily as a result of habitat restoration (8,000 acres of tidal habitat restoration and enhancements to the Yolo Bypass) that is assumed to occur under the No Action Alternative (ELT) separate from Alternative 4A. The changes in flow paths of water through the Delta and change in operation of the south Delta pumps that would occur due to facilities operations and maintenance of Alternative 4A could result in localized increases in residence time in various Delta sub-regions and decreases in residence time in other areas. Residence times during July through November was modeled for the Biological Assessment for the California WaterFix (ICF International 2016). The Proposed Action modeled in the Biological Assessment is Alternative 4A. Residence time tables for the lower Sacramento River and lower San Joaquin River show slight increases in residence time (in days) in the summer months and slight decreases in the fall months (ICF International 2016: Tables 6.1-32 and 6.1-33).

If increases in fish tissue or bird egg selenium were to occur as a result of increased residence time, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. Thus, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time would be a concern is the western Delta and Suisun Bay for sturgeon. Based on the expected minor increases in residence time in the western Delta, any increases are not expected to be of sufficient magnitude to substantially affect selenium bioaccumulation.

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 4A would result in essentially no change in selenium concentrations throughout the Delta for most biota (about 1% or less), although larger increases in selenium concentrations are predicted for sturgeon in the western Delta. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, Alternative

4A would not be expected to substantially increase the frequency with which the applicable water quality criterion or toxicity and level of concern benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon relative to the low benchmark and no exceedance of the high benchmark) or to substantially degrade the quality of water in the Delta, with regard to selenium. These changes would be similar to those described for Alternative 4.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on selenium in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

Alternative 4A would result in small (0.04–0.09 µg/L) decreases in long-term average selenium concentrations in water at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative (ELT), for the entire period modeled (Appendix 8M, *Selenium,* Table M-33). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium at these pumping plants, relative to the USEPA's draft water quality criterion of 1.3 µg/L (Appendix 8M, Table M-44). The long-term average selenium concentrations in water for Alternative 4A (range 0.16–0.20 µg/L) would be well below the draft water quality criterion of 1.3 µg/L (Appendix 8M, Table M-33).

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 4A would result in small changes (about 1% or less) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) (Appendix 8M, *Selenium,* TableM-38). Concentrations in biota would not exceed any selenium toxicity or level of concern benchmarks for Alternative 4A.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on selenium in the LLT are expected to be similar to those described above.

NEPA Effects: Relative to the No Action Alternative (ELT and LLT), Alternative 4A would result in essentially negligible changes in selenium concentrations in water upstream of the Delta. Similarly, there would be negligible changes in selenium water and most biota concentrations in the Delta, with no exceedances of benchmarks for biological effects. For sturgeon in the Delta, there would be only a small increase of threshold exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark. At the Banks and Jones pumping plants, Alternative 4A would cause no increases in the frequency with which applicable benchmarks would be exceeded and would slightly improve the quality of water in selenium concentrations. Therefore, the effects on selenium (both as waterborne and as bioaccumulated in biota) from Alternative 4A are considered to be not adverse.

CEQA Conclusion: There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources

Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 4A, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate Alternative 4A would result in essentially no change in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. The Low Toxicity Threshold Exceedance Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase slightly, from 0.94 for Existing Conditions to 1.1 for Alternative 4A. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. Overall, Alternative 4A would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 4A would cause no increases in the frequency with which applicable benchmarks would be exceeded, and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants.

Based on the above, selenium concentrations that would occur in water under Alternative 4A would not cause additional exceedances of applicable state or federal numeric or narrative water quality objectives/criteria, or other relevant water quality effects thresholds identified for this assessment, by frequency, magnitude, and geographic extent that would result in adverse effects to one or more beneficial uses within affected water bodies. In comparison to Existing Conditions, water quality conditions under Alternative 4A would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Water quality conditions under this alternative with respect to selenium would not cause long-term degradation of water quality in the affected environment, and therefore would not result in use of available assimilative capacity such that exceedances of water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. This alternative would not further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

As described for Alternative 4 (see Section 8.3.3.9) Environmental Commitments 12, 15, and 16 do not involve actions that would increase selenium loading or otherwise alter selenium concentrations or residence time such that there would be a change in selenium concentrations in water or biota.

Further, with the possible exception of changes in Delta hydrodynamics resulting from habitat restoration, Environmental Commitments 3, 4, and 6–11 would not substantially increase selenium concentrations in the water bodies of the affected environment.

While the implementation of Environmental Commitment 4 would create shallow backwater areas that could result in local increased water residence times, the extent of these areas would be minimal relative to the area of the Delta, and environmental changes associated with their development are unlikely to be of magnitude that would measurably change selenium concentrations in water or biota, relative to Existing Conditions. Further, although water residence times associated restoration could increase, they are not expected to increase without bound, and selenium concentrations in the water column would not continue to build up and be recycled in sediments and organisms as may be the case within a closed water system. However, because increases in bioavailable selenium in habitat restoration areas are uncertain, proposed avoidance and minimization measures would require evaluating risks of selenium exposure at a project level for each restoration area, minimizing to the extent practicable potential risk of additional bioaccumulation, and monitoring selenium levels in fish and/or wildlife to establish whether, or to what extent, additional bioaccumulation is occurring. See Appendix 3B, *Environmental Commitments, AMMs, and CMs*, for a description of the environmental commitment project proponents are making with respect to selenium management; and BDCP Appendix 3.C, *Avoidance and Minimization Measures*, for additional detail on this avoidance and minimization measure (AMM27).

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 would not increase selenium loading, and the amount of restoration that would occur would be minimal relative to the area of the Delta and implemented such that any localized changes in residence time are unlikely to measurably change selenium concentrations in water or biota relative to the No Action Alternative (ELT and LLT). Therefore, the effects on selenium from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 would not increase selenium loading, and the amount of restoration that would occur would be minimal relative to the area of the Delta and implemented such that any localized changes in residence time are unlikely to measurably change selenium concentrations in water or biota relative to Existing Conditions. Therefore, it is expected that with implementation of these Environmental Commitments there would be no substantial, long-term increase in selenium concentrations in water in the rivers and reservoirs upstream of the Delta, water in the Delta, or the waters exported to the SWP/CVP Export Service Areas, relative to Existing Conditions. As such, these Environmental Commitments would not cause additional exceedances of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Given the factors discussed in the assessment above and for Alternative 4 (see Section 8.3.3.9), any increases in bioaccumulation rates from waterborne selenium that could occur in some areas as a result of increased water residence times would not be of sufficient magnitude and geographic extent that any portion of the Delta would be expected to have measurably higher body burdens of selenium in aquatic organisms, and therefore would not substantially increase risk for adverse effects to beneficial uses. Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause long-term degradation of water quality resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely. Also, these Environmental Commitments would not result in substantially increased risk for adverse effects to any beneficial uses. Furthermore, although the Delta is a CWA Section 303(d)-listed water body for selenium, given the discussion in the assessment above, it is unlikely that restoration areas would result in measurable increases in selenium in fish tissues or bird eggs such that the beneficial use impairment would be made discernibly worse.

Because it is unlikely that substantial increases in selenium in fish tissues or bird eggs would occur such that effects on aquatic life beneficial uses would be anticipated, and because of the avoidance and minimization measures that are designed to further minimize and evaluate the risk of such increases (see BDCP Appendix 3.C, *Avoidance and Minimization Measures*, for more detail on AMM27) as well as the Selenium Management environmental commitment (see Appendix 3B, *Environmental Commitments, AMMs, and CMs*), this impact is considered less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance

The effects of operation of the water conveyance facilities under Alternative 4A on trace metal concentrations in surface waters upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be similar to those effects described for Alternative 4 (see Section 8.3.3.9). Given the poor association of dissolved trace metal concentrations with flow, river flow rate and reservoir storage reductions that would occur under Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be expected to result in a substantial adverse change in trace metal concentrations in the reservoirs and rivers upstream of the Delta.

In the Delta, for metals of primarily aquatic life concern (copper, cadmium, chromium, lead, nickel, silver, and zinc), average and 95th percentile trace metal concentrations of the primary source waters to the Delta are very similar, and very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based (see Tables 8-51 and 8-52 in Section 8.3.1.7, *Constituent-Specific Considerations Used in the Assessment)*. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average and 95th percentile source water concentrations for copper, cadmium, chromium, lead, nickel, silver, and zinc do not exceed their respective criteria, more frequent exceedances of criteria in the Delta would not occur. For metals of primarily human health and drinking water concern (arsenic, iron, manganese), average and 95th percentile concentrations are also very similar (see Tables 8–10 in Appendix 8N,*Trace Metals*) and average concentrations are below human health criteria. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average water concentrations for arsenic, iron, and manganese do not exceed water quality criteria, more frequent exceedances of drinking water criteria in the Delta would not be expected to occur.

Because Alternative 4A would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP Export Service Areas, relative to Existing Conditions or the No Action Alternative (ELT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on trace metals in the LLT are expected to be similar to those described above.

As such, Alternative 4A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment or substantially degrade the quality of these water bodies, with regard to trace metals.

NEPA Effects: Alternative 4A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment or substantially degrade the quality of these water bodies, with regard to trace metals, relative to the No Action Alternative (ELT and LLT). Therefore, the effects on trace metals from implementing Alternative 4A are determined to not be adverse.

CEQA Conclusion: While Alternative 4A would alter the magnitude and timing of reservoir releases north, south and east of the Delta, this would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under Alternative 4A.

Because Alternative 4A is not expected to result in substantial changes in trace metal concentrations in Delta waters, which includes Banks and Jones pumping plants, effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 present no new sources of trace metals to the affected environment, including areas upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas. CM19, which under Alternative 4 would fund projects to contribute to reducing pollutant discharges in urban stormwater, would not be implemented under Alternative 4A, thus the associated trace metal reduction described for Alternative 4 would not occur under this alternative. However, stormwater discharges would continue to be regulated by the state and contributions would be expected to be similar to Existing Conditions and the No Action Alternative (ELT and LLT). The remaining Environmental Commitments would not be expected to affect trace metal levels, because they are actions that do not affect the presence of trace metal sources. As they pertain to trace metals, implementation of these Environmental Commitments would not be expected to adversely affect beneficial uses of the affected environment or substantially degrade water quality with respect to trace metals.

NEPA Effects: Because Environmental Commitments 3, 4, 6–12, 15, and 16 present no new sources of trace metals to the affected environment, the effects on trace metal concentrations from implementing these Environmental Commitments are determined to be not adverse.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP Export Service Areas, because they present no new sources of trace metals to the affected environment. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance

As described for Alternative 4 (see Section 8.3.3.9), the operation of the water conveyance facilities under Alternative 4A is expected to have a minimal effect on TSS and turbidity levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions and the No Action Alternative (ELT and LLT). This is because the factors that would affect TSS and turbidity levels in the surface waters of these areas would be the same. TSS concentrations and turbidity levels in rivers upstream of the Delta are affected primarily by: 1) TSS concentrations and turbidity levels of the water released from the upstream reservoirs, 2) erosion occurring within the river channel beds, which is affected by river flow velocity and bank protection, 3) TSS concentrations and turbidity levels of tributary inflows, point-source inputs, and nonpoint runoff as influenced by surrounding land uses; and 4) phytoplankton, zooplankton and other biological material in the water. Within the Delta, TSS concentrations and turbidity levels in Delta waters are affected by TSS concentrations and turbidity levels of inflows (and associated sediment load), as well as fluctuation in flows within the channels due to the tides, with sediments depositing as flow velocities and turbulence are low at periods of slack tide, and sediments becoming suspended when flow velocities and turbulence increase when tides are near the maximum. TSS and turbidity variations can also be attributed to phytoplankton, zooplankton and other biological material in the water. These factors would be similar under Alternative 4A and Alternative 4, are expected to be minimally different from Existing Conditions and the No Action Alternative (ELT and LLT). Because Alternative 4A is expected to have minimal effect on TSS concentrations and turbidity levels in Delta waters, including water exported at the south Delta pumps, relative to Existing Conditions or the No Action Alternative (ELT and LLT), Alternative 4A also is expected to have minimal effect on TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters.

NEPA Effects: Because TSS concentrations and turbidity levels are expected to be minimally affected relative to the No Action Alternative (ELT and LLT), the effects on TSS and turbidity from implementing Alternative 4A are determined to not be adverse.

CEQA Conclusion: As described for Alternative 4 (see Section 8.3.3.9) changes in river flow rate and reservoir storage that would occur under Alternative 4A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative 4A, relative to Existing Conditions, because this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor CWA Section 303(d) listed constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

Environmental Commitments 3, 4, and 6–11 would involve habitat restoration actions. Creation of habitat and open water through implementation of these Environmental Commitments could affect Delta hydrodynamics and, thus, erosion and deposition potential in certain Delta channels, though the geographic extent of the effects would be substantially less than under Alternative 4, because less land would be converted under Alternative 4A. The magnitude of increases in TSS concentrations and turbidity levels in the affected channels due to higher potential of erosion cannot be readily quantified. The increases in TSS concentrations and turbidity levels in the affected channels could be substantial in localized areas, depending on how rapidly the channels equilibrate with the new tidal flux regime, after implementation of this alternative. However, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years. Within the reconfigured channels there could be localized increases in TSS concentrations and turbidity levels, but within the greater Plan Area it is expected that the TSS concentrations and turbidity levels would not be substantially different from the levels under Existing Conditions or the No Action Alternative (ELT and LLT).

CM19, which under Alternative 4 would fund projects to contribute to reducing pollutant discharges in stormwater, would not be implemented under Alternative 4A, thus the associated TSS and turbidity reduction described for Alternative 4 would not occur under this alternative. Nevertheless, stormwater discharges would still be subject to the state's NPDES program requirements to implement control measures, which would contribute to controlling TSS and turbidity in discharges.

The remaining Environmental Commitments would not be expected to affect TSS concentrations and turbidity levels, because they are actions that do not affect the presence of TSS and turbidity sources.

***NEPA Effects*:** Localized, temporary changes in TSS and turbidity could occur associated with the restoration actions of Environmental Commitments 3, 4, 6–12, 15, and 16. However, these changes would be gradual and not expected to substantially differ from No Action Alternative (ELT and LLT) conditions. Therefore, the effects on TSS and turbidity from implementing these Environmental Commitments are determined to be not adverse.

***CEQA Conclusion*:** It is expected that the TSS concentrations and turbidity levels Upstream of the Delta, in the Plan Area, and the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not be substantially different relative to Existing Conditions, except within localized areas of the Delta modified through creation of habitat and open water. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels Upstream of the Delta, in the greater Plan Area, and in the SWP/CVP Export Service Areas are not expected to be substantially different, long-term water quality degradation is not expected relative to TSS and turbidity, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor CWA Section 303(d) listed constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities for the Water Conveyance Facilities and Environmental Commitments

The potential construction-related water quality effects that would occur under Alternative 4A would be of a lower magnitude compared to the effects described for Alternative 4 (see Section 8.3.3.9). This is because the size and number of construction activities for some Environmental Commitments under Alternative 4A would be reduced, or not occur, compared to Alternative 4. The construction-related activities for the water conveyance facilities under Alternative 4A would be the same as described for Alternative 4. However, there would be substantially less area of in-water habitat restoration activities implemented under Alternative 4A compared to Alternative 4. Therefore, the amount of construction activity under Alternative 4A would be lower than described for Alternative 4, thus resulting in less potential for construction-related disturbances and contaminant discharges to surface waters.

The construction-related activities for Alternative 4A would be most extensive for the new water conveyance facilities. Construction of water conveyance facilities would involve vegetation removal, material storage and handling, excavation, overexcavation for facility foundations, surface grading, trenching, road construction, levee construction, construction site dewatering, soil stockpiling, RTM dewatering basin construction and storage operations, and other general facility construction activities (i.e., concrete, steel, carpentry, and other building trades) over approximately 7,500 acres during the course of constructing the facilities. Vegetation would be removed (via grubbing and clearing) and grading and other earthwork would be conducted at the intakes, pumping plants, the intermediate forebay, the Byron Tract Forebay, canal and gates between the Byron Tract Forebay tunnel shafts and the approach canal to the Banks Pumping Plant, borrow areas, RTM and spoil storage areas, setback and transition levees, sedimentation basins, solids handling facilities, transition structures, surge shafts and towers, substations, transmission line footings, access roads, concrete batch plants, fuel stations, bridge abutments, barge unloading facilities, and laydown areas. Construction of each intake would take nearly four years to complete.

Habitat restoration Environmental Commitments in the Delta, including restored tidal wetlands, floodplain, and related channel margin and off-channel habitats, also would involve substantial in-water construction-related activities in localized areas of the Delta. Other non-habitat restoration Environmental Commitments are not anticipated to involve construction activities that would result in substantial discharges of any constituents of concern.

NEPA Effects: Potential construction-related water quality effects may include discharges of turbidity/TSS due to the erosion of disturbed soils and associated sedimentation entering surface water bodies or other construction-related wastes (e.g., concrete, asphalt, cleaning agents, paint, and trash). Construction activities also may result in temporary or permanent changes in stormwater generation or drainage and runoff patterns (i.e., velocity, volume, and direction) that may cause or contribute to soil erosion and offsite sedimentation, such as creation of additional impervious surfaces (e.g., pavement, buildings, compacted soils), blockage or restriction of existing drainage channels, or general surface drainage changes from grading and excavation activity. Additionally, the use of heavy earthmoving equipment may result in spills and leakage of oils, gasoline, diesel fuel, and related petroleum contaminants used in the fueling and operation of such construction equipment.

Land surface grading and excavation activities, or exposure of disturbed sites immediately following construction and prior to stabilization, could result in rainfall- and stormwater-related soil erosion, runoff, and offsite sedimentation in surface water bodies. The initial runoff following construction, or return of seasonal rains to previously disturbed sites, can result in runoff with peak pollutant levels and is referred to as “first flush” storm events. Soil erosion and runoff can also result in increased concentrations and loading of organic matter, nutrients (nitrogen and phosphorus), and other contaminants contained in the soil such as trace metals, pesticides, or animal-related pathogens. Graded and exposed soils also can be compacted by heavy machinery, resulting in reduced infiltration of rainfall and runoff, thus increasing the rate of runoff (and hence contaminants) to downstream water bodies.

Construction activities also would be anticipated to involve the transport, handling, and use of a variety of hazardous substances and non-hazardous materials that may adversely affect water quality if discharged inadvertently to construction sites or directly to water bodies. Typical construction-related contaminants include petroleum products for refueling and maintenance of machinery (e.g., fuel, oils, solvents), concrete, paints and other coatings, cleaning agents, debris and trash, and human wastes. Construction activities also would involve large material storage and laydown areas, and occasional accidental spills of hazardous materials stored and used for construction may occur. Contaminants released or spilled on bare soil also may result in groundwater contamination. Dewatering operations may contain elevated levels of suspended sediment or other constituents that may cause water quality degradation.

The intensity of construction activity along with the fate and transport characteristics of the chemicals used, would largely determine the magnitude, duration, and frequency of construction-related discharges and resulting concentrations and degradation associated with the specific constituents of concern. The potential water quality concerns associated with the major categories of contaminants that might be discharged as a result of construction activity include the following.

- Suspended sediment: May increase turbidity (i.e., reduce water clarity) that can affect aquatic organisms and increase the costs and effort of removal in municipal/industrial water supplies. Downstream sedimentation can affect aquatic habitat, or cause a nuisance if it affects functions of agricultural or municipal intakes, or boat navigation.
- Organic matter: May contribute turbidity and oxygen demanding substances (i.e., reduce DO levels) that can affect aquatic organisms. Organic carbon may increase the potential for disinfection byproduct formation in municipal drinking water supplies.
- Nutrients: May contribute nitrogen, phosphorus, and other key nutrients that can contribute to nuisance biostimulation of algae and vascular aquatic plants, which may affect municipal water supplies, recreation, aquatic life, and aesthetics.
- Petroleum hydrocarbons: May contribute toxic compounds to aquatic life, and oily sheens may reduce oxygen/gas transfer in water, foul aquatic habitats, and reduce water quality for municipal supplies, recreation, and aesthetics.
- Trace constituents (metals, pesticides, synthetic organic compounds): Compounds in eroded soil or construction-related materials (e.g., paints, coatings, cleaning agents) may be toxic to aquatic life.
- Pathogens: Bacteria, viruses, and protozoans may affect aquatic life and increase human health risks via municipal water supplies, reduced recreational water quality, or contaminated shellfish beds.
- Other inorganic compounds: Construction-related materials can contain inorganic compounds such as acidic/basic materials which can change pH and may adversely affect aquatic life and habitats. Concrete contains lime which can increase pH levels, and drilling fluids may alter pH.

Some construction-related contaminants, such as PAHs that may be in some fuel and oil petroleum byproducts, may be bioaccumulative in aquatic and terrestrial organisms. Construction activities also may disturb areas where bioaccumulative constituents are present in the soil (e.g., mercury, selenium, organochlorine pesticides, PCBs, and dioxin/furan compounds), or may disturb soils that contain constituents included on the Section 303(d) lists of impaired water bodies in the affected environment. While the 303(d)-listed Delta channels impaired by mercury are widespread, impairment by selenium, pesticides, PCBs, and dioxin/furan compounds is more limited, and there are no 303(d) listings for PAH impairment. Bioaccumulation of constituents in the aquatic foodchain, and 303(d)-related impaired water bodies, arise as a result of long-term loading of a constituent or a pervasive and widespread source of constituent discharge (e.g., mercury).However, as a result of the generally localized disturbances, and intermittent and temporary nature of construction-related activities, construction would not be anticipated to result in contaminant discharges of substantial magnitude or duration to contribute to long-term bioaccumulation processes, or cause measureable long-term degradation such that existing 303(d) impairments would be made discernibly worse or TMDL actions to reduce loading would be adversely affected.

The environmental commitments for construction-related water quality protection would be specifically designed as a part of the final design, included in construction contracts as a required element, and would be implemented to avoid, prevent, and minimize the potential discharges of constituents of concern to water bodies and associated adverse water quality effects and comply with state water quality regulations. Additionally, temporary and permanent changes in stormwater drainage and runoff would be minimized and avoided through construction of new or modified drainage facilities, as described in the Chapter 3, *Description of Alternatives*. This alternative would include installation of temporary drainage bypass facilities, long-term cross drainage, and replacement of existing drainage facilities that would be disrupted due to construction of new facilities.

Construction-related activities would be conducted in accordance with the environmental commitment to develop and implement BMPs for all activities that may result in discharge of soil, sediment, or other construction-related contaminants to surface water bodies, and obtain authorization for the construction activities under the State Water Board's NPDES Stormwater General Permit for Stormwater Discharges Associated with Construction and Land Disturbance Activities (Order No. 2009-0009-DWQ/NPDES Permit No. CAS000002). The General Construction NPDES Permit requires the preparation and implementation of SWPPPs, which are the principal plans within the required PRDs that identify the proposed erosion control and pollution prevention BMPs that would be used to avoid and minimize construction-related erosion and contaminant discharges. The development of the SWPPPs, and applicability of other provisions of this General Construction Permit depends on the "risk" classification for the construction which is determined based on the potential for erosion to occur as well as the susceptibility of the receiving water to potential adverse effects of construction. While the determination of project risk level, and planning and development of the SWPPPs and BMPs to be implemented, would be completed as a part of final design and contracting for the work, the responsibility for compliance with the provisions of the General Construction Permit necessitates that BMPs are applied to all disturbance activities. In addition to the BMPs, the SWPPPs would include BMP inspection and monitoring activities, and identify responsibilities of all parties, contingency measures, agency contacts, and training requirements and documentation for those personnel responsible for installation, inspection, maintenance, and repair of BMPs. The General Construction Permit contains NALs and for pH and turbidity, and specifies storm event water quality monitoring to determine if construction is resulting in elevated discharges of these constituents, and monitoring for any non-visible contaminants determined to have been potentially released. If an NAL is determined to have been exceeded, the General Construction Permit requires the discharger to conduct a construction site and run-on evaluation to determine whether contaminant sources associated with the site's construction activity may have caused or contributed to the exceedance and immediately implement corrective actions if they are needed.

The BMPs that are routinely implemented in the construction industry and have proven successful at reducing adverse water quality effects include, but are not limited to, the following broad categories of actions (letters refer to categories of specific BMPs identified in Appendix 3B, *Environmental Commitments, AMMs, and CMs*), for which Appendix 3B identifies specific BMPs within these categories:

- Waste Management and Spill Prevention and Response (BMP categories A.2 and A.3): Waste management BMPs are designed to minimize exposure of waste materials at all construction sites and staging areas such as waste collection and disposal practices, containment and protection of wastes from wind and rain, and equipment cleaning measures. Spill prevention and response BMPs involve planning, equipment, and training for personnel for emergency event response.
- Erosion and Sedimentation Control (BMP categories A.4 and A.5): Erosion control BMPs are designed to prevent erosion processes or events including scheduling work to avoid rain events, stabilizing exposed soils; minimize offsite sediment runoff; remove sediment from onsite runoff before it leaves the site; and slow runoff rates across construction sites. Identification of appropriate temporary and long-term seeding, mulching, and other erosion control measures as necessary. Sedimentation BMPs are designed to minimize offsite sediment runoff once erosion has occurred involving drainage controls, perimeter controls, detention/sedimentation basins, or other containment features.
- Good Housekeeping and Non-Stormwater Discharge Management (BMP category A.6 and A.7): Good housekeeping BMPs are designed to reduce exposure of construction sites and materials storage to stormwater runoff including truck tire tracking control facilities; equipment washing; litter and construction debris; and designated refueling and equipment inspection/maintenance practices Non-stormwater discharge management BMPs involve runoff measures for contaminants not directly associated with rain or wind including vehicle washing and street cleaning operations.
- Construction Site Dewatering and Pipeline Testing (BMP category A.8).Dewatering BMPs involve actions to prevent discharge of contaminants present in dewatering of groundwater during construction, discharges of water from testing of pipelines or other facilities, or the indirect erosion that may be caused by dewatering discharges.
- BMP Inspection and Monitoring (BMP category A.9): Identification of clear objectives for evaluating compliance with SWPPP provisions, and specific BMP inspection and monitoring procedures, environmental awareness training, contractor and agency roles and responsibilities, reporting procedures, and communication protocols.

In addition to the Category "A" BMPs for surface land disturbances identified in the environmental commitments (Appendix 3B, *Environmental Commitments, AMMs, and CNs*), BMPs implemented also would include the Category "B" BMPs for tunnel/pipeline construction that involves actions primarily to avoid and minimize sediment and contaminant discharges associated with RTM excavation, hauling, and RTM dewatering operations. Additionally, habitat restoration activities under CM2 and CM4–CM10 would be subject to implementation of the Category "C" BMPs (In-Water Construction BMPs) and Category "D" BMPs (Tidal and Wetland Restoration) designed to minimize disturbance and direct discharge of turbidity/suspended solids to the water during in-water construction activities. Category "E" BMPs identify general permanent post-construction actions that would be implemented for all terrestrial, in-water, and habitat restoration activities and would involve planning, design, and development of final site stabilization, revegetation, and drainage control features.

Finally, acquisition of applicable environmental permits may be required for specific environmental commitments, which may include specific WDRs or CWA Section 401 water quality certifications from the appropriate Regional Water Boards, CDFW Streambed Alteration Agreements, and USACE CWA Section 404 dredge and fill permits. These other permit processes may include requirements to implement additional action-specific BMPs that may reduce potential adverse discharge effects of constituents of concern.

The potential construction-related contaminant discharges that could result from this alternative would not be anticipated to result in adverse water quality effects at a magnitude, frequency, or regional extent that would cause substantial adverse effects to aquatic life. Relative to Existing Conditions, this assessment indicates the following.

- Projects would be managed under state water quality regulations and project-defined actions to avoid and minimize contaminant discharges.
- Individual projects would generally be dispersed, and involve infrequent and temporary activities, thus not likely resulting in substantial exceedances of water quality standards or long-term degradation.
- Potential construction-related contaminant discharges would not cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Long-term water quality degradation is not anticipated, and hence would not be expected to adversely affect beneficial uses.
- By the intermittent and temporary frequency of construction-related activities and potential contaminant discharges, the constituent-specific effects would not be of substantial magnitude or duration to contribute to long-term bioaccumulation processes, or cause measureable long-term degradation such that existing 303(d) impairments would be made discernibly worse or TMDL actions to reduce loading would be adversely affected.

Consequently, because the construction-related activities for the conservation measures would be conducted with implementation of environmental commitments, including but not limited to those identified in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, with respect to the No Action Alternative conditions, this alternative would not be expected to cause constituent discharges of sufficient frequency and magnitude to result in a substantial increase of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern, and thus would not adversely affect any beneficial uses in the Delta.

In summary, with implementation of environmental commitments in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

CEQA Conclusion: As explained above, water quality effects resulting from construction-related activities would be less under Alternative 4A compared to Alternative 4, which was determined to be less than significant. Moreover, because environmental commitments would be implemented under Alternative 4A for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or CWA Section 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause CWA Section 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32: Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance

Upstream of the Delta

Adverse effects from *Microcystis* upstream of the Delta have only been documented in lakes such as Clear Lake, where eutrophic levels of nutrients give cyanobacteria a competitive advantage over other phytoplankton during the bloom season. Large reservoirs upstream of the Delta are typically characterized by low nutrient concentrations, where other phytoplankton outcompete cyanobacteria, including *Microcystis*. In the rivers and streams of the Sacramento River watershed, watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), and the San Joaquin River upstream of the Delta under Existing Conditions, bloom development is limited by high water velocity and low residence times. These conditions are not expected to change under Alternative 4A or the No Action Alternative (ELT and LLT). Consequently, any modified reservoir operations under Alternative 4A are not expected to promote *Microcystis* production upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT and LLT).

Delta

During the June through October period when *Microcystis* blooms occur in the Delta, it is a combination of flows, associated residence time, and water temperatures that are believed to most influence *Microcystis* bloom formation.

Since Delta water temperatures are largely driven by air temperature, climate change that increases air temperatures relative to Existing Conditions would be expected to increase ambient water temperatures in the Delta by 1.3–2.5°F. These climate changes in the ELT are expected to occur in the Delta under the No Action Alternative, relative to Existing Conditions. Alternative 4A operations and maintenance is not expected to cause increased Delta water temperatures, relative to Existing Conditions or the No Action Alternative.

Under Alternative 4A, a portion of the Sacramento River water which is conveyed through the Delta to the south Delta intakes under Existing Conditions would be replaced at various locations throughout the Delta by other source water due to diversion of Sacramento River water at the north Delta intakes. To determine how hydrologic effects of Alternative 4A, relative to Delta hydrology under the No Action Alternative (ELT), may affect *Microcystis* occurrence and bloom formation, flows, residence time, and peak daily channel velocity were analyzed for various Delta locations.

Frequency of given flows were assessed in the Biological Assessment for the California WaterFix (ICF International 2016) using flow in the San Joaquin River past Jersey Point and flow in the Sacramento River at Rio Vista. The San Joaquin River analysis found that flow conditions conducive to *Microcystis* blooms in the San Joaquin River would occur less frequently under the Proposed Action, which is Alternative 4A, compared to the No Action Alternative. Based on flow analysis in the Sacramento River, there could be a decrease in flows at Rio Vista compared to the No Action Alternative. Because turbid conditions and sufficient flow to create channel turbulence are the norm here, and are expected to remain consistent with Existing Conditions in the future, it is expected that current conditions will continue and that *Microcystis* blooms will not increase here (ICF International 2016).

Based on *Microcystis* life history strategy to outcompete other algal species and the inhibitory effect of flow and turbulence on its ability to do so, maximum daily channel velocities (which creates channel turbidity and turbulence) also were assessed using DSM2 velocity output for a number of locations throughout the Delta (Appendix 8P). The evaluation of flow velocities shows little to no effects on peak daily velocities under Alternative 4A compared to the No Action Alternative at each location assessed. This indicates that areas of the Delta that are currently turbid will remain turbid and vertical mixing of the water column will be similar under Alternative 4A and the No Action Alternative. As stated in Section 8.3.1.7, *Microcystis* cannot effectively retain its buoyancy or outcompete other faster growing phytoplankton in turbid, turbulent waters. Therefore, based on Alternative 4A maintaining similar to equivalent peak daily flow velocities in Delta channels (and turbidity and turbulence conditions), Alternative 4A would not be expected to substantially increase the frequency or geographic extent of Microcystis blooms in the Delta, relative to what would occur under the No Action Alternative.

Changes in flow paths of water through the Delta and change in operation of the south Delta pumps that would occur due to facilities operations and maintenance of Alternative 4A could result in localized increases in residence time in various Delta sub-regions and decreases in residence time in other areas. In addition to the effects of operations and maintenance of Alternative 4A, increases in water residence times are expected occur due to separate factors and actions concurrent with the alternative, including habitat restoration (8,000 acres of tidal habitat and enhancements in the Yolo Bypass) and sea level rise due to climate change.

Residence times in 19 Delta sub-regions during the *Microcystis* bloom season of July through October was modeled for the Biological Assessment for the California WaterFix (ICF International 2016). The Proposed Action modeled in the Biological Assessment is Alternative 4A. Modeling results show varying levels of change in residence time, depending on sub-region, month and water year type (Tables 6.6-5 through 6.6-25, ICF International 2016). DSM2 PTM output indicates residence times may increase in parts of the southern and central Delta. Because there is no published analysis of the relationship between *Microcystis* occurrence and residence time, there is uncertainty on how increased residence times may affect *Microcystis* occurrences (ICF International 2016). In some areas of the Delta currently affected by *Microcystis* blooms, decreasing median residence times in some months (decreases from 0.1 – 3.8 days) has potential to lower the magnitude and duration of *Microcystis* blooms. However, in other areas of the Delta that experience *Microcystis* blooms, longer median residence times in some months (0.1 - 16.5 days) has potential to increase the magnitude and duration of *Microcystis* blooms.

The changes in residence time are driven by a number of factors accounted for in the modeling, including diversion of Sacramento River water at the proposed north Delta intake facilities, which does not account for the flexibility of operations of the north and south Delta intakes or real-time management of reservoir releases. To ensure project operations do not create increased *Microcystis* blooms in the Delta, water flow through Delta channels would be managed through real-time operations, particularly the balancing of the north and south Delta diversions. By operating the south Delta pumps more frequently during periods conducive to increased *Microcystis* blooms, residence times would be substantially reduced from those modeled for Alternative 4A. Reducing residence times would decrease the potential for blooms to develop, and thus decrease potential microcystin increases due to project operations. As such, effects of Alternative 4A on *Microcystis* levels, and thus microcystin concentrations in the Delta, would not be made more adverse relative to Existing Conditions and the No Action Alternative (ELT and LLT).

In summary, operations and maintenance of Alt 4A is not expected to result in flow or velocity changes in the Delta that would cause substantial increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms, relative to Existing Conditions or the No Action Alternative. In some areas of the Delta that experience *Microcystis* blooms, longer median residence times in some months has potential to increase the magnitude and duration of *Microcystis* blooms. However, factors that control *Microcystis* blooms in the Delta are still under study, so there is some uncertainty regarding this impact finding. *Microcystis* blooms may also occur more frequently in the Delta in the future, relative to Existing Conditions, due to factors unrelated to the project alternative, including: 1) increased residence times resulting from restoration activities and climate change-related sea level rise and 2) climate change-related increased Delta water temperatures. To ensure project operations under Alternative 4A do not create significant increases in *Microcystis* blooms in the Delta, that may be associated with increased residence times, water flow through Delta channels would be managed through real-time operations.

SWP/CVP Export Service Area

As described above for the Delta, source waters to the south Delta intakes could be adversely affected, relative to Existing Conditions, by *Microcystis* both from an increase in Delta water temperatures associated with climate change and from an increase in water residence times. The impacts from increased Delta water residence times would be primarily related to habitat restoration (8,000 acres of tidal habitat restoration and enhancements in the Yolo Bypass) that is assumed to occur separate from Alternative 4A. The combined effect of these factors on the potential for *Microcystis* blooms in source waters to the south Delta intakes is expected to be much greater than the influence of operations and maintenance of Alternative 4A, the effects of which will be mitigated through real time operations. Increases in ambient air temperatures due to climate change relative to Existing Conditions are expected under this alternative. Increases in ambient air temperatures are expected to result in warmer ambient water temperatures, and thus conditions more suitable to *Microcystis* growth, in the water bodies of the SWP/CVP Export Service Areas. The incremental increase in long-term average air temperatures would be less at the ELT (2.0°F), compared to the LLT (4.0°F).

As discussed in the Delta section above, Alternative 4A facilities operations and maintenance is not expected to substantially adversely affect *Microcystis* blooms, relative to Existing Conditions and the No Action Alternative (ELT and LLT). Additionally, residence time and water temperature conditions in the SWP/CVP Export Service Areas are not expected to become more conducive to *Microcystis* bloom formation due to the operations and maintenance of Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), because water residence times are not projected to increase in the SWP/CVP Export Service Areas and any temperature increases there would be due to climate change and not due to Alternative 4A.

NEPA Effects: Modified reservoir operations under Alternative 4A are not expected to promote *Microcystis* production upstream of the Delta, relative to the No Action Alternative (ELT and LLT). Similarly, operations and maintenance of Alternative 4A are not expected to substantially increase water residence times or ambient water temperatures in the Delta, including at the Banks and Jones pumping plants, and thus is not expected to result in adverse effects on *Microcystis* in the Delta, relative to No Action Alternative (ELT and LLT). Lack of adverse effects on *Microcystis* in the Delta would mean that Delta waters diverted into the SWP/CVP Export Service Areas would not be adversely affected. Finally, the potential for *Microcystis* bloom formation within the SWP/CVP Export Service Area water bodies and canals would not be expected to change substantially, if at all, because water residence times are not projected to increase in the SWP/CVP Export Service Areas and any temperature increases there would be due to climate change and not due to Alternative 4A. Thus, the effects on *Microcystis* in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas from implementing Alternative 4A are determined to be not adverse.

CEQA Conclusion: Modified reservoir operations under Alternative 4A are not expected to promote *Microcystis* production upstream of the Delta, relative to the Existing Conditions. Increased frequency and magnitude of *Microcystis* blooms may occur in the Delta in the future, relative to Existing Conditions, due to increased residence times resulting from restoration activities unrelated to the project alternative, as well as climate change and sea level rise that are expected to increase Delta water temperatures. Such increases in residence time and water temperatures would not be caused by implementation of Alternative 4A. Operations and maintenance of Alternative 4A, including the use of real-time operations, are not expected to result in flow and temperature conditions in the Delta, including at the Banks and Jones pumping plants, that would cause substantial increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms. As such, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not CWA Section 303(d) listed within the affected environment and thus any increases that could occur in some areas of the Delta would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. Microcystin, the toxin produced by *Microcystis,* is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences due to climate change and sea level rise may lead to increased microcystin presence in the Delta, relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. While long-term water quality degradation related to microcystin levels may occur and, thus, impacts on beneficial uses could occur, these impacts are not related to implementation of Alternative 4A. Although there is uncertainty regarding this impact, the effects on *Microcystis* from implementing water conveyance facilities are determined to be less than significant. No mitigation is required.

Impact WQ-33: Effects on *Microcystis* Bloom Formation Resulting from Environmental Commitments

Under Alternative 4A, fisheries enhancements to the Yolo Bypass would not be implemented, but under a plan separate and distinct from Alternative 4A, enhancements to the Yolo Bypass and 8,000 acres of tidal habitat restoration would be implemented in the ELT. The Yolo Bypass enhancements are assumed to occur under the No Action Alternative, as well as 8,000 acres of tidal habitat restoration. These activities would create shallow backwater areas that could result in local warmer water and increased water residence time of magnitude and extent that could result in measurable changes on *Microcystis* levels in the Delta, relative to Existing Conditions. However, the area of tidal habitat restoration to be implemented as a component of Alternative 4A, relative to the No Action Alternative, is so small that it would have negligible effects compared to the development of 8,000 acres of tidal habitat that would be developed independent of Alternative 4A. Thus, compared to the No Action Alternative, which isolates the effects of Alternative 4A habitat actions, Alternative 4A

Environmental Commitments are not expected to contribute to measurable changes on *Microcystsis* levels in the Delta.

NEPA Effects: Based on the discussion above, the effects on *Microcystis* from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusions: Based on the discussion above, Environmental Commitments 3, 4, 6–12, 15, and 16 would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not CWA Section 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta would occur at the early long-term for reasons unassociated with implementation of the Environmental Commitments, including tidal habitat restoration. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in Microcystis occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. While long-term water quality degradation related to microcystins levels may occur and, thus, significant impacts on beneficial uses could occur, these impacts are not related to implementation of the Environmental Commitments. Therefore, the effects on *Microcystis* from implementing the Environmental Commitments are determined to be less than significant. No mitigation is required.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance and Environmental Commitments

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 4A would have a less-than-significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- Bromide
- Chloride
- DOC
- DO
- Pathogens
- Pesticides
- Trace metals
- Turbidity and TSS
- *Microcystis*

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. Chloride, DOC, and bromide concentrations also are of concern in drinking water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses.

Changes in Delta DO, pathogens, pesticides, trace metals, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Changes in *Microcystis* would be primarily due to factors unassociated with the project alternative. Thus, changes in boron, bromide, chloride, DOC, DO, pathogens, pesticides, trace metals, turbidity and TSS, and *Microcystis* in Delta outflow associated with implementation of Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT) are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay, as described for Alternative 4 (see Section 8.3.3.9).

Elevated EC is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. San Francisco Bay does not have an AGR beneficial use designation. As described for Alternative 4, salinity throughout San Francisco Bay is largely a function of the tides, as well as to some extent the freshwater inflow from upstream. However, the changes in Delta outflow due to Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would be minor compared to tidal flows, and thus no substantial adverse effects on salinity, or fish and wildlife beneficial uses, downstream of the Delta are expected.

Also, as described for Alternative 4, changes in nutrient loading would not be expected to contribute to adverse effects to beneficial uses. Changes in nitrogen (ammonia and nitrate) loading to Suisun and San Pablo Bays under Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay. The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. As described for Alternative 4, any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary. Therefore, changes in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay, relative to Existing Conditions and the No Action Alternative (ELT and LLT), shown in Appendix 8O, *San Francisco Bay Analysis*, Table 8O-1, are not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Similar to Alternative 4, loads of mercury and methylmercury, from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 4A, relative to Existing Conditions and the No Action Alternative (ELT and LLT) (Appendix 8O, *San Francisco Bay Analysis*, Table 8O-2). Also, the incremental increase in dissolved selenium concentrations in the North Bay, relative to Existing Conditions, would be negligible (0.01 μg/L) under this alternative (Appendix 8O, Table 8O-3).

NEPA Effects: Based on the discussion above, Alternative 4A, relative to the No Action Alternative (ELT and LLT), would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, selenium, nutrients (ammonia, nitrate, phosphorus), trace metals, turbidity and TSS, or *Microcystis* in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, effects on the San Francisco Bay from implementation of water conveyance facilities and Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

CEQA Conclusion: As with Alternative 4, Alternative 4A would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. Further, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals, turbidity or TSS, and *Microcystis* are anticipated in the Delta due to the implementation of Alternative 4A, relative to Existing Conditions, therefore, no substantial changes to these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow and thus, have minimal influence on salinity changes. Changes in nutrient load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. As with Alternative 4, the change in mercury and methylmercury load (which is based on source water and Delta outflow), relative to Existing Conditions, would be within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA Section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Similarly, based on Alternative 4 estimates, the increase in selenium load would be minimal, and total and dissolved selenium concentrations would be expected to be the same as Existing Conditions, and less than the target associated with white sturgeon whole-body fish tissue levels for the North Bay. Thus, the change in selenium load is not expected to contribute to water quality degradation, or make the CWA Section 303(d) selenium impairment measurably worse or cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

8.3.4.3 Alternative 2D—Dual Conveyance with Modified Pipeline/Tunnel and Intakes 1, 2, 3, 4 and 5 (15,000 cfs; Operational Scenario B)

Discussion of water quality impacts of Alternative 2D was first provided in the RDEIR/SDEIS. The water quality assessments in the RDEIR/SDEIS for boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Services Areas utilized results from water quality modeling performed for Alternative 2A in the ELT, which included Yolo Bypass improvements, 25,000 acres of tidal habitat restoration, and the EC compliance location at Emmaton relocated to Threemile Slough. The analysis of effects of Alternative 2D, presented herein, on boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Service Areas is based on revised modeling, which assumed implementation of Yolo Bypass improvements, the EC compliance location remaining at Emmaton, and no tidal habitat restoration. Because the modeling of Alternative 2D and the No Action Alternative (ELT) included Yolo Bypass Improvements, but no tidal habitat restoration, comparison of modeling results for Alternative 2D to No Action Alternative (ELT) results in the impact discussions below allows for isolating and identifying effects solely due to implementation of Alternative 2D in the ELT.

As described in Chapter 3, *Description of Alternatives*, actions associated with Alternative 4 that are not proposed to be implemented under Alternative 2D would continue to be pursued as part of existing, but separate, projects and programs associated with the 2008 USFWS and 2009 NMFS BiOps, California EcoRestore, and the 2014 California Water Action Plan. Due to the reduced suite of Environmental Commitments in Alternative 2D compared to Alternative 4 (in particular, significantly less tidal habitat restoration), the impacts to water quality due to Alternative 2D are substantially less compared to Alternative 4, particularly in the Delta.

The water quality impact conclusions for Alternative 2D remain the same as those presented in the RDEIR/SDEIS. The revisions to the assessment are in the presentation of modeled changes in concentrations, water quality criteria/objective exceedances, and use of assimilative capacity, and refinements to mitigation measures for EC.

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), substantial point and non-point sources of ammonia-N do not exist upstream of the SRWTP at Freeport in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Thus, like Alternative 4, operation of the water conveyance facilities under Alternative 2D would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative (ELT and LLT). Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

As described for Alternative 4 (see Section 8.3.3.9), a substantial decrease in Sacramento River ammonia concentrations is expected under Alternative 2D relative to Existing Conditions, due to planned lowering of ammonia in the SRWTP effluent discharge, and this is expected to decrease ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water. Concentrations of ammonia at locations not influenced notably by Sacramento River water would change little relative to Existing Conditions, due to the similarity in San Joaquin River and San Francisco Bay concentrations and the lack of expected changes in either of these concentrations. Thus, Alternative 2D would not result in substantial increases in ammonia concentrations in the Plan Area, relative to Existing Conditions.

Relative to the No Action Alternative (ELT and LLT), the primary mechanism that could potentially alter ammonia concentrations under Alternative 2D is decreased flows in the Sacramento River, which would lower dilution available to the SRWTP discharge. This flow change would be attributable only to operations of the water conveyance facilities, since the same assumptions regarding SRWTP discharge ammonia concentrations, water demands, climate change, and sea level rise apply to both Alternative 2D and the No Action Alternative (ELT and LLT). A simple mass balance calculation was performed to calculate ammonia concentrations downstream of the SRWTP discharge (i.e., downstream of Freeport) under Alternative 2D and the No Action Alternative (ELT) to assess the effects of the flow changes. Monthly average CALSIM II flows at Freeport and the upstream ammonia concentration (0.04 mg/L-N; Central Valley Water Board 2010a:5) were used, together with the SRWTP permitted average dry weather flow (181 mgd) and seasonal ammonia limitations (1.5 mg/L-N in Apr–Oct, 2.4 mg/L-N in Nov–Mar), to estimate the average change in ammonia concentrations downstream of the SRWTP. Table 8-74 shows monthly average and long-term annual average predicted concentrations under Alternative 2D. As Table 8-74 shows, average monthly ammonia concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 2D and the No Action Alternative (ELT) are expected to be similar. In comparison to the No Action Alternative (ELT), minor increases in monthly average ammonia concentrations would occur during July through September, and November under Alternative 2D. Minor decreases in ammonia concentrations are expected for Alternative 2D in January through June, and October and December. The annual average concentration under Alternative 2D would be the same as that under the No Action Alternative (ELT). Relative to the No Action Alternative (LLT), Alternative 2D (LLT) is expected to result in similar minor increases in Sacramento River ammonia concentration, because the increased water demands, climate change, and sea level rise in the LLT would occur under both alternatives, and neither would affect ammonia sources or loading. The estimated concentrations in the Sacramento River downstream of Freeport under Alternative 2D would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 2D, relative to the No Action Alternative (ELT and LLT), are not expected to substantially increase ammonia concentrations at any Delta locations.

Ammonia concentrations downstream of Freeport in the Sacramento River under Alternative 2D would be similar to those under Alternative 4 (see Table 8-67 in Section 8.3.3.9). As stated for Alternative 4, any negligible increases in ammonia concentrations that could occur at certain locations in the Delta under Alternative 2D would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regard to ammonia.

Table 8-74. Estimated Ammonia (mg/L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative Early Long-Term (ELT) and Alternative 2D

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative (ELT)	0.076	0.082	0.069	0.062	0.059	0.062	0.059	0.062	0.067	0.060	0.067	0.064	0.066
Alternative 2D ELT	0.075	0.086	0.068	0.061	0.058	0.061	0.058	0.061	0.062	0.062	0.070	0.067	0.066

SWP CVP Export Service Areas

As discussed above, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 2D, relative to Existing Conditions (in association with less diversion of water influenced by the SRWTP). Like Alternative 4, this decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in an adverse effect on beneficial uses or substantially degrade water quality of exported water, with regard to ammonia. Furthermore, as discussed above, for all areas of the Delta, including Banks and Jones pumping plants, ammonia concentrations are not expected to be substantially different under Alternative 2D (ELT) relative to the No Action Alternative (ELT), and Alternative 2D (LLT) relative to the No Action Alternative (LLT). Thus, any negligible increases in ammonia concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade water quality at these locations, with regard to ammonia.

NEPA Effects: In summary, ammonia concentrations in water bodies upstream of the Delta, in the Plan Area, and the waters exported to the SWP/CVP Export Service Areas are not expected to be substantially different under Alternative 2D relative to the No Action Alternative (ELT and LLT). Thus, effects of the water conveyance facilities on ammonia are considered to be not adverse.

CEQA Conclusion: The magnitude and direction of changes in ammonia concentrations in water bodies upstream of the Delta, in the Plan Area, or the waters exported to the SWP/CVP Export Service Areas would be approximately the same as expected under Alternative 4, relative to Existing Conditions. There would be no substantial, long-term increase in ammonia concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 2D relative to Existing Conditions. As such, Alternative 2D is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not CWA Section 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Some habitat restoration activities would occur on lands in the Delta formerly used for irrigated agriculture. Although this may decrease ammonia loading to the Delta from agriculture, increased biota in those areas as a result of restored habitat may increase ammonia loading originating from flora and fauna. Ammonia loaded from organisms is expected to be converted rapidly to nitrate by established microbial communities. Thus, these land use changes would not be expected to substantially increase ammonia concentrations in the Delta. Implementation of Environmental Commitments 12, 15, and 16 do not include actions that would affect ammonia sources or loading. Based on these findings, the effects on ammonia from the implementation Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 2D are determined to not be adverse.

***CEQA Conclusion*:** Land use changes that would occur from the Environmental Commitments are not expected to contribute substantially increase ammonia concentrations, because the amount of area to be converted would be small relative to existing habitat, and any resulting ammonia would likely be rapidly converted to nitrate. Thus, there would be no substantial, long-term increase in ammonia concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 relative to Existing Conditions. As such, implementation of these Environmental Commitments would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Because ammonia concentrations would not be expected to increase substantially from implementation of these Environmental Commitments, no long-term water quality degradation would be expected to occur and, thus, no significant impact on beneficial uses would occur. Ammonia is not CWA Section 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), under Alternative 2D there would be no expected change to the sources of boron in the Sacramento River and eastside tributary watersheds and, thus, resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease by 1%, relative to Existing Conditions (in association with the different operational components of Alternative 2D in the ELT, climate change, and increased water demands) (Appendix 8F, *Boron*, Table Bo-32). The reduced flow relative to Existing Conditions would result in possible increases in long-term average boron concentrations of up to about 0.5% relative to the Existing Conditions. Flows would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial boron increases relative to the No Action Alternative (ELT). The increased boron concentrations, relative to Existing Conditions, under Alternative 2D in the ELT would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 2D in the ELT would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Effects of Alternative 2D in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect boron sources in these areas.

Delta

Effects of water conveyance facilities on boron under Alternative 2D in the Delta would be similar to the effects discussed for Alternative 4.

The effects of Alternative 2D relative to Existing Conditions and the No Action Alternative (ELT) are discussed together because the direction and magnitude of predicted change are similar. Relative to the Existing Conditions and No Action Alternative (ELT), Alternative 2D would result in increased long-term average boron concentrations for the 16-year period modeled at most of the interior Delta locations (increases up to 3% at the S. Fork Mokelumne River at Staten Island, 10% at Franks Tract, and 13% at Old River at Rock Slough) (Appendix 8F, *Boron*, Table Bo-28). The long-term average boron concentrations at most of the western Delta assessment locations would not change measurably. The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 µg/L human health advisory objective (i.e., for children) or the 500 µg/L agricultural objective at the majority of assessment locations, which represents no change from the Existing Conditions and No Action Alternative (ELT) (Appendix 8F, *Boron*, Table Bo-3C). A small increase in the frequency of exceedances 500 µg/L agricultural objective at the Sacramento River at Mallard Island (i.e., as much as 3% in the drought period relative to the No Action Alternative [ELT]) would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations. Minor reductions in long-term average assimilative capacity of up to 8% at interior Delta locations (i.e., Old River at Rock Slough) would occur with respect to the 500 µg/L agricultural objective (Appendix 8F, *Boron*, Table Bo-29). However, because the absolute boron concentrations would still be well below the lowest 500 µg/L objective for the protection of the agricultural beneficial use under Alternative 2D, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, *Boron*, Figure Bo-6).

Effects of Alternative 2D in the Delta in the LLT, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to those described above for the ELT. Boron concentrations may be higher at western Delta locations due to greater effects of climate change on sea level rise that would occur in the LLT; however, these effects are independent of the alternative. Further, boron is of concern in waters diverted for agricultural use, which primarily occurs in the interior Delta, and based on Delta source water characteristics (see Table 8-42 in Section 8.3.1.7, *Construction-Specific Considerations Used in the Assessment*), boron concentrations in the interior Delta would be expected to remain suitable for agricultural use.

SWP/CVP Export Service Areas

Under the Alternative 2D, long-term average boron concentrations would decrease at the Banks pumping plant (24%) and at Jones pumping plant (28%) relative to Existing Conditions, and the reductions would be similar compared to No Action Alternative (ELT) (Appendix 8F, *Boron*, Table Bo-28) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing CWA Section 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading. These same effects on boron at the Banks and Jones pumping plants would be expected in the LLT, because the primary effect of climate change on sea level rise and boron concentrations is expected in the western Delta.

Maintenance of SWP and CVP facilities under Alternative 2D would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative (ELT and LLT), Alternative 2D would result in relatively small increases in long-term average boron concentrations in the Delta, not measurably increase boron levels in the lower San Joaquin River, and reduce boron levels in water exported to the SWP/CVP export service areas. However, the predicted changes would not be expected to cause exceedances of applicable objectives or further measurable water quality degradation, and thus would not constitute an adverse effect on water quality.

CEQA Conclusion: Based on the above assessment, any modified reservoir operations and subsequent changes in river flows under Alternative 2D, relative to Existing Conditions, would not be expected to result in a substantial adverse change in boron levels upstream of the Delta. Small increases in boron levels predicted for interior Delta locations in response to a shift in the Delta source water percentages would not be expected to cause exceedances of objectives, or substantial degradation of these water bodies. Alternative 2D maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 2D would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to Existing Conditions, Alternative 2D would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 2D would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing CWA Section 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

Effects on boron from implementation of Environmental Commitments under Alternative 2D would be the same as those described for Alternative 4A.

NEPA Effects: The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 for Alternative 2D present no new direct sources of boron to the affected environment, including areas upstream of the Delta, within the Delta region, and in the SWP/CVP Export Service Areas. Habitat restoration activities in the Delta, while involving increased land and water interaction within these habitats, would not be anticipated to contribute boron which is primarily associated with source water inflows to the Delta (i.e., San Joaquin River, agricultural drainage, and Bay source water). Moreover, some habitat restoration would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated boron concentrations, which would be considered an improvement compared to the No Action Alternative (ELT and LLT). Consequently, as they pertain to boron, implementation of the Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 for Alternative 2D would not present new or substantially changed sources of boron to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP Export Service Areas. As such, their implementation would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or other criteria would be exceeded in water bodies of the affected environment located upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas or substantially degrade the quality of these water bodies, with regard to boron. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), under Alternative 2D in the ELT there would be no expected change to the sources of bromide in the Sacramento River and eastside tributary watersheds. Thus, changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of bromide in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions and would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial bromide increases (Appendix 8E, *Bromide*, Table 24). Moreover, there are no existing municipal intakes on the lower San Joaquin River, which is the beneficial use most sensitive to elevated bromide concentrations. Consequently, Alternative 2D in the ELT would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the San Joaquin River, the eastside tributaries, or their associated reservoirs upstream of the Delta due to changes in bromide concentrations.

Effects of Alternative 2D in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect bromide sources in these areas.

Delta

Estimates of bromide concentrations at Delta assessment locations were generated using a mass balance approach, and using relationships between EC and chloride and between chloride and bromide and DSM2 EC output. See Section 8.3.1.3, *Plan Area*, for more information regarding these modeling approaches. The assessment below identifies changes in bromide at Delta assessment locations based on both approaches.

Based on the mass balance modeling approach for bromide, relative to Existing Conditions, Alternative 2D long-term average bromide concentrations would increase in the S. Fork Mokelumne River at Staten Island, and decrease at all other assessment locations (Appendix 8E, *Bromide*, Table 22). Average bromide concentrations at Staten Island would increase from 50 µg/L under Existing Conditions to 55 µg/L (10% increase) for the modeled 16-year hydrologic period (1976–1991). However, multiple interior and western Delta assessment locations would have an increased frequency of exceedance of 50 µg/L, which is the CALFED Drinking Water Program goal for bromide as a long-term average applied to drinking water intakes (Appendix 8E, Table 22). These locations are the S. Fork Mokelumne River at Staten Island, Franks Tract, Old River at Rock Slough, Sacramento River at Emmaton, San Joaquin River at Antioch, and Sacramento River at Mallard Island. The greatest increase in frequency of exceedance of the CALFED Drinking Water Program long-term goal of 50 µg/L would occur in the S. Fork Mokelumne River (12% increase) and Sacramento River at Emmaton (5% increase). The increase in frequency of exceedance of the 50 µg/L threshold at the other locations would be 2% or less. Similarly, these locations and North Bay Aqueduct at Barker Slough would have an increased frequency of exceedance of 100 µg/L, which is the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts (Appendix 8E, Table 22). The greatest increase in frequency of exceedance of 100 µg/L would occur at Franks Tract (6% increase). The increase in frequency of exceedance of the 100 µg/L threshold at the other locations would be 5% or less.

Changes in long-term average bromide concentrations and changes in threshold exceedance frequencies relative to the No Action Alternative (ELT) are generally of similar magnitude to those previously described relative to Existing Conditions (Appendix 8E, *Bromide*, Table 22). However, unlike the Existing Conditions comparison, relative to the No Action Alternative (ELT), long-term average bromide concentrations in the San Joaquin River at Buckley Cove and the North Bay Aqueduct at Barker Slough would increase under Alternative 2D, although the increases would be relatively small (<2%). Further, at the North Bay Aqueduct, the frequency of exceedance of the 50 µg/L would increase from 35% to 40% and the frequency of exceedance of the 100 µg/L threshold would increase from 0% to 1%. Also, there would not be an increased exceedance of the 100 µg/L threshold at Emmaton and Rock Slough.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide were consistent with the discussion above, and assessment of bromide using these modeling results lead to the same conclusions as are presented above for the mass balance approach (Appendix 8E, *Bromide*, Table 23).

The magnitude of bromide concentration increases at Mallard Slough and in the San Joaquin River at Antioch during their historical months of use, relative to Existing Conditions and the No Action Alternative (ELT), would be generally similar to or less than those described for Alternative 4 (Appendix 8E, *Bromide*, Table 25), and the frequency of exceedance of bromide thresholds would be similar (Appendix 8E, Table 22). As described for Alternative 4, the use of seasonal intakes at these locations is largely driven by acceptable water quality, and thus has historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at Antioch and Mallard Slough would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

The effects of Alternative 2D in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to that described above. There may be higher bromide concentrations in the LLT in the western Delta, but this would be associated with sea level rise, not the project alternative, because the primary source of bromide to the Delta is sea water intrusion.

SWP/CVP Export Service Areas

Under Alternative 2D, long-term average bromide concentrations at the Banks and Jones pumping plants, based on the mass balance modeling approach, would decrease. Long-term average bromide concentrations for the modeled 16-year hydrologic period at the pumping plants would decrease by as much as 50% relative to Existing Conditions and 47% relative to the No Action Alternative (ELT) (Appendix 8E, *Bromide*, Table 22). As a result, less frequent exceedances of the 50 μg/L and 100 μg/L assessment thresholds would occur and an overall improvement in SWP/CVP Export Service Areas water quality would occur respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also occur since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide are consistent with the mass balance results, and assessment of bromide using these modeling results leads to the same conclusions (Appendix 8E, Table 23).

The effects of Alternative 2D in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to that described above, because the sea level rise that could occur in the LLT would not be expected to result in substantial bromide contributions to the water exported at Banks and Jones pumping plants.

Maintenance of SWP and CVP facilities under Alternative 2D would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, the operations and maintenance activities under Alternative 2D, relative to the No Action Alternative (ELT and LLT) would result in an increased frequency of exceedance of the CALFED Drinking Water Program long-term bromide goal of 50 μg/L at the S. Fork Mokelumne River at Staten Island, Franks Tract, Sacramento River at Emmaton, San Joaquin River at Antioch, Sacramento River at Mallard Island, and North Bay Aqueduct at Barker Slough. The frequency of exceedance of the 100 μg/L threshold for protection against the formation of disinfection byproducts in treated drinking water would increase by 4% at Franks Tract, 3% at Antioch, and 1% at Staten Island, Mallard Island, and Barker Slough. However, long-term average bromide concentrations would increase only in the S. Fork Mokelumne River at Staten Island, San Joaquin River at Buckley Cove, and North Bay Aqueduct at Barker Slough; long-term average bromide concentrations at the other assessment locations will be the same or decrease. The long-term bromide concentration in the S. Fork Mokelumne River at Staten Island would be less than the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts, and the increase in the San Joaquin River at Buckley Cove and North Bay Aqueduct at Barker Slough would be minimal (<2%). Thus, these increased bromide concentrations are not expected to result in adverse effects to MUN beneficial uses, or any other beneficial use, at these locations. Based on these findings, this effect is determined to not be adverse.

CEQA Conclusion: While greater water demands under Alternative 2D would alter the magnitude and timing of reservoir releases north and east of the Delta, these activities would have negligible, if any, effect on the sources of bromide, and ultimately the concentration of bromide in the Sacramento River, the San Joaquin River, the eastside tributaries, and the various reservoirs of the related watersheds, as described for Alternative 4 (see Section 8.3.3.9).

Under Alternative 2D there would be an increased frequency of exceedance of the 50 μg/L and 100 μg/L bromide thresholds for protecting against the formation of disinfection byproducts in treated drinking water at the S. Fork Mokelumne River at Staten Island, Franks Tract, Old River at Rock Slough, Sacramento River at Emmaton, San Joaquin River at Antioch, and Sacramento River at Mallard Island. The North Bay Aqueduct at Barker Slough also would have an increased exceedance of the 100 μg/L threshold (from 0% to 1%). However, long-term average bromide concentrations would increase only in the S. Fork Mokelumne River at Staten Island and decrease at all other assessment locations. The long-term bromide concentration in the S. Fork Mokelumne River at Staten Island (55 μg/L) would be less than the 100 μg/L believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts. Further, as described for Alternative 4 (see Section 8.3.3.9), the use of seasonal intakes at Antioch and Mallard Island is largely driven by acceptable water quality, and thus has historically been opportunistic and opportunity to use these intakes would remain. Thus, these increased bromide concentrations would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Long-term average bromide concentrations at the Banks and Jones pumping plants are predicted to decrease by as much as 50% relative to Existing Conditions and there would be less frequent exceedance of bromide concentration thresholds.

Based on the above, Alternative 2D would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria because none exist for bromide. Alternative 2D would not result in any substantial change in long-term average bromide concentration or exceed 50 and 100 μg/L assessment threshold concentrations by frequency, magnitude, and geographic extent that would result in adverse effects on any beneficial uses within affected water bodies. Bromide is not a bioaccumulative constituent and thus concentrations under this alternative would not result in bromide bioaccumulating in aquatic organisms. Increases in exceedances of the 100 μg/L assessment threshold concentration would be 6% or less at all locations assessed, which is considered to be less than substantial long-term degradation of water quality. The levels of bromide degradation that may occur under the Alternative 2D would not be of sufficient magnitude to cause substantially increased risk for adverse effects on any beneficial uses of water bodies within the affected environment. Bromide is not CWA Section 303(d) listed and thus the minor increases in long-term average bromide concentrations would not affect existing beneficial use impairment because no such use impairment currently exists for bromide. Based on these findings, this impact is less than significant. No mitigation is required.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would present no new sources of bromide to the affected environment, including areas Upstream of the Delta, within the Plan Area, and the SWP/CVP Export Service Areas. Some habitat restoration activities would occur on lands in the Delta formerly used for irrigated agriculture. Such replacement or substitution of land use activity would not be expected to result in new or increased sources of bromide to the Delta. Therefore, as they pertain to bromide, implementation of these Environmental Commitments would not be expected to adversely affect MUN beneficial use, or any other beneficial uses, of the affected environment.

Environmental Commitment 4 would result in some tidal habitat restoration, however, the areal extent would be small relative to the existing and No Action Alternative tidal area and, thus not expected to appreciably affect the magnitude of daily tidal water exchange at the restoration areas or alter other hydrodynamic conditions in adjacent Delta channels that would result in measurable bromide concentration changes.

In summary, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 2D relative to the No Action Alternative (ELT and LLT), would have negligible, if any, effects on bromide concentrations. Therefore, the effects on bromide from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

***CEQA Conclusion*:** Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 2D would not present new or substantially changed sources of bromide to the affected environment. Some Environmental Commitments may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution would not be expected to substantially increase or present new sources of bromide. Thus, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would have negligible, if any, effects on bromide concentrations throughout the affected environment, would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria because none exist for bromide, and would not cause changes in bromide concentrations that would result in significant impacts on any beneficial uses within affected water bodies. Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause significant long-term water quality degradation such that there would be greater risk of significant impacts on beneficial uses, would not cause greater bioaccumulation of bromide, and would not further impair any beneficial uses due to bromide concentrations because no uses are currently impaired due to bromide levels. Based on these findings, this impact is considered less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 2D on chloride concentrations in reservoirs and rivers upstream of the Delta would be the similar to those effects described for Alternative 4 (see Section 8.3.3.9). Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. There would be no expected change to the sources of chloride in the Sacramento River and eastside tributary watersheds, and changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of chloride in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions and would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial chloride increases. Moreover, there are no existing municipal intakes on the lower San Joaquin River. Consequently, Alternative 2D in the ELT would not be expected to cause exceedances of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Effects of Alternative 2D in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect chloride sources in these areas.

Delta

Estimates of chloride concentrations at Delta assessment locations were generated using a mass balance approach and EC-chloride relationships and DSM2 EC output. See Section 8.3.1.3, *Plan Area*, for more information regarding these modeling approaches. The assessment below identifies changes in chloride at Delta assessment locations based on both approaches.

Modeling of chloride using both the mass balance approach and EC-chloride relationship predicts that Alternative 2D in the ELT would result in reduced long-term average chloride concentrations, relative to Existing Conditions, for the 16-year period modeled at all assessment locations except for the S. Fork Mokelumne River at Staten Island. The increase in long-term average chloride concentration at Staten Island would be 1 mg/L (9%) based on the mass balance modeling and 1 mg/L (3%) based on the EC-chloride relationship (Appendix 8G, *Chloride*, Tables Cl-73 and Cl-74). These increases are extremely small in absolute terms and relative to applicable water quality objectives, and are within the estimated modeling uncertainty. The results differ from Alternative 4, under which there would be increased long-term average chloride concentrations also at the North Bay Aqueduct at Barker Slough. The change in long-term average chloride concentrations relative to the No Action Alternative (ELT) would be similar to those relative to Existing Conditions.

The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses Relative to Existing Conditions

Estimates of chloride concentrations generated using EC-chloride relationships were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at Antioch and Contra Costa Pumping Plant #1. The modeled frequency of objective exceedance would decrease at the Contra Costa Pumping Plant #1 from 7% of years under Existing Conditions to 0% of years under Alternative 2D in the ELT (Appendix 8G, *Chloride*, Table Cl-64).

Evaluation of the 250 mg/L Bay-Delta WQCP objective for chloride utilized results from both the mass balance approach and EC-chloride relationship. The basis for the evaluation was the predicted number of days the objective would be exceeded for the modeled 16-year period.

Based on the mass balance approach, there would be a decreased frequency of exceedance of the 250 mg/L objective under Alternative 2D, relative to Existing Conditions, at all locations except in the Sacramento River at Mallard Island and the San Joaquin River at Antioch. In the Sacramento

River at Mallard Island, the frequency of objective exceedance would increase from 85% under Existing Conditions to 86% under Alternative 2D for the entire period modeled (Appendix 8G, *Chloride*, Table Cl-81). In the San Joaquin River at Antioch, there would be an increase in chloride objective exceedance during the drought period modeled, from 82% to 83%. These changes are within the uncertainty of the modeling approach.

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3, *Plan Area*) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 2D, the modeled frequency of objective exceedance would decrease, from 6% of modeled days under Existing Conditions, to 2% of modeled days under Alternative 2D (Appendix 8G, *Chloride*, Table Cl-63).

The mass balance results also indicate reduced assimilative capacity with respect to the 250 mg/L objective during certain months and at certain locations. In the San Joaquin River at Antioch, there would be a reduction in assimilative capacity in March and April of up to 14% for the 16-year period modeled, and 53% for the drought period modeled (Appendix 8G, *Chloride*, Table Cl-75). Assimilative capacity at the Contra Costa Pumping Plant #1 also would be reduced, in February through April and June, by up to 5% for the entire period modeled and in June by 5% for the drought period modeled. These estimates include the effect of climate change and sea level rise, as well as the alternative. Comparisons to the No Action Alternative (ELT) below provide an assessment of the effect of the alternative alone.

When utilizing the EC-chloride relationship to model chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity would be similar to those discussed when utilizing the mass balance modeling approach (Appendix 8G, *Chloride*, Tables Cl-76 and Cl-82). However, the EC-chloride relationships generally predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, *Plan Area*, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

CWA Section 303(d) Listed Water Bodies–Relative to Existing Conditions

Tom Paine Slough in the southern Delta is on the state's CWA Section 303(d) list for chloride with respect to the secondary MCL of 250 mg/L. Monthly average chloride concentrations at the Old River at Tracy Road for the 16-year period modeled, which represents the nearest DSM2-modeled location to Tom Paine Slough, would be generally similar under Alternative 2D in the ELT relative to Existing Conditions, and thus, would not be further degraded on a long-term basis (Appendix 8G, *Chloride*, Figure Cl-17).

Suisun Marsh also is on the state's CWA Section 303(d) list for chloride in association with the Bay-Delta WQCP objectives for maximum allowable salinity during the months of October through May, which establish appropriate seasonal salinity conditions for fish and wildlife beneficial uses. With respect to Suisun Marsh, the monthly average chloride concentrations for the 16-year period modeled would generally increase by <10% under Alternative 2D in the ELT relative to Existing Conditions in March and April at the Sacramento River at Mallard Island (Appendix 8G, *Chloride*, Figure Cl-18), at Collinsville (Appendix 8G, *Chloride*, Figure Cl-19), and in Montezuma Slough at Beldon's Landing (Appendix 8G, *Chloride*, Figure Cl-20), and remain similar or decrease in all other months. Chloride levels in Suisun Marsh are highly dynamic on a sub-daily basis as a result of tidal influences. The changes identified above are small relative to normal day-to-day variability in chloride in Suisun Marsh. For these reasons, any changes in chloride in Suisun Marsh are expected to have no adverse effect on marsh beneficial uses. These changes reflect the effect of climate change and sea level rise, as well as the alternative. Comparisons to the No Action Alternative (ELT) below provide an assessment of the effect of the alternative alone.

Municipal Beneficial Uses Relative to No Action Alternative (ELT)

Similar to the assessment conducted for Existing Conditions, estimates of chloride concentrations generated from EC-chloride relationships were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses. For Alternative 2D in the ELT, the modeled frequency of objective exceedance would not change at the Contra Costa Pumping Plant #1—both the No Action Alternative (ELT) and Alternative 2D in the ELT would have 0% exceedance (Appendix 8G, *Chloride*, Table Cl-64).

Based on the mass balance approach, the frequency of exceedance of the 250 mg/L objective under Alternative 2D in the ELT would be the same, or would decrease, at all locations relative to the No Action Alternative (ELT) (Appendix 8G, *Chloride*, Table Cl-81).

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3, *Plan Area*) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 2D, the modeled frequency of objective exceedance would decrease, from 8% of modeled days under the No Action Alternative (ELT), to 2% of modeled days under Alternative 2D (Appendix 8G, *Chloride*, Table Cl-63).

Estimates of long-term use of assimilative capacity using the mass balance results indicated the potential for reduced assimilative capacity with respect to the 250 mg/L objective for certain months and locations. Calculations using the long-term monthly and annual average concentrations showed that in the San Joaquin River at Antioch, there would be a reduction in assimilative capacity in April of 15% for the drought period modeled (Appendix 8G, *Chloride*, Table Cl-75). However, this approach used long-term average chloride concentrations, which can be heavily influenced by changes in a small number of years when chloride concentrations would already be very high. Additionally, when long term averages are just below the objective, very small changes in chloride that are within the modeling uncertainty can result in very high estimates of use of assimilative capacity. To further investigate the potential for water quality degradation with respect to chloride, the concentrations of chloride during individual water years was examined.

This further examination was limited to the mass balance approach, since when utilizing the EC-chloride relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity were similar to those discussed for the mass balance modeling approach (Appendix 8G, *Chloride*, Tables Cl-82 and Cl-76). However, utilizing the EC-chloride relationships generally predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, *Plan Area*, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

Figure Cl-21 in Appendix 8G, *Chloride,* shows chloride concentrations in April during the 5-year drought period (1987–1991) at Antioch, where Table Cl-75 in Appendix 8G indicated 15% use of assimilative capacity. The figure shows that during 3 of the 5 years, chloride concentrations increased relative to the No Action Alternative (ELT) and decreased in the other 2 years. The absolute differences estimated are fairly small and may be within modeling uncertainty. Figures Cl-22 and Cl-23 in Appendix 8G show a box and whisker plot and exceedance plot for April at Antioch for all dry and critical water years modeled (not just the 1987–1991 drought period). These graphs show that while the median chloride concentration is increased relative to the No Action Alternative (ELT), the maximum, 25th percentile, and 75th percentile values are all decreased. Based on this analysis, long-term degradation is not expected at Antioch in April during drought years.

Based on the low level of water quality degradation estimated for the western Delta, and the lack of exceedance of water quality objectives, Alternative 2D is not expected to have substantial adverse effects on municipal and industrial beneficial uses in the western Delta.

CWA Section 303(d) Listed Water Bodies–Relative to No Action Alternative (ELT)

With respect to the state's CWA Section 303(d) listing for chloride, Alternative 2D would generally result in changes similar to those discussed for the comparison to Existing Conditions. Monthly average chloride concentrations at Tom Paine Slough would not be further degraded on a long-term basis, based on changes that would occur in Old River at Tracy Road (Appendix 8G, *Chloride*, Figure Cl-17). Modeling indicated that monthly average chloride concentrations at source water channel locations for the Suisun Marsh remain similar or decrease relative to the No Action Alternative (ELT) (Appendix 8G, Figures Cl-18, Cl-19, and Cl-20). For these reasons, any changes in chloride in Suisun Marsh are expected to have no adverse effect on marsh beneficial uses.

The effects of Alternative 2D in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to effects in the ELT. With greater climate change and sea level rise, additional outflow may be required at certain times to prevent increases in chloride in the west Delta. Small increases in chloride concentrations may occur in some areas, but it is not expected that these increases would cause exceedance of Bay-Delta WQCP objectives of cause substantial long-term degradation that would impact municipal and industrial beneficial uses.

SWP/CVP Export Service Areas

Under Alternative 2D in the ELT, long-term average chloride concentrations at the Banks and Jones pumping plants, based on the mass balance analysis of modeling results for the 16-year period, would decrease relative to Existing Conditions. Chloride concentrations would be reduced by 49% at Banks pumping plant (Appendix 8G, *Chloride*, Table Cl-73). At Jones pumping plant, chloride concentrations would be reduced 47% (Appendix 8G, Table Cl-73). The frequency of exceedances of applicable water quality objectives would decrease relative to Existing Conditions, for both the 16-year period and the drought period modeled (Appendix 8G, Table Cl-81). The chloride concentration changes relative to the No Action Alternative (ELT) would be similar. Consequently, water exported into the SWP/CVP Export Service Areas would generally be of similar or better quality with regard to chloride relative to Existing Conditions and the No Action Alternative (ELT). Results of the modeling approach which utilized a EC-chloride relationship are consistent these results, and assessment of chloride using these modeling output results in the same conclusions as for the mass balance approach (Appendix 8G, *Chloride*, Tables Cl-74 and Cl-82).

Commensurate with the reduced chloride concentrations in water exported to the SWP/CVP Export Service Area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely alleviate chloride concentrations at Vernalis.

The effects of Alternative 2D in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be very similar to effects in the ELT. The difference in these timeframes that could contribute to EC differences between the ELT and LLT is climate change and sea level rise, and thus would not be due to the alternative.

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

***NEPA Effects*:** In summary, relative to the No Action Alternative (ELT and LLT), Alternative 2D would not result in substantially increased chloride concentrations in the Delta on a long-term average that would result in adverse effects on the municipal and industrial water supply beneficial use, or any other beneficial use. Additional exceedance of the 150 mg/L and 250 mg/L objectives is not expected, and substantial long-term degradation is not expected that would result in adverse effects on the municipal and industrial water supply beneficial use, or any other beneficial use. Based on these findings, this effect is determined to not be adverse.

***CEQA Conclusion*:** Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under Alternative 2D relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, Alternative 2D would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, Alternative 2D would not result in substantially increased chloride concentrations in the Delta on a long-term average basis that would result in adverse effects on the municipal and industrial water supply beneficial use. Additional exceedance of the 150 mg/L and 250 mg/L objectives is not expected, and substantial long-term degradation is not expected that would result in adverse effects on the municipal and industrial water supply beneficial use.

Chloride concentrations would be reduced under Alternative 2D in water exported from the Delta to the SWP/CVP Export Service Areas thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under the Alternative 2D would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 2D maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas

Based on these findings, this impact is determined to be less than significant. No mitigation is required. Despite the fact that no mitigation is required, DWR proposed to further reduce any impacts by implementing Mitigation Measure WQ-7e.

Mitigation Measure WQ-7e: Implement Terms of the Contra Costa Water District Settlement Agreement

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 2D would present no new direct sources of chloride to the affected environment, including areas Upstream of the Delta, within the Plan Area, and the SWP/CVP Export Service Areas. Consequently, as they pertain to chloride, implementation of these Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment. Moreover, some habitat restoration activities would occur on lands within the Delta currently used for irrigated agriculture. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement relative to the No Action Alternative (ELT and LLT). Therefore, the effects on chloride from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

CEQA Conclusion: Implementation of the Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 2D would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP Export Service Areas. Replacement of irrigated agricultural land uses in the Delta with habitat restoration may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance

As described in detail for Alternative 4 (see Section 8.3.3.9), DO levels are primarily affected by water temperature, flow velocity, turbulence, amounts of oxygen demanding substances present (e.g., ammonia, organics), and rates of photosynthesis (which is influenced by nutrient levels), respiration, and decomposition. Water temperature and salinity affect the maximum DO saturation level (i.e., the highest amount of oxygen the water can dissolve). Flow velocity affects the turbulence and re-aeration of the water (i.e., the rate at which oxygen from the atmosphere can be dissolved in water). High nutrient content can support aquatic plant and algae growth, which in turn generates oxygen through photosynthesis and consumes oxygen through respiration and decomposition.

As described for Alternative 4, amounts of oxygen demanding substances present (e.g., ammonia, organics) in the reservoirs and rivers upstream of the Delta, rates of photosynthesis (which is influenced by nutrient levels/loading), and respiration and decomposition of aquatic life is not expected to change sufficiently under Alternative 2D (ELT and LLT) to substantially alter DO levels relative to Existing Conditions or the No Action Alternative (ELT and LLT). Further, the rivers upstream of the Delta are well oxygenated and experience periods of supersaturation (i.e., when DO level exceeds the saturation concentration). Because these are large, turbulent rivers, any reduced DO saturation level that would be caused by an increase in temperature under Alternative 2D would not be expected to cause DO levels to be outside of the range seen historically. Flow changes that would occur under Alternative 2D would not be expected to have substantial effects on river DO levels; likely, the changes would be immeasurable. This is because sufficient turbulence and interaction of river water with the atmosphere would continue to occur to maintain water saturation levels (due to these factors) at levels similar to that of Existing Conditions and the No Action Alternative (ELT and LLT).

Also as described for Alternative 4, salinity changes would generally have relatively minor effects on Delta DO levels. Further, the relative degree of tidal exchange of flows and turbulence, which contributes to exposure of Delta waters to the atmosphere for reaeration, would not be expected to substantially change relative to Existing Conditions or the No Action Alternative (ELT and LLT), such that these factors would reduce Delta DO levels below objectives or levels that protect beneficial uses. Similarly, increased temperature under Alternative 2D (ELT and LLT), which would be due to climate change, would generally have relatively minor effects on Delta DO levels, relative to Existing Conditions.

Similar to Alternative 4, flows in the San Joaquin River at Stockton were evaluated under Alternative 2D and are shown in Figure 8-65b. The figure shows that while flows do would change somewhat, they are would generally be within the range of flows seen under Existing Conditions and the No Action Alternative. Reports indicate that the aeration facility performs adequately under the range of flows from 250–1,000 cfs (ICF International 2010). Based on the above, the expected changes in flows in the San Joaquin River at Stockton are not expected to substantially move the point of minimum DO, and therefore the aeration facility will would likely still be located appropriately to keep DO levels above Basin Plan objectives.

Overall, assuming continued operation of the aerators, the alternative is not expected to have a substantial impact adverse effect on DO in the Deep Water Ship Channel. It is expected that DO levels in the Deep Water Ship Channel, which is CWA Section 303(d) listed as impaired due to low DO, would remain similar to those under Existing Conditions and the No Action Alternative (ELT and LLT) or improve as TMDL-required studies are completed and actions are implemented to improve DO levels. DO levels in other Clean Water Act Section 303(d)-listed waterways would not be expected to change relative to Existing Conditions or the No Action Alternative (ELT and LLT), as the circulation of flows, tidal flow exchange, and re-aeration would continue to occur.

In the SWP/CVP Export Service Areas, the primary factor that would affect DO in the conveyance channels and ultimately the receiving reservoirs would be changes in the levels of nutrients and oxygen-demanding substances and DO levels in the exported water. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions or the No Action Alternative (ELT and LLT) due to water quality regulations, canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

NEPA Effects: Because DO levels are not expected to change substantially relative to the No Action Alternative (ELT and LLT), the effects on DO from implementing Alternative 2D (ELT and LLT) are determined to not be adverse.

CEQA Conclusion: The effects of Alternative 2D on DO levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for Alternative 4 (see Section 8.3.3.9). Reservoir storage reductions that would occur under Alternative 2D, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state regulates the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters, relative to Existing Conditions. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are CWA Section 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. Based on these findings, this impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Environmental Commitments 3, 4, and 6–11 would involve habitat restoration actions. The increased habitat provided by these Environmental Commitments could contribute to an increased biochemical or sediment demand, through contribution of organic carbon and plants decaying. However, the areal extent of new habitat would be small relative to existing and No Action Alternative habitat areas, and similar habitat existing in the Delta is not identified as contributing to adverse DO conditions. The remaining Environmental Commitments would not be expected to affect DO levels because they are actions that do not affect the presence of oxygen-demanding substances. Therefore, the effects on DO from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

CEQA Conclusion: It is expected that DO levels in the Upstream of the Delta Region, in the Plan Area, or in the SWP/CVP Export Service Areas following implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 2D would not be substantially different from existing DO conditions, because these would contribute to a minimal, localized change in oxygen-demanding substances associated with habitat restoration, if at all. Therefore, these Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels would be expected, long-term water quality degradation would not be expected, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are CWA Section 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and impairment of these areas would not be expected. Based on these findings, this impact would be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 2D on EC levels in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 (see Section 8.3.3.9). The extent of new urban growth would be less in the ELT, thus discharges of EC-elevating parameters in runoff and wastewater discharges to water bodies upstream of the Delta would be expected to be less than in the LLT. However, the state is regulating point source discharges of EC-related parameters and implementing a program to further decrease loading of EC-related parameters to tributaries. Based on these considerations, and those described in Section 8.3.3.9, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, or their associated reservoirs upstream of the Delta would not be expected to be outside the ranges occurring under Existing Conditions.

For the San Joaquin River, increases in EC levels under Alternative 2D could occur, but would be slightly less than those described for Alternative 4 (see Section 8.3.3.9). This is because the effects of climate change on flows, which could affect dilution of high EC discharges, would be less in the ELT. The implementation of the adopted TMDL for the San Joaquin River at Vernalis and the ongoing development of the TMDL for the San Joaquin River upstream of Vernalis are expected to contribute to improved EC levels. Based on these considerations, substantial changes in EC levels in the San Joaquin River relative to Existing Conditions would not be expected to be of sufficient magnitude and geographic extent that would result in adverse effects on any beneficial uses, or substantially degrade the quality of these water bodies, with regard to EC.

Delta

Initial review of modeling results indicated that Alternative 2D would potentially result in an increase in the number of days the Bay-Delta WQCP EC objectives would be exceeded in the Sacramento River at Emmaton, relative to Existing Conditions, and San Joaquin River at San Andreas Landing and Prisoners Point, relative to both Existing Conditions and No Action Alternative (ELT) (Appendix 8H, *Electrical Conductivity*, Table EC-26). To understand and interpret these results, considerations must be made regarding uncertainty in the modeling and results from sensitivity analyses. In addition, modeling results indicate there would be small increases in long-term monthly average EC at modeled Suisun Marsh locations relative to Existing Conditions. These locations are addressed in detail below At all other locations, the level of exceedance and modeled average EC levels under the alternative was approximately equivalent or lower than under Existing Conditions and the No Action Alternative (ELT).

Sacramento River at Emmaton

Modeling results indicated that the Emmaton EC objective would be exceeded more often under Alternative 2D than under Existing Conditions, but less often relative to the No Action Alternative (ELT). The modeling results also indicated that increases in EC could cause substantial water quality degradation in summer months of below normal, dry and critical water years. However, these increases in exceedance of the objective and degradation are expected to be addressed via real-time operations, including real time management of the north Delta and south Delta intakes, as well as Delta Cross Channel operation. Further discussion is provided below.

Modeling results indicated that the percentage of days the Emmaton EC objective would be exceeded for the entire period modeled (1976–1991) would increase from 6% under Existing Conditions to 7%; there would be a 5% decrease relative to the No Action Alternative (ELT), from 12% to 7% (Appendix 8H, *Electrical Conductivity*, Table EC-26). The percentage of days out of compliance would increase from 11% under Existing Conditions to 15%; there would be a 6% decrease relative to the No Action Alternative (ELT), from 21% to 15% (Appendix 8H, Table EC-26). The comparison of the alternative to Existing Conditions reflects changes due both to operation of the alternative as well as effects of sea level rise due to climate change. The comparison of the alternative to the No Action Alternative (ELT) reflects changes in EC due solely to operations of the alternative. Based on the comparison to the No Action Alternative (ELT), the alternative would not contribute to additional exceedance of the EC objective at Emmaton.

The results of the EC modeling indicate there would be months with substantial degradation relative to the No Action Alternative (ELT), particularly during the drought period modeled. Long-term average EC levels at Emmaton would increase in the months of July through September by 3–7% for the entire period modeled (1976–1991), and in the months of July and August by 4–29% during the drought period modeled (1987–1991), relative to the No Action Alternative (ELT) (Appendix 8H, *Electrical Conductivity*, Table EC-30). The largest increases in EC would occur in below normal, dry and critical water year types. These periods of degradation are expected to be addressed via real-time operations. The level to which modeling output depicts degradation of water quality with respect to EC is primarily a function of the modeling not being able to fully capture how the system would be operated in real-time to minimize or avoid such degradation

Discussions with SWP operators indicated that real-time operations would ensure that the Bay-Delta WQCP EC objectives at Emmaton, applicable from April 1 through August 15, would be met. In latter August and September, the Threemile Slough standard in the North Delta Water Agency Agreement and the Bay-Delta WQCP municipal and industrial objective at Rock Slough are in effect. During this period of the year, the coordinated operations of the SWP/CVP system strives to meet both standards in the most water-efficient method available to the CVP and SWP. Real-time operation would result in less EC degradation than depicted by modeling output because in order to comply with Bay-Delta WQCP objectives and the the North Delta Water Agency Agreement during the summer period, operators could, for example, increase upstream reservoir releases for necessary periods of time, reduce North Delta diversions, and/or close (short-term) the Delta Cross Channel. These options as well as real-time and forecasted tides, winds and barometric pressure are considered when the projects schedule daily operations, which the modeling does not fully capture.

Alternaltive 2D does not change the Bay-Delta WQCP objectives or the the North Delta Water Agency Agreement which are primary drivers of operations and resulting water quality in the Sacramento River at at Emmaton during late August and September. Therefore, the EC degradation at Emmaton that would occur upon implementation of Alternative 2D would be lesser than that shown by the modeling and would not be expected to differ substantially from that which would occur under the No Project Alternative because the compliance targets are not changing due to Alternative 2D during these months and real-time operations would achieve the compliance targets.

The modeling results also show that in the remaining months there would be decreases in EC relative to the No Action Alternative (ELT) of 2–27% for the entire period modeled and 2–32% for the drought period modeled. These decreases would contribute to the long-term average EC levels decreasing by 10% for the entire period modeled and 9% for the drought period modeled (Appendix 8H, Table EC-30).

San Joaquin River at San Andreas Landing

Alternative 2D is not expected to have adverse effects on EC in the San Joaquin River at San Andreas Landing, relative to Existing Conditions and the No Action Alternative (ELT). Modeling results estimated that the percentage of days the San Andreas Landing EC objective would be exceeded would increase by <1% relative to Existing Conditions, and the percentage of days out of compliance would increase from 1% under Existing Conditions to 2% (Appendix 8H, *Electrical Conductivity*, Table EC-26). San Andreas Landing average EC would decrease 15% for the entire period modeled and 12% during the drought period modeled, relative to Existing Conditions (Appendix 8H, Table EC-30). Results relative to the No Action Alternative (ELT) were similar (Appendix 8H, Table EC-30).Sensitivity analyses performed for Alternative 4 Scenario H3 at the LLT indicate that many of these exceedances are likely modeling artifacts, and the small number of remaining exceedances would be small in magnitude, lasting only a few days, and could be addressed with real time operations of the SWP and CVP (see Section 8.3.1.1, *Models Used and Their Linkages*, for a description of real time operations of the SWP and CVP). These sensitivity analyses were only run at the LLT, but it is expected that the findings can generally be extended to the ELT, because the factors affecting salinity findings in the sensitivity analysis (e.g., modeling assumptions, physical hydrodynamic mechanisms) are similar between the ELT and LLT (see Appendix 8H, Attachment 1).

San Joaquin River at Prisoners Point

Modeling results indicated that the EC objective that applies to the San Joaquin River between Jersey Point and Prisoners Point would be exceeded at Prisoners Point more often under Alternative 2D than under Existing Conditions and the No Action Alternative (ELT). However, these exceedances are expected to be able to be addressed via real-time operations, including real time management of the north Delta and south Delta intakes, as well as Head of Old River Barrier management. Further discussion is provided below.

Modeling results estimated that the percentage of days the Prisoners Point EC objective would be exceeded would increase from 6% under Existing Conditions, or 2% under the No Action Alternative (ELT), to 12%, and the percentage of days out of compliance with the EC objective would increase from 10% under Existing Conditions, or 2% under the No Action Alternative (ELT), to 13% (Appendix 8H, *Electrical Conductivity*, Table EC-26). The magnitude of the exceedances is estimated to be very small—the objective is 440 μmhos/cm, and the EC during times of exceedance was generally between 440 and 600 μmhos/cm—and the exceedances generally occurred in drier water years (4 of the 5 years in which there were exceedances were dry water year type), when flows would be lower (Appendix 8H, Figures EC-1 through EC-5). During these times, the EC in the San Joaquin River at Vernalis is greater than in the Sacramento River entering the Delta, and is high enough on its own to cause an exceedance of the Prisoners Point EC objective.

There are two main drivers of the increase in exceedances under the alternative: an increase in San Joaquin River flow at Prisoners Point during April and May under the alternative, relative to Existing Conditions and the No Action Alternative (ELT), and a reduction in the amount of Sacramento River water moving past Prisoners Point under the alternative. The result is increased San Joaquin River water at Prisoners Point, and a reduction in the dilution that the Sacramento River provides the higher EC San Joaquin River. The increase in San Joaquin River flow at Prisoners Point is due to a reduction in pumping from the south Delta under the alternative, as well as due to the presence of the Head of Old River Barrier, which increases flow in the San Joaquin River downstream of Old River by preventing flow from entering Old River. The reduction in Sacramento River water influence is due to less pumping at the south Delta pumping plants (i.e., greater pumping draws more Sacramento River water through the Delta).

Sensitivity analyses conducted for Alternative 4 Scenario H3 at the LLT indicated that if the Head of Old River Barrier was open in April and May, exceedances would be reduced by about 5 percentage points. These sensitivity analyses were only run at the LLT, but it is expected that the findings can generally be extended to the ELT. Results of the sensitivity analyses indicate that the exceedances are partly due also to operations of the alternative itself, perhaps due to Head of Old River Barrier assumptions and south Delta export differences (see Appendix 8H, Attachment 1, for more discussion of these sensitivity analyses). Appendix 8H, Attachment 2, contains a more detailed assessment of the likelihood of these exceedances estimated via modeling adversely affecting aquatic life beneficial uses. Specifically, Appendix 8H, Attachment 2, discusses whether these exceedances might have indirect effects on striped bass spawning in the Delta, and concludes that the high level of uncertainty precludes making a definitive determination for those alternatives. Additionally, by adaptively managing the Head of Old River Barrier and the fraction of south Delta versus north Delta diversions, EC levels at Prisoners Point would likely be decreased to a level that would not adversely affect aquatic life beneficial uses.

Suisun Marsh

For Suisun Marsh October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Modeling results indicate that average EC for the entire period modeled would increase in the Sacramento River at Collinsville during the months of March and April relative to Existing Conditions, by 0.1 mS/cm (Appendix 8H, *Electrical Conductivity*, Table EC-32). In Montezuma Slough at National Steel, average EC levels would increase in March through May by 0.1 mS/cm (Appendix 8H, Table EC-33). There would be similarly small increases in long-term average EC in the months of March through May in Montezuma Slough near Beldon’s Landing, Chadbourne Slough near Sunrise Duck Club, and Suisun Slough near Volanti Slough, ranging 0.1–0.3 mS/cm depending on month and location (Appendix 8H, Tables EC-34 through EC-36). Relative to the No Action Alternative (ELT), the modeled long-term average EC under the alternative would be similar or lower from October through May for these locations (Appendix 8H, Tables EC-32 through EC-36).

The Suisun Marsh EC objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated “equivalent or better protection will be provided at the location” (State Water Resources Control Board 2006:14). Long-term average EC increases relative to Existing Conditions may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the Marsh. Given the Bay-Delta WQCP narrative objective regarding “equivalent or better protection” in lieu of meeting specific numeric objectives, the small increases in EC under Alternative 2D, relative to Existing Conditions, would not be expected to adversely affect beneficial uses of Suisun Marsh. While Suisun Marsh is CWA Section 303(d) listed as impaired because of elevated EC, the potential increases in long-term average EC concentrations, relative to Existing Conditions, would not be expected to contribute to additional impairment, because the increase would be so small (<1 mS/cm) relative to the daily fluctuations in EC levels as to not be measurable and beneficial uses would not be adversely affected.

Further, the EC changes in Suisun Marsh relative to Existing Conditions reflect the influence of both operations of the alternative and sea level rise due to climate change, whereas the changes relative to the No Action Alternative (ELT) are due solely to operations of the alternative. As described above, there would be no increase in the long-term average EC at modeled Suisun Marsh locations, and for some locations long-term average EC would decrease. Therefore, it is expected that this alternative would not contribute to exceedances of EC objectives or additional impairment of beneficial uses, as affected by EC or other salinity-related parameters.

The effects of Alternative 2D in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to effects in the ELT. With greater climate change and sea level rise, additional outflow may be required at certain times to prevent increases in EC in the west Delta, but this requirement would not be due to the alternative.

SWP/CVP Export Service Areas

Under Alternative 2D, at the Banks and Jones pumping plants, there would be no exceedance of the Bay-Delta WQCP s 1,000 µmhos/cm EC objective for the entire period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-27). Relative to Existing Conditions, average EC levels under Alternative 2D would decrease 28–29% for the entire period modeled and 27% during the drought period modeled (Appendix 8H, Table EC-30). Relative to the No Action Alternative (ELT), average EC levels would similarly decrease, by 25–26% for the entire period modeled and 25% during the drought period modeled (Appendix 8H, Table EC-30). Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 2D would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas. Rather, Alternative 2D would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows.

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC Alternative 2D would result in lower average EC levels relative to Existing Conditions and the No Action Alternative (ELT) and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

The effects of Alternative 2D in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be very similar to effects in the ELT. The difference in these timeframes that could contribute to EC differences between the ELT and LLT is climate change and sea level rise, and thus would not be due to the alternative.

NEPA Effects: In summary, based on the results of the modeling and sensitivity analyses conducted, it is unlikely that there would be increased frequency of exceedance of agricultural EC objectives in the western, interior, or southern Delta. However, modeling results indicate that there could be increased long-term and drought period average EC levels during the summer months that would occur in the western Delta (i.e., in the Sacramento River at Emmaton) under Alternative 2D relative to the No Action Alternative (ELT), that could contribute to adverse effects on the agricultural beneficial uses. In addition, the increased frequency of exceedance of the San Joaquin River at Prisoners Point EC objective could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. Suisun Marsh is CWA Section 303(d) listed as impaired due to elevated EC, but EC levels are not expected to increase under Alternative 2D, relative to the No Action Alternative (ELT), and thus it is not expected to contribute to additional beneficial use impairment. The increases in EC in the Sacramento River at Emmaton, particularly during summer months of below normal, dry and critical water years, and the additional exceedances of water quality objectives in the San Joaquin River at Prisoners Point constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects.

CEQA Conclusion: River flow rate and reservoir storage reductions that would occur under Alternative 2D, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 2D would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas, and there would be no exceedance of the Bay-Delta WQCP EC objective for this area of the Delta. Average EC levels for the entire period modeled would decrease at both the Banks and Jones pumping plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

Further, relative to Existing Conditions, Alternative 2D would not result in substantial increases in long-term average EC in Suisun Marsh. Thus, EC levels in Suisun Marsh are not expected to further degrade existing EC levels and thus would not contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, any changes in long-term average EC levels would not directly cause bioaccumulative problems in fish and wildlife. Suisun Marsh is CWA Section 303(d) listed as impaired due to elevated EC, but EC levels are not expected to change substantially under Alternative 2D, relative to Existing Conditions, and thus it is not expected that they would contribute to additional beneficial use impairment.

In the Plan Area, Alternative 2D is not expected to result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded, except for at the San Joaquin River at Prisoners Point (fish and wildlife objective; 6% increase). The increased frequency of exceedance of the fish and wildlife objective at Prisoners Point could contribute to adverse effects on aquatic life (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. However, by adaptively managing the Head of Old River Barrier and the fraction of south Delta versus north Delta diversions, EC levels at Prisoners Point would likely be decreased to a level that would not adversely affect aquatic life beneficial uses.

In the Sacramento River at Emmaton, large monthly average increases in EC were modeled to occur during the summer months of the drought period, and more generally in below normal, dry and critical water year types. The increases in drought period average EC levels modeled could cause substantial water quality degradation that would potentially contribute to adverse effects on the agricultural beneficial uses in the western Delta. The comparison to Existing Conditions reflects changes in EC due to both Alternative 2D operations and climate change/sea level rise. The adverse effects expected to occur at Emmaton would be due in part to the effects of climate change/sea level rise, and in part due to Alternative 2D operations. This is evidenced by the significant effects expected in the No Action Alternative (ELT) at Emmaton relative to Existing Conditions, as well as the fact that a lesser level of adverse effects is expected at Emmaton under Alternative 2D relative to the No Action Alternative (ELT). During summer of below normal, dry and critical water years, additional flow in the Sacramento River at Emmaton would reduce or eliminate increases in EC. It is expected that for July–August of below normal, dry and critical water years, real-time operations that would include more precise management of upstream reservoir realeases on a daily basis and less pumping from the north Delta intakes and greater reliance on south Delta intakes than that modeled would allow for enough flow in the Sacramento River at Emmaton to reduce water quality degradation to levels closer to the No Action Alternative that would not be expected to adversely affect beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The western Delta is CWA Section 303(d) listed for elevated EC and the increased EC degradation that was modeled in the western Delta could make beneficial use impairment measurably worse. Based on these findings, this impact in the Plan Area is considered to be significant. Implementation of Mitigation Measure WQ-11 would be expected to reduce these effects to a less-than-significant level.

Mitigation Measure WQ-11: Avoid or Minimize Reduced Water Quality Conditions

Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 4A.

Mitigation Measure WQ-11e: Adaptively Manage Diversions at the North and South Delta Intakes to Reduce or Eliminate Water Quality Degradation in Western Delta

Please see Mitigation Measure WQ-11e under Impact WQ-11 in the discussion of Alternative 4A.

Mitigation Measure WQ-11f: Adaptively Manage Head of Old River Barrier and Diversions at the North and South Delta Intakes to Reduce or Eliminate Exceedances of the Bay-Delta WQCP Objective at Prisoners Point

Please see Mitigation Measure WQ-11f under Impact WQ-11 in the discussion of Alternative 4A.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15 and 16

NEPA Effects: The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would present no new direct sources of EC to the affected environment, including areas upstream of the Delta, within the Delta region, and in the SWP/CVP Export Service Areas. As they pertain to EC, implementation of these Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment. Moreover, some habitat restoration activities would occur on lands within the Delta currently used for irrigated agriculture. Such replacement or substitution of land use activity is not expected to result in new or increased sources of EC to the Delta and, in fact, could decrease EC through elimination of high EC agricultural runoff.

Environmental Commitment 4 would result in some tidal habitat restoration, however, the areal extent would be small relative to the existing and No Action Alternative tidal area and, thus not expected to appreciably affect the magnitude of daily tidal water exchange at the restoration areas or alter other hydrodynamic conditions in adjacent Delta channels that would result in measurable EC changes.

In summary, implementation of the Environmental Commitments would not be expected to adversely affect EC levels in the affected environment and thus would not adversely affect beneficial uses or substantially degrade water quality with regard to EC within the affected environment. Therefore, the effects on EC from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 2D would not present new or substantially changed sources of EC to the affected environment. Thus, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would have negligible, if any, adverse effects on EC levels throughout the affected environment and would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria that would result in adverse effects on any beneficial uses within affected water bodies. Further, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause significant long-term water quality degradation such that there would be greater risk of adverse effects on beneficial uses. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the Alternative 2D on mercury levels in surface waters upstream of the Delta relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because factors that affect mercury concentrations in surface waters upstream of the Delta are similar under Alternatives 4 and 2D. The changes in flow in the Sacramento River under Alternative 2D relative to Existing Conditions and the No Action Alternative (ELT) would not be of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore, mercury loading should not be substantially different due to changes in flow. In addition, even though they may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but would not change substantially because the anticipated changes in flow are not expected to substantially change mercury loading relative to Existing Conditions or the No Action Alternative (ELT).

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

Delta

The effects of Alternative 2D on waterborne concentrations of mercury (Appendix 8I, *Mercury*, Table I-17) and methylmercury (Appendix 8I, Table I-18), and fish tissue mercury concentrations for largemouth bass fillet (Appendix 8I, Tables I-21a and I-21b) were evaluated for nine Delta locations.

Increases in long-term average mercury concentrations relative to Existing Conditions and the No Action Alternative (ELT) would be very small, 0.3 ng/L or less. Also, use of assimilative capacity for mercury relative to the 25 ng/L ecological threshold under Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT), would be very low, approximately 2% or less, as a long-term average, for all Delta locations (Appendix 8I, *Mercury*, Table I-24). These concentration changes and small changes in assimilative capacity for mercury are not expected to result in adverse (or positive) effects to beneficial uses.

Changes in methylmercury concentrations in water also are expected to be very small. The greatest annual average methylmercury concentration under Alternative 2D would be 0.166 ng/L for the San Joaquin River at Buckley Cove, for the drought period modeled, which would be slightly higher than Existing Conditions (0.161 ng/L) and slightly lower than the No Action Alternative (ELT) (0.168 ng/L) (Appendix 8I, *Mercury*, Table I-18). All methylmercury concentrations in water were estimated to exceed the TMDL guidance objective of 0.06 ng/L under Existing Conditions and, therefore, no assimilative capacity exists.

Fish tissue estimates for largemouth bass fillet show small or no increases in mercury concentrations relative to Existing Conditions and the No Action Alternative (ELT) based on long-term annual average concentrations for mercury at the Delta locations (Appendix 8I, *Mercury*, Tables I-21a and I-21b). Concentrations expected for Alternative 2D, with Equation 1, show increases of 7% or less, relative to Existing Conditions and the No Action Alternative (ELT), in all years (Appendix 8I, Table I-21a). Concentrations expected with Equation 2 show increases of 10% or less relative to Existing Conditions and the No Action Alternative (ELT) in all years (Appendix 8I, Table I-21b).

Because the increases are relatively small, and it is not evident that substantive increases are expected at numerous locations throughout the Delta, these changes are expected to be within the uncertainty inherent in the modeling approach, and would likely not be measurable in the environment. See Appendix 8I, *Mercury*, for a complete discussion of the uncertainty associated with the fish tissue estimates. Briefly, the bioaccumulation models contain multiple sources of uncertainty associated with their development. These are related to: analytical variability; temporal and/or seasonal variability in Delta source water concentrations of merthylmercury;

interconversion of mercury species (i.e., the non-conservative nature of methylmercury as a modeled constituent); and limited sample size (both in number of fish and time span over which the measurements were made), among others. Although there is considerable uncertainty in the models used, the results serve as a reasonable approximations of a very complex process. Considering the uncertainty, small (i.e., <20–25%) increases or decreases in modeled fish tissue mercury concentrations at a low number of Delta locations (i.e., 2–3) should be interpreted to be within the uncertainty of the overall approach, and not predictive of actual adverse effects. Larger increases, or increases evident throughout the Delta, can be interpreted as more reliable indicators of potential adverse effects.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 2D at the Jones and Banks pumping plants would be lower than Existing Conditions and the No Action Alternative (ELT) (Appendix 8I, *Mercury*, Tables I-17 and I-18). Therefore, there would be increased assimilative capacity for mercury at these locations (Appendix 8I, Table I-24).

The largest improvements in largemouth bass tissue mercury concentrations and Exceedance Quotients ([EQs]; modeled tissue divided by TMDL guidance concentration) for Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT) at any location within the Delta are expected for the Banks and Jones pumping plants export pump locations. Concentrations expected for Alternative 2D at the export pump locations with Equation 1 in all years show decreases relative to Existing Conditions (10% to 12%) and relative to the No Action Alternative (ELT) (11% to 13%) (Appendix 8I, *Mercury*, Table I-21a). Concentrations expected for Alternative 2D at the export pump locations with Equation 2 in all years show decreases relative to Existing Conditions (14% to 17%) and relative to the No Action Alternative (ELT) (15% to 18%) (Appendix 8I, Table I-21b).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

***NEPA Effects*:** Based on the above discussion, Alternative 2D would not cause concentrations of mercury and methylmercury in water and fish tissue in the affected environment to be substantially different from the No Action Alternative (ELT and LLT) and, thus, would not cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to the No Action Alternative

(ELT and LLT), Alternative 2D would not be expected to increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Based on these findings, the effects of Alternative 2D on mercury in the affected environment are considered to be not adverse.

CEQA Conclusion**:** Under Alternative 2D, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta would not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. However, monthly average waterborne concentrations of total and methylmercury, over the period of record under Alternative 2D would be very similar to Existing Conditions. Similarly, estimates of fish tissue mercury concentrations show small differences would occur among sites for Alternative 2D as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP/CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 2D, as compared to Existing Conditions.

As such, Alternative 2D is expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to Existing Conditions, Alternative 2D would not increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects**:** The potential types of effects on mercury resulting from implementation of the Environmental Commitments under Alternative 2D would be generally similar to those described under Alternative 4 (see Section 8.3.3.9). However, the magnitude of effects on mercury and methylmercury at locations upstream of the Delta, in the Delta, and the SWP/CVP Export Service Areas related to habitat restoration would be considerably lower than described for Alternative 4. This is because the amount of habitat restoration to be implemented under Alternative 2D would be very low compared to the total proposed restoration area that would be implemented under

Alternative 4. The small amount of habitat restoration to be implemented under Alternative 2D may occur on lands in the Delta formerly used for irrigated agriculture. Habitat restoration proposed under Alternative 2D has the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the vicinity of the restored habitat areas. Design of restoration sites would be guided by Environmental Commitment 12, which requires development of site-specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time, although the potential to reduce methylmercury concentrations exists based on current research. Although Environmental Commitment 12 would be implemented with the goal to reduce this potential effect, there remain uncertainties related to site-specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta in the vicinity of the restored areas. Therefore, the effect of Environmental Commitments 3, 4, 6–12, 15, and 16 on mercury and methylmercury is considered to be adverse.

***CEQA Conclusion*:** There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 relative to Existing Conditions. However, in the Delta, due to the small amount of tidal restoration areas proposed, relative to Existing Conditions, uptake of mercury from water and/or methylation of inorganic mercury may increase in localized areas as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Although not quantifiable, on a local level, increases in methylmercury concentrations may be measurable. Methylmercury is CWA Section 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites would be guided by Environmental Commitment 12, which requires development of site-specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time, although the potential to reduce methylmercury concentrations exists based on current research. Although Environmental Commitment 12 would be implemented with the goal to reduce this potential effect, the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant. No mitigation measures would be available until specific restoration actions are proposed. Therefore, this impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (in Section 8.3.3.9), nitrate levels in the major rivers (Sacramento, Feather, American) are low, generally due to ample dilution available in the reservoirs and rivers relative to the magnitude of the point and non-point source discharges, and there is no correlation between historical water year average nitrate concentrations and water year average flow in the Sacramento River at Freeport. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 2D, relative to Existing Conditions or the No Action

Alternative (ELT), are expected to have negligible, if any, effects on average reservoir and river nitrate-N concentrations in the Sacramento River watershed upstream of the Delta.

In the San Joaquin River watershed, nitrate concentrations are higher than in the Sacramento River watershed, owing to use of nitrate based fertilizers throughout the lower watershed. The correlation between historical water year average nitrate concentrations and water year average flow in the San Joaquin River at Vernalis is a weak inverse relationship—that is, generally higher flows result in lower nitrate concentrations, while low flows result in higher nitrate concentrations (linear regression r^2=0.49; Figure 2 in Appendix 8J, *Nitrate*). Under Alternative 2D, long-term average flows at Vernalis would decrease an estimated 1% relative to Existing Conditions and would remain virtually the same relative to the No Action Alternative (ELT). Given the relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River, it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under the No Action Alternative (ELT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

Any negligible changes in nitrate concentrations that may occur under Alternative 2D in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to nitrate.

Delta

Mass balance calculations indicate that under Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT), nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Table 34). Although changes at specific Delta locations and for specific months may be substantial on a relative basis (Appendix 8J, Table 39), the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds (see *Nitrate* under Section 8.3.1.7, *Constituent-Specific Considerations Used in the Assessment*). Long-term average nitrate concentrations are anticipated to remain below 1 mg/L-N at all 11 Delta assessment locations except the San Joaquin River at Buckley Cove, where long-term average concentrations would be somewhat above 1 mg/L-N. Nevertheless, at this location, long-term average nitrate concentrations would be somewhat reduced under Alternative 2D relative to Existing Conditions, and slightly increased relative to the No Action Alternative (ELT). No additional exceedances of the MCL are anticipated at any location under Alternative 2D (Appendix 8J, Table 34).

Use of assimilative capacity relative to the drinking water MCL of 10 mg/L-N under Alternative 2D would be low or negligible (i.e., ≤4%) in comparison to both Existing Conditions and the No Action Alternative (ELT), for all locations and months, for all modeled years (1976–1991), and for the drought period (1987–1991) (Appendix 8J, *Nitrate*, Table 40).

As described for Alternative 4 (see Section 8.3.3.9), actual nitrate concentrations would likely be higher than the modeling results indicate in certain locations under Alternative 2D. This is the mass balance modeling does not account for contributions from the SRWTP, which would be implementing nitrification/partial denitrification, or Delta wastewater treatment plant dischargers that practice nitrification, but not denitrification. However, for the reasons described for Alternative 4, any increases in nitrate concentrations that may occur at certain locations within the Delta under Alternative 2D would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regard to nitrate.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

Assessment of effects of Alternative 2D on nitrate in the SWP/CVP Export Service Areas is based on effects on nitrate at the Banks and Jones pumping plants. Results of the mass balance calculations indicate that relative to Existing Conditions and the No Action Alternative (ELT), nitrate concentrations at Banks and Jones pumping plants under Alternative 2D are anticipated to decrease on a long-term average annual basis by 34% at the Banks pumping plant and 36% at the Jones pumping plant (Appendix 8J, *Nitrate*, Table 39). During the late summer, particularly in the drought period assessed, concentrations are expected to increase, but the absolute value of these changes (i.e., in mg/L-N) would be small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Areas, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.2 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP/CVP Export Service Areas. No additional exceedances of the MCL are anticipated under Alternative 2D relative to Existing Conditions and the No Action Alternative (ELT) (Appendix 8J, Table 34). On a monthly average basis and on a long-term annual average basis, for all modeled years and for the drought period only, use of assimilative capacity available under Existing Conditions and the No Action Alternative (ELT), relative to the 10 mg/L-N MCL, would be negligible (≤2%) for both Banks and Jones pumping plants (Appendix 8J, Table 38).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

Any increases in nitrate concentrations that may occur in water exported via Banks and Jones pumping plants are not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regard to nitrate.

NEPA Effects: Modified reservoir operations and subsequent changes in river flows under Alternative 2D, relative to the No Action Alternative (ELT and LLT), are expected to have negligible, if any, effects on reservoir and river nitrate concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed. In the Delta, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the 10 mg/L-N MCL are anticipated at any Delta location, and use of assimilative capacity available under the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, would be low. Long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to differ negligibly relative to the No Action Alternative

(ELT and LLT) and no additional exceedances of the 10 mg/L-N MCL are anticipated. Therefore, the effects on nitrate from implementing water conveyance facilities are considered to be not adverse.

CEQA Conclusion: Nitrate concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers). Although higher in the San Joaquin River watershed, nitrate concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 2D, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mass balance calculations indicate that under Alternative 2D, relative to Existing Conditions, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the 10 mg/L-N MCL are anticipated at any location, and use of assimilative capacity available under Existing Conditions, relative to the drinking water MCL of 10 mg/L-N, would be low or negligible (i.e., ≤4%) for virtually all locations and months.

Assessment of effects of nitrate in the SWP/CVP Export Service Areas is based on effects on nitrate concentrations at the Banks and Jones pumping plants. Results of the mass balance calculations indicate that under Alternative 2D, relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to change negligibly. No additional exceedances of the 10 mg/L-N MCL are anticipated, and use of assimilative capacity available under Existing Conditions, relative to the MCL would be negligible (i.e., ≤2%) for both Banks and Jones pumping plants for all months.

Based on the above, there would be no substantial, long-term increase in nitrate concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the SWP/CVP Export Service Areas under Alternative 2D relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because nitrate concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not CWA Section 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Some habitat restoration activities included in Environmental Commitments 3, 4, and 6–11 would occur on lands within the Delta formerly used for agriculture. As discussed for Impact WQ-2, increased biota that may result in those areas may increase ammonia, which in turn may be converted to nitrate by established microbial communities. However, the areal extent of the new habitat implemented for the Environmental Commitments would be less than the existing and No Action Alternative habitat areas, and similar habitat exists currently in the Delta and is not identified as contributing to adverse nitrate conditions. Thus, these land use changes would not be expected to substantially increase nitrate concentrations in the Delta. Implementation of Environmental Commitments 12, 15, and 16 do not include actions that would affect nitrate sources or loading. Based on these findings, the effects on nitrate from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

***CEQA Conclusion*:** Land use changes that would occur from the Environmental Commitments are not expected to substantially increase nitrate concentrations, because the amount of area to be converted would be small relative to existing habitat, and existing habitats are not known for contributing to adverse nitrate conditions. Thus, it is expected that implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because nitrate concentrations are not expected to increase substantially due to these Environmental Commitments, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 2D on DOC concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 because factors affecting DOC concentrations in these water bodies would be similar. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows under Alternative 2D would not be expected to cause substantial long-term changes in DOC concentrations in the water bodies upstream of the Delta. Any changes in DOC levels in water bodies upstream of the Delta under Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies.

Delta

Under Alternative 2D, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be less extensive, and the magnitude of predicted long-term change and relative frequency of concentration threshold exceedances would be similar to, or lower than, the changes described for Alternative 4. The effects of Alternative 2D relative to Existing Conditions and the No Action Alternative (ELT) are discussed together because the direction and magnitude of predicted change are similar. Relative to the Existing Conditions and No Action

Alternative (ELT), Alternative 2D would result in small increases in long-term average DOC concentrations for both the modeled 16-year period (1976–1991) and drought period (1987–1991) at several interior Delta locations (increases up to 0.3 mg/L at the S. Fork Mokelumne River at Staten Island, Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1) (Appendix 8K, *Organic Carbon*, Table DOC-12). The increases in average DOC concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at the Contra Costa Pumping Plant #1 associated with the 3 mg/L threshold (i.e., increase from 52% under Existing Conditions to 68% under Alternative 2D for the modeled 16-year period). The change in frequency of threshold concentration exceedances at other assessment locations would be similar or lower.

While Alternative 2D would lead to slightly higher long-term average DOC concentrations at some municipal water intakes and Delta interior locations, the predicted change would not be expected to adversely affect MUN beneficial uses, or any other beneficial use. As discussed for Alternative 4, substantial changes in ambient DOC concentrations would need to occur before significant changes in drinking water treatment plant design or operations are triggered. The increases in long-term average DOC concentrations estimated to occur at various Delta locations under Alternative 2D are of sufficiently small magnitude that they would not require existing drinking water treatment plants to substantially upgrade treatment for DOC removal above levels currently employed.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on DOC in the LLT are expected to be similar to those described above.

Relative to Existing Conditions and the No Action Alternative (ELT and LLT), Alternative 2D would lead to predicted improvements in long-term average DOC concentrations at Barker Slough, as well as Banks and Jones pumping plants (discussed below).

SWP/CVP Export Service Areas

Under the Alternative 2D, long-term average DOC concentrations would decrease at Barker Slough by 0.1 mg/L, and at both the Banks and Jones pumping plants by 0.5 mg/L, relative to Existing Conditions, and the reductions would be similar compared to No Action Alternative (ELT) (Appendix 8K, *Organic Carbon*, Table DOC-12). Decreases in long-term average DOC would result in generally lower exceedance frequencies for concentration thresholds, although the frequency of exceedances of the 3 mg/L threshold during the modeled drought period would increase at the Banks and Jones pumping plants. Relative to Existing Conditions, exceedance of the 3 mg/L threshold would increase from 57% to 73% at Banks pumping plant and from 72% to 88% at Jones pumping plant. There would be little to no increase in exceedance of the 3 mg/L threshold relative to the No Action Alternative (ELT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on DOC in the LLT are expected to be similar to those described above.

Maintenance of SWP and CVP facilities under Alternative 2D would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area.

NEPA Effects: In summary, the operations and maintenance activities under Alternative 2D, relative to the No Action Alternative (ELT and LLT), would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. The long-term average DOC concentrations at Banks and Jones pumping plants are predicted to decrease by 0.5 mg/L, while long-term average DOC concentrations for some Delta interior locations are predicted to increase by as much as 0.3 mg/L. However, the increase in long-term average DOC concentration that could occur within the Delta interior would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters. Based on these findings, the effect of operations and maintenance activities on DOC under Alternative 2D is determined to be not adverse.

CEQA Conclusion: For the same reasons described for Alternative 4, the operations and maintenance activities under Alternative 2D, relative to the Existing Conditions, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. Any modified reservoir operations and subsequent changes in river flows under Alternative 2D, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DOC levels upstream of the Delta. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, Alternative 2D would result in relatively small increases (i.e., ≤0.3 mg/L) in long-term average DOC concentrations at some interior Delta locations. The predicted increases would not substantially increase the frequency with which long-term average DOC concentrations exceeds 2, 3, or 4 mg/L. Because this alternative would lead to only slightly higher long-term average DOC concentrations at the interior Delta locations and some municipal water intakes, the predicted changes would not be expected to adversely affect MUN beneficial uses, or any other beneficial use.

Relative to Existing Conditions, Alternative 2D would result in reduced long-term average DOC concentrations at the Banks and Jones pumping plants and Barker Slough. However, Alternative 2D would result in slightly greater frequency of exceedance of the 3 mg/L DOC concentration threshold during the modeled drought period. Nevertheless, an overall improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, the operations and maintenance activities of Alternative 2D would not result in any substantial change in long-term average DOC concentration. The increases in long-term average DOC concentration that could occur within the Delta would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters or waters of the SWP/CVP Service Area. Because DOC is not bioaccumulative, the increases in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not CWA Section 303(d) listed for any water body within the affected environment. Because long-term average DOC concentrations are not expected to increase substantially, no long-term water quality degradation with respect to DOC is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Relative to existing habitat and that to be developed under the No Action Alternative (ELT and LLT), the area of new habitat restoration implemented for the Environmental Commitments would be very small. Implementation of non-habitat restoration Environmental Commitments would not be expected to have substantial, if even measurable, effect on DOC concentrations upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas, because they would present no major sources of DOC to the affected environment. Consequently, any increases in average DOC levels in the affected environment are not expected to be of sufficient frequency, magnitude and geographic extent that would adversely affect the MUN beneficial use, or any other beneficial uses, of the affected environment, nor would potential increases substantially degrade water quality with regard to DOC. Based on these findings, the effect of the Environmental Commitments on DOC is determined to be not adverse.

CEQA Conclusion: Implementation of habitat restoration (i.e., Environmental Commitments 4, 6, 7, and 10), relative to the Existing Conditions, is not expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas, because the land area proposed for restoration would be relatively small compared to existing land area and sources of DOC. Implementation of other Environmental Commitments also would not be expected to have substantial, if even measurable, effect on DOC concentrations upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas, because they would present no major sources of DOC to the affected environment. Consequently, increases in average DOC levels in the affected environment are not expected to be of sufficient frequency, magnitude and geographic extent that would adversely affect the MUN beneficial use, or any other beneficial uses, of the affected environment, nor would potential increases substantially degrade water quality with regard to DOC. Furthermore, DOC is not bioaccumulative, therefore changes in DOC concentrations would not cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not CWA Section 303(d) listed for any water body within the affected environment. Because long-term average DOC concentrations are not expected to increase substantially, no long-term water quality degradation with respect to DOC is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance

The effects of operation of the water conveyance facilities under Alternative 2D on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those effects described for Alternative 4 (see Section 8.3.3.9). As described for Alternative 4, pathogen concentrations in the Sacramento and San Joaquin Rivers have a minimal relationship to flow rate in these rivers. Further, urban runoff contributions during the dry season would be expected to be a relatively small fraction of the rivers' total flow rates. During wet weather events, when urban runoff contributions would be higher, the flows in the rivers also would be higher. Given the small magnitude of urban runoff contributions relative to the magnitude of river flows and that pathogen concentrations in the rivers have a minimal relationship to river flow rate, river flow rate and reservoir storage reductions that would occur under Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and

LLT), would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta.

The effects of Alternative 2D relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be changes in the relative percentage of water throughout the Delta being comprised of various source waters (i.e., water from the Sacramento River, San Joaquin River, Bay water, eastside tributaries, and agricultural return flow), due to potential changes in inflows particularly from the Sacramento River watershed. However, as described for Alternative 4, it is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens, because it is expected that pathogen sources in close proximity to Delta sites would have a greater influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative. As such, there is not expected to be substantial, if even measurable, changes in pathogen concentrations in the SWP/CVP Export Service Area waters.

As such, Alternative 2D would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or U.S. EPA-recommended pathogen criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to pathogens.

NEPA Effects: Because pathogen levels are expected to be minimally affected relative to the No Action Alternative (ELT and LLT), the effects on pathogens from implementing Alternative 2D are determined to be not adverse.

CEQA Conclusion: The effects of Alternative 2D on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because the factors that would affect pathogen levels in the surface waters of these areas would be similar. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is CWA Section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Environmental Commitments 3, 4, and 6–11 would involve habitat restoration actions. This could result in localized increases in wildlife-related coliforms relative to the No Action Alternative (ELT and LLT). The Delta currently supports similar habitat types and, with the exception of the CWA Section 303(d) listing for the Stockton Deep Water Ship Channel, is not recognized as exhibiting pathogen concentrations that rise to the level of adversely affecting beneficial uses. As such, the potential increase in wildlife-related coliform concentrations due to tidal habitat creation is not expected to adversely affect beneficial uses. The remaining Environmental Commitments would not be expected to affect pathogen levels, because they are actions that do not affect the presence of pathogen sources. Based on these findings, the effects on pathogens from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

***CEQA Conclusion*:** Implementation of Environmental Commitments 3, 4, and 6–11 could result in localized increases in wildlife-related coliforms relative to Existing Conditions. The Delta currently supports similar habitat types and, with the exception of the CWA Section 303(d) listing for the Stockton Deep Water Ship Channel, is not recognized as exhibiting pathogen concentrations that rise to the level of adversely affecting beneficial uses. As such, the potential increase in wildlife-related coliform concentrations due to tidal habitat creation is not expected to adversely affect beneficial uses. Therefore, the Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is CWA Section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance

The effects of Alternative 2D operations and maintenance on pesticide levels in surface waters upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT), would be similar to those expected to occur under Alternative 4 (see Section 8.3.3.9). This is because under Alternative 2D, the primary factor that would influence pesticide concentrations in surface waters upstream of the Delta—the effect of timing and magnitude of reservoir releases on dilution capacity—is expected to change by a similar degree. Changes in average winter and summer flow rates, relative to Existing Conditions and the No Action Alternative (ELT), are expected to be similar to or less than changes in flow rates expected under Alternative 4 in the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis (Appendix 8L, *Pesticides,* Tables 1 through 4). Similarly, the primary factor that would influence pesticide concentrations in surface waters of the Delta and in the SWP/CVP Export Service Areas (i.e., changes in San Joaquin River, Sacramento River and Delta Agriculture source water fractions at various Delta locations, including Banks and Jones pumping plants) is expected to change by a similar degree. The percentage change in monthly average source water fractions would be similar to changes expected under Alternative 4 (Appendix 8D, *Source Water Fingerprinting Results*).

It was concluded for Alternative 4, and thus for Alternative 2D based on similar flow changes, that the potential average summer flow reductions would not be of sufficient magnitude to substantially increase in-river pesticide concentrations or alter the long-term risk of pesticide-related effects on aquatic life beneficial uses upstream of the Delta. Greater long-term average flow reductions, and corresponding reductions in dilution/assimilative capacity, would be necessary before long-term risk of pesticide related effects on aquatic life beneficial uses would be adversely altered. Similarly, the modeled changes in the source water fractions of Sacramento River, San Joaquin River, and Delta agriculture water under Alternative 2D would not be of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of organophosphate insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

The flow changes in the LLT would be expected in the ranges of that described above for Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT), and that described for Alternative 4 relative to the No Action Alternative (LLT) in Section 8.3.3.9. Thus, similar to above and Alternative 4, the flow changes that would occur in the LLT under Alternative 2D, relative to Existing Conditions and the No Action Alternative (LLT), would not be expected to result in changes in dilution of pesticides of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses upstream of the Delta, in the Delta, or the SWP/CVP Export Service Areas.

NEPA Effects: In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers under Alternative 2D relative to the No Action Alternative (ELT and LLT) would be of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. Similarly, changes in source water fractions to the Delta would be of insufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta or CVP/SWP Export Service Areas. Therefore, the effects on pesticides from the water conveyance facilities are determined not to be adverse.

***CEQA Conclusion*:** Based on the discussion above, the effects of Alternative 2D on pesticide levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to or slightly less than those described for the Alternative 4. Alternative 2D would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta, at the 11 assessment locations analyzed for the Delta, or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous CWA Section 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions under Alternative 2D would not be expected to make any of these beneficial use impairments measurably worse. Because long-term average pesticide concentrations are not expected to increase substantially, no long-term water quality degradation with respect to pesticides is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of pesticides, and the potential short-term loading from former agricultural lands would be expected to degrade and dissipate rapidly. Therefore, relative to the No Action Alternative (ELT), the effects on pesticides from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of pesticides, and the potential short-term loading from former agricultural lands would be expected to degrade and dissipate rapidly, such that pesticide levels would differ little from Existing Conditions. Therefore, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause substantial long-term increase in pesticide concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP Export Service Areas. As such, these Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pesticide concentrations are not expected to increase substantially, no long-term water quality degradation for pesticides is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term pesticide concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. Environmental Commitments 3, 4, 6–12, 15, 16 do not include the use of pesticides known to be bioaccumulative in animals or humans, nor do the Environmental Commitments propose the use of any pesticide currently named in a CWA Section 303(d) listing of the affected environment. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance

The effects of Alternative 2D on phosphorus concentrations in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because factors which affect phosphorus concentrations in surface waters of these areas are the same under Alternative 4 and Alternative 2D. As described for Alternative 4, phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration are not anticipated under Alternative 2D, relative to Existing Conditions or the No Action Alternative (ELT), upstream of the Delta. Phosphorus concentrations may increase during January through March at locations in the Delta where the source fraction of San Joaquin River water increases, due to the higher concentration of phosphorus in the San Joaquin River during these months compared to Sacramento River water or San Francisco Bay water. However, based on the DSM2 fingerprinting results (Figures 331 through 352 in Appendix 8D, *Source Water Fingerprinting Results*), together with source water concentrations (in Figure 8-56), the magnitude of increases during these months is expected to be negligible to low (i.e., <0.02 mg/L) at all Delta locations relative to Existing Conditions and the No Action Alternative (ELT and LLT). Thus, phosphorus concentrations in the Delta and waters exported from Banks and Jones pumping plants to the SWP/CVP Export Service Areas are expected to be similar to Existing Conditions and the No Action Alternative (ELT and LLT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on phosphorus in the LLT are expected to be similar to those described above.

NEPA Effects: In summary, operation of the water conveyance facilities would have little to no effect on phosphorus concentrations in water bodies upstream of the Delta, in the Plan Area, and the waters exported to the SWP/CVP Export Service Areas, relative to the No Action Alternative (ELT and LLT). Thus, effects of the water conveyance facilities on phosphorus are considered to be not adverse.

CEQA Conclusion**:** The effects of Alternative 2D on phosphorus levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the Alternative 4. There would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 2D relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects**:** Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of phosphorus. Therefore, relative to the No Action Alternative (ELT and LLT), the effects on phosphorus from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of phosphorus. Therefore, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the SWP/CVP Export Service Areas due to implementation of these Environmental Commitments relative to Existing Conditions. Because phosphorus concentrations are not expected to increase substantially due to these Environmental Commitments, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not CWA Section 303(d) listed within the affected environment and, thus, the Environmental Commitments would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, any increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 2D on selenium concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 (see Section 8.3.3.9), because factors affecting selenium concentrations in these water bodies would be similar. Substantial point sources of selenium do not exist upstream in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Nonpoint sources of selenium within the watersheds of the Sacramento River and the eastern tributaries also are relatively low, resulting in generally low selenium concentrations in the reservoirs and rivers of those watersheds. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 2D, relative to Existing Conditions or the No Action Alternative (ELT and LLT), are expected to have negligible, if any, effects on reservoir and river selenium concentrations upstream of Freeport in the Sacramento River watershed or in the eastern tributaries upstream of the Delta. Similarly, it is expected that selenium concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under Alternative 2D, given the relatively small decreases in flows and the considerable variability in the relationship between selenium concentrations and flows in the San Joaquin River. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Delta

Alternative 2D would result in small changes in average selenium concentrations in water relative to Existing Conditions and No Action Alternative (ELT) at all modeled Delta assessment locations (Appendix 8M, *Selenium,* Table M-33). Long-term average concentrations at some interior and western Delta locations would increase by 0.01–0.04 μg/L for the entire period modeled (1976–1991). These small increases in selenium concentrations in water would result in small reductions (4% or less) in available assimilative capacity for selenium, relative to USEPA's draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-45). The long-term average selenium concentrations in water under Alternative 2D (range 0.09–0.40 μg/L) would be similar to Existing Conditions (range 0.09–0.41 μg/L) and the No Action Alternative (ELT) (range 0.09–0.39 μg/L), and would be below the draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-33).

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 2D would result in small changes (about 1% or less) in estimated selenium concentrations in most biota (whole-body fish, bird eggs [invertebrate diet or fish diet], and fish fillets) throughout the Delta, with little difference among locations (Appendix 8M, *Selenium,* Tables M-35 and M-39). Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0, indicating low probability of adverse effects. Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by about 19% relative to Existing Conditions in all years (from about 4.7 to about 5.6 mg/kg dry weight) and by about 16% relative to the No Action Alternative (ELT) in all years (from 4.8 to about 5.6 mg/kg dry weight). For sturgeon in the Sacramento River at Mallard Island concentrations are predicted to increase by about 14% relative to Existing Conditions in all years (from about 4.4 to 5.0 mg/kg dry weight) and by about 11% relative to the No Action Alternative in all years (from about 4.5 to 5.0 mg/kg dry weight) (Appendix 8M, Tables M-41 and M-42). Selenium concentrations in sturgeon during drought years are expected to increase by about 2–7% at those locations (from about 6.8 to 7.3 mg/kg dry weight) (Appendix 8M, Tables M-41 and M-42). Detection of small changes in whole-body sturgeon such as those estimated for the western Delta would require very large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at both locations (as they do for Existing Conditions and the No Action Alternative (ELT)) and for all years in the San Joaquin River at Antioch (where quotient increases from 0.94 to 1.0) (Appendix 8M, Table M-43). The High Toxicity Threshold Quotient would be less than 1.0 at both locations for all years and drought years (Appendix 8M, Table M-43).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in Appendix 8M, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium. Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on "fixed" K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Residence time of water in the Delta is expected to increase relative to Existing Conditions primarily as a result of habitat restoration (8,000 acres of tidal habitat restoration and enhancements to the Yolo Bypass) that is assumed to occur under the No Action Alternative (ELT) separate from Alternative 2D. Although estimates of the residence time increases are not available for Alternative 2D, estimates for Alternative 2 at the LLT (presented in Table 8-60a in Section 8.3.1.7 in the *Microcystis* subsection) which contained 65,000 acres of tidal restoration are available, and is expected that residence time increases under Alternative 2D would be substantially less than identified for Alternative 2 in the table.

If increases in fish tissue or bird egg selenium were to occur as a result of increased residence time, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. Thus, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time would be a concern is the western Delta and Suisun Bay for sturgeon. Based on the expected minor increases in residence time in the western Delta, any increases are not expected to be of sufficient magnitude to substantially affect selenium bioaccumulation.

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 2D would result in essentially no change in selenium concentrations throughout the Delta for most biota (less than 1%), although larger increases in selenium concentrations are predicted for sturgeon in the western Delta. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, Alternative 2D would not be expected to substantially increase the frequency with which the applicable water quality criterion or toxicity and level of concern benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon relative to the low benchmark and no exceedance of the high benchmark) or to substantially degrade the quality of water in the Delta, with regard to selenium.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on selenium in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

Alternative 2D would result in small (0.01–0.10 μg/L) decreases in long-term average selenium concentrations in water at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative (ELT), for the entire period modeled (Appendix 8M, *Selenium,* Table M-33). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium at these pumping plants, relative to the USEPA's draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-45). The long-term average selenium concentrations in water for Alternative 2D (range 0.14–0.20 μg/L) would be well below the draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-33).

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 2D would result in small changes (about 1% or less) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) (Appendix 8M, *Selenium,* Table M-39). Concentrations in biota would not exceed any selenium toxicity or level of concern benchmarks for Alternative 2D (Appendix 8M, Table M-39).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on selenium in the LLT are expected to be similar to those described above.

NEPA Effects: Relative to the No Action Alternative (ELT and LLT), Alternative 2D would result in essentially negligible changes in selenium concentrations in water upstream of the Delta. Similarly, there would be negligible changes in selenium water and most biota concentrations in the Delta, with no exceedances of benchmarks for biological effects. For sturgeon in the Delta, there would be only a small increase of threshold exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark. At the Banks and Jones pumping plants, Alternative 2D would cause no increases in the frequency with which applicable benchmarks would be exceeded and would slightly improve the quality of water in selenium concentrations. Therefore, the effects on selenium (both as waterborne and as bioaccumulated in biota) from Alternative 2D are considered to be not adverse.

CEQA Conclusion: There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 2, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate Alternative 2D would result in essentially no change in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. The Low Toxicity Threshold Exceedance Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase slightly, from 0.94 for Existing Conditions to 1.0 for Alternative 2D. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. Overall, Alternative 2D would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 2D would cause no increases in the frequency with which applicable benchmarks would be exceeded, and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants.

Based on the above, selenium concentrations that would occur in water under Alternative 2D would not cause additional exceedances of applicable state or federal numeric or narrative water quality objectives/criteria, or other relevant water quality effects thresholds identified for this assessment, by frequency, magnitude, and geographic extent that would result in adverse effects to one or more beneficial uses within affected water bodies. In comparison to Existing Conditions, water quality conditions under Alternative 2D would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Water quality conditions under this alternative with respect to selenium would not cause long-term degradation of water quality in the affected environment, and therefore would not result in use of available assimilative capacity such that exceedances of water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. This alternative would not further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 would not increase selenium loading, and the amount of restoration that would occur would be minimal relative to the area of the Delta and implemented such that any localized changes in residence time are unlikely to measurably change selenium concentrations in water or biota relative to the No Action Alternative (ELT and LLT). Therefore, the effects on selenium from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 would not increase selenium loading, and the amount of restoration that would occur would be minimal relative to the area of the Delta and implemented such that any localized changes in residence time are unlikely to measurably change selenium concentrations in water or biota relative to Existing Conditions. Therefore, it is expected that with implementation of these Environmental Commitments there would be no substantial, long-term increase in selenium concentrations in water in the rivers and reservoirs upstream of the Delta, water in the Delta, or the waters exported to the SWP/CVP Export Service Areas, relative to Existing Conditions. As such, these Environmental Commitments would not contribute to additional exceedances of applicable water quality objectives/criteria. Given the factors discussed in the assessment above and for Alternative 4 (see Section 8.3.3.9), any increases in bioaccumulation rates from waterborne selenium that could occur in some areas as a result of increased water residence times would not be of sufficient magnitude and geographic extent that any portion of the Delta would be expected to have measurably higher body burdens of selenium in aquatic organisms, and therefore would not substantially increase risk for adverse effects to beneficial uses. Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause long-term degradation of water quality resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely. Also, these Environmental Commitments would not result in substantially increased risk for adverse effects to any beneficial uses. Furthermore, although the Delta is a CWA Section 303(d)-listed water body for selenium, given the discussion in the assessment above, it is unlikely that restoration areas would result in measurable increases in selenium in fish tissues or bird eggs such that the beneficial use impairment would be made discernibly worse.

Because it is unlikely that substantial increases in selenium in fish tissues or bird eggs would occur such that effects on aquatic life beneficial uses would be anticipated, and because of the avoidance and minimization measures that are designed to further minimize and evaluate the risk of such increases (see BDCP Appendix 3.C, *Avoidance and Minimization Measures*, for more detail on AMM27) as well as the Selenium Management environmental commitment (see Appendix 3B, *Environmental Commitments, AMMs, and CMs*), this impact is considered less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance

The effects of operation of the water conveyance facilities under Alternative 2D on trace metal concentrations in surface waters upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be similar to those effects described for Alternative 4 (see Section 8.3.3.9).

Given the poor association of dissolved trace metal concentrations with flow, river flow rate and reservoir storage reductions that would occur under Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be expected to result in a substantial adverse change in trace metal concentrations in the reservoirs and rivers upstream of the Delta.

In the Delta, for metals of primarily aquatic life concern (copper, cadmium, chromium, lead, nickel, silver, and zinc), average and 95th percentile trace metal concentrations of the primary source waters to the Delta are very similar, and very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based (see Tables 8-51 and 8-52 in Section 8.3.1.7, *Construction-Specific Considerations Used in the Assessment*). No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average and 95th percentile source water concentrations for copper, cadmium, chromium, lead, nickel, silver, and zinc do not exceed their respective criteria, more frequent exceedances of criteria in the Delta would not occur. For metals of primarily human health and drinking water concern (arsenic, iron, manganese), average and 95th percentile concentrations are also very similar (see Tables 8–10 in Appendix 8N,*Trace Metals*) and average concentrations are below human health criteria. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average water concentrations for arsenic, iron, and manganese do not exceed water quality criteria, more frequent exceedances of drinking water criteria in the Delta would not be expected to occur.

Because Alternative 2D would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP Export Service Areas, relative to Existing Conditions or the No Action Alternative (ELT and LLT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on trace metals in the LLT are expected to be similar to those described above.

As such, Alternative 2D would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment or substantially degrade the quality of these water bodies, with regard to trace metals.

NEPA Effects: Alternative 2D would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment or substantially degrade the quality of these water bodies, with regard to trace metals, relative to the No Action Alternative (ELT and LLT). Therefore, the effects on trace metals from implementing Alternative 2D are determined to not be adverse.

CEQA Conclusion: While Alternative 2D would alter the magnitude and timing of reservoir releases north, south and east of the Delta, this would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under Alternative 2D.

Because Alternative 2D is not expected to result in substantial changes in trace metal concentrations in Delta waters, which includes Banks and Jones pumping plants, effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Because Environmental Commitments 3, 4, 6–12, 15, and 16 present no new sources of trace metals to the affected environment, the effects on trace metal concentrations from implementing these Environmental Commitments are determined to be not adverse.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP Export Service Areas, because they present no new sources of trace metals to the affected environment. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance

As described for Alternative 4 (see Section 8.3.3.9), the operation of the water conveyance facilities under Alternative 2D is expected to have a minimal effect on TSS and turbidity levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions and the No Action Alternative (ELT and LLT). This is because the factors that would affect TSS and turbidity levels in the surface waters of these areas would be the same. TSS concentrations and turbidity levels in rivers upstream of the Delta are affected primarily by: 1) TSS concentrations and turbidity levels of the water released from the upstream reservoirs, 2) erosion occurring within the river channel beds, which is affected by river flow velocity and bank protection, 3) TSS concentrations and turbidity levels of tributary inflows, point-source inputs, and nonpoint runoff as influenced by surrounding land uses; and 4) phytoplankton, zooplankton and other biological material in the water. Within the Delta, TSS concentrations and turbidity levels in Delta waters are affected by TSS concentrations and turbidity levels of inflows (and associated sediment load), as well as fluctuation in flows within the channels due to the tides, with sediments depositing as flow velocities and turbulence are low at periods of slack tide, and sediments becoming suspended when flow velocities and turbulence increase when tides are near the maximum. TSS and turbidity variations can also be attributed to phytoplankton, zooplankton and other biological material in the water. These factors would be similar under Alternative 2D and Alternative 4, are expected to be minimally different from Existing Conditions and the No Action Alternative (ELT and LLT). Because Alternative 2D is expected to have minimal effect on TSS concentrations and turbidity levels in Delta waters, including water exported at the south Delta pumps, relative to Existing Conditions or the No Action Alternative (ELT and LLT), Alternative 2D also is expected to have minimal effect on TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters.

NEPA Effects: Because TSS concentrations and turbidity levels are expected to be minimally affected relative to the No Action Alternative (ELT and LLT), the effects on TSS and turbidity from implementing Alternative 2D are determined to not be adverse.

CEQA Conclusion: As described for Alternative 4 (see Section 8.3.3.9) changes in river flow rate and reservoir storage that would occur under Alternative 2D, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative

2D, relative to Existing Conditions, because this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor CWA Section 303(d) listed constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Localized, temporary changes in TSS and turbidity could occur associated with the restoration actions of Environmental Commitments 3, 4, 6–12, 15, and 16. However, these changes would be gradual and not expected to substantially differ from No Action Alternative (ELT and LLT) conditions. Therefore, the effects on TSS and turbidity from implementing these Environmental Commitments are determined to be not adverse.

CEQA Conclusion: It is expected that the TSS concentrations and turbidity levels Upstream of the Delta, in the Plan Area, and the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not be substantially different relative to Existing Conditions, except within localized areas of the Delta modified through creation of habitat and open water. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels Upstream of the Delta, in the greater Plan Area, and in the SWP/CVP Export Service Areas are not expected to be substantially different, long-term water quality degradation is not expected relative to TSS and turbidity, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor CWA Section 303(d) listed constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities for the Water Conveyance Facilities and Environmental Commitments

The potential construction-related water quality effects that would occur under Alternative 2D would be similar to the effects described for Alternative 4A (see Section 8.3.4.2). This is because the type, size and number of construction activities for water conveyance facilities and Environmental Commitments that would occur under Alternative 2D would be similar to Alternative 4A. The construction-related activities for the water conveyance facilities under Alternative 2D would be similar to those described for Alternative 4A. However, there would be more construction activity associated with two additional intakes and the area of in-water habitat restoration activities implemented under Alternative 2D would be greater.

NEPA Effects: The types and magnitude of potential construction-related water quality effects associated with implementation of Alternative 2D would be very similar to the effects discussed for Alternative 4A. Nevertheless, the construction of water conveyance facilities and Environmental Commitments, with the implementation of the BMPs specified in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, and other agency permitted construction requirements, would result in the potential water quality effects being largely avoided and minimized. The specific Environmental Commitments that would be implemented under Alternative 2D would be similar to those described for Alternative 4A. Consequently, relative to the No Action Alternative (ELT), Alternative 2D would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. Therefore, with implementation of environmental commitments presented in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

CEQA Conclusion: Because environmental commitments would be implemented under Alternative 2D for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or CWA Section 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause CWA Section 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32: Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance

Upstream of the Delta

Adverse effects from *Microcystis* upstream of the Delta have only been documented in lakes such as Clear Lake, where eutrophic levels of nutrients give cyanobacteria a competitive advantage over other phytoplankton during the bloom season. Large reservoirs upstream of the Delta are typically characterized by low nutrient concentrations, where other phytoplankton outcompete cyanobacteria, including *Microcystis*. In the rivers and streams of the Sacramento River watershed, watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), and the San Joaquin River upstream of the Delta under Existing Conditions, bloom development is limited by high water velocity and low residence times. These conditions are not expected to change under Alternative 2D or the No Action Alternative (ELT and LLT). Consequently, any modified reservoir operations under Alternative 2D are not expected to promote *Microcystis* production upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT and LLT).

Delta

During the June through October period when *Microcystis* blooms occur in the Delta, it is a combination of flows, associated residence time, and water temperatures that are believed to most influence *Microcystis* bloom formation.

Under Alternative 2D, a portion of the Sacramento River water which is conveyed through the Delta to the south Delta intakes under Existing Conditions would be replaced at various locations throughout the Delta by other source water due to diversion of Sacramento River water at the north Delta intakes. The changes in flow paths of water through the Delta and change in operation of the south Delta pumps that would occur due to facilities operations and maintenance of Alternative 2D could result in localized increases in residence time in various Delta sub-regions and decreases in residence time in other areas. Because there is no published analysis of the relationship between *Microcystis* occurrence and residence time, there is uncertainty on how increased residence times may affect *Microcystis* occurrences (ICF International 2016). Further, there is substantial uncertainty regarding the extent that facilities operations and maintenance of Alternative 2D would result in a net increase in water residence times at various locations throughout the Delta, relative to Existing Conditions. In addition to the effects of operations and maintenance of Alternative 2D, increases in water residence times are expected occur due to separate factors and actions concurrent with the alternative, including habitat restoration (8,000 acres of tidal habitat and enhancements in the Yolo Bypass) and sea level rise due to climate change.

To ensure project operations do not create increased *Microcystis* blooms in the Delta, water flow through Delta channels can be managed through real-time operations, particularly the balancing of the north and south Delta diversions. By operating the south Delta pumps more frequently during periods conducive to increased *Microcystis* blooms, residence times can be managed to decrease the potential for blooms to develop, and thus decrease potential microcystin increases due to project operations. As such, effects of Alternative 2D on *Microcystis* levels, and thus microcystin concentrations in the Delta, would not be made more adverse relative to Existing Conditions and the No Action Alternative (ELT and LLT).

Water temperature is also a critical parameter that has been related to *Microcystis* blooms in the Delta. Since Delta water temperatures are largely driven by air temperature, climate change that increases air temperatures relative to Existing Conditions would be expected to increase ambient water temperatures in the Delta by 1.3–2.5°F. These climate changes in the ELT are expected to occur in the Delta under the No Action Alternative, relative to Existing Conditions. Alternative 2D operations and maintenance is not expected to cause increased Delta water temperatures, relative to Existing Conditions or the No Action Alternative.

In summary, increased frequency and magnitude of *Microcystis* blooms may occur in the Delta in the future, relative to Existing Conditions, due to factors unrelated to the project alternative, including: 1) increased residence times resulting from restoration activities and climate change-related sea level rise and 2) climate change-related increased Delta water temperatures. If *Microcystis* occurrences did increase in certain sub-regions of the Delta in the future, there would also be the potential for increased microcystin presence in the Delta, relative to Existing Conditions. To ensure project operations under Alternative 2D do not create significant increases in *Microcystis* blooms in the Delta, that may be associated with increased residence times, water flow through Delta channels would be managed through real-time operations.

SWP/CVP Export Service Area

As described above for the Delta, source waters to the south Delta intakes could be adversely affected, relative to Existing Conditions by *Microcystis* both from an increase in Delta water temperatures associated with climate change and from an increase in water residence times. The impacts from increased Delta water residence times would be primarily related to habitat restoration (8,000 acres of tidal habitat restoration and enhancements in the Yolo Bypass) that is assumed to occur separate from Alternative 2D. The combined effect of these factors on the potential for *Microcystis* blooms in source waters to the south Delta intakes is expected to be much greater than the influence of operations and maintenance of Alternative 2D, the effects of which will be mitigated through real time operations. Increases in ambient air temperatures due to climate change relative to Existing Conditions are expected under this alternative. Increases in ambient air temperatures are expected to result in warmer ambient water temperatures, and thus conditions more suitable to *Microcystis* growth, in the water bodies of the SWP/CVP Export Service Areas. The incremental increase in long-term average air temperatures would be less at the ELT (2.0°F), compared to the LLT (4.0°F).

As discussed in the Delta section above, Alternative 2D is not expected to substantially adversely affect *Microcystis* blooms, relative to Existing Conditions and the No Action Alternative (ELT and LLT). Additionally, residence time and water temperature conditions in the SWP/CVP Export Service Areas are not expected to become more conducive to *Microcystis* bloom formation due to the operations and maintenance of Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and LLT), because water residence times are not projected to increase in the SWP/CVP Export Service Areas and any temperature increases there would be due to climate change not due to Alternative 2D.

NEPA Effects: Modified reservoir operations under Alternative 2D are not expected to promote *Microcystis* production upstream of the Delta, relative to the No Action Alternative (ELT and LLT). Similarly, operations and maintenance of Alternative 2D is not expected to substantially increase water residence times or ambient water temperatures in the Delta, including at the Banks and Jones pumping plants, and thus is not expected to result in adverse effects on *Microcystis* in the Delta, relative to No Action Alternative (ELT and LLT). Lack of adverse effects on *Microcystis* in the Delta would mean that Delta waters diverted into the SWP/CVP Export Service Areas would not be adversely affected. Finally, the potential for *Microcystis* bloom formation within the SWP/CVP Export Service Area water bodies and canals would not be expected to change substantially, if at all, because water residence times are not projected to increase in the SWP/CVP Export Service Areas and any temperature increases there would be due to climate change and not due to Alternative 2D. Thus, the effects on *Microcystis* in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas from implementing Alternative 2D are determined to be not adverse.

CEQA Conclusion: Modified reservoir operations under Alternative 2D are not expected to promote *Microcystis* production upstream of the Delta, relative to the Existing Conditions. Increased frequency and magnitude of *Microcystis* blooms may occur in the Delta in the future, relative to Existing Conditions, due to increased residence times resulting from restoration activities unrelated to the project alternative, as well as climate change and sea level rise that are expected to increase Delta water temperatures. Such increases in residence time and water temperatures would not be caused by implementation of Alternative 2D. Operations and maintenance of Alternative 2D, including the use of real-time operations, are not expected to result in flow and temperature conditions in the Delta, including at the Banks and Jones pumping plants, that would cause substantial increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms. As such, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not CWA Section 303(d) listed within the affected environment and thus any increases that could occur in some areas of the Delta would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. Microcystin, the toxin produced by *Microcystis,* is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences due to climate change and sea level rise may lead to increased microcystin presence in the Delta, relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. While long-term water quality degradation related to microcystin levels may occur and, thus, impacts on beneficial uses could occur, these impacts are not related to implementation of Alternative 2D. Although there is uncertainty regarding this impact, the effects on *Microcystis* from implementing water conveyance facilities are determined to be less than significant. No mitigation is required.

Impact WQ-33: Effects on *Microcystis* Bloom Formation Resulting from Environmental Commitments

Effects on *Microcystis* from implementation of Environmental Commitments under Alternative 2D would be the same as those described for Alternative 4A.

NEPA Effects: Based on the discussion for Impact WQ-33 in Section 8.3.4.2, the effects on *Microcystis* from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusions: Based on the discussion for Impact WQ-33 in Section 8.3.4.2, Environmental Commitments 3, 4, 6–12, 15, and 16 would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not CWA Section 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta would occur at the early long-term for reasons unassociated with implementation of the Environmental Commitments, including tidal habitat restoration. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. While long-term water quality degradation related to microcystins levels may occur and, thus, significant impacts on beneficial uses could occur, these impacts are not related to implementation of the Environmental Commitments. Therefore, the effects on *Microcystis* from implementing the Environmental Commitments are determined to be less than significant. No mitigation is required.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance and Environmental Commitments

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 2D would have a less-than-significant impact/no adverse effect on the following constituents in the Delta:

- Boron

- Bromide
- Chloride
- DOC
- DO
- Pathogens
- Pesticides
- Trace metals
- Turbidity and TSS
- *Microcystis*

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. Chloride, DOC, and bromide concentrations also are of concern in drinking water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, trace metals, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Changes in *Microcystis* would be primarily due to factors unassociated with the project alternative. Thus, changes in boron, bromide, chloride, DOC, DO, pathogens, pesticides, trace metals, turbidity and TSS, and *Microcystis* in Delta outflow associated with implementation of Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and LLT) are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay, as described for Alternative 4 (see Section 8.3.3.9).

Elevated EC is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. San Francisco Bay does not have an AGR beneficial use designation. As described for Alternative 4, salinity throughout San Francisco Bay is largely a function of the tides, as well as to some extent the freshwater inflow from upstream. However, the changes in Delta outflow due to Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would be minor compared to tidal flows, and thus no substantial adverse effects on salinity, or fish and wildlife beneficial uses, downstream of the Delta are expected.

Also, as described for Alternative 4, changes in nutrient loading would not be expected to contribute to adverse effects to beneficial uses. Changes in nitrogen (ammonia and nitrate) loading to Suisun and San Pablo Bays under Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay. The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. As described for Alternative 4, any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary. Therefore, changes in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay, relative to Existing Conditions and the No Action Alternative (ELT and LLT), shown in Appendix 8O, *San Francisco Bay Analysis*, Table 8O-1, are not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Similar to Alternative 4, loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 2D, relative to Existing Conditions and the No Action Alternative (ELT and LLT) (Appendix 8O, *San Francisco Bay Analysis*, Table 8O-2). Also, the incremental increase in dissolved selenium concentrations in the North Bay, relative to Existing Conditions, would be negligible (0.01 μg/L) under this alternative (Appendix 8O, Table 8O-3).

NEPA Effects: Based on the discussion above, Alternative 2D, relative to the No Action Alternative (ELT and LLT), would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, selenium, nutrients (ammonia, nitrate, phosphorus), trace metals, turbidity and TSS, or *Microcystis* in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, effects on the San Francisco Bay from implementation of water conveyance facilities and Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

CEQA Conclusion: As with Alternative 4, Alternative 2D would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. Further, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals, turbidity or TSS, and *Microcystis* are anticipated in the Delta due to the implementation of Alternative 2D, relative to Existing Conditions, therefore, no substantial changes to these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow and thus, have minimal influence on salinity changes. Changes in nutrient load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. As with Alternative 4, the change in mercury and methylmercury load (which is based on source water and Delta outflow), relative to Existing Conditions, would be within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA Section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Similarly, based on Alternative 4 estimates, the increase in selenium load would be minimal, and total and dissolved selenium concentrations would be expected to be the same as Existing Conditions, and less than the target associated with white sturgeon whole-body fish tissue levels for the North Bay. Thus, the change in selenium load is not expected to contribute to water quality degradation, or make the CWA Section 303(d) selenium impairment measurably worse or cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

8.3.4.4 Alternative 5A—Dual Conveyance with Modified Pipeline/Tunnel and Intake 2 (3,000 cfs; Operational Scenario C)

Discussion of water quality impacts of Alternative 5A was first provided in the RDEIR/SDEIS. The water quality assessments in the RDEIR/SDEIS for boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Services Areas utilized results from water quality modeling performed for Alternative 5 in the ELT, which included Yolo Bypass improvements, 25,000 acres of tidal habitat restoration, and the EC compliance location at Emmaton relocated to Threemile Slough. The analysis of effects of Alternative 5A, presented herein, on boron, bromide, chloride, DOC, EC, mercury, nitrate, and selenium in the Delta and SWP/CVP Export Service Areas is based on revised modeling, which assumed implementation of Yolo Bypass improvements, the EC compliance location remaining at Emmaton, and no tidal habitat restoration. Because the modeling of Alternative 5A and the No Action Alternative (ELT) included Yolo Bypass Improvements, but no tidal habitat restoration, comparison of modeling results for Alternative 5A to No Action Alternative (ELT) results in the impact discussions below allows for isolating and identifying effects solely due to implementation of Alternative 5A in the ELT.

As described in Chapter 3, *Description of Alternatives*, actions associated with Alternative 4 that are not proposed to be implemented under Alternative 5A would continue to be pursued as part of existing, but separate, projects and programs associated with the 2008 USFWS and 2009 NMFS BiOps, California EcoRestore, and the 2014 California Water Action Plan. Due to the reduced suite of Environmental Commitments in Alternative 5A compared to Alternative 4 (in particular, significantly less tidal habitat restoration), the impacts to water quality due to Alternative 5A are substantially less compared to Alternative 4, particularly in the Delta.

The water quality impact conclusions for Alternative 5A remain the same as those presented in the RDEIR/SDEIS. The revisions to the assessment are in the presentation of modeled changes in concentrations, water quality criteria/objective exceedances, and use of assimilative capacity, and refinements to mitigation measures for EC.

Impact WQ-1: Effects on Ammonia Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), substantial point and non-point sources of ammonia-N do not exist upstream of the SRWTP at Freeport in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Thus, like Alternative 4, operation of the water conveyance facilities under Alternative 5A would have negligible, if any, effect on ammonia concentrations in the rivers and reservoirs upstream of the Delta relative to Existing Conditions and the No Action Alternative (ELT and LLT). Any negligible increases in ammonia-N concentrations that could occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to ammonia.

Delta

As described for Alternative 4 (see Section 8.3.3.9), a substantial decrease in Sacramento River ammonia concentrations is expected under Alternative 5A relative to Existing Conditions, due to planned lowering of ammonia in the SRWTP effluent discharge, and this is expected to decrease ammonia concentrations for all areas of the Delta that are influenced by Sacramento River water. Concentrations of ammonia at locations not influenced notably by Sacramento River water would change little relative to Existing Conditions, due to the similarity in San Joaquin River and San Francisco Bay concentrations and the lack of expected changes in either of these concentrations. Thus, Alternative 5A would not result in substantial increases in ammonia concentrations in the project area, relative to Existing Conditions.

Relative to the No Action Alternative (ELT and LLT), the primary mechanism that could potentially alter ammonia concentrations under Alternative 5A is decreased flows in the Sacramento River, which would lower dilution available to the SRWTP discharge. This flow change would be attributable only to operations of the water conveyance facilities, since the same assumptions regarding SRWTP discharge ammonia concentrations, water demands, climate change, and sea level rise apply to both Alternative 5A and the No Action Alternative (ELT and LLT). A simple mass balance calculation was performed to calculate ammonia concentrations downstream of the SRWTP discharge (i.e., downstream of Freeport) under Alternative 5A and the No Action Alternative (ELT) to assess the effects of the flow changes. Monthly average CALSIM II flows at Freeport and the upstream ammonia concentration (0.04 mg/L-N; Central Valley Water Board 2010a:5) were used, together with the SRWTP permitted average dry weather flow (181 mgd) and seasonal ammonia limitations (1.5 mg/L-N in Apr–Oct, 2.4 mg/L-N in Nov–Mar), to estimate the average change in ammonia concentrations downstream of the SRWTP. Table 8-75 shows monthly average and long-term annual average predicted concentrations under Alternative 5A. As Table 8-75 shows, average monthly ammonia concentrations in the Sacramento River downstream of Freeport (upon full mixing of the SRWTP discharge with river water) under Alternative 5A and the No Action Alternative (ELT) are expected to be similar. In comparison to the No Action Alternative (ELT), minor increases in monthly average ammonia concentrations would occur during August, September, and November under Alternative 5A. Minor decreases in ammonia concentrations are expected for Alternative 5A in January through April, June and December. The annual average concentration under Alternative 5A would be the same as that under the No Action Alternative (ELT). Relative to the No Action Alternative (LLT), Alternative 5A (LLT) is expected to result in similar minor increases in Sacramento River ammonia concentration, because the increased water demands, climate change, and sea level rise in the LLT would occur under both alternatives, and neither would affect ammonia sources or loading. The estimated ammonia concentrations in the Sacramento River downstream of Freeport under Alternative 5A would be similar to existing source water concentrations for the San Francisco Bay and San Joaquin River. Consequently, changes in source water fraction anticipated under Alternative 5A, relative to the No Action Alternative (ELT and LLT), are not expected to substantially increase ammonia concentrations at any Delta locations.

Ammonia concentrations downstream of Freeport on the Sacramento River under Alternative 5A would be similar to those under Alternative 4 (see Table 8-67 in Section 8.3.3.9). As stated for Alternative 4, any negligible increases in ammonia concentrations that could occur at certain locations in the Delta under Alternative 5A would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regard to ammonia.

Table 8-75. Estimated Ammonia (mg/L as N) Concentrations in the Sacramento River Downstream of the Sacramento Regional Wastewater Treatment Plant for the No Action Alternative Early Long-Term Timeframe (ELT) and Alternative 5A

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Annual Average
No Action Alternative (ELT)	0.076	0.082	0.069	0.062	0.059	0.062	0.059	0.062	0.067	0.060	0.067	0.064	0.066
Alternative 5A	0.076	0.085	0.068	0.061	0.058	0.061	0.058	0.062	0.064	0.060	0.068	0.068	0.066

SWP CVP Export Service Areas

As discussed above, for areas of the Delta that are influenced by Sacramento River water, including Banks and Jones pumping plants, ammonia-N concentrations are expected to decrease under Alternative 5A, relative to Existing Conditions (in association with less diversion of water influenced by the SRWTP). Like Alternative 4, this decrease in ammonia-N concentrations for water exported via the south Delta pumps is not expected to result in an adverse effect on beneficial uses or substantially degrade water quality of exported water, with regard to ammonia. Furthermore, as discussed above, for all areas of the Delta, including Banks and Jones pumping plants, ammonia concentrations are not expected to be substantially different under Alternative 5A (LLT) relative to the No Action Alternative (ELT), and Alternative 5A (LLT) relative to the No Action Alternative (LLT). Thus, any negligible increases in ammonia concentrations that could occur at Banks and Jones pumping plants would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade water quality at these locations, with regard to ammonia.

NEPA Effects: In summary, ammonia concentrations in water bodies upstream of the Delta, in the Plan Area, and the waters exported to the SWP/CVP Export Service Areas are not expected to be substantially different under Alternative 5A relative to the No Action Alternative (ELT and LLT). Thus, effects of the water conveyance facilities on ammonia are considered to be not adverse.

CEQA Conclusion: The magnitude and direction of changes in ammonia concentrations in water bodies upstream of the Delta, in the Plan Area, or the waters exported to the SWP/CVP Export Service Areas would be approximately the same as expected under Alternative 4, relative to Existing Conditions. There would be no substantial, long-term increase in ammonia concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 5A relative to Existing Conditions. As such, Alternative 5A is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because ammonia concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects on beneficial uses would occur. Ammonia is not CWA Section 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-2: Effects on Ammonia Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Some habitat restoration activities would occur on lands in the Delta formerly used for irrigated agriculture. Although this may decrease ammonia loading to the Delta from agriculture, increased biota in those areas as a result of restored habitat may increase ammonia loading originating from flora and fauna. Ammonia loaded from organisms is expected to be converted rapidly to nitrate by established microbial communities. Thus, these land use changes would not be expected to substantially increase ammonia concentrations in the Delta. Implementation of Environmental Commitments 12, 15, and 16 do not include actions that would affect ammonia sources or loading. Based on these findings, the effects on ammonia from the implementation Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 5A are determined to not be adverse.

CEQA Conclusion**:** Land use changes that would occur from the Environmental Commitments are not expected to contribute substantially increase ammonia concentrations, because the amount of area to be converted would be small relative to existing habitat, and any resulting ammonia would likely be rapidly converted to nitrate. Thus, there would be no substantial, long-term increase in ammonia concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 relative to Existing Conditions. As such, implementation of these Environmental Commitments would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. Because ammonia concentrations would not be expected to increase substantially from implementation of these Environmental Commitments, no long-term water quality degradation would be expected to occur and, thus, no significant impact on beneficial uses would occur. Ammonia is not CWA Section 303(d) listed within the affected environment and thus any minor increases that could occur in some areas would not make any existing ammonia-related impairment measurably worse because no such impairments currently exist. Because ammonia is not bioaccumulative, minor increases that could occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered less than significant. No mitigation is required.

Impact WQ-3: Effects on Boron Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), under Alternative 5A there would be no expected change to the sources of boron in the Sacramento River and eastside tributary watersheds and, thus, resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of boron in the rivers and reservoirs of these watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease by 1%, relative to Existing Conditions (in association with the different operational components of Alternative 5A in the ELT, climate change, and increased water demands) (Appendix 8F, *Boron*, Table Bo-32). The reduced flow relative to Existing Conditions would result in possible increases in long-term average boron concentrations of up to about 0.5% relative to the Existing Conditions. Flows would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial boron increases relative to the No Action Alternative (ELT). The increased boron concentrations, relative to Existing Conditions, under Alternative 5A in the ELT would not increase the frequency of exceedances of any applicable objectives or criteria and would not be expected to cause further degradation at measurable levels in the lower San Joaquin River, and thus would not cause the existing impairment there to be discernibly worse. Consequently, Alternative 5A in the ELT would not be expected to cause exceedance of boron objectives/criteria or substantially degrade water quality with respect to boron, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Effects of Alternative 5A in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect boron sources in these areas.

Delta

Effects of water conveyance facilities on boron under Alternative 5A in the Delta would be similar to the effects discussed for Alternative 4.

The effects of Alternative 5A relative to Existing Conditions and the No Action Alternative (ELT) are discussed together because the direction and magnitude of predicted change are similar. Relative to the Existing Conditions and No Action Alternative (ELT), Alternative 5A would result in increased long-term average boron concentrations for the 16-year period modeled at most of the interior Delta locations (increases up to 1% at the S. Fork Mokelumne River at Staten Island, 3% at Franks Tract, and 4% at Old River at Rock Slough) (Appendix 8F, *Boron*, Table Bo-30). The long-term average boron concentrations at most of the western Delta assessment locations would not change measurably. The long-term annual average and monthly average boron concentrations, for either the 16-year period or drought period modeled, would never exceed the 2,000 μg/L human health advisory objective (i.e., for children) or the 500 μg/L agricultural objective at the majority of assessment locations, which represents no change from the Existing Conditions and No Action Alternative (ELT) (Appendix 8F, *Boron*, Table Bo-3C). A small increase in the frequency of exceedances 500 μg/L agricultural objective at the Sacramento River at Mallard Island (i.e., as much as 5% in the drought period relative to the No Action Alternative [ELT]) would not be anticipated to substantially affect agricultural diversions which occur primarily at interior Delta locations. Minor reductions in long-term average assimilative capacity of up to 2% at interior Delta locations (i.e., Old River at Rock Slough) would occur with respect to the 500 μg/L agricultural objective (Appendix 8F, Table Bo-31). However, because the absolute boron concentrations would still be well below the lowest 500 μg/L objective for the protection of the agricultural beneficial use under Alternative 5A, the levels of boron degradation would not be of sufficient magnitude to substantially increase the risk of exceeding objectives or cause adverse effects to municipal and agricultural water supply beneficial uses, or any other beneficial uses, in the Delta (Appendix 8F, *Boron*, Figure Bo-6).

Effects of Alternative 5A in the Delta in the LLT, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to those described above for the ELT. Boron concentrations may be higher at western Delta locations due to greater effects of climate change on sea level rise that would occur in the LLT; however, these effects are independent of the alternative.

Further, boron is of concern in waters diverted for agricultural use, which primarily occurs in the interior Delta, and based on Delta source water characteristics (see Table 8-42 in Section 8.3.1.7, *Construction-Specific Considerations Used in the Assessment*), boron concentrations in the interior Delta would be expected to remain suitable for agricultural use.

SWP/CVP Export Service Areas

Under the Alternative 5A, long-term average boron concentrations would decrease at Banks pumping plant (13%) and Jones pumping plant (11%) relative to Existing Conditions, and the reductions would be similar compared to No Action Alternative (ELT) (Appendix 8F, *Boron*, Table Bo-30) as a result of export of a greater proportion of low-boron Sacramento River water. Commensurate with the decrease in exported boron concentrations, boron concentrations in the lower San Joaquin River may be reduced and would likely alleviate or lessen any expected increase in boron concentrations at Vernalis associated with flow reductions (see discussion of Upstream of the Delta), as well as locations in the Delta receiving a large fraction of San Joaquin River water. Reduced export boron concentrations also may contribute to reducing the existing CWA Section 303(d) impairment in the lower San Joaquin River and associated TMDL actions for reducing boron loading. These same effects on boron at the Banks and Jones pumping plants would be expected in the LLT, because the primary effect of climate change on sea level rise and boron concentrations is expected in the western Delta.

Maintenance of SWP and CVP facilities under Alternative 5A would not be expected to create new sources of boron or contribute towards a substantial change in existing sources of boron in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative (ELT and LLT), Alternative 5A would result in relatively small increases in long-term average boron concentrations in the Delta, not measurably increase boron levels in the lower San Joaquin River, and reduce boron levels in water exported to the SWP/CVP export service areas. However, the predicted changes would not be expected to cause exceedances of applicable objectives or further measurable water quality degradation, and thus would not constitute an adverse effect on water quality.

CEQA Conclusion: Based on the above assessment, any modified reservoir operations and subsequent changes in river flows under Alternative 5A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in boron levels upstream of the Delta. Small increases in boron levels predicted for interior Delta locations in response to a shift in the Delta source water percentages would not be expected to cause exceedances of objectives, or substantial degradation of these water bodies. Alternative 5A maintenance also would not result in any substantial increases in boron concentrations in the affected environment. Boron concentrations would be reduced in water exported from the Delta to the CVP/SWP Export Service Areas, thus reflecting a potential improvement to boron loading in the lower San Joaquin River.

Boron is not a bioaccumulative constituent, thus any increased concentrations under Alternative 5A would not result in adverse boron bioaccumulation effects to aquatic life or humans. Relative to Existing Conditions, Alternative 5A would not result in substantially increased boron concentrations such that frequency of exceedances of municipal and agricultural water supply objectives would increase. The levels of boron degradation that may occur under Alternative 5A would not be of sufficient magnitude to cause substantially increased risk for adverse effects to municipal or agricultural beneficial uses within the affected environment. Long-term average boron concentrations would decrease in Delta water exports to the SWP and CVP service area, which may contribute to reducing the existing CWA Section 303(d) impairment of agricultural beneficial uses in the lower San Joaquin River. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-4: Effects on Boron Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 for Alternative 5A present no new direct sources of boron to the affected environment, including areas upstream of the Delta, within the Delta region, and in the SWP/CVP Export Service Areas. Habitat restoration activities in the Delta, while involving increased land and water interaction within these habitats, would not be anticipated to contribute boron which is primarily associated with source water inflows to the Delta (i.e., San Joaquin River, agricultural drainage, and Bay source water). Moreover, some habitat restoration would occur on lands within the Delta currently used for irrigated agriculture, thus replacing agricultural land uses with restored habitats. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated boron concentrations, which would be considered an improvement compared to the No Action Alternative (ELT and LLT). Consequently, as they pertain to boron, implementation of the Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 for Alternative 5A would not present new or substantially changed sources of boron to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP Export Service Areas. As such, their implementation would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or other criteria would be exceeded in water bodies of the affected environment located upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas or substantially degrade the quality of these water bodies, with regard to boron. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-5: Effects on Bromide Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (see Section 8.3.3.9), under Alternative 5A in the ELT there would be no expected change to the sources of bromide in the Sacramento River and eastside tributary watersheds. Thus, changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of bromide in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions and would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial bromide increases (Appendix 8E, *Bromide*, Table 24). Moreover, there are no existing municipal intakes on the lower San Joaquin River, which is the beneficial use most sensitive to elevated bromide concentrations. Consequently, Alternative 5A in the ELT would not be expected to adversely affect the MUN beneficial use, or any other beneficial uses, of the Sacramento River, the San Joaquin River, the eastside tributaries, or their associated reservoirs upstream of the Delta due to changes in bromide concentrations.

Effects of Alternative 5A in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect bromide sources in these areas.

Delta

Estimates of bromide concentrations at Delta assessment locations were generated using a mass balance approach, and using relationships between EC and chloride and between chloride and bromide and DSM2 EC output. See Section 8.3.1.3, *Plan Area*, for more information regarding these modeling approaches. The assessment below identifies changes in bromide at Delta assessment locations based on both approaches.

Based on the mass balance modeling approach for bromide, relative to Existing Conditions, Alternative 5A long-term average bromide concentrations would increase in the S. Fork Mokelumne River at Staten Island and Sacramento River at Emmaton, and decrease at all other assessment locations (Appendix 8E, *Bromide*, Table 22). Average bromide concentrations at Staten Island would increase from 50 µg/L under Existing Conditions to 52 µg/L (4% increase), and at Sacramento River at Emmaton from 1,284 µg/L to 1,286 µg/L (<1% increase) for the modeled 16-year hydrologic period (1976–1991). However, multiple interior and western Delta assessment locations would have an increased frequency of exceedance of 50 µg/L, which is the CALFED Drinking Water Program goal for bromide as a long-term average applied to drinking water intakes (Appendix 8E, Table 22). These locations are the S. Fork Mokelumne River at Staten Island, Old River at Rock Slough, Sacramento River at Emmaton, San Joaquin River at Antioch, and Sacramento River at Mallard Island. The greatest increase in frequency of exceedance of the CALFED Drinking Water Program long-term goal of 50 µg/L would occur in the S. Fork Mokelumne River (7% increase) and Sacramento River at Emmaton (3% increase). The increase in frequency of exceedance of the 50 µg/L threshold at the other locations would be 3% or less. Also, these locations (with the exception of the S. Fork Mokelumne River) and the Franks Tract and Contra Costa Pumping Plant #1 locations would have an increased frequency of exceedance of 100 µg/L, which is the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts (Appendix 8E, Table 22). The greatest increase in frequency of exceedance of 100 µg/L would occur at Sacramento River at Emmaton (4% increase). The increase in frequency of exceedance of the 100 µg/L threshold at the other locations would be 3% or less.

Changes in long-term average bromide concentrations and changes in threshold exceedance frequencies relative to the No Action Alternative (ELT) are generally of similar magnitude to those previously described relative to Existing Conditions (Appendix 8E, *Bromide*, Table 22). However, there would not be an increased frequency of exceedance of the 50 µg/L threshold in Old River at Rock Slough, but in Barker Slough there would be a 1% increase relative to the No Action Alternative (ELT). There would not be an increased frequency of exceedance of the 100 µg/L threshold at the Sacramento River at Emmaton and Mallard Island. The frequency of exceedance of the 100 µg/L threshold would increase by 2% at Contra Costa Pumping Plant #1 and 1% at Franks Tract, Old River at Rock Slough, and the San Joaquin River at Antioch.

Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide were consistent with the discussion above, and assessment of bromide using these modeling results lead to the same conclusions as are presented above for the mass balance approach (Appendix 8E, Table 23).

Unlike Alternative 4, there would be no increased bromide concentration in Barker Slough at the North Bay Aqueduct under Alternative 5A relative to Existing Conditions and the No Action Alternative (ELT). Also, the magnitude of bromide concentration changes at Mallard Slough and in the San Joaquin River at Antioch during their historical months of use, relative to Existing Conditions and the No Action Alternative (ELT), would be generally similar to those described for Alternative 4 (Appendix 8E, *Bromide*, Table 25), and the frequency of exceedance of bromide thresholds would be similar (Appendix 8E, Table 22). As described for Alternative 4, the use of seasonal intakes at these locations is largely driven by acceptable water quality, and thus has historically been opportunistic. Opportunity to use these intakes would remain, and the predicted increases in bromide concentrations at Antioch and Mallard Slough would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

The effects of Alternative 5A in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to that described above. There may be higher bromide concentrations in the LLT in the western Delta, but this would be associated with sea level rise, not the project alternative, because the primary source of bromide to the Delta is sea water intrusion.

SWP/CVP Export Service Areas

Under Alternative 5A, long-term average bromide concentrations at the Banks and Jones pumping plants, based on the mass balance modeling approach, would decrease. Long-term average bromide concentrations for the modeled 16-year hydrologic period at the pumping plants would decrease by as much as 30% relative to Existing Conditions and 21% relative to the No Action Alternative (ELT) (Appendix 8E, *Bromide*, Table 22). As a result, less frequent exceedances of the 50 μg/L and 100 μg/L assessment thresholds would occur and an overall improvement in SWP/CVP Export Service Areas water quality would occur respective to bromide. Commensurate with the decrease in exported bromide, an improvement in lower San Joaquin River bromide would also occur since bromide in the lower San Joaquin River is principally related to irrigation water deliveries from the Delta. Results of the modeling approach which used relationships between EC and chloride and between chloride and bromide are consistent with the mass balance results, and assessment of bromide using these modeling results leads to the same conclusions (Appendix 8E, Table 23).

The effects of Alternative 5A in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to that described above, because the sea level rise that could occur in the LLT would not result in substantial bromide contributions to the water exported at Banks and Jones pumping plants.

Maintenance of SWP and CVP facilities under Alternative 5A would not be expected to create new sources of bromide or contribute towards a substantial change in existing sources of bromide in the affected environment. Maintenance activities would not be expected to cause any substantial change in bromide such that MUN beneficial uses, or any other beneficial use, would be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, the operations and maintenance activities under Alternative 5A, relative to the No Action Alternative (ELT and LLT) would result in an increased frequency of exceedance of the CALFED Drinking Water Program long-term bromide goal of 50 μg/L at the S. Fork Mokelumne River at Staten Island, Sacramento River at Emmaton, San Joaquin River at Antioch, Sacramento River at Mallard Island, and in Barker Slough. The frequency of exceedance of the 100 μg/L threshold for protection against the formation of disinfection byproducts in treated drinking water would increase by 2% at Contra Costa Pumping Plant #1 and 1% at Franks Tract, Old River at Rock Slough, and the San Joaquin River at Antioch. However, long-term average bromide concentrations would increase only in the S. Fork Mokelumne River at Staten Island and Sacramento River at Emmaton; there would be decreases in long-term average bromide concentrations at the other assessment locations. The long-term bromide concentration in the S. Fork Mokelumne River at Staten Island would be less than the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts, and the increase at Emmaton would be very small (<1%). Thus, these increased bromide concentrations are not expected to result in adverse effects to MUN beneficial uses, or any other beneficial use, at these locations. Based on these findings, this effect is determined to not be adverse.

CEQA Conclusion: While greater water demands under Alternative 5A would alter the magnitude and timing of reservoir releases north and east of the Delta, these activities would have negligible, if any, effect on the sources of bromide, and ultimately the concentration of bromide in the Sacramento River, the San Joaquin River, the eastside tributaries, and the various reservoirs of the related watersheds, as described for Alternative 4 (see Section 8.3.3.9).

Under Alternative 5A there would be an increased frequency of exceedance of the CALFED Drinking Water Program long-term bromide goal of 50 μg/L at the S. Fork Mokelumne River at Staten Island, Old River at Rock Slough, Sacramento River at Emmaton, San Joaquin River at Antioch, and Sacramento River at Mallard Island. Also, these locations (with the exception of the S. Fork Mokelumne River) and the Franks Tract and Contra Costa Pumping Plant #1 locations, would have an increased frequency of exceedance of 100 μg/L, which is the concentration believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts. However, long-term average bromide concentrations would increase only in the S. Fork Mokelumne River at Staten Island and Sacramento River at Emmaton and decrease at all other assessment locations. The long-term bromide concentration in the S. Fork Mokelumne River at Staten Island (52 μg/L) would be less than the 100 μg/L believed to be sufficient to meet currently established drinking water criteria for disinfection byproducts, and the increase at Sacramento River at Emmaton would be very small (<1%). Further, as described for Alternative 4 (see Section 8.3.3.9), the use of seasonal intakes at Antioch and Mallard Island is largely driven by acceptable water quality, and thus has historically been opportunistic and opportunity to use these intakes would remain. Thus, these increased bromide concentrations would not be expected to adversely affect MUN beneficial uses, or any other beneficial use, at these locations.

The assessment of effects on bromide in the SWP/CVP Export Service Areas is based on assessment of changes in bromide concentrations at Banks and Jones pumping plants. Long-term average bromide concentrations at the Banks and Jones pumping plants are predicted to decrease by as much as 30% relative to Existing Conditions and there would be less frequent exceedance of bromide concentration thresholds.

Based on the above, Alternative 5A would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria because none exist for bromide. Alternative 5A would not result in any substantial change in long-term average bromide concentration or exceed 50 and 100 μg/L assessment threshold concentrations by frequency, magnitude, and geographic extent that would result in adverse effects on any beneficial uses within affected water bodies. Bromide is not a bioaccumulative constituent and thus concentrations under this alternative would not result in bromide bioaccumulating in aquatic organisms. Increases in exceedances of the 100 μg/L assessment threshold concentration would be 4% or less at all locations assessed, which is considered to be less than substantial long-term degradation of water quality. The levels of bromide degradation that may occur under the Alternative 5A would not be of sufficient magnitude to cause substantially increased risk for adverse effects on any beneficial uses of water bodies within the affected environment. Bromide is not CWA Section 303(d) listed and thus the minor increases in long-term average bromide concentrations would not affect existing beneficial use impairment because no such use impairment currently exists for bromide. Based on these findings, this impact is less than significant. No mitigation is required.

Impact WQ-6: Effects on Bromide Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would present no new sources of bromide to the affected environment, including areas Upstream of the Delta, within the Plan Area, and the SWP/CVP Export Service Areas. Some habitat restoration activities would occur on lands in the Delta formerly used for irrigated agriculture. Such replacement or substitution of land use activity would not be expected to result in new or increased sources of bromide to the Delta. Therefore, as they pertain to bromide, implementation of these Environmental Commitments would not be expected to adversely affect MUN beneficial use, or any other beneficial uses, of the affected environment.

Environmental Commitment 4 would result in some tidal habitat restoration, however, the areal extent would be small relative to the existing and No Action Alternative tidal area and, thus not expected to appreciably affect the magnitude of daily tidal water exchange at the restoration areas or alter other hydrodynamic conditions in adjacent Delta channels that would result in measurable bromide concentration changes.

In summary, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 5A relative to the No Action Alternative (ELT and LLT), would have negligible, if any, effects on bromide concentrations. Therefore, the effects on bromide from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

***CEQA Conclusion*:** Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 5A would not present new or substantially changed sources of bromide to the affected environment. Some Environmental Commitments may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution would not be expected to substantially increase or present new sources of bromide. Thus, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would have negligible, if any, effects on bromide concentrations throughout the affected environment, would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria because none exist for bromide, and would not cause changes in bromide concentrations that would result in significant impacts on any beneficial uses within affected water bodies. Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause significant long-term water quality degradation such that there would be greater risk of significant impacts on beneficial uses, would not cause greater bioaccumulation of bromide, and would not further impair any beneficial uses due to bromide concentrations because no uses are currently impaired due to bromide levels. Based on these findings, this impact is considered less than significant. No mitigation is required.

Impact WQ-7: Effects on Chloride Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 5A on chloride concentrations in reservoirs and rivers upstream of the Delta would be the similar to those effects described for Alternative 4 (see Section 8.3.3.9). Chloride loading in these watersheds would remain unchanged and resultant changes in flows from altered system-wide operations would have negligible, if any, effects on the concentration of chloride in the rivers and reservoirs of these watersheds. There would be no expected change to the sources of chloride in the Sacramento River and eastside tributary watersheds, and changes in the magnitude and timing of reservoir releases north and east of the Delta would have negligible, if any, effect on the sources, and ultimately the concentration of chloride in the Sacramento River, the eastside tributaries, and the various reservoirs of the related watersheds. The modeled annual average lower San Joaquin River flow at Vernalis would decrease slightly (1%) compared to Existing Conditions and would remain virtually the same as the No Action Alternative (ELT), and thus flow changes would not result in substantial chloride increases. Moreover, there are no existing municipal intakes on the lower San Joaquin River. Consequently, Alternative 5A in the ELT would not be expected to cause exceedances of chloride objectives/criteria or substantially degrade water quality with respect to chloride, and thus would not adversely affect any beneficial uses of the Sacramento River, the eastside tributaries, associated reservoirs upstream of the Delta, or the San Joaquin River.

Effects of Alternative 5A in reservoirs and rivers upstream of the Delta in the LLT relative to Existing Conditions and the No Action Alternative (LLT) would be expected to be similar, because the climate change and sea level rise that would occur in the LLT would not affect chloride sources in these areas.

Delta

Estimates of chloride concentrations at Delta assessment locations were generated using a mass balance approach and EC-chloride relationships and DSM2 EC output. See Section 8.3.1.3, *Plan Area*, for more information regarding these modeling approaches. The assessment below identifies changes in chloride at Delta assessment locations based on both approaches.

Modeling of chloride using both the mass balance approach and EC-chloride relationship predicts that Alternative 5A in the ELT would result in reduced long-term average chloride concentrations, relative to Existing Conditions, for the 16-year period modeled at all assessment locations except for the S. Fork Mokelumne River at Staten Island. The increase in long-term average chloride concentration at Staten Island would be 1 mg/L (3%) based on the mass balance modeling and <1 mg/L (1%) based on the EC-chloride relationship (Appendix 8G, *Chloride*, Tables Cl-77 and Cl-78). These increases are extremely small in absolute terms and relative to applicable water quality objectives, and are within the estimated modeling uncertainty. This differs from Alternative 4, under which there would be increased long-term average chloride concentrations also at the North Bay Aqueduct at Barker Slough. The change in long-term average chloride concentrations relative to the No Action Alternative (ELT) would be similar to those relative to Existing Conditions.

The following outlines the modeled chloride changes relative to the applicable objectives and beneficial uses of Delta waters.

Municipal Beneficial Uses Relative to Existing Conditions

Estimates of chloride concentrations generated using EC-chloride relationships were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses on a basis of the percentage of years the chloride objective is exceeded for the modeled 16-year period. The objective is exceeded if chloride concentrations exceed 150 mg/L for a specified number of days in a given water year at Antioch and Contra Costa Pumping Plant #1. The modeled frequency of objective exceedance would decrease at the Contra Costa Pumping Plant #1 from 7% of years under Existing Conditions to 0% of years under Alternative 5A in the ELT (Appendix 8G, *Chloride*, Table Cl-64).

Evaluation of the 250 mg/L Bay-Delta WQCP objective for chloride utilized results from both the mass balance approach and EC-chloride relationship. The basis for the evaluation was the predicted number of days the objective would be exceeded for the modeled 16-year period.

Based on the mass balance approach, there would be a decreased frequency of exceedance of the 250 mg/L objective under Alternative 5A, relative to Existing Conditions, at all locations except in the Sacramento River at Mallard Island, San Joaquin River at Antioch, and the Sacramento River at Emmaton. In the Sacramento River at Mallard Island, the frequency of objective exceedance would increase from 85% under Existing Conditions to 86% under Alternative 5A for the entire period modeled (Appendix 8G, *Chloride*, Table Cl-81). In the San Joaquin River at Antioch, there would be an increase in chloride objective exceedance for the entire period modeled, from 66% under Existing Conditions to 70% under Alternative 5A. In the Sacramento River at Emmaton, there would be an increase in chloride objective exceedance during the drought period modeled, from 55% to 57%.

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3, *Plan Area*) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 5A, the modeled frequency of objective exceedance would decrease, from 6% of modeled days under Existing Conditions, to 5% of modeled days under Alternative 5A (Appendix 8G, *Chloride*, Table Cl-63).

The mass balance results also indicate reduced assimilative capacity with respect to the 250 mg/L objective during certain months and at certain locations. In the San Joaquin River at Antioch, there would be a reduction in assimilative capacity in March and April of up to 18% for the 16-year period modeled and 52% for the drought period modeled (Appendix 8G, *Chloride*, Table Cl-79). Assimilative capacity at the Contra Costa Pumping Plant #1 also would be reduced, in February through April by up to 8%, and in January of the drought period modeled by 4%.

When utilizing the EC-chloride relationship to model chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity would be similar to those discussed when utilizing the mass balance modeling approach (Appendix 8G, *Chloride*, Tables Cl-80 and Cl-82). However, the EC-chloride relationships generally predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, *Plan Area*, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

CWA Section 303(d) Listed Water Bodies–Relative to Existing Conditions

Tom Paine Slough in the southern Delta is on the state's CWA Section 303(d) list for chloride with respect to the secondary MCL of 250 mg/L. Monthly average chloride concentrations at the Old River at Tracy Road for the 16-year period modeled, which represents the nearest DSM2-modeled location to Tom Paine Slough, would be generally similar under Alternative 5A in the ELT relative to Existing Conditions, and thus, would not be further degraded on a long-term basis (Appendix 8G, *Chloride*, Figure Cl-17).

Suisun Marsh also is on the state's CWA Section 303(d) list for chloride in association with the Bay-Delta WQCP objectives for maximum allowable salinity during the months of October through May, which establish appropriate seasonal salinity conditions for fish and wildlife beneficial uses. With respect to Suisun Marsh, the monthly average chloride concentrations for the 16-year period modeled would generally increase by <10% under Alternative 5A in the ELT relative to Existing Conditions in March and April at the Sacramento River at Mallard Island (Appendix 8G, *Chloride*, Figure Cl-18), at Collinsville (Appendix 8G, Figure Cl-19), and in Montezuma Slough at Beldon's Landing (Appendix 8G, Figure Cl-20), and remain similar or decrease in all other months. Chloride levels in Suisun Marsh are highly dynamic on a sub-daily basis as a result of tidal influences. The changes identified above are small relative to normal day-to-day variability in chloride in Suisun Marsh. For these reasons, any changes in chloride in Suisun Marsh are expected to have no adverse effect on marsh beneficial uses. These changes reflect the effect of climate change and sea level rise, as well as the alternative. Comparisons to the No Action Alternative (ELT) below provide an assessment of the effect of the alternative alone.

Municipal Beneficial Uses Relative to No Action Alternative (ELT)

Similar to the assessment conducted for Existing Conditions, estimates of chloride concentrations generated from EC-chloride relationships were used to evaluate the 150 mg/L Bay-Delta WQCP objective for municipal and industrial beneficial uses. For Alternative 5A in the ELT, the modeled frequency of objective exceedance would not change at the Contra Costa Pumping Plant #1—both the No Action Alternative (ELT) and Alternative 5A in the ELT all would have 0% exceedance (Appendix 8G, *Chloride*, Table Cl-64).

Based on the mass balance approach, the frequency of exceedance of the 250 mg/L objective under Alternative 5A in the ELT would be the same, or would decrease, at all locations relative to the No Action Alternative (ELT), except in the San Joaquin River at Antioch during the drought period modeled (Appendix 8G, *Chloride*, Table Cl-81). The frequency of objective exceedance would increase from 85% to 87% at Antioch.

Similarly, estimates of chloride concentrations generated using EC-chloride relationships and DSM2 EC output (see Section 8.3.1.3, *Plan Area*) were also used to evaluate the 250 mg/L Bay-Delta WQCP objective for chloride at Contra Costa Pumping Plant #1, where daily average objectives apply. The basis for the evaluation was the predicted number of days the objective was exceeded for the modeled 16-year period. For Alternative 5A, the modeled frequency of objective exceedance would decrease, from 8% of modeled days under the No Action Alternative (ELT), to 5% of modeled days under Alternative 5A (Appendix 8G, *Chloride*, Table Cl-63).

The mass balance results indicate reduced assimilative capacity with respect to the 250 mg/L objective for certain months and locations. In the San Joaquin River at Antioch, there would be a reduction in assimilative capacity in April of 14% for the drought period modeled (Appendix 8G, *Chloride*, Table Cl-79).

When utilizing the EC-chloride relationship to model monthly average chloride concentrations for the 16-year period, trends in frequency of exceedance and use of assimilative capacity would be similar to those discussed for the mass balance modeling approach (Appendix 8G, *Chloride*, Tables Cl-80 and Cl-82). However, utilizing the EC-chloride relationships generally predicted changes of lesser magnitude, where predictions of change utilizing the mass balance approach were generally of greater magnitude, and thus more conservative. As discussed in Section 8.3.1.3, *Plan Area*, in cases of such disagreement, the approach that yielded the more conservative predictions was used as the basis for determining adverse impacts.

Figure Cl-21 in Appendix 8G, *Chloride*, shows chloride concentrations in April during the 5-year drought period (1987–1991) at Antioch, where Table Cl-79 indicated 14% use of assimilative capacity. The figure shows that during 2 of the 5 years, chloride concentrations increased relative to the No Action Alternative (ELT) and decreased in the other 3 years. The absolute differences estimated are fairly small and may be within modeling uncertainty. Figures Cl-22 and Cl-23 in Appendix 8G show a box and whisker plot and exceedance plot for April at Antioch for all dry and critical water years modeled (not just the 1987–1991 drought period). These graphs show that while the median chloride concentration is increased relative to the No Action Alternative (ELT), the maximum value decreased, while the 25th percentile and 75th percentile values remained about the same. Based on this analysis, long-term degradation is not expected at Antioch in April during drought years.

Based on the low level of water quality degradation estimated for the western Delta, and the lack of exceedance of water quality objectives, Alternative 5A is not expected to have substantial adverse effects on municipal and industrial beneficial uses in the western Delta.

CWA Section 303(d) Listed Water Bodies–Relative to No Action Alternative (ELT)

With respect to the state’s CWA Section 303(d) listing for chloride, Alternative 5A would generally result in changes similar to those discussed for the comparison to Existing Conditions. Monthly average chloride concentrations at Tom Paine Slough would not be further degraded on a long-term basis, based on changes that would occur in Old River at Tracy Road (Appendix 8G, *Chloride*, Figure Cl-17). Modeling indicated that monthly average chloride concentrations at source water channel locations for the Suisun Marsh would remain similar or decrease relative to the No Action Alternative (ELT) (Appendix 8G, Figures Cl-18, Cl-19, and Cl-20). For these reasons, any changes in chloride in Suisun Marsh are expected to have no adverse effect on marsh beneficial uses.

The effects of Alternative 5A in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to effects in the ELT. With greater climate change and sea level rise, additional outflow may be required at certain times to prevent increases in chloride in the west Delta. Small increases in chloride concentrations may occur in some areas, but it is not expected that these increases would cause exceedance of Bay-Delta WQCP objectives of cause substantial long-term degradation that would impact municipal and industrial beneficial uses.

SWP/CVP Export Service Areas

Under Alternative 5A in the ELT, long-term average chloride concentrations at the Banks and Jones pumping plants, based on the mass balance analysis of modeling results for the 16-year period, would decrease relative to Existing Conditions. Chloride concentrations would be reduced by 29% at Banks pumping plant (Appendix 8G, *Chloride*, Table Cl-77). At Jones pumping plant, chloride concentrations would be reduced 25% (Appendix 8G, *Chloride*, Table Cl-77). The frequency of exceedances of applicable water quality objectives would be the same relative to Existing Conditions (Appendix 8G, Table Cl-81). The chloride concentration changes relative to the No Action Alternative (ELT) would be similar. Consequently, water exported into the SWP/CVP Export Service Areas would generally be of similar or better quality with regard to chloride relative to Existing Conditions and the No Action Alternative (ELT). Results of the modeling approach which utilized a EC-chloride relationship are consistent these results, and assessment of chloride using these modeling output results in the same conclusions as for the mass balance approach (Appendix 8G, Tables Cl-78 and Cl-82).

Commensurate with the reduced chloride concentrations in water exported to the SWP/CVP Export Service Area, reduced chloride loading in the lower San Joaquin River would be anticipated which would likely alleviate chloride concentrations at Vernalis.

The effects of Alternative in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be very similar to effects in the ELT. The difference in these timeframes that could contribute to EC differences between the ELT and LLT is climate change and sea level rise, and thus would not be due to the alternative.

Maintenance of SWP and CVP facilities would not be expected to create new sources of chloride or contribute towards a substantial change in existing sources of chloride in the affected environment. Maintenance activities would not be expected to cause any substantial change in chloride such that any long-term water quality degradation would occur, thus, beneficial uses would not be adversely affected anywhere in the affected environment.

NEPA Effects: In summary, relative to the No Action Alternative (ELT and LLT), Alternative 5A would not result in substantially increased chloride concentrations in the Delta on a long-term average that would result in adverse effects on the municipal and industrial water supply beneficial use, or any other beneficial use. Additional exceedance of the 150 mg/L and 250 mg/L objectives is not expected, and substantial long-term degradation is not expected that would result in adverse effects on the municipal and industrial water supply beneficial use, or any other beneficial use. Based on these findings, this effect is determined to not be adverse.

CEQA Conclusion: Chloride is not a constituent of concern in the Sacramento River watershed upstream of the Delta, thus river flow rate and reservoir storage reductions that would occur under Alternative 5A relative to Existing Conditions, would not be expected to result in a substantial adverse change in chloride levels. Additionally, relative to Existing Conditions, Alternative 5A would not result in reductions in river flow rates (i.e., less dilution) or increased chloride loading such that there would be any substantial increase in chloride concentrations upstream of the Delta in the San Joaquin River watershed.

Relative to Existing Conditions, Alternative 5A would result in substantially increased chloride concentrations in the Delta on a long-term average that would result in adverse effects on the municipal and industrial water supply beneficial use. Additional exceedance of the 150 mg/L and

250 mg/L objectives is not expected, and substantial long-term degradation is not expected that would result in adverse effects on the municipal and industrial water supply beneficial use.

Chloride concentrations would be reduced under Alternative 5A in water exported from the Delta to the SWP/CVP Export Service Areas thus reflecting a potential improvement to chloride loading in the lower San Joaquin River.

Chloride is not a bioaccumulative constituent, thus any increased concentrations under the Alternative 5A would not result in substantial chloride bioaccumulation impacts on aquatic life or humans. Alternative 5A maintenance would not result in any substantial changes in chloride concentration upstream of the Delta or in the SWP/CVP Export Service Areas.

Based on these findings, this impact is determined to be less than significant. No mitigation is required. Despite the fact that no mitigation is required, DWR proposed to further reduce any impacts by implementing Mitigation Measure WQ-7e.

Mitigation Measure WQ-7e: Implement Terms of the Contra Costa Water District Settlement Agreement

Impact WQ-8: Effects on Chloride Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 5A would present no new direct sources of chloride to the affected environment, including areas Upstream of the Delta, within the Plan Area, and the SWP/CVP Export Service Areas. Consequently, as they pertain to chloride, implementation of these Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment. Moreover, some habitat restoration activities would occur on lands within the Delta currently used for irrigated agriculture. The potential reduction in irrigated lands within the Delta may result in reduced discharges of agricultural field drainage with elevated chloride concentrations, which would be considered an improvement relative to the No Action Alternative (ELT and LLT). Therefore, the effects on chloride from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

***CEQA Conclusion*:** Implementation of the Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 5A would not present new or substantially changed sources of chloride to the affected environment upstream of the Delta, within Delta, or in the SWP/CVP Export Service Areas. Replacement of irrigated agricultural land uses in the Delta with habitat restoration may result in some reduction in discharge of agricultural field drainage with elevated chloride concentrations, thus resulting in improved water quality conditions. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-9: Effects on Dissolved Oxygen Resulting from Facilities Operations and Maintenance

As described in detail for Alternative 4 (see Section 8.3.3.9), DO levels are primarily affected by water temperature, flow velocity, turbulence, amounts of oxygen demanding substances present (e.g., ammonia, organics), and rates of photosynthesis (which is influenced by nutrient levels), respiration, and decomposition. Water temperature and salinity affect the maximum DO saturation level (i.e., the highest amount of oxygen the water can dissolve). Flow velocity affects the turbulence and re-aeration of the water (i.e., the rate at which oxygen from the atmosphere can be dissolved in water). High nutrient content can support aquatic plant and algae growth, which in turn generates oxygen through photosynthesis and consumes oxygen through respiration and decomposition.

As described for Alternative 4, amounts of oxygen demanding substances present (e.g., ammonia, organics) in the reservoirs and rivers upstream of the Delta, rates of photosynthesis (which is influenced by nutrient levels/loading), and respiration and decomposition of aquatic life is not expected to change sufficiently under Alternative 5A (ELT and LLT) to substantially alter DO levels relative to Existing Conditions or the No Action Alternative (ELT and LLT). Further, the rivers upstream of the Delta are well oxygenated and experience periods of supersaturation (i.e., when DO level exceeds the saturation concentration). Because these are large, turbulent rivers, any reduced DO saturation level that would be caused by an increase in temperature under Alternative 5A would not be expected to cause DO levels to be outside of the range seen historically. Flow changes that would occur under Alternative 5A would not be expected to have substantial effects on river DO levels; likely, the changes would be immeasurable. This is because sufficient turbulence and interaction of river water with the atmosphere would continue to occur to maintain water saturation levels (due to these factors) at levels similar to that of Existing Conditions and the No Action Alternative (ELT and LLT).

Also as described for Alternative 4, salinity changes would generally have relatively minor effects on Delta DO levels. Further, the relative degree of tidal exchange of flows and turbulence, which contributes to exposure of Delta waters to the atmosphere for reaeration, would not be expected to substantially change relative to Existing Conditions or the No Action Alternative (ELT and LLT), such that these factors would reduce Delta DO levels below objectives or levels that protect beneficial uses. Similarly, increased temperature under Alternative 5A (ELT and LLT), which would be due to climate change, would generally have relatively minor effects on Delta DO levels, relative to Existing Conditions.

Similar to Alternative 4, flows in the San Joaquin River at Stockton under Alternative 5A were evaluated and are shown in Figure 8-65b. The figure shows that while flows do would change somewhat, they are would generally be within the range of flows seen under Existing Conditions and the No Action Alternative. Reports indicate that the aeration facility performs adequately under the range of flows from 250–1,000 cfs (ICF International 2010). Based on the above, the expected changes in flows in the San Joaquin River at Stockton are not expected to substantially move the point of minimum DO, and therefore the aeration facility will would likely still be located appropriately to keep DO levels above Basin Plan objectives.

Overall, assuming continued operation of the aerators, the alternative is not expected to have a substantial impact adverse effect on DO in the Deep Water Ship Channel. It is expected that DO levels in the Deep Water Ship Channel, which is CWA Section 303(d) listed as impaired due to low DO, would remain similar to those under Existing Conditions and the No Action Alternative (ELT and LLT) or improve as TMDL-required studies are completed and actions are implemented to improve DO levels. DO levels in other Clean Water Act Section 303(d)-listed waterways would not be expected to change relative to Existing Conditions or the No Action Alternative (ELT and LLT), as the circulation of flows, tidal flow exchange, and re-aeration would continue to occur.

In the SWP/CVP Export Service Areas, the primary factor that would affect DO in the conveyance channels and ultimately the receiving reservoirs would be changes in the levels of nutrients and oxygen-demanding substances and DO levels in the exported water. Because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions or the No Action Alternative (ELT and LLT) due to water quality regulations, canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

NEPA Effects: Because DO levels are not expected to change substantially relative to the No Action Alternative (ELT and LLT), the effects on DO from implementing Alternative 5A (ELT and LLT) are determined to not be adverse.

CEQA Conclusion: The effects of Alternative 5A on DO levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for Alternative 4 (see Section 8.3.3.9). Reservoir storage reductions that would occur under Alternative 5A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DO levels in the reservoirs, because oxygen sources (surface water aeration, aerated inflows, vertical mixing) would remain. Similarly, river flow rate reductions would not be expected to result in a substantial adverse change in DO levels in the rivers upstream of the Delta, given that mean monthly flows would remain within the ranges historically seen under Existing Conditions and the affected river are large and turbulent. Any reduced DO saturation level that may be caused by increased water temperature would not be expected to cause DO levels to be outside of the range seen historically. Finally, amounts of oxygen demanding substances and salinity would not be expected to change sufficiently to affect DO levels.

It is expected there would be no substantial change in Delta DO levels in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to DO. DO levels would be affected by nutrient loading, which the state regulates the discharges of, and this loading would not be expected to lower DO levels relative to Existing Conditions based on historical DO levels. Further, the anticipated changes in salinity would have relatively minor effects on DO levels, and tidal exchange, which contribute to the reaeration of Delta waters would not be expected to change substantially.

There is not expected to be substantial, if even measurable, changes in DO levels in the SWP/CVP Export Service Areas waters, relative to Existing Conditions, because the biochemical oxygen demand of the exported water would not be expected to substantially differ from that under Existing Conditions (due to water quality regulations), canal turbulence and exposure of the water to the atmosphere and the algal communities that exist within the canals would establish an equilibrium for DO levels within the canals. The same would occur in downstream reservoirs.

Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels are expected, long-term water quality degradation would not be expected to occur, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are CWA Section 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and DO-related impairment of these areas would not be expected. Based on these findings, this impact would be less than significant. No mitigation is required.

Impact WQ-10: Effects on Dissolved Oxygen Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Environmental Commitments 3, 4, 6–11 would involve habitat restoration actions. The increased habitat provided by these Environmental Commitments could contribute to an increased biochemical or sediment demand, through contribution of organic carbon and plants decaying. However, the areal extent of new habitat would be small relative to the existing and No Action Alternative habitat areas, and similar habitat existing in the Delta is not identified as contributing to adverse DO conditions. The remaining Environmental Commitments would not be expected to affect DO levels because they are actions that do not affect the presence of oxygen-demanding substances. Therefore, the effects on DO from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

CEQA Conclusion: It is expected that DO levels in the Upstream of the Delta Region, in the Plan Area, or in the SWP/CVP Export Service Areas following implementation of Environmental Commitments 3–12, 15, and 16 under Alternative 5A would not be substantially different from existing DO conditions, because these would contribute to a minimal, localized change in oxygen-demanding substances associated with habitat restoration, if at all. Therefore, these Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would result in significant impacts on any beneficial uses within affected water bodies. Because no substantial changes in DO levels would be expected, long-term water quality degradation would not be expected, and, thus, beneficial uses would not be adversely affected. Various Delta waterways are CWA Section 303(d)-listed for low DO, but because no substantial decreases in DO levels would be expected, greater degradation and impairment of these areas would not be expected. Based on these findings, this impact would be less than significant. No mitigation is required.

Impact WQ-11: Effects on Electrical Conductivity Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 5A on EC levels in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 (see Section 8.3.3.9). The extent of new urban growth would be less in the ELT, thus discharges of EC-elevating parameters in runoff and wastewater discharges to water bodies upstream of the Delta would be expected to be less than in the LLT. However, the state is regulating point source discharges of EC-related parameters and implementing a program to further decrease loading of EC-related parameters to tributaries. Based on these considerations, and those described in Section 8.3.3.9, EC levels (highs, lows, typical conditions) in the Sacramento River and its tributaries, the eastside tributaries, or their associated reservoirs upstream of the Delta would not be expected to be outside the ranges occurring under Existing Conditions.

For the San Joaquin River, increases in EC levels under Alternative 5A could occur, but would be slightly less than those described for Alternative 4 (see Section 8.3.3.9). This is because the effects of climate change on flows, which could affect dilution of high EC discharges, would be less in the ELT. The implementation of the adopted TMDL for the San Joaquin River at Vernalis and the ongoing development of the TMDL for the San Joaquin River upstream of Vernalis are expected to contribute to improved EC levels. Based on these considerations, substantial changes in EC levels in the San

Joaquin River relative to Existing Conditions would not be expected to be of sufficient magnitude and geographic extent that would result in adverse effects on any beneficial uses, or substantially degrade the quality of these water bodies, with regard to EC.

Delta

Initial review of modeling results indicated that Alternative 5A would potentially result in an increase in the number of days the Bay-Delta WQCP EC objectives would be exceeded in the Sacramento River at Emmaton and the San Joaquin River at Jersey Point relative to Existing Conditions, the San Joaquin River at San Andreas Landing relative to Existing Conditions and the No Action Alternative (ELT), and the San Joaquin River at Prisoners Point relative to the No Action Alternative (ELT) (Appendix 8H, *Electrical Conductivity*, Table EC-26). To understand and interpret these results, considerations must be made regarding uncertainty in the modeling and results from sensitivity analyses. In addition, modeling results indicate there would be small increases in long-term monthly average EC at modeled Suisun Marsh locations relative to Existing Conditions. These locations are addressed in detail below. At all other locations, the level of exceedance and modeled average EC levels under the alternative was approximately equivalent or lower than under Existing Conditions and the No Action Alternative (ELT).

Sacramento River at Emmaton

Modeling results indicated that the Emmaton EC objective would be exceeded more often under Alternative 5A than under Existing Conditions, but less often relative to the No Action Alternative (ELT). The modeling results also indicated that increases in EC could cause substantial water quality degradation in summer months of dry and critical water years. However, these increases in exceedance of the objective and degradation are expected to be addressed via real-time operations, including real time management of the north Delta and south Delta intakes, as well as Delta Cross Channel operation. Further discussion is provided below.

Modeling results indicated that the percentage of days the Emmaton EC objective would be exceeded for the entire period modeled (1976–1991) would increase from 6% under Existing Conditions to 10%; there would be a decrease of 2% relative to the No Action Alternative (ELT), from 12% to 10% (Appendix 8H, *Electrical Conductivity*, Table EC-26). The percentage of days out of compliance would increase from 11% under Existing Conditions to 20%; there would be a decrease of 1% relative to the No Action Alternative (ELT), from 21% to 20% (Appendix 8H, Table EC-26). The comparison of the alternative to Existing Conditions reflects changes due both to operation of the alternative as well as effects of sea level rise due to climate change. The comparison of the alternative to the No Action Alternative (ELT) reflects changes in EC due solely to operations of the alternative. Based on the comparison to the No Action Alternative (ELT), the alternative would not contribute to additional exceedance of the EC objective at Emmaton.

The results of the EC modeling indicate there would be months with substantial degradation relative to the No Action Alternative (ELT), particularly during the drought period modeled. Long-term average EC levels at Emmaton would increase in the months of July through September and November by 1–7% for the entire period modeled (1976–1991), and in the months of July, August, and November by 1–25% during the drought period modeled (1987–1991), relative to the No Action Alternative (ELT) (Appendix 8H, *Electrical Conductivity*, Table EC-31). The largest increases in EC would occur in dry and critical water year types. These periods of degradation are expected to be addressed via real-time operations. The level to which modeling output depicts degradation of water quality with respect to EC is primarily a function of the modeling not being able to fully capture how the system would be operated in real-time to minimize or avoid such degradation

Discussions with SWP operators indicated that real-time operations would ensure that the Bay-Delta WQCP EC objectives at Emmaton, applicable from April 1 through August 15, would be met. In latter August and September, the Threemile Slough standard in the North Delta Water Agency Agreement and the Bay-Delta WQCP municipal and industrial objective at Rock Slough are in effect. During this period of the year, the coordinated operations of the SWP/CVP system strives to meet both standards in the most water-efficient method available to the CVP and SWP. Real-time operation would result in less EC degradation than depicted by modeling output because in order to comply with Bay-Delta WQCP objectives and the the North Delta Water Agency Agreement during the summer period, operators could, for example, increase upstream reservoir releases for necessary periods of time, reduce North Delta diversions, and/or close (short-term) the Delta Cross Channel. These options as well as real-time and forecasted tides, winds and barometric pressure are considered when the projects schedule daily operations, which the modeling does not fully capture.

Alternaltive 5A does not change the Bay-Delta WQCP objectives or the the North Delta Water Agency Agreement which are primary drivers of operations and resulting water quality in the Sacramento River at at Emmaton during late August and September. Therefore, the EC degradation at Emmaton that would occur upon implementation of Alternative 5A would be lesser than that shown by the modeling and would not be expected to differ substantially from that which would occur under the No Project Alternative because the compliance targets are not changing due to Alternative 5A during these months and real-time operations would achieve the compliance targets.

The modeling results also show that in the remaining months there would be decreases in EC relative to the No Action Alternative (ELT) of 2–7% for the entire period modeled and 1–10% for the drought period modeled. These decreases would contribute to the long-term average EC levels being similar to No Action Alternative (ELT) for the entire period modeled and decreasing by 1% for the drought period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-31).

San Joaquin River at San Andreas Landing

Alternative 5A is not expected to have adverse effects on EC in the San Joaquin River at San Andreas Landing, relative to Existing Conditions and the No Action Alternative (ELT). Modeling results estimated that the percentage of days the San Andreas Landing EC objective would be exceeded would increase by <1% relative to Existing Conditions, and the percentage of days out of compliance would increase from 1% under Existing Conditions to 2% (Appendix 8H, *Electrical Conductivity*, Table EC-26). San Andreas Landing average EC would decrease by 7% for the entire period modeled and 3% during the drought period modeled, relative to Existing Conditions (Appendix 8H, *Electrical Conductivity*, Table EC-31). Results relative to the No Action Alternative (ELT) were similar (Appendix 8H, *Electrical Conductivity*, Table EC-31). Sensitivity analyses performed for Alternative 4 Scenario H3 at the LLT indicate that many of these exceedances are likely modeling artifacts, and the small number of remaining exceedances would be small in magnitude, lasting only a few days, and could be addressed with real time operations of the SWP and CVP (see Section 8.3.1.1, *Models Used and Their Linkages*, for a description of real time operations of the SWP and CVP). These sensitivity analyses were only run at the LLT, but it is expected that the findings can generally be extended to the ELT, because the factors affecting salinity findings in the sensitivity analysis (e.g., modeling assumptions, physical hydrodynamic mechanisms) are similar between the ELT and LLT (see Appendix 8H Attachment 1,).

San Joaquin River at Prisoners Point

Modeling results indicated that the EC objective that applies to the San Joaquin River between Jersey Point and Prisoners Point would be exceeded at Prisoners Point more often under Alternative 5A than under the No Action Alternative (ELT), but less often relative to Existing Conditions. The exceedances relative to the No Action Alternative (ELT) are expected to be able to be addressed via real-time operations, including real time management of the north Delta and south Delta intakes, as well as Head of Old River Barrier management. Further discussion is provided below.

Modeling results estimated that the percentage of days the Prisoners Point EC objective would be exceeded would increase from 2% under the No Action Alternative (ELT) to 4% and the percentage of days out of compliance with the EC objective would increase from 2% under the No Action Alternative (ELT) to 6% (Appendix 8H, *Electrical Conductivity*, Table EC-26). The magnitude and duration of these differences is expected to be within the modeling uncertainty, indicating no measurable change in EC would be expected in the environment.

San Joaquin River at Jersey Point

Modeling results indicated that the EC objective that applies between the San Joaquin River at Jersey Point and Prisoners Point also would be exceeded at Jersey Point more often under Alternative 5A than under Existing Conditions, and less often relative to the No Action Alternative (ELT). At Jersey Point, modeling results estimated that the percentage of days the EC objective would be exceeded would change from 0% under Existing Conditions, or 3% under the No Action Alternative (ELT), to 2%, and the percentage of days out of compliance with the EC objective would change from 0% under Existing Conditions, or 3% under the No Action Alternative (ELT), to 2% (Appendix 8H, *Electrical Conductivity*, Table EC-26). The incremental change in the frequency of objective exceedance relative to the No Action Alternative (ELT), which reflects only the effects due to the alternative, and not effects of climate change, sea level rise and water demands, would be a reduction of 1%. Therefore, the alternative would not contribute to additional exceedances of the EC objective at Jersey Point.

Suisun Marsh

For Suisun Marsh October–May is the period when Bay-Delta WQCP EC objectives for protection of fish and wildlife apply. Modeling results indicate that average EC for the entire period modeled would increase in the Sacramento River at Collinsville during the months of March and April relative to Existing Conditions, by 0.1 mS/cm (Appendix 8H, *Electrical Conductivity*, Table EC-32). In Montezuma Slough at National Steel, average EC levels would increase in March through May by 0.1–0.2 mS/cm (Appendix 8H, *Electrical Conductivity*, Table EC-33).). There would be similarly small increases in long-term average EC in the months of March through May in Montezuma Slough near Beldon's Landing, Chadbourne Slough near Sunrise Duck Club, and Suisun Slough near Volanti Slough, ranging 0.1–0.4 mS/cm depending on month and location (Appendix 8H, *Electrical Conductivity*, Tables EC-34 through EC-36). Relative to the No Action Alternative (ELT), the modeled long-term average EC under the alternative would be similar or lower from October through May for these locations (Appendix 8H, *Electrical Conductivity*, Tables EC-32 through EC-36).

The Suisun Marsh EC objectives are expressed as a monthly average of daily high tide EC, which does not have to be met if it can be demonstrated "equivalent or better protection will be provided at the location" (State Water Resources Control Board 2006:14). Long-term average EC increases relative to Existing Conditions may, or may not, contribute to adverse effects on beneficial uses, depending on how and when wetlands are flooded, soil leaching cycles, how agricultural use of water is managed, and future actions taken with respect to the Marsh. Given the Bay-Delta WQCP narrative objective regarding “equivalent or better protection” in lieu of meeting specific numeric objectives, the small increase in EC under Alternative 5A, relative to Existing Conditions, would not be expected to adversely affect beneficial uses of Suisun Marsh. While Suisun Marsh is CWA Section 303(d) listed as impaired because of elevated EC, the potential increases in long-term average EC concentrations, relative to Existing Conditions, would not be expected to contribute to additional impairment, because the increase would be so small (<1 mS/cm) relative to the daily fluctuations in EC levels as to not be measurable and beneficial uses would not be adversely affected.

Further, the EC changes in Suisun Marsh relative to Existing Conditions reflect the influence of both operations of the alternative and sea level rise due to climate change, whereas the changes relative to the No Action Alternative (ELT) are due solely to operations of the alternative. As described above, there would be no increase in the long-term average EC at modeled Suisun Marsh locations, and for some locations long-term average EC would decrease. Therefore, it is expected that this alternative would not contribute to exceedances of EC objectives or additional impairment of beneficial uses, as affected by EC or other salinity-related parameters.

The effects of Alternative 5A in the LLT in the Delta region, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be similar to effects in the ELT. With greater climate change and sea level rise, additional outflow may be required at certain times to prevent increases in EC in the west Delta, but this requirement would not be due to the alternative.

SWP/CVP Export Service Areas

Under Alternative 5A, at the Banks pumping plant, the frequency of exceedance of the EC objective would be 1% for the entire period modeled and 2% for the drought period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-27). Relative to Existing Conditions, average EC levels under Alternative 5A would decrease 19% for the entire period modeled and 17% during the drought period modeled (Appendix 8H, *Electrical Conductivity*, Table EC-31). Relative to the No Action Alternative (ELT), average EC levels would similarly decrease, by 15% for the entire period modeled and drought period modeled ((Appendix 8H, *Electrical Conductivity*, Table EC-31).

At the Jones pumping plant, the frequency of exceedance of the EC objective would be 1% for the entire period modeled and 0% for the drought period modeled. Relative to Existing Conditions, average EC levels under Alternative 5A would decrease 16% for the entire period modeled and 17% during the drought period modeled. Relative to the No Action Alternative (ELT), average EC levels would similarly decrease, by 13% for the entire period modeled and 15% for the drought period modeled ((Appendix 8H, *Electrical Conductivity*, Table EC-31).

Based on the decreases in long-term average EC levels that would occur at the Banks and Jones pumping plants, Alternative 5A would not cause degradation of water quality with respect to EC in the SWP/CVP Export Service Areas. Rather, Alternative 5A would improve long-term average EC conditions in the SWP/CVP Export Service Areas.

Commensurate with the EC decrease in exported waters, an improvement in lower San Joaquin River average EC levels would be expected since EC in the lower San Joaquin River is, in part, related to irrigation water deliveries from the Delta. While the magnitude of this expected lower San Joaquin River improvement in EC is difficult to predict, the relative decrease in overall loading of EC-elevating constituents to the Export Service Areas would likely alleviate or lessen any expected increase in EC at Vernalis related to decreased annual average San Joaquin River flows.

The export area of the Delta is listed on the state's CWA Section 303(d) list as impaired due to elevated EC Alternative 5A would result in lower average EC levels relative to Existing Conditions and the No Action Alternative (ELT) and, thus, would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters.

The effects of Alternative 5A in the LLT in the SWP/CVP Export Service Areas, relative to Existing Conditions and the No Action Alternative (LLT), would be expected to be very similar to effects in the ELT. The difference in these timeframes that could contribute to EC differences between the ELT and LLT is climate change and sea level rise, and thus would not be due to the alternative.

NEPA Effects: In summary, based on the results of the modeling and sensitivity analyses conducted, it is unlikely that there would be increased frequency of exceedance of agricultural EC objectives in the western, interior, or southern Delta. However, modeling results indicate that there could be increased long-term and drought period average EC levels during the summer months that would occur in the western Delta (i.e., in the Sacramento River at Emmaton) under Alternative 5A relative to the No Action Alternative (ELT), that could contribute to adverse effects on the agricultural beneficial uses. In addition, the increased frequency of exceedance of the San Joaquin River at Prisoners Point EC objective could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. Suisun Marsh is CWA Section 303(d) listed as impaired due to elevated EC, but EC levels are not expected to increase under Alternative 5A, relative to the No Action Alternative (ELT), and thus it is not expected to contribute to additional beneficial use impairment. The increases in EC in the Sacramento River at Emmaton, particularly during summer months of dry and critical water years, and the additional exceedances of water quality objectives in the San Joaquin River at Prisoners Point constitute an adverse effect on water quality. Mitigation Measure WQ-11 would be available to reduce these effects.

CEQA Conclusion: River flow rate and reservoir storage reductions that would occur under Alternative 5A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in EC levels in the reservoirs and rivers upstream of the Delta, given that: changes in the quality of watershed runoff and reservoir inflows would not be expected to occur in the future; the state's regulation of point-source discharge effects on Delta salinity-elevating parameters and the expected further regulation as salt management plans are developed; the salt-related TMDLs adopted and being developed for the San Joaquin River; and the expected improvement in lower San Joaquin River average EC levels commensurate with the lower EC of the irrigation water deliveries from the Delta.

Relative to Existing Conditions, Alternative 5A would not result in any substantial increases in long-term average EC levels in the SWP/CVP Export Service Areas, and exceedance of the Bay-Delta WQCP EC objective would be infrequent. Average EC levels for the entire period modeled would decrease at both the Banks and Jones pumping plants and, thus, this alternative would not contribute to additional beneficial use impairment related to elevated EC in the SWP/CVP Export Service Areas waters. Rather, this alternative would improve long-term EC levels in the SWP/CVP Export Service Areas, relative to Existing Conditions.

Further, relative to Existing Conditions, Alternative 5A would not result in substantial increases in long-term average EC in Suisun Marsh. Thus, EC levels in Suisun Marsh are not expected to further degrade existing EC levels and thus would not contribute additionally to adverse effects on the fish and wildlife beneficial uses. Because EC is not bioaccumulative, any changes in long-term average EC levels would not directly cause bioaccumulative problems in fish and wildlife. Suisun Marsh is CWA Section 303(d) listed as impaired due to elevated EC, but EC levels are not expected to change substantially under Alternative 5A, relative to Existing Conditions, and thus it is not expected that they would contribute to additional beneficial use impairment.

In the Plan Area, Alternative 5A is not expected to result in an increase in the frequency with which Bay-Delta WQCP EC objectives are exceeded, except for at the San Joaquin River at Jersey Point (fish and wildlife objective: 2% increase). The increased frequency of exceedance is due to the combined effects of operations of the alternative along with climate change, sea level rise and increased water demands. A comparison to the No Action Alternative (ELT) results reveals that the alternative would not contribute to additional exceedance at Jersey Point and, thus, there would likely be no adverse effects to aquatic life at Jersey Point. However, there would be a discernible increased frequency of exceedance of the fish and wildlife objective at Prisoners Point that could contribute to adverse effects on aquatic life (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact. However, by adaptively managing the Head of Old River Barrier and the fraction of south Delta versus north Delta diversions, EC levels at Prisoners Point would likely be decreased to a level that would not adversely affect aquatic life beneficial uses.

Average EC levels at Emmaton were modeled to increase by 9% during the drought period modeled. The largest monthly average increases in EC were modeled to occur during the summer months of the drought period, and more generally in dry and critical water year types. The increases in drought period average EC levels modeled could cause substantial water quality degradation that would potentially contribute to adverse effects on the agricultural beneficial uses in the western Delta. The comparison to Existing Conditions reflects changes in EC due to both Alternative 5A operations and climate change/sea level rise. The adverse effects expected to occur at Emmaton would be due in part to the effects of climate change/sea level rise, and in part due to Alternative 5A operations. This is evidenced by the significant effects expected in the No Action Alternative (ELT) at Emmaton relative to Existing Conditions, as well as the fact that a lesser level of adverse effects is expected at Emmaton under Alternative 5A relative to the No Action Alternative (ELT). During summer of dry and critical water years, additional flow in the Sacramento River at Emmaton would reduce or eliminate increases in EC. It is expected that for July–August of dry and critical water years, real-time operations that would include more precise management of upstream reservoir realeases on a daily basis and less pumping from the north Delta intakes and greater reliance on south Delta intakes than that modeled would allow for enough flow in the Sacramento River at Emmaton to reduce water quality degradation to levels closer to the No Action Alternative that would not be expected to adversely affect beneficial uses. Because EC is not bioaccumulative, the increases in long-term average EC levels would not directly cause bioaccumulative problems in aquatic life or humans. The western Delta is CWA Section 303(d) listed for elevated EC and the increased EC degradation that was modeled in the western Delta could make beneficial use impairment measurably worse.

Based on these findings, this impact in the Plan Area is considered to be significant. Implementation of Mitigation Measure WQ-11 would be expected to reduce these effects to a less-than-significant level.

Mitigation Measure WQ-11: Avoid or Minimize Reduced Water Quality Conditions

Please see Mitigation Measure WQ-11 under Impact WQ-11 in the discussion of Alternative 4A.

Mitigation Measure WQ-11e: Adaptively Manage Diversions at the North and South Delta Intakes to Reduce or Eliminate Water Quality Degradation in Western Delta

Please see Mitigation Measure WQ-11e under Impact WQ-11 in the discussion of Alternative 4A.

Impact WQ-12: Effects on Electrical Conductivity Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: The implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would present no new direct sources of EC to the affected environment, including areas upstream of the Delta, within the Delta region, and in the SWP/CVP Export Service Areas. As they pertain to EC, implementation of these Environmental Commitments would not be expected to adversely affect any of the beneficial uses of the affected environment. Moreover, some habitat restoration activities would occur on lands within the Delta currently used for irrigated agriculture. Such replacement or substitution of land use activity is not expected to result in new or increased sources of EC to the Delta and, in fact, could decrease EC through elimination of high EC agricultural runoff.

Environmental Commitment 4 would result in some tidal habitat restoration, however, the areal extent would be small relative to the existing and No Action Alternative tidal area and, thus not expected to appreciably affect the magnitude of daily tidal water exchange at the restoration areas or alter other hydrodynamic conditions in adjacent Delta channels that would result in measurable EC changes.

In summary, implementation of the Environmental Commitments would not be expected to adversely affect EC levels in the affected environment and thus would not adversely affect beneficial uses or substantially degrade water quality with regard to EC within the affected environment. Therefore, the effects on EC from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 under Alternative 4A would not present new or substantially changed sources of EC to the affected environment. Some Environmental Commitments may replace or substitute for existing irrigated agriculture in the Delta. This replacement or substitution is not expected to substantially increase or present new sources of EC, and could actually decrease EC loads to Delta waters. Thus, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would have negligible, if any, adverse effects on EC levels throughout the affected environment and would not cause exceedance of applicable state or federal numeric or narrative water quality objectives/criteria that would result in adverse effects on any beneficial uses within affected water bodies. Further, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause significant long-term water quality degradation such that there would be greater risk of adverse effects on beneficial uses. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-13: Effects on Mercury Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of the Alternative 5A on mercury levels in surface waters upstream of the Delta relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because factors that affect mercury concentrations in surface waters upstream of the Delta are similar under Alternatives 4 and 5A. The changes in flow in the Sacramento River under Alternative 5A relative to Existing Conditions and the No Action Alternative (ELT) would not be of the magnitude of storm flows, in which substantial sediment-associated mercury is mobilized. Therefore, mercury loading should not be substantially different due to changes in flow. In addition, even though they may be flow-affected, total mercury concentrations remain well below criteria at upstream locations. Any negligible changes in mercury concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to mercury. Both waterborne methylmercury concentrations and largemouth bass fillet mercury concentrations are expected to remain above guidance levels at upstream of Delta locations, but would not change substantially because the anticipated changes in flow are not expected to substantially change mercury loading relative to Existing Conditions or the No Action Alternative (ELT).

The upstream of Delta areas in the north will benefit from the implementation of the Cache Creek, Sulfur Creek, Harley Gulch, and Clear Lake Mercury. TMDLs and the State Water Board's Statewide Mercury Control Program. These projects will target specific sources of mercury and methylation upstream of the Delta and could result in net improvement to Delta mercury loading in the future. The implementation of these projects could help to ensure that upstream of Delta environments will not be substantially degraded for water quality with respect to mercury or methylmercury.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

Delta

The effects of Alternative 5A on waterborne concentrations of mercury (Appendix 8I, *Mercury*, Table I-17) and methylmercury (Appendix 8I, *Mercury*, Table I-18), and fish tissue mercury concentrations for largemouth bass fillet (Appendix 8I, *Mercury*, Tables I-22a and I-22b) were evaluated for nine Delta locations.

Increases in long-term average mercury concentrations relative to Existing Conditions and the No Action Alternative (ELT) would be very small, 0.2 ng/L or less. Also, use of assimilative capacity for mercury relative to the 25 ng/L ecological threshold under Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT), would be very low, about 1% or less, as a long-term average, for all Delta locations (Appendix 8I, *Mercury*, Table I-25). These concentration changes and small changes in assimilative capacity for mercury are not expected to result in adverse (or positive) effects to beneficial uses.

Changes in methylmercury concentrations in water also are expected to be very small. The greatest annual average methylmercury concentration under Alternative 5A would be 0.168 ng/L for the San Joaquin River at Buckley Cove, for the drought period modeled, which would be slightly higher than Existing Conditions (0.161 ng/L) and the same as the No Action Alternative (ELT) (0.168 ng/L) (Appendix 8I, *Mercury*, Table I-18). All methylmercury concentrations in water were estimated to exceed the TMDL guidance objective of 0.06 ng/L under Existing Conditions and, therefore, no assimilative capacity exists.

Fish tissue estimates for largemouth bass fillet show small or no increases in mercury concentrations relative to Existing Conditions and the No Action Alternative (ELT) based on long-term annual average concentrations for mercury at the Delta locations. Concentrations expected for Alternative 5A, with Equation 1, show increases of 5% or less, relative to Existing Conditions and the No Action Alternative (ELT), in all years (Appendix 8I, *Mercury*, Table I-22a). With Equation 2, increases relative to Existing Conditions and the No Action Alternative (ELT) are estimated to be 7% or less (Appendix 8I, *Mercury*, Table I-22b).

Because the increases are relatively small, and it is not evident that substantive increases are expected at numerous locations throughout the Delta, these changes are expected to be within the uncertainty inherent in the modeling approach, and would likely not be measurable in the environment. See Appendix 8I, *Mercury*, for a complete discussion of the uncertainty associated with the fish tissue estimates. Briefly, the bioaccumulation models contain multiple sources of uncertainty associated with their development. These are related to: analytical variability; temporal and/or seasonal variability in Delta source water concentrations of merthylmercury; interconversion of mercury species (i.e., the non-conservative nature of methylmercury as a modeled constituent); and limited sample size (both in number of fish and time span over which the measurements were made), among others. Although there is considerable uncertainty in the models used, the results serve as a reasonable approximations of a very complex process. Considering the uncertainty, small (i.e., < 20–25%) increases or decreases in modeled fish tissue mercury concentrations at a low number of Delta locations (i.e., 2–3) should be interpreted to be within the uncertainty of the overall approach, and not predictive of actual adverse effects. Larger increases, or increases evident throughout the Delta, can be interpreted as more reliable indicators of potential adverse effects.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

The analysis of mercury and methylmercury in the SWP/CVP Export Service Areas was based on concentrations estimated at the Banks and Jones pumping plants. Both waterborne total and methylmercury concentrations for Alternative 5A, at the Jones and Banks pumping plants were lower than Existing Conditions and the No Action Alternative (ELT) (Appendix 8I, *Mercury*, Tables I-17 and I-18). Therefore, mercury shows an increased assimilative capacity at these locations (Appendix 8I, *Mercury*, Table I-24).

The largest improvements in largemouth bass tissue mercury concentrations and Exceedance Quotients ([EQs]); modeled tissue divided by TMDL guidance concentration) for Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT) at any location within the Delta are expected for the Banks and Jones pumping plants export pump locations. Concentrations expected for Alternative 5A at the export pump locations with Equation 1 in all years show decreases relative to Existing Conditions (4% to 5%) and relative to the No Action Alternative (ELT) (6%) (Appendix 8I, *Mercury*, Table I-22a). Concentrations expected for Equation 2 in all years show decreases relative to Existing Conditions (6% to 7%) and relative to the No Action Alternative (ELT) (8%) (Appendix 8I, *Mercury*, Table I-22a).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on mercury in the LLT are expected to be similar to those described above.

NEPA Effects: Based on the above discussion, Alternative 5A would not cause concentrations of mercury and methylmercury in water and fish tissue in the affected environment to be substantially different from the No Action Alternative (ELT and LLT) and, thus, would not cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to the No Action Alternative (ELT and LLT), Alternative 5A would not be expected to increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Based on these findings, the effects of Alternative 5A on mercury in the affected environment are considered to be not adverse.

CEQA Conclusion: Under Alternative 5A, greater water demands and climate change would alter the magnitude and timing of reservoir releases and river flows upstream of the Delta in the Sacramento River watershed and eastside tributaries, relative to Existing Conditions. Concentrations of mercury and methylmercury upstream of the Delta would not be substantially different relative to Existing Conditions due to the lack of important relationships between mercury/methylmercury concentrations and flow for the major rivers.

Methylmercury concentrations exceed criteria at all locations in the Delta and no assimilative capacity exists. However, monthly average waterborne concentrations of total and methylmercury, over the period of record under Alternative 5A would be very similar to Existing Conditions. Similarly, estimates of fish tissue mercury concentrations show small differences would occur among sites for Alternative 5A as compared to Existing Conditions for Delta sites.

Assessment of effects of mercury in the SWP/CVP Export Service Areas were based on effects on mercury concentrations and fish tissue mercury concentrations at the Banks and Jones pumping plants. The Banks and Jones pumping plants are expected to show increased assimilative capacity for waterborne mercury and decreased fish tissue concentrations of mercury for Alternative 5A, as compared to Existing Conditions.

As such, Alternative 5A is expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because mercury concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Because any increases in mercury or methylmercury concentrations are not likely to be measurable, changes in mercury concentrations or fish tissue mercury concentrations would not make any existing mercury-related impairment measurably worse. In comparison to Existing Conditions, Alternative 5A would not increase levels of mercury by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of mercury in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-14: Effects on Mercury Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: The potential types of effects on mercury resulting from implementation of the Environmental Commitments under Alternative 5A would be generally similar to those described under Alternative 4 (see Section 8.3.3.9). However, the magnitude of effects on mercury and methylmercury at locations upstream of the Delta, in the Delta, and the SWP/CVP Export Service Areas related to habitat restoration would be considerably lower than described for Alternative 4. This is because the amount of habitat restoration to be implemented under Alternative 5A would be very low compared to the total proposed restoration area that would be implemented under Alternative 4. The small amount of habitat restoration to be implemented under Alternative 5A may occur on lands in the Delta formerly used for irrigated agriculture. Habitat restoration proposed under Alternative 5A has the potential to increase water residence times and increase accumulation of organic sediments that are known to enhance methylmercury bioaccumulation in biota in the vicinity of the restored habitat areas. Design of restoration sites would be guided by Environmental Commitment 12, which requires development of site-specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time, although the potential to reduce methylmercury concentrations exists based on current research. Although Environmental Commitment 12 would be implemented with the goal to reduce this potential effect, the uncertainties related to site-specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta in the vicinity of the restored areas. Therefore, the effect of Environmental Commitments 3, 4, 6–12, 15, and 16 on mercury and methylmercury is considered to be adverse.

CEQA Conclusion: There would be no substantial, long-term increase in mercury or methylmercury concentrations or loads in the rivers and reservoirs upstream of the Delta or the waters exported to the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 relative to Existing Conditions. However, in the Delta, due to the small amount of tidal restoration areas proposed, relative to Existing Conditions, uptake of mercury from water and/or methylation of inorganic mercury may increase in localized areas as part of the creation of new, marshy, shallow, or organic-rich restoration areas. Although not quantifiable, on a local level, increases in methylmercury concentrations may be measurable. Methylmercury is CWA Section 303(d)-listed within the affected environment, and therefore any potential measurable increase in methylmercury concentrations would make existing mercury-related impairment measurably worse. Because mercury is bioaccumulative, increases in water-borne mercury or methylmercury that could occur in some areas could bioaccumulate to somewhat greater levels in aquatic organisms and would, in turn, pose health risks to fish, wildlife, or humans. Design of restoration sites would be guided by Environmental Commitment 12, which requires development of site-specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time, although the potential to reduce methylmercury concentrations exists based on current research. Although Environmental Commitment 12 would be implemented with the goal to reduce this potential effect, the uncertainties related to site specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta result in this potential impact being considered significant. No mitigation measures would be available until specific restoration actions are proposed. Therefore, this impact is considered significant and unavoidable.

Impact WQ-15: Effects on Nitrate Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

As described for Alternative 4 (in Section 8.3.3.9), nitrate levels in the major rivers (Sacramento, Feather, American) are low, generally due to ample dilution available in the reservoirs and rivers relative to the magnitude of the point and non-point source discharges, and there is no correlation between historical water year average nitrate concentrations and water year average flow in the Sacramento River at Freeport. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 5A, relative to Existing Conditions or the No Action Alternative (ELT), are expected to have negligible, if any, effects on average reservoir and river nitrate-N concentrations in the Sacramento River watershed upstream of the Delta.

In the San Joaquin River watershed, nitrate concentrations are higher than in the Sacramento River watershed, owing to use of nitrate based fertilizers throughout the lower watershed. The correlation between historical water year average nitrate concentrations and water year average flow in the San Joaquin River at Vernalis is a weak inverse relationship—that is, generally higher flows result in lower nitrate concentrations, while low flows result in higher nitrate concentrations (linear regression r^2=0.49; Figure 2 in Appendix 8J, *Nitrate*). Under Alternative 5A, long-term average flows at Vernalis would decrease an estimated 1% relative to Existing Conditions and would remain virtually the same relative to the No Action Alternative (ELT). Given the relatively small decreases in flows and the weak correlation between nitrate and flows in the San Joaquin River, it is expected that nitrate concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under the No Action Alternative (ELT and LLT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

Any negligible changes in nitrate concentrations that may occur under Alternative 5A in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies, with regard to nitrate.

Delta

Mass balance calculations indicate that under Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT), nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives (Appendix 8J, *Nitrate*, Table 34). Although changes at specific Delta locations and for specific months may be substantial on a relative basis (Appendix 8J, *Nitrate*, Table 41), the absolute concentration of nitrate in Delta waters would remain low (<1.4 mg/L-N) in relation to the drinking water MCL of 10 mg/L-N, as well as all other thresholds (see *Nitrate* under Section 8.3.1.7, *Constituent-Specific Considerations Used in the Assessment*). Long-term average nitrate concentrations are anticipated to remain below 1 mg/L-N at all 11 Delta assessment locations except the San Joaquin River at Buckley Cove, where long-term average concentrations would be somewhat above 1 mg/L-N. Nevertheless, at this location, long-term average nitrate concentrations would be somewhat reduced under Alternative 5A relative to Existing Conditions and slightly increased relative to the No Action Alternative (ELT). No additional exceedances of the MCL are anticipated at any location under Alternative 5A (Appendix 8J, *Nitrate*, Table 34).

Use of assimilative capacity relative to the drinking water MCL of 10 mg/L-N under Alternative 5A would be low or negligible (i.e., <3%) in comparison to both Existing Conditions and the No Action Alternative (ELT), for all locations and months, for all modeled years (1976–1991), and for the drought period (1987–1991) (Appendix 8J, *Nitrate*, Table 42).

As described for Alternative 4, actual nitrate concentrations would likely be higher than the modeling results indicate in certain locations under Alternative 5A. This is the mass balance modeling does not account for contributions from the SRWTP, which would be implementing nitrification/partial denitrification, or Delta wastewater treatment plant dischargers that practice nitrification, but not denitrification. However, for the reasons described for Alternative 4, any increases in nitrate concentrations that may occur at certain locations within the Delta under Alternative 5A would not be of frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the water quality at these locations, with regard to nitrate.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

Assessment of effects of Alternative 5A on nitrate in the SWP/CVP. Export Service Areas is based on effects on nitrate at the Banks and Jones pumping plants. Results of the mass balance calculations indicate that relative to Existing Conditions and the No Action Alternative (ELT), nitrate concentrations at Banks and Jones pumping plants under Alternative 5A are anticipated to decrease on a long-term average annual basis by 17% at the Banks pumping plant and 14% at the Jones pumping plant (Appendix 8J, *Nitrate*, Table 41). During the late summer, particularly in the drought period assessed, concentrations are expected to increase, but the absolute value of these changes (i.e., in mg/L-N) would be small. Additionally, given the many factors that contribute to potential algal blooms in the SWP and CVP canals within the Export Service Areas, and the lack of studies that have shown a direct relationship between nutrient concentrations in the canals and reservoirs and problematic algal blooms in these water bodies, there is no basis to conclude that these small (i.e., generally <0.2 mg/L-N), seasonal increases in nitrate concentrations would increase the potential for problem algal blooms in the SWP/CVP Export Service Areas. No additional exceedances of the MCL are anticipated under Alternative 5A relative to Existing Conditions and the No Action Alternative (ELT) (Appendix 8J, *Nitrate*, Table 34). On a monthly average basis and on a long-term annual average basis, for all modeled years and for the drought period only, use of assimilative capacity available under Existing Conditions and the No Action Alternative (ELT), relative to the 10 mg/L-N MCL, would be negligible (<2%) for both Banks and Jones pumping plants (Appendix 8J, *Nitrate*, Table 42).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on nitrate in the LLT are expected to be similar to those described above.

Any increases in nitrate concentrations that may occur in water exported via Banks and Jones pumping plants are not expected to result in adverse effects to beneficial uses or substantially degrade the quality of exported water, with regard to nitrate.

NEPA Effects: Modified reservoir operations and subsequent changes in river flows under Alternative 5a, relative to the No Action Alternative (ELT and LLT), are expected to have negligible, if any, effects on reservoir and river nitrate concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed. In the Delta, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the 10 mg/L-N MCL are anticipated at any Delta location, and use of assimilative capacity available under the No Action Alternative, relative to the drinking water MCL of 10 mg/L-N, would be low. Long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to differ negligibly relative to the No Action Alternative (ELT and LLT) and no additional exceedances of the 10 mg/L-N MCL are anticipated. Therefore, the effects on nitrate from implementing water conveyance facilities are considered to be not adverse.

CEQA Conclusion: Nitrate concentrations are generally low in the reservoirs and rivers of the watersheds, owing to substantial dilution available for point sources and the lack of substantial nonpoint sources of nitrate upstream of the SRWTP in the Sacramento River watershed, and in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers).Although higher in the San Joaquin River watershed, nitrate concentrations are not well-correlated with flow rates. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 5A, relative to Existing Conditions, are expected to have negligible, if any, effects on reservoir and river nitrate concentrations upstream of Freeport in the Sacramento River watershed and upstream of the Delta in the San Joaquin River watershed.

In the Delta, results of the mass balance calculations indicate that under Alternative 5A, relative to Existing Conditions, nitrate concentrations throughout the Delta are anticipated to remain low (<1.4 mg/L-N) relative to adopted objectives. No additional exceedances of the 10 mg/L-N MCL are anticipated at any location, and use of assimilative capacity available under Existing Conditions, relative to the drinking water MCL of 10 mg/L-N, would be low or negligible (i.e., <3%) for virtually all locations and months.

Assessment of effects of nitrate in the SWP/CVP Export Service Areas is based on effects on nitrate concentrations at the Banks and Jones pumping plants. Results of the mass balance calculations indicate that under Alternative 5A, relative to Existing Conditions, long-term average nitrate concentrations at Banks and Jones pumping plants are anticipated to change negligibly. No additional exceedances of the 10 mg/L-N MCL are anticipated, and use of assimilative capacity available under Existing Conditions, relative to the MCL would be negligible (i.e., <2%) for both Banks and Jones pumping plants for all months.

Based on the above, there would be no substantial, long-term increase in nitrate concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the SWP/CVP Export Service Areas under Alternative 5A relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because nitrate concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not CWA Section 303(d) listed within the affected environment and thus any increases that may occur in some areas and months would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, increases that may occur in some areas and months would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-16: Effects on Nitrate Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Some habitat restoration activities included in Environmental Commitments 3, 4, and 6–11 would occur on lands within the Delta formerly used for agriculture. As discussed for Impact WQ-2, increased biota that may result in those areas may increase ammonia, which in turn may be converted to nitrate by established microbial communities. However, the areal extent of the new habitat implemented for the Environmental Commitments would be less than the existing and No Action Alternative habitat areas, and similar habitat exists currently in the Delta and is not identified as contributing to adverse nitrate conditions. Thus, these land use changes would not be expected to substantially increase nitrate concentrations in the Delta. Implementation of Environmental Commitments 12, 15, and 16 do not include actions that would affect nitrate sources or loading. Based on these findings, the effects on nitrate from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

***CEQA Conclusion*:** Land use changes that would occur from the Environmental Commitments are not expected to substantially increase nitrate concentrations, because the amount of area to be converted would be small relative to existing habitat, and existing habitats are not known for contributing to adverse nitrate conditions. Thus, it is expected that implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because nitrate concentrations are not expected to increase substantially due to these Environmental Commitments, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Nitrate is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing nitrate-related impairment measurably worse because no such impairments currently exist. Because nitrate is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-17: Effects on Dissolved Organic Carbon Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 5A on DOC concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 because factors affecting DOC concentrations in these water bodies would be similar. Moreover, long-term average flow and DOC levels in the Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated. Thus changes in system operations and resulting reservoir storage levels and river flows under Alternative 5A would not be expected to cause substantial long-term changes in DOC concentrations in the water bodies upstream of the Delta. Any changes in DOC levels in water bodies upstream of the Delta under Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be of sufficient frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies.

Delta

Under Alternative 5A, the geographic extent of effects pertaining to long-term average DOC concentrations in the Delta would be less extensive, and the magnitude of predicted long-term change and relative frequency of concentration threshold exceedances would be lower than described for Alternative 4. The effects of Alternative 5A relative to Existing Conditions and the No Action Alternative (ELT) are discussed together because the direction and magnitude of predicted change are similar. Relative to the Existing Conditions and No Action Alternative (ELT), Alternative 5A would result in small increases in long-term average DOC concentrations for both the modeled 16-year period (1976–1991) and drought period (1987–1991) at several interior Delta locations (increases up to 0.1 mg/L at Franks Tract, Old River at Rock Slough, and Contra Costa Pumping Plant #1) (Appendix 8K, *Organic Carbon*, Table DOC-13). The increases in average DOC concentrations would correspond to more frequent concentration threshold exceedances, with the greatest change occurring at the Contra Costa Pumping Plant #1 associated with the 3 mg/L threshold (i.e., increase from 52% under Existing Conditions to 61% under Alternative 5A for the modeled 16-year period). The change in frequency of threshold concentration exceedances at other assessment locations would be similar or lower.

While Alternative 5A would lead to slightly higher long-term average DOC concentrations at some municipal water intakes and Delta interior locations, the predicted change would not be expected to adversely affect MUN beneficial uses, or any other beneficial use. As discussed for Alternative 4, substantial changes in ambient DOC concentrations would need to occur before significant changes in drinking water treatment plant design or operations are triggered. The increases in long-term average DOC concentrations estimated to occur at various Delta locations under Alternative 5A are of sufficiently small magnitude that they would not require existing drinking water treatment plants to substantially upgrade treatment for DOC removal above levels currently employed.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on DOC in the LLT are expected to be similar to those described above.

Relative to Existing Conditions and the No Action Alternative (ELT and LLT), Alternative 5A would lead to predicted improvements in long-term average DOC concentrations at Barker Slough, as well as Banks and Jones pumping plants (discussed below).

SWP/CVP Export Service Areas

Under the Alternative 5A, long-term average DOC concentrations would decrease at Barker Slough by 0.1 mg/L, and at both the Banks and Jones pumping plants by 0.2 mg/L, relative to Existing Conditions. Reductions would be similar compared to No Action Alternative (ELT) (Appendix 8K, *Organic Carbon*, Table DOC-13). Decreases in long-term average DOC would result in generally lower exceedance frequencies for concentration thresholds, although the frequency of exceedances of the 3 mg/L threshold during the modeled drought period would increase at the Banks and Jones pumping plants. Relative to Existing Conditions, exceedance of the 3 mg/L threshold would increase from 57% 70% at Banks pumping plant and from 72% to 85% at Jones pumping plant. There would be little to no increase in exceedance of the 3 mg/L threshold relative to the No Action Alternative (ELT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on DOC in the LLT are expected to be similar to those described above.

Maintenance of SWP and CVP facilities under Alternative 5A would not be expected to create new sources of DOC or contribute towards a substantial change in existing sources of DOC in the affected area.

NEPA Effects: In summary, the operations and maintenance activities under Alternative 5A, relative to the No Action Alternative (ELT and LLT), would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. The long-term average DOC concentrations at the Barker Slough and Banks and Jones pumping plants are predicted to decrease by 0.2 mg/L, while long-term average DOC concentrations for some Delta interior locations are predicted to increase by as much as 0.1 mg/L. However, the increase in long-term average DOC concentration that could occur within the Delta interior would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters. Based on these findings, the effect of operations and maintenance activities on DOC under Alternative 5A is determined to be not adverse.

CEQA Conclusion: For the same reasons described for Alternative 4, the operations and maintenance activities under Alternative 5A, relative to the Existing Conditions, would not cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. Any modified reservoir operations and subsequent changes in river flows under Alternative 5A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in DOC levels upstream of the Delta. Moreover, long-term average flow and DOC at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in DOC concentrations upstream of the Delta.

Relative to Existing Conditions, the Alternative 5A would result in relatively small increases (i.e., ≤0.1 mg/L) in long-term average DOC concentrations at some interior Delta locations. The predicted increases would not substantially increase the frequency with which long-term average DOC concentrations exceeds 2, 3, or 4 mg/L. Because this alternative would lead to only slightly higher long-term average DOC concentrations at the interior Delta locations and some municipal water intakes, the predicted changes would not be expected to adversely affect MUN beneficial uses, or any other beneficial use.

Relative to Existing Conditions, Alternative 5A would result in reduced long-term average DOC concentrations at the Banks and Jones pumping plants and Barker Slough. However, Alternative 5A would result in slightly greater frequency of exceedance of the 3 mg/L DOC concentration threshold during the modeled drought period. Nevertheless, an overall improvement in DOC-related water quality would be predicted in the SWP/CVP Export Service Areas.

Based on the above, the operations and maintenance activities of Alternative 5A would not result in any substantial change in long-term average DOC concentration. The increases in long-term average DOC concentration that could occur within the Delta would not be of sufficient magnitude to adversely affect the MUN beneficial use, or any other beneficial uses, of Delta waters or waters of the SWP/CVP Service Area. Because DOC is not bioaccumulative, the increases in long-term average DOC concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not CWA Section 303(d) listed for any water body within the affected environment. Because long-term average DOC concentrations are not expected to increase substantially, no long-term water quality degradation with respect to DOC is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-18: Effects on Dissolved Organic Carbon Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Relative to existing habitat and that to be developed under the No Action Alternative (ELT and LLT), the area of new habitat restoration implemented for the Environmental Commitments would be very small. Implementation of non-habitat restoration Environmental Commitments would not be expected to have substantial, if even measurable, effect on DOC concentrations upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas, because they would present no major sources of DOC to the affected environment. Consequently, any increases in average DOC levels in the affected environment are not expected to be of sufficient frequency, magnitude and geographic extent that would adversely affect the MUN beneficial use, or any other beneficial uses, of the affected environment, nor would potential increases substantially degrade water quality with regard to DOC. Based on these findings, the effect of the Environmental Commitments on DOC is determined to be not adverse.

CEQA Conclusion: Implementation of habitat restoration Environmental Commitments is not expected to cause a substantial long-term change in DOC concentrations in the water bodies upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas, relative to the Existing Conditions, because the land area proposed for restoration would be relatively small compared to existing land area and sources of DOC. Implementation of other Environmental Commitments also would not be expected to have substantial, if even measurable, effect on DOC concentrations upstream of the Delta, within the Delta, and in the SWP/CVP Export Service Areas, because they would present no major sources of DOC to the affected environment. Consequently, increases in average DOC levels in the affected environment are not expected to be of sufficient frequency, magnitude and geographic extent that would adversely affect the MUN beneficial use, or any other beneficial uses, of the affected environment, nor would potential increases substantially degrade water quality with regard to DOC. Furthermore, DOC is not bioaccumulative, therefore changes in DOC concentrations would not cause bioaccumulative problems in aquatic life or humans. Finally, DOC is not causing beneficial use impairments and thus is not CWA Section 303(d) listed for any water body within the affected environment. Because long-term average DOC concentrations are not expected to increase substantially, no long-term water quality degradation with respect to DOC is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-19: Effects on Pathogens Resulting from Facilities Operations and Maintenance

The effects of operation of the water conveyance facilities under Alternative 5A on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those effects described for Alternative 4 (see Section 8.3.3.9). As described for Alternative 4, pathogen concentrations in the Sacramento and San Joaquin Rivers have a minimal relationship to flow rate in these rivers. Further, urban runoff contributions during the dry season would be expected to be a relatively small fraction of the rivers' total flow rates. During wet weather events, when urban runoff contributions would be higher, the flows in the rivers also would be higher. Given the small magnitude of urban runoff contributions relative to the magnitude of river flows and that pathogen concentrations in the rivers have a minimal relationship to river flow rate, river flow rate and reservoir storage reductions that would occur under Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be expected to result in a substantial adverse change in pathogen concentrations in the reservoirs and rivers upstream of the Delta.

The effects of Alternative 5A relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be changes in the relative percentage of water throughout the Delta being comprised of various source waters (i.e., water from the Sacramento River, San Joaquin River, Bay water, eastside tributaries, and agricultural return flow), due to potential changes in inflows particularly from the Sacramento River watershed. However, as described for Alternative 4, it is expected there would be no substantial change in Delta pathogen concentrations in response to a shift in the Delta source water percentages under this alternative or substantial degradation of these water bodies, with regard to pathogens, because it is expected that pathogen sources in close proximity to Delta sites would have a greater influence on pathogen levels at the site, rather than the primary source(s) of water to the site. In-Delta potential pathogen sources, including water-based recreation, tidal habitat, wildlife, and livestock-related uses, would continue under this alternative. As such, there is not expected to be substantial, if even measurable, changes in pathogen concentrations in the SWP/CVP Export Service Area waters.

As such, Alternative 5A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or U.S. EPA-recommended pathogen criteria would be exceeded in water bodies of the affected environment located upstream of the Delta or substantially degrade the quality of these water bodies, with regard to pathogens.

NEPA Effects: Because pathogen levels are expected to be minimally affected relative to the No Action Alternative (ELT and LLT), the effects on pathogens from implementing Alternative 5A are determined to not be adverse.

CEQA Conclusion: The effects of Alternative 5A on pathogen levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas, relative to Existing Conditions, would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because the factors that would affect pathogen levels in the surface waters of these areas would be similar. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is CWA Section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-20: Effects on Pathogens Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Environmental Commitments 3, 4, and 6–11 would involve habitat restoration actions. This could result in localized increases in wildlife-related coliforms relative to the No Action Alternative (ELT and LLT). The Delta currently supports similar habitat types and, with the exception of the CWA Section 303(d) listing for the Stockton Deep Water Ship Channel, is not recognized as exhibiting pathogen concentrations that rise to the level of adversely affecting beneficial uses. As such, the potential increase in wildlife-related coliform concentrations due to tidal habitat creation is not expected to adversely affect beneficial uses. The remaining Environmental Commitments would not be expected to affect pathogen levels, because they are actions that do not affect the presence of pathogen sources. Based on these findings, the effects on pathogens from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to not be adverse.

***CEQA Conclusion*:** Implementation of Environmental Commitments 3, 4, and 6–11 could result in localized increases in wildlife-related coliforms relative to Existing Conditions. The Delta currently supports similar habitat types and, with the exception of the CWA Section 303(d) listing for the Stockton Deep Water Ship Channel, is not recognized as exhibiting pathogen concentrations that rise to the level of adversely affecting beneficial uses. As such, the potential increase in wildlife-related coliform concentrations due to tidal habitat creation is not expected to adversely affect beneficial uses. Therefore, the Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pathogen concentrations are not expected to increase substantially, no long-term water quality degradation for pathogens is expected to occur and, thus, no adverse effects on beneficial uses would occur. The San Joaquin River in the Stockton Deep Water Ship Channel is CWA Section 303(d) listed for pathogens. Because no measurable increase in Deep Water Ship Channel pathogen concentrations are expected to occur on a long-term basis, further degradation and impairment of this area is not expected to occur. Finally, pathogens are not bioaccumulative constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-21: Effects on Pesticide Concentrations Resulting from Facilities Operations and Maintenance

The effects of Alternative 5A operations and maintenance on pesticide levels in surface waters upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT), would be similar to those expected to occur under Alternative 4 (see Section 8.3.3.9). This is because under Alternative 5A, the primary factor that would influence pesticide concentrations in surface waters upstream of the Delta—the effect of timing and magnitude of reservoir releases on dilution capacity—is expected to change by a similar degree. Changes in average winter and summer flow rates, relative to Existing Conditions and the No Action Alternative (ELT), are expected to be similar to or less than changes in flow rates expected under Alternative 4 in the Sacramento River at Freeport, American River at Nimbus, Feather River at Thermalito and the San Joaquin River at Vernalis (Appendix 8L, *Pesticides,* Tables 1–4). Similarly, the primary factor that would influence pesticide concentrations in surface waters of the Delta and in the SWP/CVP Export Service Areas (i.e., changes in San Joaquin River, Sacramento River and Delta Agriculture source water fractions at various Delta locations, including Banks and Jones pumping plants) is expected to change by a similar degree. The percentage change in monthly average source water fractions would be similar to changes expected under Alternative 4 (Appendix 8D, *Source Water Fingerprinting Results*).

It was concluded for Alternative 4, and thus for Alternative 5A based on similar flow changes, that the potential average summer flow reductions would not be of sufficient magnitude to substantially increase in-river pesticide concentrations or alter the long-term risk of pesticide-related effects on aquatic life beneficial uses upstream of the Delta. Greater long-term average flow reductions, and corresponding reductions in dilution/assimilative capacity, would be necessary before long-term risk of pesticide related effects on aquatic life beneficial uses would be adversely altered. Similarly, the modeled changes in the source water fractions of Sacramento River, San Joaquin River, and Delta agriculture water under Alternative 5A would not be of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta. Based on the general observation that San Joaquin River, in comparison to the Sacramento River, is a greater contributor of organophosphate insecticides in terms of greater frequency of incidence and presence at concentrations exceeding water quality benchmarks, modeled increases in Sacramento River fraction at Banks and Jones would generally represent an improvement in export water quality respective to pesticides.

The flow changes in the LLT would be expected in the ranges of that described above for Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT), and that described for Alternative 4 relative to the No Action Alternative (LLT) in Section 8.3.3.9. Thus, similar to above and Alternative 4, the flow changes that would occur in the LLT under Alternative 5A, relative to Existing Conditions and the No Action Alternative (LLT), would not be expected to result in changes in dilution of pesticides of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses upstream of the Delta, in the Delta, or the SWP/CVP Export Service Areas.

NEPA Effects: In summary, the changes in long-term average flows on the Sacramento, Feather, American, and San Joaquin Rivers under Alternative 5A relative to the No Action Alternative (ELT and LLT) would be of insufficient magnitude to substantially increase the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in these water bodies upstream of the Delta. Similarly, changes in source water fractions to the Delta would be of insufficient magnitude to substantially alter the long-term risk of pesticide-related water quality degradation and related toxicity to aquatic life in the Delta or CVP/SWP Export Service Areas. Therefore, the effects on pesticides from the water conveyance facilities are determined not to be adverse.

CEQA Conclusion: Based on the discussion above, the effects of Alternative 5A on pesticide levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to or slightly less than those described for the Alternative 4. Alternative 5A would not result in any substantial change in long-term average pesticide concentration or result in substantial increase in the anticipated frequency with which long-term average pesticide concentrations would exceed aquatic life toxicity thresholds or other beneficial use effect thresholds upstream of the Delta, at the 11 assessment locations analyzed for the Delta, or the SWP/CVP service area. Numerous pesticides are currently used throughout the affected environment, and while some of these pesticides may be bioaccumulative, those present-use pesticides for which there is sufficient evidence for their presence in waters affected by SWP and CVP operations (i.e., diazinon, chlorpyrifos, diuron, and pyrethroids) are not considered bioaccumulative, and thus changes in their concentrations would not directly cause bioaccumulative problems in aquatic life or humans. Furthermore, while there are numerous CWA Section 303(d) listings throughout the affected environment that name pesticides as the cause for beneficial use impairment, the modeled changes in upstream river flows and Delta source water fractions under Alternative 5A would not be expected to make any of these beneficial use impairments measurably worse. Because long-term average pesticide concentrations are not expected to increase substantially, no long-term water quality degradation with respect to pesticides is expected to occur and, thus, no adverse effects on beneficial uses would occur. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-22: Effects on Pesticide Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of pesticides, and the potential short-term loading from former agricultural lands would be expected to degrade and dissipate rapidly. Therefore, relative to the No Action Alternative (ELT and LLT), the effects on pesticides from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of pesticides, and the potential short-term loading from former agricultural lands would be expected to degrade and dissipate rapidly, such that pesticide levels would differ little from Existing Conditions. Therefore, implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause substantial long-term increase in pesticide concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP Export Service Areas. As such, these Environmental Commitments are not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because pesticide concentrations are not expected to increase substantially, no long-term water quality degradation for pesticides is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term pesticide concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. Environmental Commitments 3, 4, 6–12, 15, 16 do not include the use of pesticides known to be bioaccumulative in animals or humans, nor do the Environmental Commitments propose the use of any pesticide currently named in a CWA Section 303(d) listing of the affected environment. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-23: Effects on Phosphorus Concentrations Resulting from Facilities Operations and Maintenance

The effects of Alternative 5A on phosphorus concentrations in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas would be similar to those described for Alternative 4 (see Section 8.3.3.9). This is because factors which affect phosphorus concentrations in surface waters of these areas are the same under Alternative 4 and Alternative 5A. As described for Alternative 4, phosphorus loading to waters upstream of the Delta is not anticipated to change, and because changes in flows do not necessarily result in changes in concentrations or loading of phosphorus to these water bodies, substantial changes in phosphorus concentration are not anticipated under Alternative 5A, relative to Existing Conditions or the No Action Alternative (ELT), upstream of the Delta. Phosphorus concentrations may increase during January through March at locations in the Delta where the source fraction of San Joaquin River water increases, due to the higher concentration of phosphorus in the San Joaquin River during these months compared to Sacramento River water or San Francisco Bay water. However, based on the DSM2 fingerprinting results (Figures 353–374 in Appendix 8D, *Source Water Fingerprinting Results*), together with source water concentrations (in Figure 8-56), the magnitude of increases during these months is expected to be negligible to low (i.e., <0.02 mg/L) at all Delta locations relative to Existing Conditions and the No Action Alternative (ELT and LLT). Thus, phosphorus concentrations in the Delta and waters exported from Banks and Jones pumping plants to the SWP/CVP Export Service Areas are expected to be similar to Existing Conditions and the No Action Alternative (ELT and LLT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on phosphorus in the LLT are expected to be similar to those described above.

NEPA Effects: In summary, operation of the water conveyance facilities would have little to no effect on phosphorus concentrations in water bodies upstream of the Delta, in the Plan Area, and the waters exported to the SWP/CVP Export Service Areas, relative to the No Action Alternative (ELT and LLT). Thus, effects of the water conveyance facilities on phosphorus are considered to be not adverse.

CEQA Conclusion**:** The effects of Alternative 5A on phosphorus levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions would be similar to those described for the Alternative 4. There would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Plan Area, or the waters exported to the CVP and SWP service areas under Alternative 5A relative to Existing Conditions. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because phosphorus concentrations are not expected to increase substantially, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not CWA Section 303(d) listed within the affected environment and thus any minor increases that may occur in some areas would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, minor increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-24: Effects on Phosphorus Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of phosphorus. Therefore, relative to the No Action Alternative (ELT and LLT), the effects on phosphorus from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 do not involve actions that would contribute long-term additional loading of phosphorus. Therefore, there would be no substantial, long-term increase in phosphorus concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the waters exported to the SWP/CVP Export Service Areas due to implementation of these Environmental Commitments relative to Existing Conditions. Because phosphorus concentrations are not expected to increase substantially due to these Environmental Commitments, no long-term water quality degradation is expected to occur and, thus, no adverse effects to beneficial uses would occur. Phosphorus is not CWA Section 303(d) listed within the affected environment and, thus, the Environmental Commitments would not make any existing phosphorus-related impairment measurably worse because no such impairments currently exist. Because phosphorus is not bioaccumulative, any increases that may occur in some areas would not bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-25: Effects on Selenium Concentrations Resulting from Facilities Operations and Maintenance

Upstream of the Delta

The effects of Alternative 5A on selenium concentrations in reservoirs and rivers upstream of the Delta would be similar to those effects described for Alternative 4 (see Section 8.3.3.9), because factors affecting selenium concentrations in these water bodies would be similar. Substantial point sources of selenium do not exist upstream in the Sacramento River watershed, in the watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), or upstream of the Delta in the San Joaquin River watershed. Nonpoint sources of selenium within the watersheds of the Sacramento River and the eastern tributaries also are relatively low, resulting in generally low selenium concentrations in the reservoirs and rivers of those watersheds. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 5A, relative to Existing Conditions or the No Action Alternative (ELT and LLT), are expected to have negligible, if any, effects on reservoir and river selenium concentrations upstream of Freeport in the Sacramento River watershed or in the eastern tributaries upstream of the Delta. Similarly, it is expected that selenium concentrations in the San Joaquin River would be minimally affected, if at all, by anticipated changes in flow rates under Alternative 5A, given the relatively small decreases in flows and the considerable variability in the relationship between selenium concentrations and flows in the San Joaquin River. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Delta

Alternative 5A would result in small changes in average selenium concentrations in water relative to Existing Conditions and No Action Alternative (ELT) at all modeled Delta assessment locations (Appendix 8M, *Selenium,* Table M-33). Long-term average concentrations at some interior and western Delta locations would increase by 0.01 µg/L for the entire period modeled (1976–1991). These small increases in selenium concentrations in water would result in small reductions (2% or less) in available assimilative capacity for selenium, relative to USEPA's draft water quality criterion of 1.3 µg/L (Appendix 8M, Table M-46). The long-term average selenium concentrations in water under Alternative 5A (range 0.09–0.39 µg/L) would be similar to Existing Conditions (range 0.09–0.41 µg/L) and the No Action Alternative (ELT) (range 0.09–0.39 µg/L), and would be below the draft water quality criterion of 1.3 µg/L (Appendix 8M, Table M-33).

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 5A would result in small changes (less than 1%) in estimated selenium concentrations in most biota (whole-body fish, bird eggs [invertebrate diet or fish diet], and fish fillets) throughout the Delta, with little difference among locations (Appendix 8M, *Selenium,* Tables M-36 and M-40). Level of Concern Exceedance Quotients (i.e., modeled tissue divided by Level of Concern benchmarks) for selenium concentrations in those biota for all years and for drought years are less than 1.0, indicating low probability of adverse effects. Similarly, Advisory Tissue Level Exceedance Quotients for selenium concentrations in fish fillets for all years and drought years are less than 1.0. Estimated selenium concentrations in sturgeon for the San Joaquin River at Antioch are predicted to increase by 7% relative to Existing Conditions (from about 4.7 to about 5.0 mg/kg dry weight) and by 4% relative to the No Action Alternative (ELT) in all years (from about 4.8 to about 5.0 mg/kg dry weight). For sturgeon in the Sacramento River at Mallard Island concentrations are predicted to increase by about 5% relative to Existing Conditions in all years (from about 4.4 to 4.6 mg/kg dry weight) and by 3% relative to the No Action Alternative in all years (from about 4.5 to 4.6 mg/kg dry weight) (Appendix 8M, *Selenium,* Tables M-41 and M-42). Selenium concentrations in sturgeon during drought years are expected to increase by about 3–5% relative to Existing Conditions (from about 6.8 to 7.2 mg/kg dry weight) and 1–2% relative to the No Action Alternative at those locations (from about 7.0 to 7.2 mg/kg dry weight) (Appendix 8M, *Selenium,* Tables M-41 and M-42). Detection of small changes in whole-body sturgeon such as those estimated for the western Delta would require very large sample sizes because of the inherent variability in fish tissue selenium concentrations. Low Toxicity Threshold Exceedance Quotients for selenium concentrations in sturgeon in the western Delta would exceed 1.0 for drought years at both locations (as they do for Existing Conditions and the No Action Alternative (ELT)); for all years the Exceedance Quotient would be 1.0 or less (Appendix 8M, Table M-43). The High Toxicity Threshold Quotient would be less than 1.0 at both locations for all years and drought years (Appendix 8M, Table M-43).

The disparity between larger estimated changes for sturgeon and smaller changes for other biota is attributable largely to differences in modeling approaches, as described in Appendix 8M, *Selenium*. The model for most biota was calibrated to encompass the varying concentration-dependent uptake from waterborne selenium concentrations (expressed as the K_d, which is the ratio of selenium concentrations in particulates [as the lowest level of the food chain] relative to the waterborne concentration) that was exhibited in data for largemouth bass in 2000, 2005, and 2007 at various locations across the Delta. In contrast, the modeling for sturgeon could not be similarly calibrated at the two western Delta locations and used literature-derived uptake factors and trophic transfer factors for the estuary from Presser and Luoma (2013). As noted in the Appendix 8M, there was a significant negative log-log relationship of K_d to waterborne selenium concentration that reflected the greater bioaccumulation rates for bass at low waterborne selenium than at higher concentrations. There was no difference in bass selenium concentrations in the Sacramento River at Rio Vista in comparison to the San Joaquin River at Vernalis in 2000, 2005, and 2007 [Foe 2010], despite a nearly 10-fold difference in waterborne selenium. Thus, there is more confidence in the site-specific modeling based on the Delta-wide model that was calibrated for bass data than in the estimates for sturgeon based on "fixed" K_ds for all years and for drought years without regard to waterborne selenium concentration at the two locations in different time periods.

Residence time of water in the Delta is expected to increase relative to Existing Conditions primarily as a result of habitat restoration (8,000 acres of tidal habitat restoration and enhancements in the Yolo Bypass) that is assumed to occur under the No Action Alternative (ELT) separate from Alternative 5A. Although estimates of the residence time increases are not available for Alternative 5A, estimates for Alternative 5 at the Late Long Term (presented in Table 8-60a in Section 8.3.1.7 in the *Microcystis* subsection) which contained 65,000 acres of tidal restoration are available, and is expected that residence time increases under Alternative 5A would be substantially less than identified for Alternative 5 in the table.

If increases in fish tissue or bird egg selenium were to occur as a result of increased residence time, the increases would likely be of concern only where fish tissues or bird eggs are already elevated in selenium to near or above thresholds of concern. That is, where biota concentrations are currently low and not approaching thresholds of concern (which, as discussed above, is the case throughout the Delta, except for sturgeon in the western Delta), changes in residence time alone would not be expected to cause them to then approach or exceed thresholds of concern. Thus, the most likely area in which biota tissues would be at levels high enough that additional bioaccumulation due to increased residence time would be a concern is the western Delta and Suisun Bay for sturgeon. Based on the expected minor increases in residence time in the western Delta, any increases are not expected to be of sufficient magnitude to substantially affect selenium bioaccumulation.

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 5A would result in essentially no change in selenium concentrations throughout the Delta for most biota (less than 1%), although larger increases in selenium concentrations are predicted for sturgeon in the western Delta. Concentrations of selenium in sturgeon would exceed only the lower benchmark during the drought period, indicating a low potential for effects. The modeling of bioaccumulation for sturgeon is less calibrated to site-specific conditions than that for other biota, which was calibrated on a robust dataset for modeling of bioaccumulation in largemouth bass as a representative species for the Delta. Overall, Alternative 5A would not be expected to substantially increase the frequency with which the applicable water quality criterion or toxicity and level of concern benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon relative to the low benchmark and no exceedance of the high benchmark) or to substantially degrade the quality of water in the Delta, with regard to selenium. These changes would be similar to those described for Alternative 4.

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on selenium in the LLT are expected to be similar to those described above.

SWP/CVP Export Service Areas

Alternative 5A would result in small (0.03 μg/L) decreases in long-term average selenium concentrations in water at the Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative (ELT), for the entire period modeled (Appendix 8M, *Selenium,* Table M-33). These decreases in long-term average selenium concentrations in water would result in increases in available assimilative capacity for selenium at these pumping plants, relative to the USEPA's draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-46). The long-term average selenium concentrations in water for Alternative 5A (range 0.18–0.25 μg/L) would be well below the draft water quality criterion of 1.3 μg/L (Appendix 8M, Table M-33).

Relative to Existing Conditions and the No Action Alternative (ELT), Alternative 5A would result in small changes (about 1% or less) in estimated selenium concentrations in biota (whole-body fish, bird eggs [invertebrate diet], bird eggs [fish diet], and fish fillets) (Appendix 8M, *Selenium,* Table M-40). Concentrations in biota would not exceed any selenium toxicity or level of concern benchmarks for Alternative 5A (Appendix 8M, Table M-40).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on selenium in the LLT are expected to be similar to those described above.

NEPA Effects: Relative to the No Action Alternative (ELT and LLT), Alternative 5A would result in essentially negligible changes in selenium concentrations in water upstream of the Delta. Similarly, there would be negligible changes in selenium water and most biota concentrations in the Delta, with no exceedances of benchmarks for biological effects. For sturgeon in the Delta, there would be only a small increase of threshold exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark. At the Banks and Jones pumping plants, Alternative 5A would cause no increases in the frequency with which applicable benchmarks would be exceeded and would slightly improve the quality of water in selenium concentrations. Therefore, the effects on selenium (both as waterborne and as bioaccumulated in biota) from Alternative 5A are considered to be not adverse.

***CEQA Conclusion*:** There are no substantial point sources of selenium in watersheds upstream of the Delta, and no substantial nonpoint sources of selenium in the watersheds of the Sacramento River and the eastern tributaries. Nonpoint sources in the San Joaquin Valley that contribute selenium to the Delta will be controlled through a TMDL developed by the Central Valley Water Board (2001) for the lower San Joaquin River, established limits for the Grassland Bypass Project, and Basin Plan objectives (Central Valley Regional Water Quality Control Board 2010d; State Water Resources Control Board 2010b, 2010c) that are expected to result in decreasing discharges of selenium from the San Joaquin River to the Delta. Consequently, any modified reservoir operations and subsequent changes in river flows under Alternative 5A, relative to Existing Conditions, are expected to cause negligible changes in selenium concentrations in water. Any negligible changes in selenium concentrations that may occur in the water bodies of the affected environment located upstream of the Delta would not be of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of these water bodies as related to selenium.

Relative to Existing Conditions, modeling estimates indicate Alternative 5A would result in essentially no change in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. The Low Toxicity Threshold Exceedance

Quotient for selenium concentrations in sturgeon for all years in the San Joaquin River at Antioch would increase slightly, from 0.94 for Existing Conditions to 1.0 for Alternative 5A. Concentrations of selenium in sturgeon would exceed only the lower benchmark during the drought period, indicating a low potential for effects. Overall, Alternative 5A would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium.

Assessment of effects of selenium in the SWP/CVP Export Service Areas is based on effects on selenium concentrations at the Banks and Jones pumping plants. Relative to Existing Conditions, Alternative 5A would cause no increases in the frequency with which applicable benchmarks would be exceeded, and would slightly improve the quality of water in selenium concentrations at the Banks and Jones pumping plants.

Based on the above, selenium concentrations that would occur in water under Alternative 5A would not cause additional exceedances of applicable state or federal numeric or narrative water quality objectives/criteria, or other relevant water quality effects thresholds identified for this assessment, by frequency, magnitude, and geographic extent that would result in adverse effects to one or more beneficial uses within affected water bodies. In comparison to Existing Conditions, water quality conditions under Alternative 5A would not increase levels of selenium by frequency, magnitude, and geographic extent such that the affected environment would be expected to have measurably higher body burdens of selenium in aquatic organisms, thereby substantially increasing the health risks to wildlife (including fish) or humans consuming those organisms. Water quality conditions under this alternative with respect to selenium would not cause long-term degradation of water quality in the affected environment, and therefore would not result in use of available assimilative capacity such that exceedances of water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. This alternative would not further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial use to be made discernibly worse. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-26: Effects on Selenium Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Environmental Commitments 3, 4, 6–12, 15, and 16 would not increase selenium loading, and the amount of restoration that would occur would be minimal relative to the area of the Delta and implemented such that any localized changes in residence time are unlikely to measurably change selenium concentrations in water or biota relative to the No Action Alternative (ELT and LLT). Therefore, the effects on selenium from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusion: Environmental Commitments 3, 4, 6–12, 15, and 16 would not increase selenium loading, and the amount of restoration that would occur would be minimal relative to the area of the Delta and implemented such that any localized changes in residence time are unlikely to measurably change selenium concentrations in water or biota relative to Existing Conditions. Therefore, it is expected that with implementation of these Environmental Commitments there would be no substantial, long-term increase in selenium concentrations in water in the rivers and reservoirs upstream of the Delta, water in the Delta, or the waters exported to the SWP/CVP Export Service Areas, relative to Existing Conditions. As such, these Environmental Commitments would not contribute to additional exceedances of applicable water quality objectives/criteria. Given the factors discussed in the assessment above and for Alternative 4 (see Section 8.3.3.9), any increases in bioaccumulation rates from waterborne selenium that could occur in some areas as a result of increased water residence times would not be of sufficient magnitude and geographic extent that any portion of the Delta would be expected to have measurably higher body burdens of selenium in aquatic organisms, and therefore would not substantially increase risk for adverse effects to beneficial uses. Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause long-term degradation of water quality resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely. Also, these Environmental Commitments would not result in substantially increased risk for adverse effects to any beneficial uses. Furthermore, although the Delta is a CWA Section 303(d)-listed water body for selenium, given the discussion in the assessment above, it is unlikely that restoration areas would result in measurable increases in selenium in fish tissues or bird eggs such that the beneficial use impairment would be made discernibly worse.

Because it is unlikely that substantial increases in selenium in fish tissues or bird eggs would occur such that effects on aquatic life beneficial uses would be anticipated, and because of the avoidance and minimization measures that are designed to further minimize and evaluate the risk of such increases (see BDCP Appendix 3.C, *Avoidance and Minimization Measures*, for more detail on AMM27) as well as the Selenium Management environmental commitment (see Appendix 3B, *Environmental Commitments, AMMs, and CMs*), this impact is considered less than significant. No mitigation is required.

Impact WQ-27: Effects on Trace Metal Concentrations Resulting from Facilities Operations and Maintenance

The effects of operation of the water conveyance facilities under Alternative 5A on trace metal concentrations in surface waters upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT and LLT) would be similar to those effects described for Alternative 4 (see Section 8.3.3.9).

Given the poor association of dissolved trace metal concentrations with flow, river flow rate and reservoir storage reductions that would occur under Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not be expected to result in a substantial adverse change in trace metal concentrations in the reservoirs and rivers upstream of the Delta.

In the Delta, for metals of primarily aquatic life concern (copper, cadmium, chromium, lead, nickel, silver, and zinc), average and 95th percentile trace metal concentrations of the primary source waters to the Delta are very similar, and very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria, including those that are hardness-based (see Tables 8-51 and 8-52 in Section 8.3.1.7, *Construction-Specific Considerations Used in the Assessment*). No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average and 95th percentile source water concentrations for copper, cadmium, chromium, lead, nickel, silver, and zinc do not exceed their respective criteria, more frequent exceedances of criteria in the Delta would not occur. For metals of primarily human health and drinking water concern (arsenic, iron, manganese), average and 95th percentile concentrations are also very similar (see Tables 8–10 in Appendix 8N,*Trace Metals*) and average concentrations are below human health criteria. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that the average water concentrations for arsenic, iron, and manganese do not exceed water quality criteria, more frequent exceedances of drinking water criteria in the Delta would not be expected to occur.

Because Alternative 5A would not result in substantial increases in trace metal concentrations in the water exported from the Delta or diverted from the Sacramento River through the proposed conveyance facilities, there is not expected to be substantial changes in trace metal concentrations in the SWP/CVP Export Service Areas, relative to Existing Conditions or the No Action Alternative (ELT and LLT).

In the LLT, the Delta source water fractions may be different from those occurring in the ELT due to changes in upstream hydrology and Delta hydrodynamics from additional climate change and sea level rise. These effects would occur independent of the alternative and, thus, the alternative-specific effects on trace metals in the LLT are expected to be similar to those described above.

As such, Alternative 5A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment or substantially degrade the quality of these water bodies, with regard to trace metals.

NEPA Effects: Alternative 5A would not be expected to substantially increase the frequency with which applicable Basin Plan objectives or CTR criteria would be exceeded in the water bodies of the affected environment or substantially degrade the quality of these water bodies, with regard to trace metals, relative to the No Action Alternative (ELT and LLT). Therefore, the effects on trace metals from implementing Alternative 5A are determined to not be adverse.

CEQA Conclusion: While Alternative 5A would alter the magnitude and timing of reservoir releases north, south and east of the Delta, this would have no substantial effect on the various watershed sources of trace metals. Moreover, long-term average flow and trace metals at Sacramento River at Hood and San Joaquin River at Vernalis are poorly correlated; therefore, changes in river flows would not be expected to cause a substantial long-term change in trace metal concentrations upstream of the Delta.

Average and 95th percentile trace metal concentrations are very similar across the primary source waters to the Delta. Given this similarity, very large changes in source water fraction would be necessary to effect a relatively small change in trace metal concentration at a particular Delta location. Moreover, average and 95th percentile trace metal concentrations for these primary source waters are all below their respective water quality criteria. No mixing of these three source waters could result in a metal concentration greater than the highest source water concentration, and given that trace metals do not already exceed water quality criteria, more frequent exceedances of criteria in the Delta would not be expected to occur under Alternative 5A.

Because Alternative 5A is not expected to result in substantial changes in trace metal concentrations in Delta waters, which includes Banks and Jones pumping plants, effects on trace metal concentrations in the SWP/CVP Export Service Area are expected to be negligible.

As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur in water bodies of the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-28: Effects on Trace Metal Concentrations Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

NEPA Effects: Because Environmental Commitments 3, 4, 6–12, 15, and 16 present no new sources of trace metals to the affected environment, the effects on trace metal concentrations from implementing these Environmental Commitments are determined to be not adverse.

CEQA Conclusion: Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not cause substantial long-term increase in trace metal concentrations in the rivers and reservoirs upstream of the Delta, in the Delta Region, or the SWP/CVP Export Service Areas, because they present no new sources of trace metals to the affected environment. As such, this alternative is not expected to cause additional exceedance of applicable water quality objectives by frequency, magnitude, and geographic extent that would cause adverse effects on any beneficial uses of waters in the affected environment. Because trace metal concentrations are not expected to increase substantially, no long-term water quality degradation for trace metals is expected to occur and, thus, no adverse effects to beneficial uses would occur. Furthermore, any negligible changes in long-term trace metal concentrations that may occur throughout the affected environment would not be expected to make any existing beneficial use impairments measurably worse. The trace metals discussed in this assessment are not considered bioaccumulative, and thus would not directly cause bioaccumulative problems in aquatic life or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-29: Effects on TSS and Turbidity Resulting from Facilities Operations and Maintenance

As described for Alternative 4 (see Section 8.3.3.9), the operation of the water conveyance facilities under Alternative 5A is expected to have a minimal effect on TSS and turbidity levels in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas relative to Existing Conditions and the No Action Alternative (ELT and LLT). This is because the factors that would affect TSS and turbidity levels in the surface waters of these areas would be the same. TSS concentrations and turbidity levels in rivers upstream of the Delta are affected primarily by: 1) TSS concentrations and turbidity levels of the water released from the upstream reservoirs, 2) erosion occurring within the river channel beds, which is affected by river flow velocity and bank protection, 3) TSS concentrations and turbidity levels of tributary inflows, point-source inputs, and nonpoint runoff as influenced by surrounding land uses; and 4) phytoplankton, zooplankton and other biological material in the water. Within the Delta, TSS concentrations and turbidity levels in Delta waters are affected by TSS concentrations and turbidity levels of inflows (and associated sediment load), as well as fluctuation in flows within the channels due to the tides, with sediments depositing as flow velocities and turbulence are low at periods of slack tide, and sediments becoming suspended when flow velocities and turbulence increase when tides are near the maximum. TSS and turbidity variations can also be attributed to phytoplankton, zooplankton and other biological material in the water. These factors would be similar under Alternative 5A and Alternative 4, are expected to be minimally different from Existing Conditions and the No Action Alternative (ELT and LLT). Because Alternative 5A is expected to have minimal effect on TSS concentrations and turbidity levels in Delta waters, including water exported at the south Delta pumps, relative to Existing Conditions or the No Action Alternative (ELT and LLT), Alternative 5A also is expected to have minimal effect on TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters.

NEPA Effects: Because TSS concentrations and turbidity levels are expected to be minimally affected relative to the No Action Alternative (ELT and LLT), the effects on TSS and turbidity from implementing Alternative 5A are determined to not be adverse.

CEQA Conclusion: As described for Alternative 4 (see Section 8.3.3.9) changes in river flow rate and reservoir storage that would occur under Alternative 5A, relative to Existing Conditions, would not be expected to result in a substantial adverse change in TSS concentrations and turbidity levels in the reservoirs and rivers upstream of the Delta, given that suspended sediment concentrations are more affected by season than flow. Within the Delta, geomorphic changes associated with sediment transport and deposition are usually gradual, occurring over years, and high storm event inflows would not be substantially affected. Thus, it is expected that the TSS concentrations and turbidity levels in the affected channels would not be substantially different from the levels under Existing Conditions. There is not expected to be substantial, if even measurable, changes in TSS concentrations and turbidity levels in the SWP/CVP Export Service Areas waters under Alternative 5A, relative to Existing Conditions, because this alternative is not expected to result in substantial changes in TSS concentrations and turbidity levels at the south Delta export pumps, relative to Existing Conditions. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels are not expected to be substantially different, long-term water quality degradation is not expected, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor CWA Section 303(d) listed constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-30: Effects on TSS and Turbidity Resulting from Implementation of Environmental Commitments 3, 4, 6–12, 15, and 16

***NEPA Effects*:** Localized, temporary changes in TSS and turbidity could occur associated with the restoration actions of Environmental Commitments 3, 4, 6–12, 15, and 16. However, these changes would be gradual and not expected to substantially differ from No Action Alternative (ELT and LLT) conditions. Therefore, the effects on TSS and turbidity from implementing these Environmental Commitments are determined to be not adverse.

***CEQA Conclusion*:** It is expected that the TSS concentrations and turbidity levels Upstream of the Delta, in the Plan Area, and the SWP/CVP Export Service Areas due to implementation of Environmental Commitments 3, 4, 6–12, 15, and 16 would not be substantially different relative to Existing Conditions, except within localized areas of the Delta modified through creation of habitat and open water. Therefore, this alternative is not expected to cause additional exceedance of applicable water quality objectives where such objectives are not exceeded under Existing Conditions. Because TSS concentrations and turbidity levels Upstream of the Delta, in the greater Plan Area, and in the SWP/CVP Export Service Areas are not expected to be substantially different, long-term water quality degradation is not expected relative to TSS and turbidity, and, thus, beneficial uses are not expected to be adversely affected. Finally, TSS and turbidity are neither bioaccumulative nor CWA Section 303(d) listed constituents. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

Impact WQ-31: Water Quality Effects Resulting from Construction-Related Activities for the Water Conveyance Facilities and Environmental Commitments

The potential construction-related water quality effects that would occur under Alternative 5A would similar to the effects described for Alternative 4A (see Section 8.3.4.2). This is because the type, size, and number of construction activities for water conveyance facilities and Environmental Commitments that would occur under Alternative 5A would be similar to Alternative 4A. The construction-related activities for the water conveyance facilities under Alternative 5A would be similar to those described for Alternative 4A. However, there would be less construction activity due to the fewer intakes constructed and the area of in-water habitat restoration activities implemented under Alternative 5A would be less.

NEPA Effects: The types and magnitude of potential construction-related water quality effects associated with implementation of Alternative 2D would be very similar to the effects discussed for Alternative 4A. Nevertheless, the construction of water supply facilities and Environmental Commitments, with the implementation of the BMPs specified in Appendix 3B, *Environmental Commitments, AMMs, and CMs*, and other agency permitted construction requirements, would result in the potential water quality effects being largely avoided and minimized. The specific Environmental Commitments that would be implemented under Alternative 5A would be similar to those described for Alternative 4A. Consequently, relative to the No Action Alternative (ELT), Alternative 5A would not be expected to cause exceedance of applicable water quality objectives/criteria or substantial water quality degradation with respect to constituents of concern, and thus would not adversely affect any beneficial uses upstream of the Delta, in the Delta, or in the SWP/CVP Export Service Areas. Therefore, with implementation of environmental commitments presented in Appendix 3B, the potential construction-related water quality effects are considered to be not adverse.

CEQA Conclusion: Because environmental commitments would be implemented under Alternative 5A for construction-related activities along with agency-issued permits that also contain construction requirements to protect water quality, the construction-related effects, relative to Existing Conditions, would not be expected to cause or contribute to substantial alteration of existing drainage patterns which would result in substantial erosion or siltation on- or off-site, substantial increased frequency of exceedances of water quality objectives/criteria, or substantially degrade water quality with respect to the constituents of concern on a long-term average basis, and thus would not adversely affect any beneficial uses in water bodies upstream of the Delta, within the Delta, or in the SWP/CVP Export Service Areas. Moreover, because the construction-related activities would be temporary and intermittent in nature, the construction would involve negligible discharges, if any, of bioaccumulative or CWA Section 303(d) listed constituents to water bodies of the affected environment. As such, construction activities would not contribute measurably to bioaccumulation of contaminants in organisms or humans or cause CWA Section 303(d) impairments to be discernibly worse. Based on these findings, this impact is determined to be less than significant. No mitigation is required.

Impact WQ-32: Effects on *Microcystis* Bloom Formation Resulting from Facilities Operations and Maintenance

Upstream of the Delta

Adverse effects from *Microcystis* upstream of the Delta have only been documented in lakes such as Clear Lake, where eutrophic levels of nutrients give cyanobacteria a competitive advantage over other phytoplankton during the bloom season. Large reservoirs upstream of the Delta are typically characterized by low nutrient concentrations, where other phytoplankton outcompete cyanobacteria, including *Microcystis*. In the rivers and streams of the Sacramento River watershed, watersheds of the eastern tributaries (Cosumnes, Mokelumne, and Calaveras Rivers), and the San Joaquin River upstream of the Delta under Existing Conditions, bloom development is limited by high water velocity and low residence times. These conditions are not expected to change under Alternative 5A or the No Action Alternative (ELT and LLT). Consequently, any modified reservoir operations under Alternative 5A are not expected to promote *Microcystis* production upstream of the Delta, relative to Existing Conditions and the No Action Alternative (ELT and LLT).

Delta

During the June through October period when *Microcystis* blooms occur in the Delta, it is a combination of flows, associated residence time, and water temperatures that are believed to most influence *Microcystis* bloom formation.

Under Alternative 5A, a portion of the Sacramento River water which is conveyed through the Delta to the south Delta intakes under Existing Conditions would be replaced at various locations throughout the Delta by other source water due to diversion of Sacramento River water at the north Delta intakes. The changes in flow paths of water through the Delta and change in operation of the south Delta pumps that would occur due to facilities operations and maintenance of Alternative 5A could result in localized increases in residence time in various Delta sub-regions and decreases in residence time in other areas. Because there is no published analysis of the relationship between *Microcystis* occurrence and residence time, there is uncertainty on how increased residence times may affect *Microcystis* occurrences (ICF International 2016). Further,, in general, there is substantial uncertainty regarding the extent that facilities operations and maintenance of Alternative 5A would result in a net increase in water residence times at various locations throughout the Delta, relative to Existing Conditions. In addition to the effects of operations and maintenance of Alternative 5A, increases in water residence times are expected occur due to separate factors and actions concurrent with the alternative, including habitat restoration (8,000 acres of tidal habitat restoration and enhancements in the Yolo Bypass) and sea level rise due to climate change.

To ensure project operations do not create increased *Microcystis* blooms in the Delta, water flow through Delta channels can be managed through real-time operations particularly the balancing of the north and south Delta diversions. By operating the south Delta pumps more frequently during periods conducive to increased *Microcystis* blooms, residence times can be managed to decrease the potential for blooms to develop, and thus decrease potential microcystin increases due to project operations. As such, effects of Alternative 5A on *Microcystis* levels, and thus microcystin concentrations in the Delta, would not be made more adverse relative to Existing Conditions and the No Action Alternative (ELT and LLT).

Water temperature is also a critical parameter that has been related to *Microcystis* blooms in the Delta. Since Delta water temperatures are largely driven by air temperature, climate change that increases air temperatures relative to Existing Conditions would be expected to increase ambient water temperatures in the Delta by 1.3–2.5°F. These climate changes in the ELT are expected to occur in the Delta under the No Action Alternative, relative to Existing Conditions. Alternative 5A operations and maintenance is not expected to cause increased Delta water temperatures, relative to Existing Conditions or the No Action Alternative.

In summary, increased frequency and magnitude of *Microcystis* blooms may occur in the Delta in the future, relative to Existing Conditions, due to factors unrelated to the project alternative, including: 1) increased residence times resulting from restoration activities and climate change-related sea level rise and 2) climate change-related increased Delta water temperatures. If *Microcystis* occurrences did increase in certain sub-regions of the Delta in the future, there would also be the potential for increased microcystin presence in the Delta, relative to Existing Conditions. To ensure project operations under Alternative 2D do not create significant increases in *Microcystis* blooms in the Delta, that may be associated with increased residence times, water flow through Delta channels would be managed through real-time operations.

SWP/CVP Export Service Area

As described above for the Delta, source waters to the south Delta intakes could be adversely affected relative to Existing Conditions by *Microcystis* both from an increase in Delta water temperatures associated with climate change, and from an increase in water residence times. The impacts from increased Delta water residence times would be primarily related to habitat restoration (8,000 acres of tidal habitat restoration and enhancements in the Yolo Bypass) that is assumed to occur separate from Alternative 5A. The combined effect of these factors on the potential for *Microcystis* blooms in source waters to the south Delta intakes is expected to be much greater than the influence of operations and maintenance of Alternative 5A, the effects of which will be mitigated through real time operations. Increases in ambient air temperatures due to climate change relative to Existing Conditions are expected under this alternative. Increases in ambient air temperatures are expected to result in warmer ambient water temperatures, and thus conditions more suitable to *Microcystis* growth, in the water bodies of the SWP/CVP Export Service Areas. The incremental increase in long-term average air temperatures would be less at the ELT (2.0°F), compared to the LLT (4.0°F).

As discussed in the Delta section above, Alternative 5A is not expected to substantially adversely affect by *Microcystis* blooms, relative to Existing Conditions and the No Action Alternative (ELT and LLT). Additionally, residence time and water temperature conditions in the SWP/CVP Export Service Areas are not expected to become more conducive to *Microcystis* bloom formation due to the operations and maintenance of Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT), because water residence times are projected to increase in the SWP/CVP Export Service Areas and any temperature increases there would be due to climate change not due to Alternative 2D.

NEPA Effects: Modified reservoir operations under Alternative 5A are not expected to promote *Microcystis* production upstream of the Delta, relative to the No Action Alternative (ELT and LLT). Similarly, operations and maintenance of Alternative 5A is not expected to substantially increase water residence times or ambient water temperatures in the Delta, including at the Banks and Jones pumping plants, and thus is not expected to result in adverse effects on *Microcystis* in the Delta, relative to No Action Alternative (ELT and LLT). Lack of adverse effects on *Microcystis* in the Delta would mean that Delta waters diverted into the SWP/CVP Export Service Areas would not be adversely affected. Finally, the potential for *Microcystis* bloom formation within the SWP/CVP Export Service Area water bodies and canals would not be expected to change substantially, if at all, because water residence times are not projected to increase in the SWP/CVP Export Service Areas and any temperature increases there would be due to climate change and not due to Alternative 5A. Thus, the effects on *Microcystis* in surface waters upstream of the Delta, in the Delta, and in the SWP/CVP Export Service Areas from implementing Alternative 5A are determined to be not adverse.

CEQA Conclusion: Modified reservoir operations under Alternative 5A are not expected to promote *Microcystis* production upstream of the Delta, relative to the Existing Conditions. Increased frequency and magnitude of *Microcystis* blooms may occur in the Delta in the future, relative to Existing Conditions, due to increased residence times resulting from restoration activities unrelated to the project alternative, as well as climate change and sea level rise that are expected to increase Delta water temperatures. Such increases in residence time and water temperatures would not be caused by implementation of Alternative 5A. Operations and maintenance of Alternative 5A, including the use of real-time operations, are not expected to result in flow and temperature conditions in the Delta, including at the Banks and Jones pumping plants, that would cause substantial increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms. As such, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment. *Microcystis* and microcystins are not CWA Section 303(d) listed within the affected environment and thus any increases that could occur in some areas of the Delta would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. Microcystin, the toxin produced by *Microcystis,* is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences due to climate change and sea level rise may lead to increased microcystin presence in the Delta, relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. While long-term water quality degradation may occur and, thus, impacts on beneficial uses could occur, these impacts are not related to implementation of Alternative 5A. Although there is uncertainty regarding this impact, the effects on *Microcystis* from implementing water conveyance facilities are determined to be less than significant. No mitigation is required.

Impact WQ-33: Effects on *Microcystis* Bloom Formation Resulting from Environmental Commitments

Effects on *Microcystis* from implementation of Environmental Commitments under Alternative 5A would be the same as those described for Alternative 4A.

NEPA Effects: Based on the discussion for Impact WQ-33 in Section 8.3.4.2, the effects on *Microcystis* from implementing Environmental Commitments 3, 4, 6–12, 15, and 16 are determined to be not adverse.

CEQA Conclusions: Based on the discussion for Impact WQ-33 in Section 8.3.4.2, Environmental Commitments 3, 4, 6–12, 15, and 16 would not be expected to cause additional exceedance of applicable water quality objectives/criteria by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment.

Microcystis and microcystins are not CWA Section 303(d) listed within the affected environment and thus any increases that could occur in some areas would not make any existing *Microcystis* impairment measurably worse because no such impairments currently exist. However, it is possible that increases in the frequency, magnitude, and geographic extent of *Microcystis* blooms in the Delta would occur at the early long-term for reasons unassociated with implementation of the Environmental Commitments, including tidal habitat restoration. Further, microcystin is bioaccumulative in the Delta foodweb (Lehman 2010). Thus, potential increases in *Microcystis* occurrences may lead to increased microcystin presence in the Delta relative to Existing Conditions. This has potential to cause microcystins to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose health risks to fish, wildlife or humans. While long-term water quality degradation related to microcystins levels may occur and, thus, significant impacts on beneficial uses could occur, these impacts are not related to implementation of the Environmental Commitments. Therefore, the effects on *Microcystis* from implementing the Environmental Commitments are determined to be less than significant. No mitigation is required.

Impact WQ-34: Effects on San Francisco Bay Water Quality Resulting from Facilities Operations and Maintenance and Environmental Commitments

The effects analysis presented in the preceding impacts (Impact WQ-1 through WQ-33) concluded that Alternative 5A would have a less-than-significant impact/no adverse effect on the following constituents in the Delta:

- Boron
- Bromide
- Chloride
- DOC
- DO
- Pathogens
- Pesticides
- Trace metals
- Turbidity and TSS
- *Microcystis*

Elevated concentrations of boron are of concern in drinking and agricultural water supplies. Chloride, DOC, and bromide concentrations also are of concern in drinking water supplies. However, waters in the San Francisco Bay are not designated to support MUN and AGR beneficial uses. Changes in Delta DO, pathogens, pesticides, trace metals, and turbidity and TSS are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the Delta. Changes in *Microcystis* would be primarily due to factors unassociated with the project alternative. Thus, changes in boron, bromide, chloride, DOC, DO, pathogens, pesticides, trace metals, turbidity and TSS, and *Microcystis* in Delta outflow associated with implementation of Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT and LLT) are not anticipated to be of a frequency, magnitude and geographic extent that would adversely affect any beneficial uses or substantially degrade the quality of the of San Francisco Bay, as described for Alternative 4 (see Section 8.3.3.9).

Elevated EC is of concern for its effects on the AGR beneficial use and fish and wildlife beneficial uses. San Francisco Bay does not have an AGR beneficial use designation. As described for Alternative 4, salinity throughout San Francisco Bay is largely a function of the tides, as well as to some extent the freshwater inflow from upstream. However, the changes in Delta outflow due to Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would be minor compared to tidal flows, and thus no substantial adverse effects on salinity, or fish and wildlife beneficial uses, downstream of the Delta are expected.

Also, as described for Alternative 4, changes in nutrient loading would not be expected to contribute to adverse effects to beneficial uses. Changes in nitrogen (ammonia and nitrate) loading to Suisun and San Pablo Bays under Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT and LLT), would not adversely impact primary productivity in these embayments because light limitation and grazing currently limit algal production in these embayments. Nutrient levels and ratios are not considered a direct driver of *Microcystis* and cyanobacteria levels in the North Bay. The only postulated effect of changes in phosphorus loads to Suisun and San Pablo Bays is related to the influence of nutrient stoichiometry on primary productivity. However, there is uncertainty regarding the impact of nutrient ratios on phytoplankton community composition and abundance. As described for Alternative 4, any effect on phytoplankton community composition would likely be small compared to the effects of grazing from introduced clams and zooplankton in the estuary. Therefore, changes in total nitrogen and phosphorus loading that would occur in Delta outflow to San Francisco Bay, relative to Existing Conditions and the No Action Alternative (ELT and LLT), shown in Appendix 8O, *San Francisco Bay Analysis*, Table 8O-1, are not expected to result in degradation of water quality with regard to nutrients that would result in adverse effects to beneficial uses.

Similar to Alternative 4, loads of mercury and methylmercury from the Delta to San Francisco Bay are estimated to change relatively little due to changes in source water fractions and net Delta outflow that would occur under Alternative 5A, relative to Existing Conditions and the No Action Alternative (ELT and LLT) (Appendix 8O, *San Francisco Bay Analysis*, Tables 8O-2). Also, there would be no incremental increase in dissolved selenium concentrations in the North Bay, relative to Existing Conditions under this alternative (Appendix 8O, Table 8O-3).

NEPA Effects: Based on the discussion above, Alternative 5A, relative to the No Action Alternative (ELT and LLT), would not cause further degradation to water quality with respect to boron, bromide, chloride, DO, DOC, EC, mercury, pathogens, pesticides, selenium, nutrients (ammonia, nitrate, phosphorus), trace metals, turbidity and TSS, or *Microcystis* in the San Francisco Bay. Further, changes in these constituent concentrations in Delta outflow would not be expected to cause changes in Bay concentrations of frequency, magnitude, and geographic extent that would adversely affect any beneficial uses. In summary, effects on the San Francisco Bay from implementation of water conveyance facilities and Environmental Commitments 3, 4, 6–12, 15, and 16 are considered to be not adverse.

CEQA Conclusion: As with Alternative 4, Alternative 5A would not be expected to cause long-term degradation of water quality in San Francisco Bay resulting in sufficient use of available assimilative capacity such that occasionally exceeding water quality objectives/criteria would be likely and would result in substantially increased risk for adverse effects to one or more beneficial uses. Further, this alternative would not be expected to cause additional exceedance of applicable water quality objectives/criteria in the San Francisco Bay by frequency, magnitude, and geographic extent that would cause significant impacts on any beneficial uses of waters in the affected environment.

Any changes in boron, bromide, chloride, and DOC in the San Francisco Bay would not adversely affect beneficial uses, because the uses most affected by changes in these parameters, MUN and AGR, are not beneficial uses of the Bay. Further, no substantial changes in DO, pathogens, pesticides, trace metals, turbidity or TSS, and *Microcystis* are anticipated in the Delta due to the implementation of Alternative 5A, relative to Existing Conditions, therefore, no substantial changes to these constituents levels in the Bay are anticipated. Changes in Delta salinity would not contribute to measurable changes in Bay salinity, as the change in Delta outflow would be two to three orders of magnitude lower than (and thus minimal compared to) the Bay's tidal flow and thus, have minimal influence on salinity changes. Changes in nutrient load, relative to Existing Conditions, are expected to have minimal effect on water quality degradation, primary productivity, or phytoplankton community composition. As with Alternative 4, the change in mercury and methylmercury load (which is based on source water and Delta outflow), relative to Existing Conditions, would be within the level of uncertainty in the mass load estimate and not expected to contribute to water quality degradation, make the CWA Section 303(d) mercury impairment measurably worse or cause mercury/methylmercury to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Similarly, based on Alternative 4 estimates, the increase in selenium load would be minimal, and total and dissolved selenium concentrations would be expected to be the same as Existing Conditions, and less than the target associated with white sturgeon whole-body fish tissue levels for the North Bay. Thus, the change in selenium load is not expected to contribute to water quality degradation, or make the CWA Section 303(d) selenium impairment measurably worse or cause selenium to bioaccumulate to greater levels in aquatic organisms that would, in turn, pose substantial health risks to fish, wildlife, or humans. Based on these findings, this impact is considered to be less than significant. No mitigation is required.

8.3.5 Cumulative Analysis

The cumulative effects analysis for water quality considers past, present, and reasonably foreseeable projects or programs in combination with the effects of the project alternatives. This assessment discusses only water quality constituents which could be affected, in part, from construction and implementation of the project alternatives. Constituents or constituent groups which could not be affected by the project alternatives are identified and addressed in the water quality Screening Analysis presented in Appendix 8C. The majority of the constituents assessed in the Screening Analysis have not been detected in the major source waters to the Delta, and others that have been detected have generally not exceeded water quality objectives/criteria or would not be affected by construction and implementation of the project alternatives. Consequently, they are not specifically addressed in this cumulative assessment. For a discussion of cumulative effects related to water temperature, see Chapter 11, *Fish and Aquatic Resources*.

Table 8-76. Effects on Water Quality from the Programs, Projects, and Policies Considered for Cumulative Analysis

Agency	Program/Project	Status	Description of Program/Project	Effects on Water Quality
Regulatory-, Discharge-, and Source Control-Related Actions				
Sacramento Regional County Sanitation District	SRWTP Facility Upgrade Project (EchoWater Project)	Final Environmental Impact Report certified September 2014; construction has been initiated	Upgrade existing secondary treatment facilities to advanced unit processes including improved nitrification/denitrification and filtration.	Reduced discharge concentration and mass of many constituents in wastewater to Sacramento River.
Sacramento County, Sacramento, Citrus Heights, Elk Grove, Folsom, Galt, and Rancho Cordova	Sacramento Stormwater Quality Partnership	Ongoing and future actions	Development and implementation of federal stormwater compliance programs	Reduced discharge concentration and mass of many constituents in stormwater to Sacramento River.
San Joaquin County, Stockton, Tracy, and the State Water Resources Control Board	San Joaquin County, Stockton, and Tracy Stormwater Management Programs	Ongoing and future actions	Development and implementation of federal stormwater compliance programs	Reduced discharge concentration and mass of many constituents in stormwater to San Joaquin River.
Yolo County, Public Works Division	Yolo County Stormwater Management Program	Ongoing and future actions	Development and implementation of federal stormwater compliance programs	Reduced discharge concentration and mass of many constituents in stormwater to Yolo Bypass.
Central Valley Water Board	Irrigated Lands Regulatory Program	Ongoing and future actions	Prevent agricultural discharges from impairing the waters that receive runoff.	Reduced discharge concentration and mass of many constituents in agricultural drainage to the Delta and tributaries.
Bureau of Reclamation and San Luis & Delta Mendota Water Authority	Grassland Bypass Project, 2010-2019	Ongoing and future actions	Agricultural drainage management actions to reduce selenium discharges.	Goal is regulatory compliance for reduced selenium discharges to San Joaquin River.
Bureau of Reclamation and San Luis & Delta Mendota Water Authority	Agricultural Drainage Selenium Management Program Plan	Ongoing and future actions	Agricultural drainage management actions to reduce selenium discharges.	Goal is regulatory compliance for reduced selenium discharges to San Joaquin River.
California Department of Water Resources and Bureau of Reclamation	Franks Tract Project	Proposed	Proposed operable gates to control channel flows at key locations to reduce sea water intrusion.	Goal is reduced western Delta salinity.
Central Valley Water Board	Sacramento-San Joaquin Delta Estuary TMDL for Methylmercury	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of mercury and methylmercury formation.

Agency	Program/Project	Status	Description of Program/Project	Effects on Water Quality
Central Valley Water Board	Total Maximum Daily Load for Selenium in the Lower San Joaquin River	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of selenium.
Central Valley Water Board	San Joaquin River Selenium TMDL	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of selenium.
Central Valley Water Board	Central Valley Pesticide TMDL	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of pesticides.
Central Valley Water Board	Salt and Boron TMDL for the Lower San Joaquin River	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of salts and boron.
Central Valley Water Board	Cache Creek, Bear Creek, Sulphur Creek, and Harley Gulch TMDL for Mercury	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of mercury and methylmercury formation.
Central Valley Water Board	Clear Lake Mercury TMDL	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of mercury and methylmercury formation.
Central Valley Water Board	American River TMDL for Methylmercury	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of mercury and methylmercury formation.
Central Valley Water Board	Central Valley Organochlorine Pesticide TMDL	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of legacy organochlorine pesticides.
Central Valley Water Board	Central Valley Diuron TMDL	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of diruon pesticide.
Central Valley Water Board	Central Valley Pyrethroid Pesticides TMDL	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of pyrethroid pesticides.
Central Valley Water Board	Stockton Urban Waterbodies Pathogen TMDL	Ongoing and future actions	Regulatory and implementation actions to achieve compliance with water quality objectives.	Goal is reduced source loading of pathogens in urban stormwater runoff.

Agency	Program/Project	Status	Description of Program/Project	Effects on Water Quality
Bureau of Reclamation, U.S. Fish and Wildlife Service, and California Department of Water Resources	Biological Opinion on the Long-Term Operations of the Central Valley Project and State Water Project (Delta smelt)	Ongoing and future actions	Regulatory program and actions for CVP/SWP water supply operations for recovery of Delta smelt population. Actions include habitat, flow, and water quality management.	Actions may affect seasonal and long-term Delta water quality conditions.
U.S. Department of Commerce, National Marine Fisheries Service, Bureau of Reclamation, and California Department of Water Resources	Biological Opinion and Conference Opinion on the Long-Term Operations of the Central Valley Project and State Water Project	Ongoing and future actions	Regulatory program and actions for CVP/SWP water supply operations for recovery of special-status anadromous fish. Actions include habitat, flow, and water quality management.	Actions may affect seasonal and long-term Delta water quality conditions.
Restoration Actions				
California Department of Fish and Wildlife	Ecosystem Restoration Program Conservation Strategy		Actions to address the critical environmental conditions in the Delta and Suisun Marsh/Bay including Delta flows and habitat restoration.	Changes in tidal prism and salinity patterns; potential incremental increase methylmercury formation and contribution to Delta load.
California Department of Fish and Wildlife, U.S. Fish and Wildlife Service, Bureau of Reclamation, and Suisun Marsh Charter Group	Suisun Marsh Habitat Management, Preservation, and Restoration Plan	Ongoing	Seasonal wetland and tidal marsh restoration actions in Suisun Marsh.	Changes in tidal prism and salinity patterns; potential incremental increase methylmercury formation and contribution to Delta load.
California Department of Water Resources	Dutch Slough Tidal Marsh Restoration Project	Final Environmental Impact Report, September 2014	Seasonal wetland and tidal marsh restoration actions in western Delta.	Changes in tidal prism and salinity patterns; potential incremental increase methylmercury formation and contribution to Delta load.
California Department of Water Resources and Department of Fish and Wildlife	Cache Slough Area Restoration	Ongoing and future actions	Enhancement and restoration of existing and potential open water, marsh, floodplain and riparian habitat in northern Delta.	Changes in tidal prism and salinity patterns; potential incremental increase methylmercury formation and contribution to Delta load.
Reclamation District 2093	Liberty Island Conservation Bank	Future	Tidal marsh restoration project in northern Delta.	Changes in tidal prism and salinity patterns; potential incremental increase methylmercury formation and contribution to Delta load.

Agency	Program/Project	Status	Description of Program/Project	Effects on Water Quality
California Department of Water Resources	California Water Action Plan	Initiated in January 2014	This plan lays out a roadmap for the next 5 years for actions that would fulfill 10 key themes. In addition, the plan describes certain specific actions and projects that call for improved water management throughout the state.	Actions implemented may affect seasonal and long-term Delta water quality conditions.
Delta Conservancy	California EcoRestore	Initiated in 2015	This program will accelerate and implement a suite of Delta restoration actions for up to 30,000 acres of fish and wildlife habitat by 2020.	Potential for effects on water quality at various Delta locations related to changes in hydrodynamics near restoration actions.

8.3.5.1 Cumulative Effects of the No Action Alternative

Water quality conditions upstream of the Delta, in the Delta Region, and in the SWP/CVP export service areas of the affected environment are expected to change as a result of past, present, and reasonably foreseeable future projects, population growth, climate change, and changes in water quality regulations (e.g., completion of TMDLs, adoption of new or more restrictive criteria/objectives). Many past, present, and reasonably foreseeable future projects are identified and described in Appendix 3D, *Defining Existing Conditions, No Action Alternative, No Project Alternative, and Cumulative Impact Conditions*, and specific projects or regulatory programs that are either ongoing or proposed for future implementation, and thus, could affect future cumulative water quality conditions, are listed in Table 8-76. The combined water quality effects of projects considered in the cumulative condition will vary, including potential contribution to the degradation of various water quality parameters, whereas others will function to improve constituent-specific water quality in certain areas. Future population growth may produce increased constituent loadings to the water bodies of the affected environment through increased urban stormwater runoff, increased POTW discharges, and changes in land uses. Climate change is anticipated to cause salinity increases in the western and southern Delta due to sea level rise. This is evidenced by the increase in violations of the Bay-Delta WQCP electrical conductivity objective in the Sacramento River at Emmaton under the No Action Alternative, relative to Existing Conditions, as described in Section 8.3.3.1. Conversely, changes in water quality regulations generally are in a direction that will result in improvements in water quality (e.g., increased monitoring and restrictions on urban stormwater runoff, completion of TMDLs to lessen or eliminate existing beneficial use impairments through improved water quality, more restrictive regulations on POTW discharges, new and/or more restrictive water quality criteria/objectives in Basin Plans).

Some water quality constituents are at levels under Existing Conditions that cause some impact to beneficial uses. These include:

- Bromide
- Chloride

- Electrical Conductivity
- Mercury
- Organic Carbon
- Pesticides and Herbicides
- Selenium

Under the cumulative No Action Alternative, even with consideration of the factors that will affect water quality discussed above, these constituents are expected to remain at levels that will cause some impact to beneficial uses. In addition, the frequency, magnitude, and geographic extent of *Microcystis* blooms in Delta waters may increase in the future as Delta water temperatures increase due to climate change. Thus, for the purposes of NEPA, water quality conditions for the constituents listed above, and possibly for *Microcystis* blooms in Delta waters as well, under the cumulative No Action Alternative constitute an adverse environmental condition. The cumulative effect of the No Action Alternative for all other water quality constituents is not adverse.

Although the constituents listed above are at levels under Existing Conditions that cause some impact to beneficial uses, the only constituents for which the cumulative effects of the No Action Alternative are expected to adversely affect beneficial uses, relative to Existing Conditions, are electrical conductivity, chloride, and possibly *Microcystis* blooms in Delta waters, due to the effects of climate change and sea level rise. Thus, for the purposes of CEQA, water quality conditions for electrical conductivity chloride, and *Microcystis* blooms in Delta waters under the cumulative No Action Alternative constitute a significant environmental condition. The cumulative effect of the No Action Alternative for all other water quality constituents is less than significant, relative to Existing Conditions.

8.3.5.2 Concurrent Project Effects

The constituent assessments of the BDCP alternatives evaluated the effects of the water conveyance facilities, plus the hydrodynamic effects of CM2 and CM4, separately from the effects of CM2–CM21. Similarly, the constituent assessments for Alternatives 4A, 2D, and 5A evaluated the effects of the water conveyance facilities separately from the effects of the Environmental Commitments. This section discusses the potential for the concurrent implementation of the water conveyance facilities with the other conservation measures/Environmental Commitments under the action alternatives to result in more substantial effects to water quality than identified in the separate constituent assessments of these project components. This discussion is organized according to the geographic regions of the affected environment—Upstream of Delta, Delta Region, SWP/CVP Export Service Areas—because implementation of the project components differs in these areas. For the SWP/CVP Export Service Areas region of the affected environment (e.g., south of Delta and North Bay Aqueduct) the discussion of concurrent water quality effects is based on water quality changes in the Delta at the export pumping plants, because no conservation measures/Environmental Commitments would be implemented in this portion of the affected environment.

Upstream of the Delta

BDCP Alternatives

In areas upstream of the Delta, the conservation measures or components of these measures that would be implemented in addition to the water conveyance facilities would be: 1) *CM2 Yolo Bypass*

FIsheries Enhancement, 2) *CM18 Conservation Hatcheries*, and 3) *CM19 Urban Stormwater Treatment*. CM2 is not expected to alter water quality in the Sacramento River, as the measure is primarily to improve fish habitat through modifications to Fremont Weir to increase the frequency, duration and magnitude of floodplain inundation in the bypass. CM18 involves the operation of a new fish hatchery, discharges from which would be required to meet NPDES permit requirements to protect water quality and beneficial uses. CM19 may involve actions to improve stormwater quality coming from urban areas outside the Delta, but that drain to Delta waters, and would result in either no effect or beneficial effects on water quality upstream of the Delta. All other conservation measures would be implemented in the Delta region. Maintenance activities associated with the physical structures would not result in substantial, adverse effects on water quality. Consequently, the concurrent implementation of the water conveyance facilities and restoration activities under the BDCP alternatives would not result in new, more adverse effects/significant impacts to water quality beyond those described in the separate impact assessments for these alternatives.

Alternatives 4A, 2D, and 5A

None of the conservation measures discussed for the BDCP alternatives for the upstream of Delta region would be implemented as components of Alternatives 4A, 2D, and 5A, and no Environmental Commitments would be implemented in this region. Consequently, the concurrent implementation of the water conveyance facilities and Environmental Commitments under Alternatives 4A, 2D, and 5A would not result in new, more adverse effects/significant impacts on water quality beyond those described in the separate impact assessments for these alternatives.

Delta and SWP/CVP Export Service Areas

BDCP Alternatives

The water quality assessment for the Delta region concluded that the separate impacts of the water conveyance facilities and CM2–CM21 under the BDCP alternatives would not be adverse/would be less than significant for ammonia, boron, DO, nitrate+nitrite, pathogens, phosphorus, trace metals, and turbidity/TSS. For water quality conditions of these constituents to be adverse/ significant under the concurrent implementation of the water conveyance facilities and CM2–CM21 would require that CM2–C21 implementation contribute additional loading of these constituents or otherwise alter conditions beyond the hydrodynamic effects of the water conveyance facilities to result in adverse conditions. However, when considered concurrently, CM1–CM21 are not expected to result in new, previously unidentified adverse/significant impacts, relative to the individual impact determinations, for the reasons provided below.

- **Ammonia:** Ammonia concentrations under the water conveyance facilities will be lower in the Delta due to lower Sacramento River concentrations resulting from a separate project being implemented by the Sacramento Regional County Sanitation District, which will result substantially reduced ammonia discharges from the Sacramento Regional Wastewater Treatment Plant. CM2–CM21 are not expected to substantially alter ammonia concentrations in the affected environment. Thus, concurrent implementation of CM1–CM21 would not result in adverse ammonia conditions.

- **Boron and Trace Metals:** CM2–CM21 would not present new or substantially changed sources of boron or trace metals in the Delta. Thus, their concurrent implementation with CM1 would not result in adverse boron and trace metals conditions.

- **DO:** DO conditions under the water conveyance facilities are expected to be similar to Existing Conditions, and CM2–CM21 are not expected to contribute oxygen-demanding substances at levels that would adversely affect DO levels. Further, CM14 would contribute to improving DO conditions in the Stockton Deep Water Channel. Thus, concurrent implementation of CM1–CM21 would not result in adverse DO conditions.
- **Nitrate+nitrite:** Long-term average nitrate+nitrite concentrations are anticipated to remain low with implementation of the water conveyance facilities. CM2–CM21 would not present new or substantially changed sources of nitrate+nitrite in the Delta. Conversely, it is expected there may be a decrease in nitrate+nitrite concentrations as lands used for agriculture are converted for restoration, thus reducing fertilizer application on these lands. Thus, their concurrent implementation with the water conveyance facilities would not result in adverse nitrate+nitrite conditions.
- **Pathogens:** Pathogens conditions under the water conveyance facilities are expected to be similar to Existing Conditions. Thus, its concurrent implementation with the restoration activities would not make pathogens conditions adverse.
- **Phosphorus:** The water conveyance facilities are not expected to substantially change phosphorus concentrations, because concentrations in Delta source water are similar throughout the year. The restoration activities are not anticipated to contribute additional phosphorus load. Thus, concurrent implementation of the water conveyance facilities with the restoration activities would not result in adverse phosphorus conditions.
- **Turbidity/TSS:** Turbidity/TSS conditions under the water conveyance facilities are expected to be similar to Existing Conditions. Thus, its concurrent implementation with the restoration activities would not make turbidity/TSS conditions adverse.

The assessment of bromide, chloride, and EC conditions in the Delta concluded that CM1 plus the hydrodynamic effects associated with CM2 and CM4 under the BDCP alternatives would result in an adverse effect/significant and unavoidable impact, to varying degrees. Implementation of CM2–CM21 would not present new or substantially changed sources of these constituents in the Delta beyond the effects on hydrodynamics. Thus, their concurrent implementation with CM1 would not result in more adverse/significant bromide, chloride, and EC conditions than has been described for the separate conservation measures.

The assessment of dissolved organic carbon (DOC) conditions in the Delta concluded that implementation of CM1 of Alternatives 1A–3, 4, or 5 would not result in an adverse effect/significant impact, whereas, implementation of CM2–CM21 under these alternatives would result in an adverse/significant and unavoidable impact associated with the creation of the restoration areas. Concurrent implementation of CM1 with CM2–CM21 under Alternatives 1A–3, 4, or 5 is not expected to result in more adverse/significant impacts than described for the separate conservation measures, because the long-term average DOC increases resulting from CM1 would be comparatively small and within the uncertainty in the contributions that would result from the restorations areas. Conversely, the assessment of CM1 under Alternatives 6A–9 concluded significant and unavoidable impacts for DOC. The adverse/significant conditions under CM1 concurrent with the conditions anticipated for CM2–CM21 may be more adverse/significant than when considered separately, particularly because the projected long-term average DOC increases under CM1 would be a measurable, additive contribution.

The assessment of pesticide conditions in the Delta concluded that implementation of CM1 under Alternatives 1A–3, 4, or 5 would not result in an adverse effect/significant impact, whereas Alternatives 6A–9 would result in significant and unavoidable impacts for pesticides, because of potential adverse increases at Franks Tract, Rock Slough, and Contra Costa Pumping Plant No. 1. The assessment of CM2–CM21, for all alternatives, identified an adverse/significant and unavoidable impact associated with *CM13 Invasive Aquatic Vegetation Control*. However, concurrent implementation of CM1 with CM2–CM21, under all BDCP alternatives, is not expected to result in more adverse/significant impacts than described for the separate conservation measures, because the effects of CM13 would primarily occur in the vicinity of pesticide application, and mitigation is proposed to apply pesticides in a manner that minimizes the risk to human health, non-target organisms, and the aquatic ecosystem.

The assessment of mercury conditions in the Delta concluded that implementation of CM1 under Alternatives 1A–3, 4, or 5 would not result in an adverse effect/significant impact, whereas, implementation of CM2–CM21 under these alternatives would result in an adverse/significant and unavoidable impact associated with the creation of the restoration areas. Concurrent implementation of CM1 with CM2–CM21 under Alternatives 1A–3, 4, or 5 is not expected to result in more adverse/significant impacts than described for the separate conservation measures, because the mercury conditions in water and fish resulting from CM1 would be similar to Existing Conditions. Conversely, the assessment of CM1 under Alternatives 6A–9 concluded significant and unavoidable impacts for mercury. The adverse/significant conditions under CM1 concurrent with the conditions anticipated for CM2–CM21 may be more adverse/significant than when considered separately, particularly because of the bioaccumulative properties of mercury and because the Delta is already impaired due to elevated mercury.

The assessment of selenium conditions in the Delta concluded that implementation of CM1 under Alternatives 1A–3, 4, or 5 would not result in an adverse effect/significant impact, whereas conditions under Alternatives 6A–9 would be adverse/significant and unavoidable. Selenium conditions resulting from implementation of CM2–CM21 under all BDCP alternatives were determined to not be adverse/less than significant. Of concern for selenium is increased exposure of aquatic organisms through increased water residence time and selenium concentrations. However, the impact assessment concluded that CM2–CM21 would not contribute substantially to these conditions, because factors would also be in place to minimize selenium exposure, including TMDLs to reduce loading to the system, wetland design to prevent buildup of selenium in restoration areas, and implementation of *AMM27 Selenium Management* (see Appendix 3.C, *Avoidance and Minimization Measures*, of the BDCP). Thus, concurrent implementation of CM1 and CM2–CM21 is not anticipated to result in more adverse/significant impacts than has been described for the separate conservation measures.

The assessment of *Microcystis* conditions in the Delta concluded that CM1 plus the hydrodynamic effects associated with CM2 and CM4 under the BDCP alternatives would result in an adverse effect/significant impact. Effects of CM2–CM21, beyond the increase in residence time and localized water temperature described in the separate impacts assessments, would not present new, previously unidentified impacts. Thus, concurrent implementation of CM1–CM21 would not result in more adverse/significant *Microcystis* conditions than has been described for the separate conservation measures.

Alternatives 4A, 2D, and 5A

The water quality assessment for the Delta region concluded that the separate impacts of the water conveyance facilities and Environmental Commitments under Alternatives 4A, 2D, and 5A would not be adverse/would be less than significant for ammonia, boron, bromide, chloride, DO, nitrate+nitrite, dissolved organic carbon, pathogens, pesticides, phosphorus, selenium, trace metals, turbidity/TSS, and *Microcystis*. For water quality conditions of these constituents to be adverse/ significant under the concurrent implementation of the water conveyance facilities and Environmental Commitments would require that the Environmental Commitments implementation contribute additional loading of these constituents or otherwise alter conditions beyond the hydrodynamic effects of the water conveyance facilities to result in adverse conditions. However, when considered concurrently, the water conveyance facilities and Environmental Commitments are not expected to result in new, previously unidentified adverse/significant impacts, relative to the individual impact determinations.

As described above for the BDCP alternatives, ammonia concentrations under the non-HCP alternatives' water conveyance facilities would be lower in the Delta, and the Environmental Commitments are not expected to substantially alter ammonia concentrations in the affected environment. Thus, concurrent implementation of the water conveyance facilities and Environmental Commitments would not result in adverse ammonia conditions.

Similarly, the Environmental Commitments would not present new or substantially changed sources of boron, bromide, chloride, DO-consuming substances, nitrate+nitrite, pathogens, pesticides, phosphorus, trace metals, or turbidity/TSS in the Delta. Thus, their concurrent implementation with water conveyance facilities would not result in adverse conditions for these constituents.

The assessment of EC conditions in the Delta concluded that water conveyance facilities under Alternatives 4A, 2D, and 5A would result in not adverse/less than significant impacts with implementation of identified mitigation measures. Implementation of Environmental Commitments would not present new or substantially changed sources of salinity-related constituents in the Delta that would affect EC levels. Thus, their concurrent implementation with water conveyance facilities would not result in more adverse/significant EC conditions than has been described for the separate project components.

The assessment of mercury conditions in the Delta concluded that the water conveyance facilities under Alternatives 4A, 2D, and 5A would not result in an adverse effect/significant impact, whereas, implementation of Environmental Commitments under these alternatives would result in an adverse/significant and unavoidable impact associated with the creation of the restoration areas. Concurrent implementation of water conveyance facilities with the Environmental Commitments is not expected to result in more adverse/significant impacts than described for the separate project components, because the mercury conditions in water and fish resulting from water conveyance facilities would be similar to Existing Conditions.

8.3.5.3 Cumulative Effects of the Action Alternatives

When the effects of the action alternatives on water quality are considered in connection with the potential effects of past, present, and reasonably foreseeable projects or programs, the potential cumulative effects on water quality range from beneficial to potentially adverse, depending upon water quality constituent/parameter and location. This cumulative analysis thus follows the list approach outlined in CEQA guidelines 15130(b)(1), the list including the defined past, present, and foreseeable actions in Appendix 3D, *Defining Existing Conditions, No Action Alternative, No Project Alternative, and Cumulative Impact Conditions*, and in particular the future potential actions listed in Table 8-76.

If the cumulative water quality condition (which includes implementation of the action alternative along with past, present, and reasonably foreseeable future projects, population growth, climate change, and changes in water quality regulations) for a constituent or group of constituents within a defined region of the affected environment is determined not to be adverse for the purposes of NEPA compliance (or less than significant under CEQA), then no further assessment is conducted. No further assessment is conducted because a cumulative condition that is non-adverse (NEPA terminology) or less than significant (CEQA terminology) demonstrates that the action alternative would not have adverse effects that are individually minor but that would "cumulate" or "be additive" with those of other past, present, and reasonably foreseeable projects to result in an adverse (significant) cumulative effect.

Conversely, if the cumulative water quality condition for a particular constituent is determined to be adverse for NEPA purposes or significant for CEQA purposes, then further assessment is conducted. For compliance with State CEQA Guidelines Section 15130, further assessment is provided to determine if implementation of the action alternatives would contribute considerably to that significantly impacted cumulative condition. If implementation of an action alternative would not contribute considerably to the significantly impacted cumulative water quality condition identified, then no further mitigation is required. However, if implementation of an action alternative would contribute considerably to the adverse (significant) cumulative water quality condition identified, then mitigation for the action alternative's cumulatively considerable contribution to the identified adverse (significant) cumulative water quality condition is proposed (if any is at least potentially feasible). For the purposes of NEPA compliance, the context and intensity of the potential action alternative-related contribution to any adverse (significant) cumulative condition is evaluated and mitigation measures are identified that would reduce or minimize the action alternative's contribution to the cumulative impact.

The potential for cumulative impacts on water quality for the action alternatives is assessed for: 1) construction-related activities, 2) water conveyance facilities operations and maintenance, and 3) implementation of conservation measures/Environmental Commitments for the same geographic scope (Affected Environment) as done for individual action alternatives analyses. Each action alternative is assessed for each of these three impact assessment categories. Effects are specifically discussed by region of the affected environment (i.e., Upstream of the Delta, Delta Region, and SWP/CVP Export Service Areas) and by constituent or constituent groups. Individual discussions for specific action alternatives are provided only if the anticipated effects under one or more action alternatives can be meaningfully distinguished from the effects anticipated under other alternatives. If the contributions of the various action alternatives to a cumulative condition cannot be readily distinguished from one another, then a single assessment that addresses all action alternatives is provided.

Cumulative Impact WQ-1: Cumulative Impacts on Water Quality Resulting from Construction-Related Activities

Upstream of the Delta

BDCP Alternatives

Construction activities upstream of the Delta would be tied to conservation measures for the BDCP alternatives. Conservation measures or components of these measures that would be constructed in areas upstream of the Delta would be: 1) *CM2 Yolo Bypass Fisheries Enhancement* (i.e., the Fremont Weir component of the action), 2) *CM18 Conservation Hatcheries* (i.e., the new hatchery facility), and 3) *CM19 Urban Stormwater Treatment*. Neither the construction to be undertaken nor the techniques and conservation measures to be employed upstream of the Delta would differ sufficiently among alternatives to warrant separate alternative-specific discussions here. Hence, the BDCP alternatives are discussed collectively in this cumulative assessment. Construction of individual components necessitated by CM2, CM18, and CM19 could involve site preparation and earthwork adjacent to water bodies of the affected environment. If so, their construction also would include water quality protection actions in the form of environmental commitments (see Appendix 3B, *Environmental Commitments, AMMs, and CMs*) and related water quality protection actions issued in agency permits required for construction and operation of facilities. Such actions would include SWPPPs that would minimize erosion of soils into water bodies and would minimize/eliminate the direct spilling of earthmoving equipment fuels, oils, and other construction materials into water bodies, thus minimizing any effects on water quality in adjacent water bodies. Other water quality protection actions issued in agency permits would include those in the State Water Board's NPDES Stormwater General Permit for Stormwater Discharges Associated with Construction and Land Disturbance Activities (Order No. 2009-0009-DWQ/NPDES Permit No. CAS000002), project-specific WDRs or CWA Section 401 water quality certification from the appropriate Central Valley Water Board, CDFW Streambed Alteration Agreements, and USACE CWA Section 404 dredge and fill permits. Thus, construction activities associated with the BDCP Alternatives would not contribute considerably to any adverse (significant) cumulative water quality condition upstream of the Delta, nor would construction-related effects make an otherwise non-adverse (significant) cumulative water quality condition adverse in this region.

Alternatives 4A, 2D, and 5A

Alternatives 4A, 2D, and 5A do not include related Environmental Commitments in the upstream of Delta region; thus, the construction-related effects described above for the BDCP alternatives do not apply to these alternatives.

Delta

The construction of new conveyance facilities under all action alternatives, and construction associated with implementing restoration actions, particularly CM2–CM10 under the BDCP alternatives (Environmental Commitments 3, 4, 6, 7, and 9–10 under Alternatives 4A, 2D, and 5A), could result in elevated turbidity/TSS in surface waters adjacent to construction activities due to the erosion of disturbed soils and associated sedimentation entering Delta waterways or other construction-related wastes (e.g., concrete, asphalt, cleaning agents, paint, and trash). In addition, the use of heavy earthmoving equipment adjacent to Delta waterways may result in spills and leakage of oils, gasoline, diesel fuel, and related petroleum contaminants used in the fueling and operation of such construction equipment. The extensive construction activities that will be necessary to implement the new conveyance facilities, and CM4–CM10 under the BDCP alternatives (Environmental Commitments 4, 6, 7, and 9–10 under Alternatives 4A, 2D, and 5A) would involve a variety of land disturbances in the Delta including vegetation removal; grading and excavation of soils; establishment of roads-bridges, staging, and storage areas; in-water sediment dredging and dredge material storage; and hauling and placement or disposal of excavated soils and dredge materials. Although the number of intakes to be constructed, pipeline alignments and other construction aspects vary among the action alternatives, all action alternatives involve sufficient construction activities that, if conducted improperly, could adversely affect Delta water quality.

Although action alternatives having greater number of intakes and greater construction activities pose a greater overall potential to adversely affected water quality, adverse water quality effects for all action alternatives will be avoided or reduced to less than substantial levels in the same manner, which is by implementing proper conservation measures and obtaining and abiding by agency-issued permits need for construction activities (e.g., State Water Board's NPDES Stormwater General Permit for Stormwater Discharges Associated with Construction and Land Disturbance Activities (Order No. 2009-0009-DWQ/NPDES Permit No. CAS000002), possibly project-specific WDRs, CWA Section 401 water quality certification from the appropriate Central Valley Water Board, CDFW Streambed Alteration Agreements, and USACE CWA Section 404 dredge and fill permits). Because of this commonality among alternatives regarding potential for construction-related water quality effects, and the common means of avoiding or reducing such effects, all action alternatives are assessed collectively rather than individually.

As described for all action alternatives in Sections 8.3.3 and 8.3.4, the implementation of construction-related environmental commitments (Appendix 3B, *Environmental Commitments, AMMs, and CMs*) and abiding by agency-issued permits need for construction activities will reduce potential construction-related water quality impacts in the Delta to less-than-significant levels. Moreover, the cumulative condition for turbidity/TSS and petroleum contaminants in Delta waters are not expected to be adverse. This is due, in large part, to the implementation (or planned implementation) of construction-related environmental commitments (Appendix 3B) and agency permitted construction "best management practices" for construction of not only the selected action alternative (including its conservation measures/Environmental Commitments), but also other past, present, and reasonably foreseeable future projects. Because construction-related effects on all water quality constituents/parameters would be minimized through environmental commitments (Appendix 3B) and permitted construction "best management practices" in the agency-issued permits discussed above, construction activities associated with the action alternatives would not contribute considerably to any adverse (significant) cumulative water quality condition in the Delta, nor would construction-related effects make an otherwise non-adverse (significant) cumulative water quality condition adverse.

SWP/CVP Export Service Areas

Because construction-related activities associated with the action alternatives are not expected to contribute considerably to any adverse (significant) cumulative Delta water quality condition, including conditions at the Banks and Jones pumping plants, which are the primary locations of water export to the SWP/CVP Export Service Areas, the construction of these alternatives would not contribute considerably to any adverse (significant) cumulative water quality condition in water bodies located in the SWP/CVP Export Service Areas.

NEPA Effects: The action alternatives involve minimal construction elements upstream of the Delta and would include implementation of construction-related environmental commitments (Appendix 3B, *Environmental Commitments, AMMs, and CMs*) that would mitigate any temporary construction-related effects on water quality. Thus their construction would not adversely affect any cumulative water quality constituent/parameter condition upstream of the Delta. Construction of conveyance facilities and conservation measures/Environmental Commitments for the action alternatives could potentially result in temporary water quality effects on Delta turbidity/TSS levels and petroleum contaminants. However, the cumulative condition for Delta turbidity/TSS and petroleum contaminants would not be adverse for several reasons. First, there is currently no adverse conditions for turbidity/TSS levels and petroleum contaminants in the Delta. Second, implementation of construction-related environmental commitments (Appendix 3B) for the action alternative to be implemented and use of related construction BMPs for other projects would reduce effects on these and other Delta water quality constituents/parameters. Third, because construction-related effects on water quality are temporary in nature, they tend not to be cumulative over time (i.e., construction effects on water quality are not permanent).

CEQA Conclusion. The temporary construction-related effects on water quality resulting from constructing the action alternatives, including conservation measures/Environmental Commitments, would not contribute considerably to any significant cumulative Delta water quality condition, nor would construction-related effects make an otherwise non-adverse cumulative Delta water quality condition for any constituent/parameter potentially significant. Because construction-related activities are not expected to contribute considerably to any significant cumulative Delta water quality condition, they also would not contribute considerably to any sgnificant cumulative water quality condition in water bodies located in the SWP/CVP Export Service Areas. No mitigation is required.

Cumulative Impact WQ-2: Cumulative Impacts on Water Quality Upstream of the Delta Resulting from Facilities Operations and Maintenance and Conservation Measures (or Environmental Commitments)

Constituent loading from upstream watersheds and resultant concentrations/levels in the water bodies upstream of the Delta would remain unchanged, or would be negligibly affected, by implementation of facilities operations and maintenance under the action alternatives. Changes in seasonal reservoir storage levels and river flows from altered system-wide operations under the action alternatives would have negligible, if any, effects on water quality in the rivers and reservoirs upstream of the Delta. Consequently, facilities operations and maintenance under any of the action alternatives would not be expected to contribute considerably to any cumulative water quality condition within the affected environment, upstream of the Delta.

Conservation measures or components of these measures that would be implemented as part of the BDCP alternatives in areas upstream of the Delta would be: 1) *CM2 Yolo Bypass Fisheries Enhancement*, 2) *CM18 Conservation Hatcheries*, and 3) *CM19 Urban Stormwater Treatment*. CM2 is a fish enhancement measure and, thus, is not expected to alter water quality upstream of the Delta. (Note: Alternatives 4A, 2D, and 5A do not contain Environmental Commitments related to CM2, CM18, or CM19). CM18 involves the operation of a new fish hatchery, discharges from which would be required to meet NPDES permit requirements to protect water quality and beneficial uses. CM19 may involve actions to improve stormwater quality coming from urban areas outside the Delta, but that drain to Delta waters, and would result in either no effect or beneficial effects on water quality upstream of the Delta. All other conservation measures would be implemented in the Delta region.

Maintenance activities associated with the physical structures would not result in substantial, adverse effects on water quality. Consequently, the implementation of CM2–CM21 is not expected to contribute considerably to any cumulative water quality condition within the affected environment, upstream of the Delta.

NEPA Effects: Implementation of the action alternatives facilities operations and maintenance, and their associated conservation measures/Environmental Commitments, would have negligible, if any, water quality effects on water bodies of the affected environment located upstream of the Delta. Any negligible effects that may occur would not contribute considerably to any adverse cumulative water quality condition in water bodies upstream of the Delta, nor would the action alternatives effects make an otherwise non-adverse cumulative water quality condition for any constituent/parameter adverse.

CEQA Conclusion. Because the potential effects of facilities operations and maintenance and associated conservation measures/Environmental Commitments on water quality upstream of the Delta would be minimal, implementation of the action alternatives would not contribute considerably to any significant cumulative water quality condition upstream of the Delta, No mitigation is required.

Cumulative Impact WQ-3: Cumulative Impacts on Water Quality in the Delta and SWP/CVP Export Service Areas Resulting from Facilities Operations and Maintenance and Conservation Measures (or Environmental Commitments)

When the effects of implementing any one of the action alternatives on water quality are considered (including the new conveyance facilities, fish screens, gates and other physical structures and their operations and maintenance activities) together with the potential effects of projects listed in Appendix 3D, *Defining Existing Conditions, No Action Alternative, No Project Alternative, and Cumulative Impact Conditions*, and Table 8-76, the cumulative water quality condition in the Delta Region and SWP/CVP Export Service Areas for the following constituents is considered to not be adverse. Additional discussion for these water quality constituents is provided below.

- Ammonia
- Boron
- DO
- Nitrate + Nitrite
- Pathogens
- Phosphorus
- Trace metals
- Turbidity/TSS

Ammonia

Ammonia levels are not expected to be adverse under the cumulative condition as a result of the Sacramento Regional Wastewater Treatment Plant, and other publicly owned treatment works (POTWs) that discharge to the Delta, nitrifying their effluent that is discharged to Delta tributaries and waters.

Boron

The lower San Joaquin River is listed on the State's CWA Section 303(d) list of impaired water bodies for salt and boron (State Water Resources Control Board 2011). Boron is paired with salt in this listing due to its regular association with saline waters. The Central Valley Water Board has prepared a TMDL with an implementation program where it is expected that actions taken to control salts also will control boron as well (Central Valley Water Board 2004). With regulatory actions being taken to improve boron concentrations (and salinity in general on the San Joaquin River), the cumulative condition for boron is considered to not be adverse.

Dissolved Oxygen

DO throughout the Delta is generally suitable for beneficial use protection, with the notable exception of the Stockton Deep Water Ship Channel. The TMDL for DO and related actions (e.g., Stockton Deep Water Ship Channel aeration facility) is expected to further improve DO levels in the future. Thus, DO levels under the cumulative condition are not expected to be adverse.

Nitrate/Nitrite

Similar to ammonia levels, nitrate/nitrite levels in the Delta may be reduced in the future as POTWs discharging to Delta waters implement de-nitrification processes. The Central Valley Water Board is currently permitting such requirements with regularity and thus notable reductions in POTW-related nitrate/nitrite discharges are expected in the future, and other new or greater sources are not anticipated that would offset such point-source reductions. Thus, nitrate/nitrite levels under the cumulative condition are not expected to be adverse.

Pathogens

Similarly, increasingly stringent state regulations on both POTWs and urban runoff through the NPDES program is anticipated to reduce pathogen loading to Delta waters from these sources. As discussed in the project-specific analyses of alternatives, pathogen levels in the Delta are most affected by local factors, primarily local land uses and associated runoff from such lands. Conversion of Delta agricultural lands to tidal wetlands under the action alternatives may alter levels of coliforms and *E. coli* (either up or down), but would be expected to reduce loading of *Cryptosporidium*. Moreover, increased municipal wastewater discharges resulting from future population growth would not be expected to measurably increase pathogen concentrations in receiving waters due to State and Federal water quality regulations requiring disinfection of effluent discharges and the State's implementation of Title 22 filtration requirements for many wastewater dischargers in the Sacramento River and San Joaquin River watersheds. Municipal stormwater regulations and permits have become increasingly stringent in recent years, and such further regulation of urban stormwater runoff is expected to continue in the future. The ability of storm water BMPs to consistently reduce pathogen loadings and the extent of future implementation is uncertain, but would be expected to improve as new technologies are continually tested and implemented. Also, some of the urbanization may occur on lands used by other pathogens sources, such as grazing lands, resulting in a change in pathogen source, but not necessarily an increase (and possibly a decrease) in pathogen loading. In sum, Delta pathogen levels are not anticipated to be adverse under the cumulative condition.

Phosphorus

Primary sources of phosphorus to Delta waters include agriculture, municipal POTWs, individual septic treatment systems, urban runoff, stream bank erosion, and decaying plant material. Currently, Delta phosphorous levels are not of substantial concern to state water quality regulatory agencies, nor is there clear evidence that phosphorous levels are adversely affecting Delta beneficial uses. Due to increased regulations and regulatory monitoring anticipated in the future, which may include water quality objectives for phosphorus at some point in the future, loading from agriculture, municipal POTWs, individual septic treatment systems, and urban runoff are all expected to remain at similar levels to that under current conditions, or decline, under the future cumulative condition. Loadings from stream bank erosion and decaying plants are not expected to change notably in the future. Hence, phosphorus levels are not anticipated to be adverse under the cumulative condition.

Trace Metals

Primary sources of trace metals to Delta waters include acid mine drainage (e.g., zinc, cadmium, copper, lead) from abandoned and inactive mines (i.e., Iron Mountain and Spring Creek mines) in the Shasta watershed area, which enter the Sacramento River system through Shasta Lake and Keswick Reservoir, agriculture (e.g., copper and zinc), POTW discharges (e.g., copper, zinc, and aluminum), and urban runoff (e.g., zinc, copper, lead, cadmium). Continued efforts to control acid mine drainage into the Sacramento River system and increasingly stringent regulations are expected in the future. Monitoring and regulatory controls on agricultural runoff, POTW discharges, and urban runoff are anticipated to prevent trace metal concentration under the cumulative condition from becoming adverse.

Turbidity/TSS

Future land use changes could have minor effects on TSS concentrations and turbidity levels throughout the affected environment. Site-specific and temporal exceptions may occur due to localized temporary construction activities, dredging activities, development, or other land use changes. These localized actions would generally require agency permits that would regulate and limit both their short-term and long-term effects on TSS concentrations and turbidity levels to less-than substantial levels. Construction activities are closely regulated under construction NPDES permits, which require the preparation of SWPPPs and the implementation of agency permitted construction BMPs that will minimize sedimentation into adjacent water bodies which would, in turn, increase turbidity/TSS. Moreover, construction projects are short-term in nature and thus their effects on turbidity/TSS tend not to be additive among multiple construction activities over time. Consequently, Delta turbidity/TSS levels under the cumulative condition are not expected to be adverse.

Because the cumulative water quality condition in the Delta for the constituents discussed above are considered to not be adverse in the Delta when considering all past, present, and reasonably foreseeable projects and regulatory actions, and because this cumulative condition includes the anticipated effects of implementing the facilities operations and maintenance of any one of the action alternatives, along with their associated conservation measures/Environmental Commitments, none of these alternatives would contribute to an adverse (significant) cumulative condition for these constituents either in the Delta Region or the SWP/CVP Export Service Areas.

Cumulative water quality conditions for the constituents listed below are considered to be adverse, or have reasonable potential to be adverse, in portions of the Delta. Adverse (significant) cumulative water quality conditions for these constituents are expected when the effects of implementing any one of the action alternatives on water quality are considered (including the new conveyance facilities, fish screens, gates and other physical structures and their operations and maintenance activities) together with the effects of past, present, and reasonably foreseeable projects, including those listed in Appendix 3D, *Defining Existing Conditions, No Action Alternative, No Project Alternative, and Cumulative Impact Conditions*.

- Bromide
- Chloride
- Electrical Conductivity
- Mercury
- *Microcystis* Blooms
- Organic Carbon
- Pesticides and Herbicides
- Selenium

Each of the constituents listed above, for which the cumulative Delta conditions are determined to be adverse, or potentially adverse, are discussed further below to determine whether implementation of the action alternatives would contribute considerably to these adverse (significant) cumulative water quality conditions.

Bromide

The cumulative condition for bromide is considered adverse in the Delta, because of marked increases in bromide concentrations anticipated to occur in the northwest Delta, including at the North Bay Aqueduct intake at Barker Slough. The primary driver of the adverse (significant) cumulative condition is the amount and location of tidal habitat restoration assumed to be implemented as part of the cumulative condition. This tidal habitat restoration would be implemented a component of the BDCP alternatives' conservation measures, or as part of separate actions (e.g., the California Water Action Plan/EcoRestore) for Alternatives 4A, 2D, and 5A, which will affect Delta hydrodynamics. Another contributing factor is sea water intrusion associated with climate change.

Increased bromide concentrations would not be anticipated to occur in the SWP/CVP Export Service Areas south of the Delta due to greater source fraction of Sacramento River water on an annual average basis at the south Delta pumps under all action alternatives. Therefore, the cumulative condition for bromide in the SWP/CVP Export Service Areas with implementation of any of the alternatives is not expected to be adverse.

BDCP Alternatives

Alternatives 1A–6C and 9, which include up to 65,000 acres of tidal restoration as part of conservation measures, would increase long-term average bromide concentrations at Barker Slough to levels substantially higher than those under Existing Conditions. Alternative 7 would not increase the long-term average bromide concentration at this location, and Alternative 8 would only increase it slightly. However, all alternatives would increase the drought period average bromide concentration at Barker Slough substantially, relative to concentrations during the drought period analyzed under Existing Conditions (Appendix 8E, *Bromide*). Based on their causing substantially increased average bromide concentrations at Barker Slough in the northwest Delta on a long-term average basis and/or during drought periods, implementation of the BDCP alternatives would contribute substantially to the adverse (significant) cumulative condition in the Delta for bromide.

Construction and implementation of the North Bay Aqueduct Alternative Intake Project would provide water from the Sacramento River that is very low in bromide to the existing service area of the North Bay Aqueduct, reducing the potential effects of cumulative bromide concentration increases on water treatment facilities and end-users of water from the North Bay Aqueduct.

Alternatives 4A, 2D, and 5A

The amount of tidal habitat restoration assumed for Alternatives 4A, 2D, and 5A is substantially less than assumed for the BDCP alternatives, such that these alternatives are not expected to significantly affect Delta hydrodynamics and source water fractions. Modeling results (Appendix 8E, *Bromide*) show that long-term and drought period average bromide concentrations with implementation of Alternatives 4A, 2D, and 5A water conveyance facilities, and some assumed habitat restoration, would be similar to or decrease relative to Existing Conditions. Thus, Alternatives 4A, 2D, and 5A would not contribute substantially to the adverse (significant) cumulative condition in the Delta for bromide.

Chloride

The cumulative condition for chloride is considered adverse in the Delta, because of marked increases in chloride concentrations anticipated to occur in the western Delta and potentially Suisun Marsh, One driver of the increased chloride concentrations is the amount and location of tidal habitat restoration to be implemented and assumed as part of the cumulative condition. This tidal habitat restoration would be implemented a component of the BDCP alternatives' conservation measures, or as part of separate actions (e.g., the California Water Action Plan/EcoRestore) for Alternatives 4A, 2D, and 5A, which will affect Delta hydrodynamics. Another contributing factor is sea level rise and intrusion associated with climate change.

The cumulative condition for chloride would not be adverse in the SWP/CVP Export Service Areas due to greater source fraction of Sacramento River water on an annual average basis at the south Delta pumps under all action alternatives.

BDCP Alternatives

Regarding the frequency of exceeding the 150 mg/L Bay-Delta WQCP objective at Antioch and Contra Costa Canal Pumping Plant #1, the modeling and assessment approach indicated that Alternatives 1A–1C, 3, and 7–9 would result in a substantial increase in the frequency of objective exceedance. Regarding the frequency of exceeding the 250 mg/l chloride objective at Antioch, the modeling and assessment approach indicated that Alternatives 1A–1C, 3, and 5 would result in a substantial increase in the frequency of exceeding this objective, relative to Existing Conditions, whereas Alternative 9 would cause only a minor increase in frequency of exceedance and Alternatives 6A–8 would result in a reduction in frequency of exceeding the 250 mg/L chloride objective (Appendix 8G, *Chloride*). Regarding exceedance of Bay-Delta WQCP water quality objectives for chloride, staff from DWR and Reclamation shall continue to monitor Delta water quality conditions and adjust operations of the SWP and CVP in real time as necessary to meet water quality objectives. These decisions take into account real-time conditions and are able to account for many factors that the best available models cannot simulate. These water quality objectives are legally enforceable means of protecting beneficial uses in the Delta, and are and will continue to be included in the Bay-Delta WQCP. This ensures that these commitments are enforceable obligations that will continue to affect operations and protect water quality. DWR and Reclamation have a good history of compliance with water quality objectives (see Sections 8.1.3.4 and 8.1.3.7 for more detail). Considering these real-time actions, the good history of compliance with objectives, and the uncertainty inherent in the modeling approach (as discussed in Sections 8.3.1.1 and 8.3.1.3), it is likely that any objective exceedance could be avoided through real-time operation of the SWP and CVP. Nevertheless, water quality degradation could occur that may not be addressed through real-time operations. Depending on siting and design of tidal restoration areas, the BDCP alternatives could substantially increase chloride levels in some areas of Suisun Marsh relative to Existing Conditions, primarily during the October through May period. Hence, based on their respective effects on increased chloride levels in Suisun Marsh and the increased water quality degradation in the western Delta, implementation of facilities operations and maintenance under the BDCP alternatives would contribute substantially to this adverse (significant) cumulative condition for chloride. Additionally, implementation of tidal habitat restoration would increase the tidal exchange volume in the Delta, and thus may contribute to increased chloride concentrations in the Bay source water as a result of increased salinity intrusion. As such, CM4 is expected to contribute to this adverse (significant) cumulative condition. Implementation of CM2, CM3, and CM5–CM21 would not contribute substantially to this adverse (significant) cumulative condition.

Alternatives 4A, 2D, and 5A

Implementation of facilities operations and maintenance under Alternatives 4A, 2D, and 5A would not be expected to contribute substantially to the adverse (significant) cumulative condition for chloride, as modeling results show that operations would not contribute to substantial adverse changes in chloride concentrations at modeled Delta locations. Additionally, unlike the BDCP alternatives, implementation of tidal habitat restoration would not be expected to contribute to increased chloride concentrations, because the areal extent of the new restoration area would be a relatively small portion of the existing and planned Delta tidal habitat areas and, thus, not expected to measurably affect the Delta hydrodynamics. As such, implementation of Environmental Commitments associated with these alternatives would not contribute substantially to this adverse (significant) cumulative condition.

Electrical Conductivity

The cumulative condition for EC is considered to be adverse, at various Delta locations and Suisun Marsh, depending on action alternative implemented. One driver of the adverse EC conditions is the amount and location of tidal habitat restoration to be implemented and assumed as part of the cumulative condition. This tidal habitat restoration would be implemented a component of the BDCP alternatives' conservation measures, or as part of separate actions (e.g., the California Water Action Plan/EcoRestore) for Alternatives 4A, 2D, and 5A, which will affect Delta hydrodynamics. Another contributing factor is sea level rise and intrusion associated with climate change.

EC levels at the south Delta export pumps would improve under all alternatives and thus the cumulative EC condition at the export pumps would not be adverse. As such, cumulative EC levels in the SWP/CVP Export Service Areas would not be adverse.

BDCP Alternatives

Alternatives 1A–3 and 5–9 are expected to result in more frequent exceedances of the Bay-Delta WQCP EC objective in the Sacramento River at Emmaton, relative to Existing Conditions. This is due in part to the definition of these alternatives, in which the compliance point is moved from Emmaton to Threemile Slough. Although modeling of Alternative 4 indicated more frequent exceedance of the Emmaton objective as well, these results were for modeling that was originally performed for Alternative 4 assuming the Emmaton compliance point shifted to Threemile Slough, but Alternative 4 now does not include a change in compliance point from Emmaton to Threemile Slough. Sensitivity analyses performed indicated that Alternative 4 is not expected to result in more frequent exceedances of the Emmaton objective, but that water supply and water quality conditions could be either under greater stress or under stress earlier in the year, and salinity EC levels at Emmaton and in the western Delta may increase as a result, leading to EC water quality degradation and increased possibility of impacts adverse effects to agricultural beneficial uses. Similarly, water quality degradation is expected to occur at Emmaton and other areas of the western Delta under all alternatives during parts of the summer, and on an annual average basis for Alternatives 1, 3, 4 Scenarios H1 and H2, and 9. To the extent that exceedances of this objective or substantial water quality degradation is expected, these impacts could lead to effects on agricultural beneficial uses. Increases in EC in the San Joaquin River at San Andreas Landing are expected for parts of the summer under all alternatives, and depending on the nature of the increases, may result in water quality degradation that could lead to effects on agricultural beneficial uses.

Moreover, in the central Delta at Prisoner's Point, Alternatives 2A–C, 4 (Operational Scenarios H1 through H4), and 6A–8 would result in substantially increased frequency of exceedance of the EC objective, whereas Alternative 5 would cause a lesser increase in frequency of exceedance, and Alternatives 1A–C, 3, and 9 would have little to no effect on frequency of exceedance of the EC objective at Prisoner's Point (Appendix 8H). These exceedances could contribute to adverse effects on fish and wildlife beneficial uses (specifically, indirect adverse effects on striped bass spawning), though there is a high degree of uncertainty associated with this impact.

Alternatives 1A–5 and 9 could substantially increase EC levels in Suisun Marsh relative to Existing Conditions, primarily during the October through May period, whereas Alternatives 6A–8 would result in somewhat lesser (but still substantial) increases in Suisun Marsh.

Based on their adverse effects on EC levels in Suisun Marsh as well as the adverse effects in the western and interior Delta, the BDCP alternatives would all contribute substantially to the adverse (significant) cumulative conditions for EC in the Delta. Additionally, implementation of tidal habitat restoration under CM4 would increase the tidal exchange volume in the Delta, and thus may contribute to increased EC concentrations in the Bay source water as a result of increased salinity intrusion. As such, CM4 is expected to contribute to this adverse (significant) cumulative condition. Implementation of CM2, CM3, and CM5–CM21 would not contribute substantially to this adverse (significant) cumulative condition.

Alternatives 4A, 2D, and 5A

Under Alternatives 4A, 2D, and 5A, the cumulative condition for EC is considered to be adverse in the Delta due primarily to periodically high levels of EC in the western Delta associated with sea water intrusion, and also in the south Delta. Implementation of facilities operations and maintenance under these action alternatives, along with Mitigation Measure WQ-11, would not be expected to contribute substantially to this adverse (significant) cumulative condition for EC, because no additional exceedance of Bay-Delta WQCP EC objectives would be expected, and substantial long-term degradation with respect to EC would be avoided. Additionally, unlike under the BDCP alternatives, implementation of tidal habitat restoration would not be expected contribute to increased EC levels, because the areal extent of the new restoration area would be a relatively small portion of the existing and planned Delta tidal habitat areas and, thus, not expected to measurably affect the Delta hydrodynamics. As such, implementation of Environmental Commitments is not expected to contribute to this adverse (significant) cumulative condition.

Mercury

Numerous regulatory efforts have been implemented or are under development to control and reduce mercury loading to the Delta, Upstream of the Delta and in the SWP/CVP Export Service Areas, which include a Delta mercury TMDL, methylmercury TMDL, and their implementation strategies (e.g., methylmercury control studies), increased restrictions on point-source discharges such as POTWs, greater restrictions on suction dredging in Delta tributary watersheds, and continued clean-up actions on mine drainage in the upper watersheds. A key challenge surrounds the pool of mercury deposited in the sediments of the Delta which cannot be readily or rapidly reduced, despite efforts to reduce future loads in Delta tributaries, and serves as a source for continued methylation and bioaccumulation of methylmercury by Delta biota. Consequently, mercury levels in Delta waters are considered to be an adverse (significant) cumulative condition.

BDCP Alternatives

Facilities operations and maintenance (CM1) of Alternatives 1A–5 would not be expected to substantially alter the cumulative condition for mercury and the mercury impairment in the Delta or contribute substantially to the adverse (significant) cumulative mercury condition in the SWP/CVP Export Service Areas. Facilities operations and maintenance (CM1) of Alternatives 6A–9 would be expected to contribute substantially to the adverse (significant) cumulative condition for mercury in the Delta, since fish tissue concentrations are expected to increase measurably at several locations throughout the Delta. Implementation of CM4 (tidal wetland habitat), CM5 (floodplain habitat), CM10 (freshwater marsh habitat), and CM2 (Yolo Bypass fisheries enhancements) could create conditions resulting in increased methylation of mercury within the Delta per unit time, increased biotic exposure to and uptake of methylmercury, and resulting increased mercury bioaccumulation in fish tissues. The methylation of mercury in these restored wetland habitats would contribute substantially to the cumulative condition for mercury in the Delta.

Alternatives 4A, 2D, and 5A

Facilities operations and maintenance of Alternatives 4A, 2D, and 5A would not be expected to substantially alter the cumulative condition for mercury and the mercury impairment in the Delta or contribute considerably to the adverse (significant) cumulative mercury condition in the SWP/CVP Export Service Areas. Mercury and methylmercury concentrations in water are not expected to change substantially under Alternatives 4A, 2D, and 5A. Fish tissue concentrations showed increases at some locations, but because the increases would be relatively small, and it is not evident that substantive increases are expected at numerous locations throughout the Delta, the changes were considered to be within the uncertainty inherent in the modeling approach, and would likely not be measurable in the environment.

The amount of new habitat restoration to be implemented for the Environmental Commitments of Alternatives 4A, 2D, and 5A would be relatively small compared to the areal extent of the Delta, but implementation would be expected to contribute considerably to certain localized areas (i.e., near where the wetland restoration areas are planned) within the Delta through the potential for increased mercury methylation in these restored wetland habitats. Design of restoration sites would be guided by Environmental Commitment 12 of the action alternatives, which requires development of site-specific mercury management plans as restoration actions are implemented. The effectiveness of minimization and mitigation actions implemented according to the mercury management plans is not known at this time, although the potential to reduce methylmercury concentrations exists based on current research. Although Environmental Commitment 12 would be implemented with the goal to reduce this potential effect, the uncertainties related to site-specific restoration conditions and the potential for increases in methylmercury concentrations in the Delta could contribute substantially to the cumulative condition for mercury in the Delta.

As such, conveyance facility operation and maintenance is not expected to contribute to the adverse (significant) cumulative condition for mercury, but tidal habit restoration Environmental Commitments implemented under Alternatives 4A, 2D, and 5A could contribute to this adverse condition in localized areas.

Microcystis Blooms

The cumulative condition for *Microcystis* and, thus, microcystin concentrations is considered adverse in the Delta due to conditions being more favorable for their production. This includes future increased water temperatures associated with climate change and increased water residence times associated with climate change/sea level rise and habitat restoration that will enhance conditions for *Microcystis* blooms. *Microcystis* blooms can occur in the Delta during the June through September period of the year.

Climate change is expected to cause an increase in average Delta water temperatures during the summer and early fall months. Increased water temperatures could lead to earlier attainment of the water temperature threshold of 19°C required to initiate *Microcystis* bloom in the Delta, and thus earlier occurrences of *Microcystis* blooms, relative to Existing Conditions. Warmer water temperatures could also increase bloom duration and magnitude, relative to Existing Conditions. Nevertheless, it should be noted that projected Delta water temperature increases would be due entirely to climate change, and not due to the implementation of the action alternatives. Because climate change is assumed under the No Action Alternative, potential water temperature-driven increases in *Microcystis* blooms in the Delta, relative to Existing Conditions, also would occur under the No Action Alternative. Therefore, no water temperature-driven increases in *Microcystis* blooms would occur in the Delta under the action alternatives, relative to the No Action Alternative.

An increase in residence time throughout the Delta is also expected due to climate change and sea level rise, although this change is believed to be fairly small in most areas of the Delta. Restoration areas, implemented either as part of the conservation measures of the BDCP alternatives, or separate actions under Alternatives 4A, 2D, and 5A, could also contribute to increased residence times.

BDCP Alternatives

The BDCP alternatives, including the implementation of habitat restoration under CM2 and CM4, would increase water residence times in the Delta during the summer period, relative to Existing Conditions and the No Action Alternative. Longer residence times in portions of the Delta may potentially increase the frequency, magnitude, and geographic extent of *Microcystis* blooms in Delta waters, relative to Existing Conditions and the No Action Alternative. Siting and design of restoration areas has substantial influence on the magnitude of residence time increases that would occur under the BDCP alternatives. However, the expected residence time changes under the BDCP alternatives, compared to Existing Conditions and the No Action Alternative, are in a direction and of magnitude that could lead to an increase in Delta *Microcystis* blooms.

Water diverted from the Sacramento River in the North Delta is expected to be unaffected by *Microcystis* and microcystins. However, the fraction of water flowing through the Delta that reaches the existing south Delta intakes is expected to be influenced by an increase in the frequency, magnitude, and geographic extent of *Microcystis* blooms as discussed above. Therefore, relative to Existing Conditions and the No Action Alternative, the addition of Sacramento River water from the North Delta under the BDCP alternatives serves to dilute *Microcystis* and microcystins in water diverted from the South Delta with water that is not expected to contain them. Because the degree to which *Microcystis* blooms, and thus microcystins concentrations, will increase in source water from the South Delta is unknown, it cannot be determined whether the BDCP alternatives will result in increased or decreased levels of microcystins in the mixture of source waters exported from Banks and Jones pumping plants, relative to Existing Conditions and the No Action Alternative.

Implementation of the BDCP alternatives (including CM2 and CM4) would contribute substantially to the adverse (significant) cumulative condition for *Microcystis* through their effects on residence time. Conversely, because projected Delta water temperature increases are due entirely to climate change, and are not due to the implementation of BDCP alternatives, implementation of the BDCP alternatives would not contribute substantially to the adverse (significant) cumulative condition for *Microcystis* via changes to Delta water temperature.

Alternatives 4A, 2D, and 5A

Change in flow paths of water through the Delta would occur under Alternatives 4A, 2D, and 5A, which could result in localized increases in residence time in various Delta sub-regions, and decreases in residence time in other areas. Implementation of the small amount of habitat restoration within the Delta, associated with the alternatives' Environmental Commitments, also could affect residence times at the affected areas. While there is uncertainty regarding the degree to which the alternatives would affect water residence times in the Delta, it is anticipated that the combined effects of restoration (to be implemented separate from the alternatives, e.g., EcoRestore), sea level rise and climate change will drive the residence time changes and that the alternatives and other cumulative projects would not contribute considerably to the adverse *Microcystis* and microcystins condition in the Delta, in particular because the amount of habitat restoration by the alternatives to be implemented would be so limited in area and location as it would not be able to affect residence times Delta-wide.

As described for the BDCP alternatives, the water flowing through the Delta that would reach the south Delta intakes is expected to be influenced by the increased frequency, magnitude, and geographic extent of *Microcystis* blooms associated with restoration (to be implemented separate from the alternatives, e.g., EcoRestore), sea level rise, and climate change. Water diverted from the Sacramento River in the north Delta that would be conveyed to the south Delta intakes is expected to be unaffected by *Microcystis* and microcystins. Therefore, the addition of Sacramento River water from the north Delta under Alternatives 4A, 2D, and 5A at the south Delta intakes would serve to dilute *Microcystis* and microcystins-containing water diverted from the south Delta with water that is not expected to contain them. Because the degree to which *Microcystis* blooms, and thus microcystins concentrations, will increase in source water from the south Delta is unknown, it cannot be determined whether levels of microcystins in the mixture of source waters exported from Banks and Jones pumping plants will be higher or lower, relative to Existing Conditions. However, because the Sacramento River water contributed to the south Delta intakes will likely be unaffected by *Microcystis* and microcystins, the alternatives would not contribute considerably to any future adverse *Microcystis* and microcystins condition in the SWP/CVP Export Service Areas.

Organic Carbon

Delta water quality conditions for DOC are anticipated to be adverse under the cumulative condition.

BDCP Alternatives

Facilities operations and maintenance (CM1) for Alternatives 1A–5 would not contribute considerably to the adverse (significant) cumulative condition for DOC within Delta waters based on modeling results showing little effect of these alternatives on long-term average concentrations. Conversely, Alternatives 6A–9 would result in increased DOC levels at Franks Tract, Rock Slough and Contra Costa PP No. 1. Under these alternatives, long-term average DOC concentration could increase by up to 46%, relative to Existing Conditions. Thus, the DOC contributions from alternatives 6A–9 at Franks Tract, Rock Slough and Contra Costa PP No. 1 (i.e., interior Delta locations) are determined to contribute considerably to the adverse (significant) cumulative condition for DOC in the Delta. However, overall, modeling results for the south Delta pumps and thus the SWP/CVP export service area predict a long-term improvement in export service area water quality, primarily through a reduction in exports of water exceeding 4 mg/L. This is particularly true for Alternatives 6A–9 where notable improvements to DOC levels at the south Delta pumps would occur. Hence, facilities operations and maintenance (CM1) for Alternatives 6A–9 would contribute substantially to adverse (significant) cumulative conditions in the interior Delta, but would improve cumulative DOC conditions at the south Delta pumps and thus in the SWP/CVP Export Service Areas.

In addition, implementation of CM4 (tidal wetland habitat), CM5 (floodplain habitat), and CM10 (freshwater marsh habitat) would create substantial new localized sources of DOC to Delta waters, and in some circumstances would substitute for existing sources related to replaced agriculture. In addition, CM2 would create greater localized source loading of DOC to Delta waters, to the degree that the Yolo Bypass is inundated more frequently and/or to a greater geographic extent under the alternatives, relative to Existing Conditions. Depending on localized hydrodynamics and proximity to municipal drinking water intakes, such restoration activities could contribute substantial amounts of DOC to municipal raw water supplies. The potential for substantial increases in long-term average DOC concentrations related to the habitat restoration elements of CM4, CM5, and CM10 could contribute to long-term water quality degradation with respect to DOC and, thus, adversely affect the MUN beneficial use at various interior Delta locations. Hence, implementation of CM2–CM21 would contribute substantially to the adverse (significant) cumulative condition for DOC.

Alternatives 4A, 2D, and 5A

Similar to Alternatives 1A–5, facilities operations and maintenance for Alternatives 4A, 2D, and 5A would not contribute considerably to the adverse (significant) cumulative condition for DOC within Delta waters based on modeling results showing little effect of these alternatives on long-term average concentrations. However, there would not be expected to be substantial contributions of

DOC from habitat restoration areas under Alternatives 4A, 2D, and 5A, because the area to be converted for new habitat would be small compared to areal extent of the Delta and existing habitat areas and loading sources. As such, facilities operations and maintenance and Environmental Commitments implemented under Alternatives 4A, 2D, and 5A would be minimal and are not expected to considerably contribute to this adverse condition.

Pesticides and Herbicides

Pesticide and herbicide use within and upstream of the Delta are changing continuously. Historically, when society has substituted one class of pesticide for another without a corresponding change in patterns of use (i.e., substitution of organochlorines with organophosphates), incidence of non-target toxicity or environmental harm has changed and perhaps been lessened, but has remained nevertheless. While factors such as TMDLs and future development of more target specific and less toxic pesticides will ultimately influence the future cumulative condition for pesticides, forecasting whether these various efforts will ultimately be successful at resolving current pesticide related impairments requires considerable speculation. As such it is conservatively assumed that the cumulative condition will be adverse with respect to pesticides and herbicides in the Delta. The greater source fraction of Sacramento River water on an annual average basis at the south Delta pumps under all action alternatives would be expected to result in the cumulative condition for pesticides and herbicides in the SWP/CVP Export Service Areas to not be adverse.

BDCP Alternatives

Alternatives 1A–5 are not expected to contribute considerably to the adverse (significant) cumulative condition due to facilities operations and maintenance (CM1). However, implementation of CM1 under Alternatives 6A–9 would result in long-term average San Joaquin River source water fractions at Franks Tract, Rock Slough and Contra Costa PP No. 1 (interior Delta) increasing considerably for some months such that the long-term risk of pesticide-related toxicity to aquatic life could substantially increase at these locations. Additionally, the potential for increased incidence of pesticide related toxicity could include pesticides such as chlorpyrifos and diazinon for which existing Clean Water Act Section 303(d) listings exist for the Delta, and thus existing beneficial use impairment could be made discernibly worse. In addition, implementation of CM13 (nonnative aquatic vegetation control) under the BDCP alternatives would be expected to contribute substantially to the adverse (significant) cumulative condition for pesticides and herbicides in the Delta.

Alternatives 4A, 2D, and 5A

Alternatives 4A, 2D, and 5A are not expected to contribute considerably to the adverse (significant) cumulative condition due to facilities operations and maintenance, because the changes in the source water fractions of Sacramento River, San Joaquin River, and Delta agriculture water due to these alternatives would not be expected to be of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta.

Selenium

The lower San Joaquin River and the western Delta are listed as impaired in accordance with Section 303(d) of the Clean Water Act for exceeding selenium water quality objectives or bioaccumulation in biota. The San Joaquin River impairment is listed as extending from the Mud Slough confluence to the Airport Way Bridge near Vernalis, a reach distance of about 43 river miles. Selenium occurs naturally throughout the lower San Joaquin River watershed, with elevated concentrations of selenium occurring in the shallow groundwater within the Grassland Watershed. Subsurface agricultural drainage discharges from this area are the major source of selenium to the San Joaquin River and Delta. Load allocations for agricultural subsurface drainage discharges from the Grassland Drainage Area have been developed through completion of the lower San Joaquin River selenium TMDL and the Grassland Bypass Project. The Grassland Bypass Project prevents discharge of subsurface agricultural drainage water into wildlife refuges and wetlands. The Grassland Area Farmers have been successful in meeting TMDL wasteload allocations and continue to utilize and expand the San Joaquin River Water Quality Improvement Project. Moreover, the Grassland Area Farmers continue to work closely with the Central Valley Water Board and U.S. Bureau of Reclamation to further develop and improve their drainage solutions for the Grassland Drainage Area. Despite these improvements in reducing selenium loading to the San Joaquin River and Delta, it is anticipated that the cumulative condition for selenium in the lower San Joaquin River and Delta will remain adverse.

While there have been improvements to selenium concentrations in San Francisco Bay, due in part to the petroleum refineries implementing controls that have decreased selenium in their discharges, the bay is currently CWA Section 303(d) listed as impaired for elevated selenium. TMDLs that will be developed to address the impairment would be expected to contribute to some reduction in selenium in the bay, including the North Bay, which is partially influenced by Delta outflow. Thus, it is anticipated that the future cumulative condition would be no worse, and possibly better than, existing conditions, but will remain adverse.

BDCP Alternatives

Facilities operations and maintenance (CM1) of Alternatives 1A–5 would not be expected to substantially alter the cumulative condition for selenium and selenium impairment in the Delta. Modeled selenium concentrations in sturgeon in the western Delta, in the San Joaquin River at Antioch and the Sacramento River at Mallard Island would increase under Alternatives 6A–9 by 17–42%, which may represent a measurable increase in the environment. These increases would contribute to low toxicity benchmarks being exceeded on average, in all years, and to high toxicity benchmarks being approached or exceeded during drought years. These increases would further degrade water quality by measurable levels, on a long-term basis, for selenium and, thus, cause the CWA Section 303(d)-listed impairment of beneficial uses to be made discernibly worse. These potentially measurable increases would contribute substantially to the adverse (significant) cumulative condition for selenium in the Delta. However, the greater Sacramento River flow fraction at the south Delta pumps under all BDCP alternatives would be expected to result in reduced selenium concentrations in the SWP/CVP Export Service Areas and thus would not contribute to the adverse (significant) cumulative condition. Implementation of CM4 (tidal wetland habitat), CM5 (floodplain habitat), and CM10 (freshwater marsh habitat) could create conditions resulting in increased flow residence time at the restored Delta locations, which could increase biotic exposure to and uptake of selenium, potentially resulting in increased selenium bioaccumulation in fish tissues. The potential for increased biotic exposure in and near these restored wetland habitats would contribute substantially to the adverse (significant) cumulative condition for selenium in the Delta. However, *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, would be available to reduce BDCP-related effects associated with selenium.

Alternatives 4A, 2D, and 5A

Facilities operations and maintenance of Alternatives 4A, 2D, and 5A would not be expected to substantially alter the cumulative condition for selenium and selenium impairment in the Delta. Modeling estimates indicate these alternatives would result in essentially no change in selenium concentrations in water or most biota throughout the Delta, with no exceedances of benchmarks for biological effects. Concentrations of selenium in sturgeon would exceed only the lower benchmark, indicating a low potential for effects. Overall, these alternatives would not be expected to substantially increase the frequency with which applicable benchmarks would be exceeded in the Delta (there being only a small increase for sturgeon exceedance relative to the low benchmark for sturgeon and no exceedance of the high benchmark) or substantially degrade the quality of water in the Delta, with regard to selenium. The greater Sacramento River flow fraction at the south Delta pumps under Alternatives 4A, 2D, and 5A would result in reduced selenium concentrations in the SWP/CVP Export Service Areas and thus would not contribute to the adverse (significant) cumulative condition.

While the implementation of Environmental Commitment 4: Tidal Natural Communities Restoration would create shallow backwater areas that could result in local increased water residence times, the extent of these areas would be minimal relative to the area of the Delta, and environmental changes associated with their development are unlikely to be of magnitude that would measurably change selenium concentrations in water or biota, relative to Existing Conditions. Further, although water residence times associated with restoration could increase, they are not expected to increase without bound, and selenium concentrations in the water column would not continue to build up and be recycled in sediments and organisms as may be the case within a closed water system. Further, proposed avoidance and minimization measures (AMMs) would require evaluating risks of selenium exposure at a project level for each restoration area, minimizing to the extent practicable potential risk of additional bioaccumulation, and monitoring selenium levels in fish and/or wildlife to establish whether, or to what extent, additional bioaccumulation is occurring. See BDCP Appendix 3.C, *Avoidance and Minimization Measures*, for additional detail on AMM27. Because selenium concentrations are not expected to build up in these areas and because *AMM27 Selenium Managemen*t, which affords for site-specific measures to reduce effects, would be available to reduce effects associated with selenium, the restored habitats are not expected to contribute considerably to the adverse (significant) cumulative condition.

Facilities operations and maintenance of Alternatives 4A, 2D, and 5A would not be expected to substantially alter the cumulative condition for the selenium impairment in the Delta or contribute considerably to the cumulative selenium condition in North Bay. Selenium concentrations in water in the Delta are not expected to change substantially under Alternatives 4A, 2D, and 5A, and thus these alternatives would not be expected to contribute considerable additional loading to the North Bay that would worsen the impairment.

NEPA Effects: The cumulative water quality conditions are considered to be adverse for bromide, chloride, electrical conductivity, mercury, *Microcystis* blooms, organic carbon, pesticides and herbicides, and selenium in areas of the Delta, and thus may adversely affect beneficial uses of the Delta such as domestic, agricultural, municipal and industrial water supply and recreation, aesthetic, and fish and wildlife resources.

BDCP Alternatives

The implementation of the BDCP alternatives would contribute substantially to these adverse (significant) cumulative water quality conditions. With respect to bromide, chloride, and electrical conductivity, implementation of the BDCP alternatives would improve water quality conditions for these constituents at the Banks and Jones pumping plants in the south Delta and thus in the SWP/CVP Export Service Areas. Mitigation measures, conservation measures, and environmental commitments have been developed to mitigate the contributions of the BDCP alternatives to the adverse (significant) cumulative water quality conditions elsewhere in the Delta for bromide (WQ-5), chloride (WQ-7), electrical conductivity (WQ-11), mercury (CM12), *Microcystis* blooms (WQ-32a and WQ-32b), organic carbon (WQ-17 and WQ-18), pesticides and herbicides (WQ-21 and WQ-22) and selenium (*AMM27 Selenium Management*).

Alternatives 4A, 2D, and 5A

The implementation of the water conveyance facilities operations and maintenance component of Alternatives 4A, 2D, and 5A, including Mitigation Measure WQ-11 proposed for EC, would not contribute considerably to adverse (significant) cumulative water quality conditions for these constituents. With respect to chloride and EC, implementation of Alternatives 4A, 2D, and 5A would improve water quality conditions for these constituents at the Banks and Jones pumping plants in the south Delta and thus in the SWP/CVP Export Service Areas. The implementation of habitat restoration Environmental Commitments could contribute considerably to the adverse (significant) cumulative water quality condition for mercury. Environmental Commitment 12 would be implemented to minimize conditions that promote the production of methylmercury.

CEQA Conclusion: Separate conclusions are provided for the BDCP alternatives and Alternatives 4A, 2D, and 5A.

BDCP Alternatives

The cumulative Delta water quality conditions are anticipated to be significant for bromide, chloride, electrical conductivity, mercury, *Microcystis* blooms, organic carbon, pesticides and herbicides, and selenium.

The incremental effects of the BDCP alternatives would be cumulatively considerable with respect to significant cumulative bromide, chloride, *Microcystis*, and electrical conductivity conditions at various western and interior Delta locations. However, implementation of the BDCP alternatives would not contribute considerably, and would, in fact, improve conditions for these constituents (except *Microcystis*) at the Banks and Jones pumping plants in the south Delta and thus in the SWP/CVP Export Service Areas. It cannot be determined whether the BDCP alternatives will result in increased or decreased levels of microcystins in the mixture of source waters exported from Banks and Jones pumping plants, relative to Existing Conditions.

Implementation of WQ-5 may reduce impacts on bromide relative to municipal and industrial beneficial uses in Barker Slough, but it is not known whether actions to reduce this impact under the mitigation measures are feasible. Implementation of Mitigation Measures WQ-7a, WQ-7b, WQ-11a, and WQ-11b may reduce impacts on chloride relative to municipal and industrial beneficial uses and EC relative to agricultural beneficial uses in the western Delta, but it is not known whether actions to reduce this impact under the mitigation measures are feasible. Implementation of Mitigation measure WQ-11c may reduce potential impacts of EC on fish and wildlife beneficial uses in the interior Delta, but it is not known whether actions to reduce this impact under the mitigation measure are feasible. Thus, for these impacts, the contribution to the adverse (significant) cumulative condition is expected to remain significant. Implementation of Mitigation Measures WQ-7d and WQ-11d is expected to reduce the contribution of impacts on chloride and EC water quality degradation in Suisun Marsh to a less-than-significant level. Implementation of WQ-32 may reduce potential impacts on *Microcystis* in the Delta, but it is not known whether actions to reduce this impact under the mitigation measure are feasible; thus, the contribution to the adverse (significant) cumulative condition is expected to remain significant.

Regarding mercury and selenium, facilities operations and maintenance (CM1) would not be expected to contribute considerably to the significant cumulative mercury and selenium conditions in the Delta for Alternatives 1A–5, but would be expected to contribute to these conditions for Alternatives 6A–9. Implementation of CM4, CM5, and CM10 would be expected to contribute considerably to certain localized areas (i.e., near where the wetland restoration areas are planned) within the Delta through the potential for increased mercury methylation and selenium bioaccumulation in these restored wetland habitats. Although CM12 is designed to reduce these effects for mercury, it is not known if these actions would be feasible and could effectively reduce the incremental contribution to the adverse (significant) cumulative condition to a less-than-significant level. However, with implementation of *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, the incremental effects of these CMs on selenium would not be expected to be cumulatively considerable. Likewise, CM2 would create greater localized source loading of methylmercury to Delta waters, to the degree that the Yolo Bypass would be inundated more frequently and/or to a greater geographic extent under the alternatives, relative to Existing Conditiosn. Conversely, CM2 is not expected to contribute considerably to future Delta selenium levels and thus would not be expected to affect future bioaccumulation of selenium in Delta fish tissues.

For organic carbon, implementation of facilities operations and maintenance (CM1) for Alternatives 6A–9 would contribute considerably to the significant cumulative organic carbon condition in the Delta, but Alternatives 1A–C, 2A–C, 3, 4 and 5 would not contribute considerably to this cumulative condition. Conservation Measures 4, 5, and 10, through the ability of these new wetlands to load additional organic carbon to Delta waters, would contribute considerably to the significant adverse (significant) cumulative organic carbon condition in the Delta. In addition, CM2 would create greater localized source loading of DOC to Delta waters for all BDCP alternatives, to the degree that the Yolo Bypass would be inundated more frequently and/or to a greater geographic extent under the alternatives, relative to Existing Conditions. Implementation of Mitigation Measure WQ-17 and WQ-18 may reduce these contributions, but it is unknown whether these actions would be feasible and would effectively reduce the incremental contribution to the adverse (significant) cumulative condition to a less-than-significant level. These cumulative effects are not expected to extend to the south Delta pumps or the SWP/CVP Export Service Areas.

Implementation of facilities operations and maintenance (CM1) for Alternatives 6A–9 would contribute considerably to the adverse (significant) cumulative pesticide and herbicide condition in the Delta, but Alternatives 1A–5 would not contribute considerably to this significant cumulative condition. Also, implementation of CM13 (nonnative aquatic vegetation control) is the only conservation measure identified that would contribute considerably to the cumulative pesticide and herbicide condition in the Delta. However, with implementation of Mitigation Measure WQ-22, the contribution to the cumulative condition of CM13 is expected to be less than significant. The cumulative effects for pesticides and herbicides are not expected to extend to the SWP/CVP Export Service Areas due to the increases in Sacramento River source fraction at Banks and Jones pumping plants under all BDCP alternatives and its generally lower levels of pesticides relative to the San Joaquin River source water.

Alternatives 4A, 2D, and 5A

The incremental effects of the water conveyance facilities operations and maintenance component of Alternatives 4A, 2D, and 5A, including Mitigation Measure WQ-11 proposed for EC, would not be expected to be cumulatively considerable for chloride and EC conditions in the Delta. Implementation of Alternatives 4A, 2D, and 5A would, in fact, improve conditions for these constituents at the Banks and Jones pumping plants in the south Delta and thus in the SWP/CVP Export Service Areas.

Facilities operations and maintenance under Alternatives 4A, 2D, and 5A would not be expected to contribute considerably to the significant cumulative *Microcystis* condition in the Delta through increased residence times in the Delta during the summer period. Similarly, Environmental Commitments are not expected to contribute to this significant cumulative condition, because the area of restoration would be so small as to have no net effect on through-Delta residence time.

Facilities operations and maintenance would not be expected to contribute considerably to the significant cumulative mercury and selenium conditions in the Delta. Implementation of habitat restoration Environmental Commitments could contribute considerably to the significant cumulative mercury condition at certain localized areas within the Delta (i.e., near where the wetland restoration areas are planned) through the potential for increased mercury methylation in these restored wetland habitats. Although Environmental Commitment 12 is designed to reduce these effects for mercury, it is not known if these actions would be feasible and could effectively reduce the incremental contribution to the adverse (significant) cumulative condition to a less-than-significant level. With implementation of *AMM27 Selenium Management*, which affords for site-specific measures to reduce effects, the incremental effects of habitat restoration on selenium would not be expected to be cumulatively considerable.

Implementation of facilities operations and maintenance for Alternatives 4A, 2D, and 5A would not contribute considerably to the significant cumulative organic carbon condition in the Delta. Habitat restoration Environmental Commitments would potentially load additional organic carbon to Delta waters, but contributions are not expected to be cumulatively considerable, because the land area proposed for restoration would be relatively small compared to existing land area and sources of DOC as to not have an effect on DOC concentrations.

Implementation of facilities operations and maintenance for Alternatives 4A, 2D, and 5A would not contribute considerably to the adverse (significant) cumulative pesticide and herbicide condition in the Delta, because the changes in the source water fractions of Sacramento River, San Joaquin River, and Delta agriculture water, due to the alternatives, would not be expected to be of sufficient magnitude to substantially alter the long-term risk of pesticide-related toxicity to aquatic life, nor adversely affect other beneficial uses of the Delta. Further, the Environmental Commitments would not involve actions that would contribute to additional pesticide loading, and thus would not contribute considerably to the significant cumulative pesticide condition in the Delta.

Mitigation Measures

BDCP Alternatives

The following conservation measure mitigation measures, and environmental commitment have been developed to mitigate the contributions of the BDCP alternatives to the adverse (significant) cumulative water quality conditions described above for bromide (Mitigation Measure WQ-5), chloride (Mitigation Measure WQ-7), electrical conductivity (Mitigation Measures WQ-11a, 11b, 11c, and 11d), mercury (CM12), organic carbon (Mitigation Measures WQ-17 and WQ-18), pesticides and herbicides (Mitigation Measure WQ-22) and selenium (*AMM27 Selenium Management*). As noted for the BDCP alternatives in Section 8.3.3, it is expected that the impacts on these constituents would remain significant and unavoidable with mitigation.

Alternatives 4A, 2D, and 5A

The following mitigation measures and Environmental Commitment have been developed to mitigate the contributions of Alternatives 4A, 2D, and 5A to the adverse (significant) cumulative water quality conditions described above for electrical conductivity (Mitigation Measures WQ-11e and 11f) and mercury (Environmental Commitment 12). As noted for these alternatives in Section 8.3.4, it is expected that the impacts on mercury would remain significant and unavoidable with mitigation; however, impacts on EC would be reduced to a less-than-significant level.
