Potential passage impediments to adult immigration include temporary beaver dams, flashboard dams, pipeline crossings and natural waterfalls. These barriers exist primarily at low flows and likely impede upstream migration of fall-run Chinook salmon and potentially early migrating adult steelhead (Vanicek 1993). As flows increase during winter months, after the irrigation season and the beginning of winter rains, most barriers are likely passable during higher flows. On Miners Ravine, Cottonwood Dam is the largest impediment to upstream migration and is considered a complete barrier to upstream migration (DWR 2002c). Cottonwood Dam blocks several miles of potential steelhead spawning and rearing habitat.

HARVEST/ANGLING IMPACTS

Dry Creek is open for recreational fishing from the fourth Saturday in May through October 15. Regulations call for catch and release fishing for trout. These angling restrictions are protective of steelhead as it is doubtful that adult steelhead would be present during this time period.

WATER TEMPERATURE

Although little water temperature data exists for Dry Creek, during the winter months, water temperatures are likely suitable for steelhead adult immigration.

WATER QUALITY

Sediment toxicity testing in the Dry Creek watershed indicates potential heavy metals toxicity associated with sediment in Secret Ravine (ECORP Consulting 2003). The presence of sediment toxicity would not likely effect steelhead adult immigration.

FLOW CONDITIONS

Instream flows during the rainy season, generally from October through April, consist primarily of groundwater discharge and surface runoff. Maximum monthly mean flows typically occur during February, and range from 165 cfs to 591 cfs (City of Roseville 2003).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

As flows increase during winter months, after the irrigation season and the beginning of winter rains, most barriers are likely passable during higher flows. On Miners Ravine, Cottonwood Dam is the largest impediment to upstream migration and is considered a complete barrier to

upstream migration (DWR 2002c). Cottonwood Dam blocks several miles of potential steelhead spawning and rearing habitat.

HARVEST/ANGLING IMPACTS

Dry Creek is open for recreational fishing from the fourth Saturday in May through October 15. Regulations call for catch and release fishing for trout. These angling restrictions are protective of steelhead as it is doubtful steelhead would be spawning during this time period.

WATER TEMPERATURE

Although historic water temperature data for Dry Creek is limited, during the winter months, water temperatures are likely suitable for steelhead spawning.

WATER QUALITY

Sediment toxicity in Dry Creek would not directly effect steelhead spawning but, spawning success would likely be negatively impacted.

FLOW CONDITIONS

Instream flows during the rainy season, generally from October through April, consist primarily of groundwater discharge and surface runoff. Maximum monthly mean flows typically occur during February, and range from 165 cfs to 591 cfs (City of Roseville 2003).

SPAWNING HABITAT AVAILABILITY

Several reaches within Miners Ravine have been identified with high sediment loading (DWR 2002c). High sediment loads create embededness (infilling of interstitial spaces). Generally, riffles with greater than 20 percent embededness are considered unsuitable for spawning. A survey of Miners Ravine found that only 17 of 87 riffles had embededness less than 25 percent (DWR 2002c). This survey also found that the most common substrate fractions sand and silt, not cobbles and gravel.

PHYSICAL HABITAT ALTERATION

Within the Dry Creek watershed, numerous canals, aqueducts, siphons, reservoirs, ponds, dams, pipelines and other natural and man-made water features have significantly altered the habitat from historic conditions.

HATCHERY EFFECTS

The CDFG Native Anadromous Fish and Watershed Branch initiated a reconnaissance level assessment of steelhead distribution and abundance, relative to stream habitat conditions, in 1998 and 1999. At that time, steelhead escapement to the upper Dry Creek watershed was estimated at a few hundred fish, with the most suitable spawning and rearing habitat in Secret Ravine and to a lesser extent, Miners Ravine.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Dry Creek is open for recreational fishing from the fourth Saturday in May through October 15. Regulations call for catch and release fishing for trout. These angling restrictions are somewhat

protective of steelhead embryo incubation as most eggs would have hatched prior to the beginning of the fishing season.

WATER TEMPERATURE

During the winter months, water temperatures are likely suitable for steelhead embryo incubation.

WATER QUALITY

Sediment toxicity testing in the Dry Creek watershed indicates potential heavy metals toxicity associated with sediment in Secret Ravine (ECORP Consulting 2003). The presence of sediment toxicity would affect salmonid eggs and young. A recent risk assessment identified sediment as the primary stressor for Chinook salmon in Secret Ravine (ECORP Consulting 2003).

FLOW CONDITIONS

Instream flows during the rainy season, generally from October through April, consist primarily of groundwater discharge and surface runoff. Maximum monthly mean flows typically occur during February, and range from 165 cfs to 591 cfs (City of Roseville 2003). Although these flow fluctuations could result in some redd dewatering, it is likely that they mimic historic conditions where redds would occur.

JUVENILE REARING AND OUTMIGRATION

PASSAGE IMPEDIMENTS/BARRIERS

Numerous beaver dams occur within both Miners and Secret ravines (Vanicek 1993). Beaver dams are generally beneficial to fish habitat because they contribute to the creation of pool habitat and they detain water and release it slowly, potentially maintaining and stabilizing downstream flows. However, beaver dams can present passage impediments to outmigrating juvenile steelhead, particularly at low flows.

WATER TEMPERATURE

The upper limit for steelhead growth and development is reported to be 65°F. Also, 65°F was found to be within the preferred water temperature range (i.e., 62.6°F to 68.0°F) and supported high growth of Nimbus strain juvenile steelhead (Cech and Myrick 1999). Increasing levels of thermal stress to this life stage may reportedly occur above 65°F. For example, Kaya *et al.* (1977) reported that the upper avoidance water temperature for juvenile rainbow trout was measured at 68°F to 71.6°F.

Water temperatures, as measured in Dry Creek below the confluence of Secret and Miners ravines typically begin exceeding 65°F in early May and by the end of May normally exceed 70°F (Sierra Business Council 2003). Water temperatures remain above 70°F normally until the end of September and fall below 65°F by mid-October (Sierra Business Council 2003).

Based on sampling conducted by CDFG during the 1998 to 2000 time period, Secret Ravine provides good steelhead rearing habitat while Miners Ravine provides less consistent habitat quality in terms of water temperatures (Sierra Business Council 2003).

WATER QUALITY

Sediment toxicity testing in the Dry Creek watershed indicates potential heavy metals toxicity associated with sediment in Secret Ravine (ECORP Consulting 2003). The presence of sediment toxicity would affect salmonid eggs and young. A recent risk assessment identified sediment as the primary stressor for Chinook salmon in Secret Ravine (ECORP Consulting 2003).

FLOW CONDITIONS

Instream flows during the rainy season, generally from October through April, consist primarily of groundwater discharge and surface runoff. Maximum monthly mean flows typically occur during February, and range from 165 cfs to 591 cfs (City of Roseville 2003). Reportedly, summer instream flows in lower Dry Creek consist primarily of irrigation return and runoff, groundwater discharge, and treated wastewater effluent from the Dry Creek WWTP (EIP Associates 1993). Recorded monthly mean flows in Dry Creek range from a low of 14.3 cfs in August to 378 cfs in February (ECORP Consulting 2003). Minimum monthly mean flows during July and August typically range from 12 cfs to 17 cfs (City of Roseville 2003).

Juvenile rearing habitat in Miners Ravine is considered marginal. Low-flow conditions during the summer months are considered a constraint to rearing juvenile salmonids in Miners Ravine (ECORP Consulting 2003).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Areas within the Dry Creek watershed have experienced significant loss of riparian habitat resulting in increased bank erosion and associated sediment loading. The loss of riparian habitat has also resulted in higher water temperatures in the downstream reach.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Within the Dry Creek watershed, numerous canals, aqueducts, siphons, reservoirs, ponds, dams, pipelines and other natural and man-made water features significantly influence the local hydrology.

LOSS OF FLOODPLAIN HABITAT

The lower Dry Creek watershed has an extensive record of flooding and flood damage, and the most recent flooding occurrences are reported to have occurred in 1986, 1995 and 1997.

ENTRAINMENT

During the irrigation season, there are temporary diversion dams throughout Dry Creek. All of these diversions are unscreened or poorly screened creating a high risk of entrainment for outmigrating juvenile salmonids. However, most of these dams are not operational during peak juvenile steelhead outmigration.

PREDATION

In the mainstem of Dry Creek, downstream of the Miners and Secret ravine confluences, the fish community consists mostly of spotted bass, Sacramento pikeminnow and Sacramento sucker with spotted bass accounting for the largest portion of fish biomass (ECORP Consulting 2003). Spotted bass also occur in the upper watershed including both Miners and Secret ravines. Both

spotted bass and Sacramento pikeminnow are known to be important predators of juvenile salmonids.

HATCHERY EFFECTS

It is not likely that Central Valley hatchery operations directly affect juvenile salmonids in the Dry Creek watershed.

4.3.8.4 FEATHER RIVER

The Feather River watershed is located at the north end of the Sierra Nevada. The watershed is bounded by the volcanic Cascade Range to the north, the Great Basin on the east, the Sacramento Valley on the west, and higher elevation portions of the Sierra Nevada on the south. The Feather River watershed upstream of Oroville Dam is approximately 3,600 square miles and comprises approximately 68 percent of the Feather River Basin. Downstream of Oroville Dam, the basin extends south and includes the drainage of the Yuba and Bear Rivers. The Yuba River joins the Feather River near the City of Marysville, 39 river miles downstream of the City of Oroville, and the confluence of the Bear River and the Feather River is 55 river miles downstream of the City of Oroville. Approximately 67 miles downstream of the City of Oroville, the Feather River flows into the Sacramento River, near the town of Verona, about 21 river miles upstream of Sacramento. The Feather River watershed, upstream of the confluence of the Sacramento and Feather Rivers, has an area of about 5,900 square miles.

ADULT IMMIGRATION AND HOLDING

The adult immigration and holding life stage for steelhead in the Feather River occurs from September through April, with peak migration extending from October through November (McEwan 2001; Moyle 2002).

PASSAGE IMPEDIMENTS/BARRIERS

The Fish Barrier Dam at RM 67 presents an impassable barrier to upstream migration for anadromous salmonids. There are no other known passage impediments to upstream migrating adult steelhead in the lower Feather River.

HARVEST/ANGLING IMPACTS

The sportfishery in the lower Feather River currently allows the taking of hatchery trout or steelhead (identified by an adipose fin-clip) year-round. The taking of wild steelhead is not permitted. Unusually high densities of fish during the fall in the lower Feather River likely create favorable poaching opportunities.

WATER TEMPERATURE

Suitable water temperatures for adult steelhead migrating upstream to spawning grounds range from 46.0°F to 52.0°F (NMFS 2000; NMFS 2002; SWRCB 2003). In the lower Feather River, water temperatures are only within the “suitable” range for this life stage during the winter months. Under a 1983 agreement between CDFG and DWR, water temperatures are generally maintained at under 65°F from June 1 through September 30 above the Thermalito Afterbay Outlet (DWR 1983).

WATER QUALITY

Water quality in the lower Feather River likely does not affect steelhead adult immigration.

FLOW CONDITIONS

Except during flood events, flows in the reach of the lower Feather River extending downstream to the Thermalito Afterbay Outlet are maintained at a constant 600 cfs. Under the new Settlement Agreement, as part of the FERC relicensing for the Oroville Facilities, flows in the Low Flow Channel will be increased to a constant 800 cfs (FERC 2007). The instream flow requirements below the Thermalito Afterbay Outlet are 1,700 cfs from October through March and 1,000 cfs from April through September. It is likely that flow conditions in the lower Feather River seldom affect this life stage.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

There are no known passage impediments to upstream migrating adult steelhead in the lower Feather River downstream of the Fish Barrier Dam.

HARVEST/ANGLING IMPACTS

The sportfishery in the lower Feather River currently allows the taking of hatchery steelhead (adipose fin-clip) year-round. Wild steelhead may not be taken. Unusually high densities of anadromous salmonids in the lower Feather River likely create favorable poaching opportunities.

WATER TEMPERATURE

Optimal spawning temperatures for steelhead range from 39°F to 52°F (CDFG 1991c). Water temperatures in the lower Feather River range from 47°F in the winter to as high as 65°F in the summer; however, releases are made from the coldwater pool in Lake Oroville Reservoir and this cold water generally provides suitable water temperatures in the Low Flow Channel (i.e., reach of the river extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet)

WATER QUALITY

Water quality in the lower Feather River likely does not affect steelhead spawning.

FLOW CONDITIONS

Except during flood events, flows in the reach of the lower Feather River extending downstream to the Thermalito Afterbay Outlet are maintained at a constant 600 cfs. Under the new Settlement Agreement, as part of the FERC relicensing for the Oroville Facilities, flows in the Low Flow Channel will be increased to a constant 800 cfs (FERC 2007). The instream flow requirements below the Thermalito Afterbay Outlet are 1,700 cfs from October through March and 1,000 cfs from April through September. It is likely that flow conditions in the lower Feather River seldom affect steelhead spawning.

SPAWNING HABITAT AVAILABILITY

Based on results from PHABSIM, the steelhead spawning habitat index in the upper reach has a very low magnitude and has no distinct optimum over the range of flow between 150 and 1,000 cfs. In the lower reach, there is a maximum in the index apparent at a flow just under 1,000 cfs.

The difference in magnitude and peak can be attributed to the relative scarcity of smaller substrate particle sizes utilized by spawning steelhead (in comparison to adult Chinook salmon) in the Oroville project area of the Feather River (DWR 2004e).

PHYSICAL HABITAT ALTERATION

The Oroville Facilities physically block the upstream basin contributions of gravel, sediment, and large woody debris from the lower Feather River, and the upstream passage of anadromous salmonids to historical spawning areas. This has resulted in a gradual depletion of suitable spawning gravels for steelhead.

HATCHERY EFFECTS

The FRFH steelhead are part of the Central Valley steelhead DPS, and also appear to compose over 95 percent of the steelhead population in the lower Feather River. As such, the FRFH is maintaining the spatial structure of the DPS and the Feather River steelhead population. The natural population is not self-sustaining in any appreciable number, primarily due to the basin morphology, and relative lack of steelhead habitat in the lower Feather River, and inaccessibility to habitat above Oroville Dam.

FRFH trucks its fall-run production to San Pablo Bay for release. Effects of out-of-basin release include a high degree of straying of adult returns into other streams, with implications to native spring and fall Chinook salmon of competition over habitat and threats to genetic integrity. Straying of fall-run has resulted in the homogeneity of the Central Valley fall-run component of the Central Valley fall-/late fall-run ESU.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The sportfishery in the lower Feather River currently allows the taking of hatchery steelhead (adipose fin-clip) year-round. It is possible that steelhead redds could be disrupted by wading anglers.

WATER TEMPERATURE

Water temperatures in the Low Flow Channel are normally below 55°F during the steelhead embryo incubation life stage of December through April and seldom exceed 57°F in May (DWR 2001).

WATER QUALITY

As part of the FERC relicensing process for the Oroville facilities, six of the relicensing studies specifically address metals contamination in the lower Feather River. As part of these studies, water quality samples were collected at 17 locations within the lower Feather River. Samples exceeding aquatic life water quality criteria occurred for four constituents: total aluminum, iron, copper, and lead. In the reach of the Feather River extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet, 19 percent of the water quality samples exceeded aquatic life water quality criteria. Samples taken from the reach of the Feather River extending from the Thermalito Afterbay Outlet downstream to the confluence with the Sacramento River were variable, but all were higher than the upstream reach and 3 exceeded aquatic life water

quality criteria 100 percent of the time. Copper exceeded aquatic life water quality criteria in 5 of 276 samples; two of these occurrences were in the reach of the Feather River extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet. Iron only exceeded aquatic life water quality criteria at three sampling locations; all locations were downstream of the lower Feather River confluence with Honcut Creek. Lead exceeded aquatic life water criteria only once at several stations, but three or four times at the two most downstream stations on the Feather River.

FLOW CONDITIONS

Adverse affects on developing embryos could occur if a flow fluctuation caused redds to become dewatered while eggs were incubating. Oroville facilities releases are regulated and subject to regulatory flow criteria. Flows in the Low Flow Channel are maintained at a constant 600 cfs where almost all spawning of steelhead occurs. Under the new Settlement Agreement, as part of the FERC relicensing for the Oroville Facilities, flows in the Low Flow Channel will be increased to a constant 800 cfs (FERC 2007).

JUVENILE REARING AND OUTMIGRATION

Almost 100 percent of juvenile steelhead rearing in the lower Feather River occurs upstream of the Thermalito Afterbay Outlet (DWR and Reclamation 2000). Emigration of juvenile steelhead principally occurs from June through September (DWR and Reclamation 2000).

WATER TEMPERATURE

Naturally spawned Feather River steelhead have been observed to rear successfully at water temperatures below 65°F (DWR and Reclamation 2000). Water temperatures in the Low Flow Channel normally remain below 62°F year-round and are suitable for juvenile steelhead rearing. Water temperatures downstream of the Thermalito Afterbay Outlet are generally warmer, with the maximum mean daily water temperature at the Thermalito Afterbay Outlet reaching approximately 70°F in the summer (DWR 2001). Because daily summer water temperatures generally exceed 70°F below the Thermalito Afterbay Outlet, it is unlikely that steelhead rear in the lower reach of the river (DWR and Reclamation 2000).

WATER QUALITY

As discussed above under embryo incubation, heavy metal concentrations can occasionally exceed established water quality criteria.

FLOW CONDITIONS

Flows in the Low Flow Channel of the Feather River, where most juvenile rearing of salmonids occurs, is maintained at a constant 600 cfs year-round except during flood events. Some flow fluctuations may occur downstream of the Thermalito Afterbay Outlet that have the potential to strand juvenile rearing or outmigrating salmonids. Since 2001, DWR has been conducting a juvenile stranding study on Chinook salmon and steelhead in the lower Feather River. Empirical observations and aerial surveys identified over 30 areas that have the potential to strand juveniles with flow decreases. However, sampling of isolated areas indicated relatively little juvenile salmonid stranding. Furthermore the proportion of stranded salmonids represented a very small percentage (<<1 percent) of the estimated number of emigrants (DWR 2004).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Fixed flows in the lower Feather River have resulted in fewer channel forming or re-shaping events leading to a lack of habitat diversity. This lack of diversity results in unnatural riparian conditions and a lack of recruitment of riparian vegetation.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Channel complexity refers to the diversity of geomorphic features in a particular river reach. Features such as undercut banks, meanders, point bars side channels and backwaters all provide habitat for juvenile salmonids. Regulation of the lower Feather River by the Oroville facilities has changed both streamflow and sediment discharge. Attenuation of peak flows, decreased winter flows, increased summer flows, and changes to flow frequencies have led to a general decrease in channel complexity downstream of Oroville Dam. Because several species and races of fish occur in the lower Feather River, a diversity of habitat types is required. Decreases in channel diversity lead to a decrease in habitat diversity and quality.

The high concentration of spawning salmonids in the Low Flow Channel results in a high concentration of juveniles in the Low Flow Channel. Based on historic accounts of juvenile salmonid emigration, the current peak in the emigration period is somewhat earlier than pre-dam conditions (Painter *et al.* 1977; Warner 1954). Seesholtz *et al.* (2003) further report that substantial numbers of juveniles remain in the Low Flow Channel through the end of June. Seesholtz *et al.* (2003) speculate that this early emigration may be caused by competition with other juvenile salmonids, including Chinook salmon and hatchery steelhead, for rearing habitat.

LOSS OF FLOODPLAIN HABITAT

Regular intermediate flood flushing flows to maintain geomorphic function of the river and replenish fish and riparian habitats are generally rare in the lower Feather River because of flow regulation by the Oroville facilities. Lack of frequent high flow/flood events has led to a lack of floodplain renewal and connectivity to the channel.

ENTRAINMENT

The main diversion on the lower Feather River downstream of the Thermalito Afterbay occurs at Sunset Pumps at RM 38.6. The pumps divert 65,500 acre-feet of water annually. Although the diversion is screened, the mesh size does not meet NOAA or CDFG criteria, and some entrainment of juvenile salmonids likely occurs.

PREDATION

Counts of known predators on juvenile anadromous salmonids are reported to be very low in the Low Flow Channel (Seesholtz *et al.* 2003). Naturally spawned steelhead are an exception because little is known about their relative abundance. Because water temperatures are relatively low in the Low Flow Channel, it is doubtful that significant predation occurs in this reach by non-salmonid species.

Significant numbers of predators do reportedly exist in the High Flow Channel below the Thermalito Afterbay Outlet. Analysis of CWT recovery data indicates that predation on hatchery-reared Feather River Chinook salmon released in the Feather River is high, however

further analysis reveals that most of this predation takes place in the Sacramento River downstream of the Feather River confluence (DWR 2004).

One aspect of the Oroville Project operations and facilities that may enhance predation in the High Flow Channel is that the high density of juveniles in the Low Flow Channel may cause early emigration of juvenile salmonids. Because juvenile rearing habitat in the Low Flow Channel is limited, juveniles may be forced to emigrate from the area due to competition for resources. Relatively small juvenile salmonids may be less capable of avoiding predators than those that rear to a larger size in the Low Flow Channel prior to beginning their seaward migration.

HATCHERY EFFECTS

Although most Feather River steelhead are likely of hatchery-origin, the release of yearling steelhead to the Feather River likely creates predation and competition for resources with smaller naturally spawned steelhead

4.3.8.5 BEAR RIVER

The Bear River originates on the west side of the Sierra just below Lake Spaulding at the 5,500-foot elevation and flows southwest 65 miles to its confluence with the Feather River at RM 12 of the Feather, draining portions of Nevada, Placer, Sutter and Yuba counties. Anadromous salmonids have access to 15 miles of habitat in the Bear River. The South Sutter Irrigation District Dam (SSIDD) presents an impassable barrier and marks the upstream extent of currently accessible anadromous salmonid habitat. Inadequate streamflow in the Bear River prevents the establishment of a self-sustaining steelhead population (JSA 2004).

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The SSIDD presents an impassable barrier and marks the upstream extent of currently accessible anadromous salmonid habitat.

HARVEST/ANGLING IMPACTS

Recreational angling is permitted in the Bear River from the last Saturday in April through November 15. Because water temperatures in the Bear Rive likely prevent an early migration of steelhead into the Bear River, very few steelhead would be harvested in the recreational fishery.

WATER TEMPERATURE

The USFWS's CVPIA *Tributary Production Enhancement Report* of May 1998 identifies high water temperatures as one of the factors limiting steelhead production in the Bear River. However, water temperatures should be cool enough by November to support steelhead adult immigration.

WATER QUALITY

Water quality in the Bear River is generally considered to be good and should be adequate to support steelhead adult immigration.

FLOW CONDITIONS

Inadequate streamflow in the Bear River prevents the establishment of a self-sustaining steelhead population (JSA 2004). However, during periods of high flows, steelhead are known to utilize the river for limited spawning (JSA 2004).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

The SSIDD presents an impassable barrier and marks the upstream extent of currently accessible anadromous salmonid habitat. During periods of low flows or dry water years, steelhead may not have access to spawning habitat in the Bear River.

HARVEST/ANGLING IMPACTS

Recreational angling is permitted in the Bear River from the last Saturday in April through November 15. This time period should be protective of any steelhead spawning that may occur in the river.

WATER TEMPERATURE

During winter months, water temperatures in the Bear River are adequate to support steelhead spawning.

WATER QUALITY

Water quality in the Bear River is generally considered to be good and should not present adverse conditions to steelhead spawning.

FLOW CONDITIONS

Inadequate streamflow in the Bear River prevents the establishment of a self-sustaining steelhead population (JSA 2004). However, during periods of high flows, steelhead are known to utilize the river for limited spawning (JSA 2004).

SPAWNING HABITAT AVAILABILITY

Habitat conditions in the Bear River below Camp Far West Reservoir currently are not favorable for natural production of anadromous fish, including Chinook salmon and steelhead. Salmonid reproduction is severely limited by silted spawning gravels.

PHYSICAL HABITAT ALTERATION

The primary modification to habitat in the Bear River stems from water diversions during the irrigation season. Additionally, the Bear River was far more heavily impacted by hydraulic mining (i.e., tons of mining sediment per unit of drainage area) than the Yuba or American Rivers. Closure of Rollins Dam caused a significant reduction in sediment yields and very little sediment remains in the middle Bear today. It is estimated that 125 million cubic meters (160 million cubic yards) of mining sediment is stored in the lower Bear. The high volume of mining sediment, in combination with restricting levees, has caused the lower Bear River to change from wide and shallow to deeply incised.

HATCHERY EFFECTS

Because environmental conditions do not support a self-sustaining population of steelhead in the Bear River, those steelhead that do spawn during high flow years have likely originated from the FRFH.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Recreational angling is permitted in the Bear River from the last Saturday in April through November 15. This time period should prevent the inadvertent disruption of redds by wading anglers.

WATER TEMPERATURE

The USFWS's CVPIA *Tributary Production Enhancement Report* of May 1998 identifies high water temperatures as one of the factors limiting steelhead production in the Bear River. However, steelhead embryos developing during the winter months should not be affected by warm water temperatures.

WATER QUALITY

The Bear River is considered to be an impaired water body by the SWRCB. The pollutant or stressor in the river downstream of Camp Far West Reservoir is diazinon and the pollutant upstream is mercury (JSA 2004). Agricultural runoff is the likely source of diazinon (JSA 2004). These pollutants could adversely impact developing steelhead embryos.

FLOW CONDITIONS

The USFWS's CVPIA *Tributary Production Enhancement Report* identifies instream flows as one of the factors limiting steelhead production in the Bear River. Because steelhead spawning likely only occurs during wet years, flows should be adequate to support embryo incubation.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

The USFWS's CVPIA *Tributary Production Enhancement Report* identifies high water temperatures as one of the factors limiting steelhead production in the Bear River. Warm water temperatures during the summer months likely preclude steelhead juvenile rearing in the Bear River.

WATER QUALITY

Water quality in the Bear River is generally considered to be good. However, the river is considered to be an impaired water body by the SWRCB. The pollutant or stressor in the river downstream of Camp Far West Reservoir is diazinon and the pollutant upstream is mercury (JSA 2004). Agricultural runoff is the likely source of diazinon (JSA 2004).

FLOW CONDITIONS

During the dry summer months, flows in Bear River sometimes decrease to zero at the USGS gaging site near Wheatland (JSA 2004). The USFWS's CVPIA *Tributary Production*

Enhancement Report identifies instream flows as one of the factors limiting steelhead production in the Bear River.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Much of the lower Bear River is under private ownership and the condition of riparian habitat has not been investigated. However, it is likely that some riparian habitat has been degraded due to agricultural encroachment into the riparian zone.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

This watershed is one of the most heavily managed in California for water conveyance. Flows are largely controlled by the Nevada Irrigation System and PG&E. The present system of diversions also results in fluctuations that are harder on the riverine habitat and fisheries than the more gradual natural seasonal variations.

LOSS OF FLOODPLAIN HABITAT

The Bear River was far more heavily impacted by hydrologic mining than the Yuba or American rivers and, unlike the Yuba or American rivers, contains a large volume of mining sediment stored in its main channel which is subjected to continual erosion. It is estimated that 125 million cubic meters (160 million cubic yards) of mining sediment is stored in the lower Bear River. The high volume of mining sediment, in combination with restricting levees, has caused the lower Bear River to change from wide and shallow to deeply incised (Sierra Club Website 2007).

ENTRAINMENT

The USFWS's CVPIA *Tributary Production Enhancement Report* identifies unscreened diversions as one of the factors limiting steelhead production in the Bear River.

PREDATION

The same suite of predators (e.g., large and smallmouth bass) as exists in the lower Feather River likely occurs in the Bear River.

HATCHERY EFFECTS

Steelhead released from the Feather River Hatchery may intercept and prey on naturally spawned steelhead emigrating from the Bear River.

4.3.8.6 YUBA RIVER

The Yuba River watershed encompasses 1,339 square miles on the western slopes of the Sierra Nevada Mountain Range, and is located in portions of Sierra, Placer, Yuba, and Nevada counties (Reynolds *et al.* 1993). The primary watercourses of the upper Yuba River watershed are the South, Middle, and North Yuba rivers, which flow into Englebright Reservoir. The lower Yuba River, from Englebright Dam downstream to the confluence with the Feather River, is approximately 24 miles long, and supports a wild Chinook salmon and steelhead fishery.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Englebright Dam, at RM 24, presents an impassable barrier to anadromous salmonid upstream migration and marks the upstream extent of currently accessible steelhead habitat in the Yuba River. Physical passage impediments on the lower Yuba River are primarily limited to the passability of Daguerre Point Dam fish ladders during certain flow conditions. The design of Daguerre Point Dam fish ladders are suboptimal, as currently operated by the USACE. For example, during high flows across the spillway, the fish ladder is obscured making it difficult for salmonids migrating upstream to find the entrances to the fish ladders. Both ladders tend to become loaded with organic material and sediment, which can directly inhibit passage and/or reduce attraction flows at the ladder entrances. The fish ladder exits are close to the spillway, which can result in fish being swept back over the dam while attempting to exit the ladder. The policy of the USACE is to close the fish ladders when the water surface elevation reaches 130 feet, and remain closed until the water surface elevation drops to an elevation of 127 feet.

Options to improve fish passage at Daguerre Point Dam were identified in the Bulletin 250 Fish Passage Improvement Program (DWR 2005b). The Project Modification Report recently completed by the USACE included engineering surveys, hydraulic evaluation, and a preliminary environmental assessment. There is no anticipated date for the implementation or completion of improvements to Daguerre Point Dam.

HARVEST/ANGLING IMPACTS

Fishing for steelhead on the lower Yuba River is regulated by CDFG. CDFG 2007-2008 angling regulations permit fishing for steelhead from the mouth of the Yuba River to the Highway 20 Bridge with only artificial lures with barbless hooks all year-round. A harvest of one hatchery steelhead (identified by an adipose fin clip) limit is permitted all year from the mouth of the Yuba to the Highway 20 Bridge. From the Highway 20 Bridge to Englebright Dam, fishing for steelhead is permitted from December 1 through August 31 only. During this time, no harvest is permitted. The use of artificial lures with barbless hooks in the lower Yuba River is considered a stressor to immigrating and holding steelhead during August through November.

The extent to which steelhead are targeted for poaching is unknown. However, due to their ESA listing, any level of poaching or angler harvest may constitute a significant limiting factor to the population

WATER TEMPERATURE

Upstream spawning migration of adult steelhead has been reported to cease at temperatures < 39.2°F and ≥ 64.4°F. CDFG found in-river water temperatures to be near or above 57°F at the Marysville gage until after mid-October and into November.

WATER QUALITY

Water quality in the lower Yuba River is adequate to support steelhead adult immigration.

FLOW CONDITIONS

The Yuba Goldfields are located along the lower Yuba River near Daguerre Point Dam, approximately 10 miles north of Marysville. The area of the Goldfields is approximately 8,000 acres. The Goldfields have been used for gold mining for about 100 years. As a result thousands of acres of continuous mounds of cobble and rock terrain have been left behind. As a result of

the permeability of the substrates composing the Goldfields, several interconnected channels and ponds have formed throughout the area. Surface water and subsurface water in the ponds and canals of the Goldfields are hydraulically connected to the Yuba River downstream of Daguerre Point Dam via an outlet canal.

Prior to 2003, a fraction of the lower Yuba River steelhead population routinely migrated from the mainstem of the Yuba River into the Yuba Goldfields via the outlet canal. In 2003, a fish barrier was constructed at the outlet canal to prevent fish from entering the Yuba Goldfields. High flows during May 2004 breached the barrier structure. However, repairs to the fish barrier have been subsequently made, and the integrity of the barrier is monitored during high flows. Therefore, for the most part, the Yuba Goldfields does not present a direct threat to anadromous salmonids in the lower Yuba River. However, as mentioned above, high flows can create partial barriers to upstream migration at Daguerre Point Dam.

SPAWNING

Steelhead spawn in the lower Yuba River from January through April. Suitable steelhead spawning habitat occurs in the Garcia Pit Gravel Reach and the Daguerre Point Dam Reach. However, only 5 steelhead redds were found below Daguerre Point Dam in 2003, versus 45 redds upstream of Daguerre Point Dam (USFWS 2003c).

PASSAGE IMPEDIMENTS/BARRIERS

From Daguerre Point Dam upstream to Englebright Dam there are no barriers to upstream adult immigration.

HARVEST/ANGLING IMPACTS

Recreational angling impacts to spawning steelhead in the Yuba River are similar to those discussed above for adult immigration.

WATER TEMPERATURE

Average daily water temperatures recorded at Daguerre Point Dam from 1997 to 2001 ranged from 50.3°F in January to 53.7°F in April. These temperatures are adequate to support steelhead spawning.

WATER QUALITY

Water quality in the lower Yuba River is adequate to support steelhead spawning.

FLOW CONDITIONS

USFWS (2008) developed steelhead WUA-flow relationships for the lower Yuba River from suitability habitat criteria developed on the lower Yuba River. These relationships indicate that potential spawning habitat is maximized at flows around 1,400 cfs above Daguerre Point Dam. Flows ranging from 700 to 2,700 cfs provide good habitat availability (defined as greater than 80 percent of the maximum habitat) above Daguerre Point Dam. Currently, flow regimes in the lower Yuba River range from 600 to 700 cfs depending on water year type.

SPAWNING HABITAT AVAILABILITY

Most spawning habitat in the lower Yuba River is upstream of Daguerre Point Dam. Although water temperatures below the dam are likely suitable for steelhead spawning, gravel downstream of the dam is embedded with silt (YCWA 2000). Spawning habitat above Daguerre is considered marginal as Englebright Dam blocks recruitment of spawning gravel to the lower Yuba River.

PHYSICAL HABITAT ALTERATION

The most extensive habitat alterations in the lower Yuba River have occurred as a result of gold mining operations. The Yuba Goldfields are located along the lower Yuba River near Daguerre Point Dam, approximately 10 miles north of Marysville. The area of the Goldfields is approximately 8,000 acres. The Goldfields have been used for gold mining for about 100 years. As a result thousands of acres of continuous mounds of cobble and rock terrain have been left behind. As a result of the permeability of the substrates composing the Goldfields, several interconnected channels and ponds have formed throughout the area. Surface water in the ponds and canals of the Goldfields are hydraulically connected to the Yuba River. A proportion of flow entering the Goldfields is eventually returned to the Yuba River downstream of Daguerre Point Dam via an outlet canal. Prior to 2003, a fraction of the lower Yuba River Chinook salmon population (e.g., spring-run, fall-run, and late-fall-run) and, presumably, steelhead routinely migrated from the mainstem of the Yuba River into the Yuba Goldfields via the outlet canal. In 2003, a fish barrier was constructed at the outlet canal to prevent fish from entering the Yuba Goldfields. However, fish were still observed passing the barrier during flood or high flow events.

HATCHERY EFFECTS

The lower Yuba River is currently thought to support a self-sustaining population of steelhead while the lower Feather River population of steelhead is mostly of hatchery-origin. It is likely that some straying of Feather River steelhead into the lower Yuba River occurs.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because the lower Yuba River supports a year-round recreational fishery, it is possible that some level of redd disturbance by wading anglers occurs.

WATER TEMPERATURE

Steelhead embryo incubation primarily occurs in the lower Yuba River from January through July (CALFED Website 2005). The intragravel residence times of incubating eggs and alevins (yolk-sac fry) are highly dependent upon water temperatures. Maximum steelhead embryo survival reportedly occurs in water temperatures ranging from 41°F to 56°F (USFWS 1995c). The average water temperature in the Yuba River at Daguerre Point Dam is typically around 47°F in January and February and rises to approximately 56°F in July.

WATER QUALITY

Water quality in the lower Yuba River is generally good. There is a concern that a substantial amount of mercury may be in the Yuba Goldfields that could be mobilized by flood events but this would likely be downstream of developing embryos.

FLOW CONDITIONS

On March 1, 2001, the SWRCB issued a D-1644 which specified flow requirements limiting the magnitude and rate of flow reductions in the lower Yuba River to prevent salmonid redd dewatering and juvenile stranding. The seasonal flow requirements to protect salmonid redds were based on a redd dewatering study conducted by YWCA (SWRCB 2001).

Pursuant to the SWRCB's RD-1644 and agreements between CDFG and YCWA, daily flow fluctuations below Englebright Dam must not be reduced to less than 55 percent of the maximum daily flow release that previously occurred from September 15 to October 31. In addition, during the period from November 1 to March 31 the flow downstream of Englebright Dam cannot be reduced to less than 65 percent of the maximum flow release that occurred during the November through March 31 period, or the minimum instream flow requirement, whichever is greater (SWRI 2002).

FERC issued a License Amendment for the Yuba Project (Project No. 2246) on November 22, 2005, which imposes a more protective set of flow fluctuation and ramping requirements for the Yuba Project. The new criteria govern YCWA's releases of water from the Narrows II Powerhouse and require YCWA to make reasonable efforts to operate New Bullards Bar and Englebright reservoirs to avoid flow fluctuations in the lower Yuba River.

JUVENILE REARING AND OUTMIGRATION

The vast majority of steelhead emigrate as yearlings during October through May, with a relatively small percentage of individuals remaining in the lower Yuba River and emigrating as two or three year olds.

WATER TEMPERATURE

The average daily mean water temperature downstream of Daguerre Point Dam from October through May ranges between 57.5°F in October to 57.8°F in May at Marysville (SWRI 2002). These temperatures are within the suitable range for juvenile steelhead rearing and outmigration.

WATER QUALITY

Water quality in the lower Yuba River is generally good. There is a concern that a substantial amount of mercury may be in the Yuba Goldfields that could be mobilized by flood events.

FLOW CONDITIONS

Field observations on the lower Yuba River indicate that both natural and controlled flow reductions can cause some degree of fish stranding (YCWA 1998; YCWA 1999). The magnitude of stranding is site-specific and associated with the specific developmental stage of the fry prior to the onset of flow reductions, channel morphology, and aquatic habitat characteristics.

There are two types of stranding that are associated with flow reductions:

- Stranding associated with the rate of flow reductions (i.e., ramping rates), which determines if the juvenile fish can react quickly enough to avoid being stranded from exposed substrates in side channels and channel margins as flows decrease; and

- ❑ Stranding associated with the magnitude of flow reductions, regardless of ramping rate, which determines the extent of stranding within off channel habitats as flows decrease.

The SWRCB requires that YCWA, in consultation with the CDFG, NMFS, and USFWS verify that salmon fry are being protected from dewatering events during controlled flow reductions on the lower Yuba River. However, some level of mortality associated with controlled flow reductions is unavoidable, and therefore should be considered as a factor when assessing threats to juvenile salmonids in the lower Yuba River (YCWA 1999).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The reduction of peak flows in the late winter and spring have resulted in a reduction of riparian vegetation. There is a wide variation throughout the growing season of willow regeneration because each species of willow requires flows at specific periods for reproduction and growth. Cottonwood regeneration is also more prominent under natural flow regimes (YCWA 2000).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Attenuated peak flows and controlled flow regimes have altered the areas geomorphology and have affected the natural meandering of the river downstream of Englebright Dam.

LOSS OF FLOODPLAIN HABITAT

Controlled flows and decreases in peak flows has reduced the frequency of floodplain inundation resulting in a separation of the river channel from its natural floodplain.

ENTRAINMENT

As juvenile steelhead pass Daguerre Point Dam, physical injury may occur as they pass over the dam or through its fish ladders (SWRI 2002). Water diversions in the lower Yuba River generally begin in the early spring and extend through the fall. As a result, potential threats to juvenile steelhead occur at the Hallwood-Cordua and South Yuba Brophy diversions.

Fish screens recently installed at the Hallwood-Cordua diversion are considered to be an improvement over those previously present but, the current pipe design may not allow sufficient flow to completely eliminate juvenile salmonid losses at the diversion.

The South Yuba – Brophy system diverts water through an excavated channel from the south bank of the lower Yuba River to Daguerre Point Dam. The water is then subsequently diverted through a porous rock dike that is intended to exclude fish. The current design of this rock structure does not meet NMFS or CDFG juvenile fish screen criteria (SWRI 2002).

There are also three major screened diversions on the lower Yuba River located upstream of Daguerre Point Dam: (1) the Browns Valley Pumpline Diversion Facility; (2) the South-Yuba/Brophy Water District Canal; and (3) the Hallwood-Cordua Canal. In addition, there are 16 unscreened water diversion facilities downstream of Daguerre Point Dam (SWRI 2002) which could potentially entrain juvenile salmonids in the lower Yuba River.

PREDATION

The extent of predation on juvenile steelhead in the Yuba River is not well documented, however, several non-native introduced known predators of juvenile salmonids are found in the Yuba River including striped bass, American shad and black bass species. Sacramento pikeminnow, a native predatory species is also found in the lower Yuba River. Manmade

alterations to the lower Yuba River channel (i.e., Daguerre Point Dam) may provide more predation opportunities for pikeminnow than would occur under natural conditions.

HATCHERY EFFECTS

The extent of potential hatchery effects on juvenile steelhead in the lower Yuba River is unknown. It is possible that some hatchery-reared steelhead from the FRFH may move into the lower Yuba River in search of rearing habitat. Some competition for resources with naturally spawned steelhead could occur as a result.

4.3.8.7 BUTTE CREEK

Butte Creek flows from the western slope of the Sierra Nevada through a steep canyon for approximately 25 miles and meets the valley floor near Chico. The Centerville Diversion Dam, located immediately downstream of the DeSabra Powerhouse is generally considered to be the upper limit of anadromous salmonid habitat.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Butte Creek is a highly developed watershed system with multiple diversions as well as water imports from foreign sources. Fish passage through Butte Creek is affected by about 22 major structures and an estimated 60 to 80 minor structures (e.g., pump diversions). Currently, it is estimated that salmonids have access to approximately 53 miles of Butte Creek (DWR 2005a).

HARVEST/ANGLING IMPACTS

Recreational harvest of steelhead, as stated in the CDFG 2007-2008 fishing regulations, is limited to catch and release, and occurs from November 15 through February 15 with gear restrictions including artificial lures and barbless hooks only.

WATER TEMPERATURE

Water temperatures during the steelhead adult immigration time period are suitable for this life stage.

WATER QUALITY

Available data indicate that overall water quality in Butte Creek ranges from good to excellent in the upper watershed and degrades in quality lower in the system (Butte Creek Watershed Website 2004). Both pH and dissolved oxygen concentrations appear to be below CVRWQCB criteria all of the time. Turbidity, mineral concentrations, nutrient loads and heavy metal concentrations (e.g., lead) have at times exceeded Central Valley RWQCB criteria for short periods of time (Butte Creek Watershed Website 2004). Although water quality is somewhat degraded, it should be adequate to support steelhead adult immigration.

FLOW CONDITIONS

Because there are no large storage facilities on Butte Creek, flow regimes during the winter months when agriculture diversions are not occurring tend to mimic the historic hydrology of the watershed.

SPAWNING

Steelhead primarily spawn in stream reaches between the Parrot-Phelan Diversion Dam and the Quartz Bowl Falls with some fish reaching Centerville Diversion Dam.

PASSAGE IMPEDIMENTS/BARRIERS

There are no significant passage impediments in the reach of Butte Creek where most steelhead spawning would occur during the winter months.

HARVEST/ANGLING IMPACTS

Potential angling impacts to spawning steelhead are similar to those describe above for the adult immigration life stage.

WATER TEMPERATURE

Water temperatures during the winter months when steelhead would be spawning are within the suitable range for this life stage.

WATER QUALITY

Water quality in Butte Creek where steelhead spawning is likely to occur is generally considered of high quality.

FLOW CONDITIONS

PG&E's minimum instream flow requirement at the Lower Centerville Diversion Dam is 40 cfs from June 1 to September 14. Flows in Butte Creek begin to increase during the steelhead spawning period from November through April. Because there are no large storage facilities on Butte Creek, flow regimes during the winter months when agriculture diversions are not occurring tend to mimic the historic hydrology of the watershed.

SPAWNING HABITAT AVAILABILITY

In Butte Creek, the spawning area for steelhead extends from the Centerville Head Dam downstream to the vicinity of the Western Canal Siphon crossing. Steelhead generally spawn upstream of the Parrott-Phelan diversion. Spawning gravel in the reach of the creek from the Centerville Head Dam downstream to the vicinity of Helltown is extremely limited, with the major gravel beds existing below the Centerville Powerhouse (Butte Creek Watershed Website 2004).

PHYSICAL HABITAT ALTERATION

Hydropower generation has altered flows in Butte Creek since about 1908. The reach of Butte Creek from the Centerville Powerhouse downstream to the Parrott-Phelan Dam has undergone and continues to undergo residential development. Channel modification projects designed to repair or prevent flood-related damage to roads and houses have degraded natural processes

which serve to recruit gravel, provide instream cover and forage, and provide holding pools (Butte Creek Watershed Website 2004).

HATCHERY EFFECTS

Steelhead are produced at both the Feather River Hatchery, south of Butte Creek, and the Coleman National Hatchery, north of Butte Creek. It is possible that some hatchery produced steelhead could stray into Butte Creek. The extent to which hatchery steelhead from the Feather River Hatchery or the Coleman National Hatchery steelhead stray into Butte Creek is unknown.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because Butte Creek is open to angling year-round, there may be some inadvertent negative impacts to embryo incubation from anglers wading through redds or otherwise disturbing substrates containing redds.

WATER TEMPERATURE

The optimum water temperature range reported for steelhead embryo incubation is between 48°F and 52°F (NMFS 2000). Mean monthly water temperatures in Butte Creek near Chico (DWR Gage) generally remain suitable during the embryo incubation period until May, when they reach approximately 56°F.

WATER QUALITY

Turbidity, mineral concentrations, nutrient loads and heavy metal concentrations (e.g., lead) have at times exceeded Central Valley RWQCB criteria for short periods of time (Butte Creek Watershed Website 2004). Any of these factors could affect developing steelhead embryos, however, most developing embryos would be higher up in the watershed where conditions are better.

FLOW CONDITIONS

Fluctuation in flows during the embryo incubation period which could potentially cause redd dewatering events have not been reported to date.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures during the period when flows are managed and juvenile steelhead would be present, are likely near optimal ranges. However, water temperatures could be a concern during the late spring and summer for juvenile rearing in the lower reaches of Butte Creek near the Sutter Bypass.

WATER QUALITY

Available data indicate that overall water quality in Butte Creek ranges from good to excellent in the upper watershed and degrades in quality lower in the system (Butte Creek Watershed Website 2004). Both pH and dissolved oxygen concentrations appear to be below CVRWQCB criteria all of the time. Turbidity, mineral concentrations, nutrient loads and heavy metal

concentrations (e.g., lead) have at times exceeded Central Valley RWQCB criteria for short periods of time (Butte Creek Watershed Website 2004).

FLOW CONDITIONS

Butte Creek is primarily a free flowing stream lacking large dams to control or buffer flows (CDFG 1999a). Flows are highly variable with the majority of out migration of juveniles occurring during high flow events (CDFG 1999a). The extent to which flow fluctuations from water diversions in Butte Creek may affect juvenile salmonid habitat availability and cause juvenile stranding is currently unknown.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The distribution of riparian habitat, particularly in the lower reaches of Butte Creek has been reduced by anthropogenic changes for flood control, agriculture and urbanization (Butte Creek Watershed Website 2004).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

The reach of Butte Creek from the Centerville Powerhouse downstream to the Parrott-Phelan Dam has undergone and continues to undergo residential development. Channel modification projects designed to repair or prevent flood-related damage to roads and houses have degraded natural processes which serve to recruit gravel, provide instream cover and forage, and provide summer holding pools (Butte Creek Watershed Website 2004).

LOSS OF FLOODPLAIN HABITAT

Although Butte Creek is bordered by levees in some areas, it also passes through Butte Slough and the Sutter Bypass where connectivity to the floodplain still exists to some extent (Butte Creek Watershed Website 2004)

ENTRAINMENT

In Butte Creek most water diversion facilities have been screened or modified to prevent juvenile fish entrainment (PG&E 2005).

PREDATION

The extent of predation on juvenile steelhead in the Butte Creek is not well documented, however, several known predators of juvenile salmonids are found in the Butte Creek. Striped bass are commonly found in the Sacramento River as well as in Butte Creek. The Sacramento pikeminnow is another well know predator of juvenile salmonids and has been documented as far upstream in the Sacramento River as the RBDD suggesting the presence of pikeminnow in Butte Creek (NMFS 1996b). Increasing flow regulation and associated increasing temperatures, in addition to increased turbulence associated with spillways, may cause increased predator upstream movement, increased predator success, and increased predator survival (NMFS 1996b).

HATCHERY EFFECTS

There are likely no adverse effects due to hatchery production on juveniles in Butte Creek. However, naturally produced steelhead juveniles that utilize portions of the Sutter Bypass for rearing may encounter hatchery produced salmon and steelhead resulting in potential competition for resources.

4.3.8.8 BIG CHICO CREEK

Big Chico Creek originates on Colby Mountain, located in Tehama County, California. The creek flows 45 miles to its confluence with the Sacramento River in Butte County. The creek's elevation ranges from 120 feet at the Sacramento River to 6000 feet at Colby Mountain. A portion of Big Chico Creek flows through the city of Chico, California's Bidwell Park and California State University, Chico.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Big Chico Creek has no major reservoirs, but has five small dams and three natural barriers that could impede anadromous fish migration. Presently, 24 miles of Big Chico Creek are accessible to steelhead (DWR 2005b).

Five Mile Dam was built by the USACE for the purpose of flood control in 1963. The dam effectively split the Big Chico Creek flows into three separate channels, Big Chico Creek, Sycamore Channel, and Lindo Channel. The design of the flood control structure creates a ponding effect upstream during flood events. This causes gravels to drop out of suspended load upstream of the diversion which creates gravel bar that blocks the flow to Lindo Channel unless it is mechanically removed. As a result, Lindo Channel frequently lacks sufficient flows to allow upstream migrants to pass, and has the potential to trap adults within the channel during immigration to spawning areas upstream (DWR 2005b).

The Iron Canyon fish ladder was built in the late 1950s to facilitate fish passage through Bidwell Park. This structure has been damaged, and frequently impedes adult salmonid upstream migration. Currently, a project is underway to repair the fish ladder to allow fish passage to an additional 9 miles of spawning habitat over a wider range of flows (CDFG Website 2005). In addition, fish passage through the narrow canyon walls of Bear Hole, located downstream of the Iron Canyon fish ladder, impedes fish passage during low flows.

HARVEST/ANGLING IMPACTS

Recreational catch and release of trout is allowed from the mouth of Big Chico creek to one mile downstream of Bidwell Park during June 16 through October 15, and from October 16 through February 15 with gear restrictions (i.e., artificial lures and barbless hooks only); and from Bear Hole to the Big Chico Creek Ecological Reserve from November 1 through April 30 with gear restrictions (i.e., artificial lure and barbless hooks only). Fishing between the upper boundaries of Big Chico Creek Ecological Reserve to Higgins Hole Falls is prohibited year-round.

WATER TEMPERATURE

Water temperatures in Big Chico Creek normally fall below 60°F by late October and are under 50°F by the beginning of December, when adult steelhead would be immigrating. These temperatures are suitable for that life stage.

WATER QUALITY

Water quality in Big Chico Creek and Lindo Channel has been degraded by cadmium, mercury, and other metals associated with gold mining in the upper watershed. However, Big Chico

Creek currently meets EPA water quality constituent standards and should be adequate to support steelhead adult immigration.

FLOW CONDITIONS

Flow conditions in Big Chico Creek during normal and wet years are adequate to support steelhead adult immigration. During dry years, low flows may create passage impediments or even strand upstream migrating steelhead in Lindo Channel.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

The first barrier to upstream migration on Big Chico Creek occurs in Iron Canyon where a jumble of boulders has accumulated in the Creek. These boulders present an impassable barrier at normal flows but allow passage at high flow (Big Chico Creek Watershed Alliance Website 2007). The Iron Canyon fish ladder was built in the late 1950s to facilitate fish passage. This structure has been damaged, and frequently impedes adult salmonid upstream migration. Currently, a project is underway to repair the fish ladder to allow fish passage to an additional nine miles of spawning habitat over a wider range of flows (CDFG Website 2005). The waterfall at Higgins Hole is currently thought to be the uppermost barrier to anadromous fish migrations (CDFG 2001a).

HARVEST/ANGLING IMPACTS

Most steelhead spawning occurs upstream of the Ecological Reserve where fishing is closed year-round. Therefore, harvest and angling impacts to steelhead are minimized in Big Chico Creek.

WATER TEMPERATURE

The reported optimum water temperature range for steelhead during the spawning period is between 46.0°F and 52°F (USFWS 1995b). Mean monthly water temperatures in Big Chico Creek near Chico (DWR gage) from during the spawning period from 1999 through 2005 ranged from approximately 47°F in November to 54°F in April.

WATER QUALITY

Water quality in Big Chico Creek and Lindo Channel has been degraded by cadmium, mercury, and other metals associated with gold mining in the upper watershed. However, Big Chico Creek currently meets EPA water quality constituent standards and is adequate to support steelhead spawning.

FLOW CONDITIONS

The Iron Canyon fish ladder was built in the late 1950s to facilitate fish passage through Bidwell Park. This structure has been damaged, and frequently impedes adult salmonid upstream migration. Currently, a project is underway to repair the fish ladder to allow fish passage to an additional 9 miles of spawning habitat over a wider range of flows.

SPAWNING HABITAT AVAILABILITY

A survey of spawning gravels was conducted by DWR in 1997 to determine the gravel size distribution at various spawning sites in Big Chico Creek. The sites were located along Big Chico Creek at Highway 32; below the Five-Mile Area flood control structure; and at Rose Avenue. The gravel sizes ranged from 20 mm to 100 mm (approximately 1 to 4 inches) in mean diameter. Gravels within these ranges are considered to be suitable for salmonid spawning (Big Chico Creek Watershed Alliance Website 2007).

Gravel recruitment downstream of the Five-Mile Flood Diversion Complex is reduced and gravel also becomes trapped in the One-Mile Pond from which it is customarily removed rather than transported downstream (Big Chico Creek Watershed Alliance Website 2007). Additionally, the practice of removing large woody debris from urban and floodway stream reaches has reduced habitat and increased streambed scouring (Big Chico Creek Watershed Alliance Website 2007).

PHYSICAL HABITAT ALTERATION

The presence of dams on Big Chico Creek limits the composition and volume of sediments transported which reduces the supply of spawning gravels downstream of the dams. Large volumes of suspended sediment in the bedload are deposited within the stilling pond above Five-Mile area. As a result, coarse sediments are not transported downstream below the Five-Mile area. At Chico's One Mile Recreation Area, the flow is again reduced and additional volumes of sediment are deposited on the upstream side of the dam. Low-flow silt transport in the Big Chico Creek has been increased by swimming pool clean out and summer water activities by humans, dogs and horses. Unlike high-flow conditions in which silt only deposits where flow velocity is reduced in backwater and overflow sites, silt carried during low flow settles out in riffles and pools where it degrades habitat for spawning (Big Chico Creek Watershed Alliance Website 2007).

HATCHERY EFFECTS

Steelhead are produced at both the Feather River Hatchery, south of Big Chico Creek, and the Coleman National Hatchery, north of Big Chico Creek. It is possible that some hatchery produced steelhead could stray into Big Chico Creek.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Most steelhead spawning occurs upstream of the Ecological Reserve where fishing is closed year-round. Therefore, harvest and angling impacts to developing steelhead embryos are minimized in Big Chico Creek.

WATER TEMPERATURE

The average monthly water temperature in Big Chico Creek near Chico (DWR Gage) from November through July from 1999 through 2004 ranged from approximately 50°F in November to approximately 75°F in July. Water temperatures in the upper reaches of Big Chico Creek are likely more suitable during the peak embryo incubation period; however, developing embryos from late spawning steelhead could be negatively affected by high water temperatures.

WATER QUALITY

Water quality in Big Chico Creek and Lindo Channel has been degraded by cadmium, mercury, and other metals associated with gold mining in the upper watershed. Although, Big Chico Creek currently meets EPA water quality constituent standards, heavy metal contamination may cause decreased survival of developing embryos.

FLOW CONDITIONS

Due to flood control management structures (e.g., Lindo Channel and the Sycamore Creek Bypass Channel) Big Chico Creek lacks the flows necessary to maintain the optimal substrate size distributions for the successful incubation of salmonid embryos. Substrates are often dominated by small gravel, sand, and fine sediments which reduce the interstitial spaces between substrates. Such reductions can result in decreased water flow through redds, leading to low dissolved oxygen concentrations, and poor removal of metabolic wastes. These conditions could reduce embryo growth rates, fitness, and survival. In addition, steelhead embryos are generally less tolerant of fine sediments due to the smaller surface area of the ova.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in Big Chico Creek, downstream of Iron Canyon, are not suitable for salmonids during the summer months. Most juvenile rearing of steelhead occurs in the foothill reaches (Big Chico Creek Watershed Alliance Website 2007).

WATER QUALITY

Water quality in Big Chico Creek and Lindo Channel has been degraded by cadmium, mercury, and other metals associated with gold mining in the upper watershed. The California State University, Chico reported significant concentrations of fecal coliform bacteria during the summer months due to Sycamore pool, which is heavily used swimming hole. Although, Big Chico Creek currently meets EPA water quality constituent standards water quality conditions, particularly during the summer months could lead to decreased juvenile survival.

FLOW CONDITIONS

Flows in Big Chico creek begin to decline in the late-spring and are continuous only in the main channel by summer. The Lindo Channel and Mud Creek channels have only intermittent flow during most years during the summer months (DWR 2005a). As a result of these receding flows there is a potential that juvenile fish emigrating later in the spring may be exposed to sub-optimal water temperatures and stranding due to receding flows in Big Chico Creek and its flood control channels (CDFG 2001a).

Lindo Channel often ceases to flow, sometimes trapping downstream migrants several times during a single season (Ward *et al.* 2004). However, a habitat evaluation of Big Chico Creek, Lindo Channel, and Mud Creek conducted by CDFG in 2001 determined that these waterways provided juvenile steelhead with a variety of habitats with suitable cover, substrates, and water temperatures during the winter and early spring (CDFG 2001a).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Anthropogenic changes in the Big Chico Creek watershed have reduced or degraded riparian habitat. However, some programs are underway to improve riparian habitat by various groups in the area. For example, there has been marked improvement in riparian habitat in Lindo Channel between Manzanita Avenue and Mangrove Avenue (Big Chico Creek Watershed Alliance Website 2007).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Some of the valley reaches in Lindo Channel, Mud and Rock creeks that are maintained for flood control, lack sufficient vegetation to maintain stream structure (Big Chico Creek Watershed Alliance Website 2007).

LOSS OF FLOODPLAIN HABITAT

Flows in Big Chico Creek, as it emerges onto the Chico Fan at the Five-Mile Recreation area are regulated for flood control by diversion of flows into two bypass channels: Lindo Channel and the Sycamore Creek Bypass Channel. This has resulted in a disconnection of the river to its normal floodplain and likely results in less habitat diversity in the lower reaches of Big Chico Creek (Big Chico Creek Watershed Alliance Website 2007).

ENTRAINMENT

Entrainment and/or impingement of juvenile fish at the various flood control structures and diversions in Big Chico Creek could potentially cause physical harm to rearing and emigrating juveniles during high flows in the winter and early spring. As a result these structures constitute a chronic threat to the juvenile steelhead rearing and emigration life stages.

PREDATION

The extent of predation on juvenile steelhead in the Big Chico Creek is not well documented, however, several known predators of juvenile salmonids are found in the Big Chico Creek. Smallmouth bass are abundant in the valley zone of Big Chico Creek. Smallmouth bass are particularly abundant in dry years while in wet years, high flows typically scour the fish from streams (Big Chico Creek Watershed Alliance Website 2007). Big Chico Creek also supports a population of brown trout which are a known piscivorous species (Big Chico Creek Watershed Alliance Website 2007). Sacramento pikeminnow, which is a native species known to prey on juvenile salmonids is also present in Big Chico Creek. The presence of manmade instream structures may confer an advantage to pikeminnow altering the natural predator-prey dynamics of the two species.

HATCHERY EFFECTS

There are likely no direct effects on juvenile salmonids in Big Chico Creek presented by hatcheries.

4.3.8.9 DEER CREEK

Deer Creek is part of the lower Cascade Mountain Range and drains an area of approximately 229 square miles. Deer Creek meets the Sacramento River near the town of Vina at RM 230.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The first natural barrier in the stream is a falls about nine miles upstream of Polk Springs and approximately 40 miles from the mouth. This falls is about 16 feet high, and salmon had never been known to pass beyond it until a fish ladder was constructed in 1943. There is a second falls on Deer Creek about ten miles upstream of the falls near Polk Springs. This falls is a sheer drop of about 20 feet. A fish ladder was also constructed at this barrier in early 1950s, and is only functioning during the time steelhead would be migrating upstream (Deer Creek Conservancy Website 2007). The ladder is closed during the time when spring-run Chinook salmon would be migrating upstream because very little holding habitat exists above this point.

There are also diversion dams on Deer Creek that can provide passage impediments to adult steelhead during low flows. All of the diversion structures have CDFG designed and operated fish ladders and screens (Deer Creek Conservancy Website 2007).

HARVEST/ANGLING IMPACTS

Recreational angling on Deer Creek is restricted to catch-and-release only. Additionally, the fishery is closed from November 15 through the end of April which coincides with peak steelhead immigration timing.

WATER TEMPERATURE

Water temperatures in Deer Creek during the late-fall and winter time period are low enough to adequately support steelhead adult immigration.

WATER QUALITY

Water quality monitoring in Deer Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy Website 2007; DWR 2005a). Deer Creek currently meets EPA water quality standards.

FLOW CONDITIONS

Steelhead begin migration into Deer Creek during the late-fall and winter, primarily when flows increase from storms. Because there are no large storage facilities on Deer Creek, winter flows tend to mimic historic natural conditions.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

There are no significant barriers to upstream migration within the reach of Deer Creek upstream from Dillon Cove in the lower canyon reach to upper Deer Creek Falls where most steelhead spawning occurs.

HARVEST/ANGLING IMPACTS

Deer Creek is closed to fishing during the winter months when steelhead would be spawning.

WATER TEMPERATURE

Water temperatures during the winter months when steelhead would be spawning are sufficiently low to support this life stage.

WATER QUALITY

Water quality in Deer Creek is adequate to support steelhead spawning.

FLOW CONDITIONS

There has been no salmonid flow habitat relationships developed for salmonids in Deer Creek. Because there are no major storage facilities on Deer Creek, winter flow patterns in the area where steelhead spawning occurs, mimic natural patterns.

SPAWNING HABITAT AVAILABILITY

Steelhead habitat in the upper watershed is considered to be excellent with an abundance of spawning gravel (DWR 2005a; USFWS 1999). Flood protection, cattle grazing and water diversions have had a negative effect on habitat in the lower watershed. Stream channelization has reduced the opportunities for gravel deposition. Gravels that might have been deposited are likely to be washed downstream during high flow events because of the increased shear stress produced in these straightened reaches (DWR 2005a; USFWS 1999).

PHYSICAL HABITAT ALTERATION

While habitat in the upper watershed is relatively pristine, channelization has occurred in the lower watershed reducing opportunities for natural deposition of spawning gravel. Additionally, water diversions have led to low-flow conditions which can effect habitat availability (DWR 2005a; USFWS 1999).

HATCHERY EFFECTS

Deer Creek is likely supporting a small self-sustaining population of steelhead. However, because significant numbers of steelhead are produced by hatcheries in the Central Valley, it is likely that hatchery fish occasionally stray into Deer Creek.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Deer Creek is closed to fishing during most of the embryo incubation life stage, therefore disturbance of redds by wading anglers should be minimal.

WATER TEMPERATURE

Water temperatures in Deer Creek, when embryos are incubating, are suitable for this life stage.

WATER QUALITY

Water quality monitoring in Deer Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy

Website 2007; DWR 2005a). Deer Creek currently meets EPA water quality standards and should not present problems to developing embryos.

FLOW CONDITIONS

There are no significant water diversions in the upstream reaches (i.e., primary spawning habitat) of Deer Creek that could result in unnatural flow fluctuations that could cause redd dewatering events.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures throughout the Deer Creek watershed are suitable for juvenile steelhead rearing except for the summer months when temperatures in the lower watershed become too high to support juvenile steelhead rearing. Cold water refugia are likely available during the summer months in the upper watershed.

WATER QUALITY

Deer Creek currently meets EPA water quality standards and should not present problems to juvenile steelhead.

FLOW CONDITIONS

The explicit time period when juvenile steelhead emigrate from Deer Creek is not known. However, it is likely that it occurs from October through May as seasonal flows increase. The extent to which flow fluctuations from water diversions in Deer Creek may cause juvenile stranding is currently unknown.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Recent studies have concluded that aquatic habitat in Deer Creek is limited by the current flood control project. Effects of the flood control project include lack of habitat diversity and riparian vegetation due to channel maintenance and clearing (MacWilliams *et al.* 2004)

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Flood control activities such as stream channelization and clearing have led to a lack of habitat diversity by constraining high flow and flood events between the levees (MacWilliams *et al.* 2004).

LOSS OF FLOODPLAIN HABITAT

The Deer Creek Flood Control Project was completed by the USACE in 1953. About 16 km of levees were built along lower Deer Creek to control flooding and the channel was straightened and cleared. As a result of this work, natural geomorphic processes were disrupted and the riparian zone was limited to a small band within the constructed levees effectively severing the connection between Deer Creek and the floodplain (MacWilliams *et al.* 2004).

ENTRAINMENT

Entrainment of juvenile steelhead in Deer Creek is assumed to be low because the three water diversions from Deer Creek have fish screens that comply with CDFG fish screen design criteria. These screens are operated, maintained and monitored by CDFG.

PREDATION

Green sunfish, largemouth and smallmouth bass, striped bass and American shad are all piscivorous species that have been introduced to the Sacramento watershed. It is likely that sunfish and bass species both occur in Deer Creek and the loss of natural stream function associated with flood control measures likely enhances predation opportunities, particularly in the lower reaches of the stream.

HATCHERY EFFECTS

There are likely no direct effects of hatchery operations on juvenile steelhead in Deer Creek.

4.3.8.10 MILL CREEK

Mill Creek is an eastside tributary to the Sacramento River that flows in a southwesterly direction for approximately 60 miles and drains 134 square miles. The creek originates near a thermal spring area in Lassen Volcanic National Park at an elevation of approximately 8,200 feet. It initially flows through meadows and dense forests and then descends rapidly through a steep rock canyon into the Sacramento Valley. Upon emerging from the canyon, the creek flows 8 miles across the Sacramento Valley floor, entering the Sacramento River about 1 mile north of the town of Tehama, near Los Molinos, at an elevation of approximately 200 feet.

The Revised Draft AFRP identifies Mill Creek as one of the high priority tributaries to the upper Sacramento River, particularly for its populations of spring-run Chinook salmon and steelhead.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Prior to 1997, Clough Dam created a partial barrier to upstream migration in Mill Creek and was utilized as a counting station. In 1997, a flood breached Clough Dam allowing unimpaired access to the Mill Creek watershed (CDFG 1999b).

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Mill Creek. For purposes of fishing regulations, the creek is divided into two reaches. From the Lassen National Park boundary downstream to the USGS gaging station at the mouth of Mill Creek Canyon, fishing with barbless hooks and artificial lures is allowed from the last Saturday in April through November 15. From that point downstream to the mouth, fishing is allowed from June 16 through September 30. Therefore, some migrating steelhead could be affected by the recreational fishery.

WATER TEMPERATURE

Water temperatures are suitable during the late fall and winter months to support steelhead immigration.

WATER QUALITY

Water quality in Mill Creek is adequate to support steelhead adult immigration.

FLOW CONDITIONS

There are no major water storage facilities on Mill Creek and water diversions are not occurring during the time adult steelhead are immigrating to the Mill Creek watershed. Therefore, flows during the adult immigration life stage tend to mimic historic conditions that occurred under natural flow regimes.

SPAWNING

In Mill Creek, steelhead spawning occurs from approximately the Lassen National Park Boundary downstream to the Little Mill Creek confluence (SRCS Report 1997).

PASSAGE IMPEDIMENTS/BARRIERS

There are no known passage impediments for steelhead within the area used for spawning.

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Mill Creek. For purposes of fishing regulations, the creek is divided into two reaches. From the Lassen National Park boundary downstream to the USGS gaging station at the mouth of Mill Creek Canyon, fishing with barbless hooks and artificial lures is allowed from the last Saturday in April through November 15. From that point downstream to the mouth, fishing is allowed from June 16 through September 30. Under existing regulations, spawning steelhead are not likely to be affected by the recreational fishery.

WATER TEMPERATURE

Water temperatures in the upper reaches of Mill Creek during the steelhead spawning period are adequate to support steelhead spawning.

WATER QUALITY

Water quality in Mill Creek is suitable for steelhead spawning.

FLOW CONDITIONS

There have been no flow habitat relationships developed for salmonids in Mill Creek. Because there are no major water storage facilities on Mill Creek and diversions are not occurring during the steelhead spawning season, flows likely mimic natural conditions.

SPAWNING HABITAT AVAILABILITY

The upper reaches of Mill Creek located above diversion dams reportedly provide excellent salmonid spawning habitat (DWR 2005a). Approximately 48 miles of potential spawning habitat exists from the confluence of Little Mill Creek upstream to Morgan Hot Springs (Klamath Resources Information Website 2007).

PHYSICAL HABITAT ALTERATION

The Mill Creek watershed is relatively long and narrow, with steep slopes. Steep slopes adjacent to the main channel have served as barriers to activity and land use allocations have protected these areas such that the mainstem of the stream is essentially undisturbed (CDFG 1999b).

HATCHERY EFFECTS

Steelhead are produced at the CNFH and the current steelhead population in Mill Creek may be augmented by hatchery strays.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Recreational fishing in Mill Creek is not permitted during most of the steelhead embryo incubation life stage.

WATER TEMPERATURE

Salmonid redds are located in the upstream reaches of Mill Creek which are generally characterized as having favorable water temperatures during the majority of the embryo incubation period.

WATER QUALITY

Water quality monitoring in Mill Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum and copper have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy Website 2007; DWR 2005a). Erosion from recent volcanic deposits in and near Lassen Volcanic National Park, in the headwaters of Mill Creek, contributes turbidity to the stream nearly year-round (CDFG 1999b). Although not known to occur, any of these water quality factors could negatively impact developing steelhead embryos.

FLOW CONDITIONS

Flow conditions in the upstream reaches of Mill Creek are not affected by water diversions. As a result, any changes in flow that could potentially result in decreased oxygen flow, or redd dewatering events would be due to natural fluctuations in streamflow.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Mill Creek reportedly provides relatively good habitat for juvenile salmonids (DWR 2005a). Water temperatures within the upper watershed are likely suitable for juvenile steelhead rearing year-round. During summer months, water temperatures in the lower reaches of Mill Creek may become too warm to support steelhead rearing.

WATER QUALITY

Water quality monitoring in Mill Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum and copper have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy Website 2007; DWR 2005a). Erosion from recent volcanic deposits in and near Lassen Volcanic National Park, in the headwaters of Mill Creek, contributes turbidity to the stream nearly year-round (CDFG 1999b). Although not reported to have occurred, any of these factors could adversely affect juvenile steelhead.

FLOW CONDITIONS

The extent to which flow fluctuations from water diversions in Mill Creek may affect juvenile salmonid habitat availability and cause juvenile stranding is currently unknown.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The Mill Creek watershed is relatively long and narrow, with steep slopes. Steep slopes adjacent to the main channel have served as barriers to activity and land use allocations have protected these areas such that the mainstem of the stream is essentially undisturbed (CDFG 1999b).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Because the Mill Creek watershed is relatively long and narrow, with steep slopes, little natural river function has been lost

LOSS OF FLOODPLAIN HABITAT

Because Mill Creek is a relatively narrow watershed with steep slopes, there is little natural connection with the floodplain. However, in the lower 8-miles of Mill Creek the creek does connect with the floodplain under high flows.

ENTRAINMENT

In Mill Creek, fish screens have been in place at all diversions, although some mortality of juvenile salmonids is still reported to occur (Klamath Resource Information System Website 2007).

PREDATION

Smallmouth bass, brown trout and green sunfish are all non-native predators known to exist in Mill Creek. The extent of predation that occurs on juvenile steelhead is unknown.

HATCHERY EFFECTS

Hatchery operations within the Central Valley likely have no effect on juvenile steelhead in Mill Creek.

4.3.8.11 ANTELOPE CREEK

Antelope Creek flows southwest from the foothills of the Cascade Range entering the Sacramento River nine miles southeast of the town of Red Bluff. The drainage is approximately 123 square miles and the average stream discharge is 107,200 acre-feet per year.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Though there are diversion structures in the valley sections of Antelope Creek, there are no major impoundments. Anadromous fish (spring- and fall-run Chinook salmon and steelhead) have been able to maintain passage to the upper watershed (Klamath Resource Information System Website 2007).

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Antelope Creek. For purposes of fishing regulations, the creek is divided into two reaches. From the confluence with the north fork downstream to the USGS gaging station at the mouth of Antelope Creek Canyon, fishing with barbless hooks and artificial lures is allowed from the last Saturday in April through November 15. From that point downstream to the mouth, fishing is allowed from June 16 through September 30. Therefore, the recreational fishery is closed for most of the steelhead adult immigration life stage.

WATER TEMPERATURE

Water temperatures in Antelope Creek are adequate to support adult steelhead immigration during the late fall and winter months.

WATER QUALITY

Water quality in Antelope Creek is sufficient to support adult steelhead immigration.

FLOW CONDITIONS

Because there are no major water storage facilities on Antelope Creek and water diversions normally occur during the late spring and summer months, flows in Antelope Creek during the steelhead immigration time period mimic those of historic conditions.

SPAWNING

Based on reported observations of spring-run Chinook salmon spawning, the potential range and distribution for steelhead spawning is equal to approximately 9 miles, and extends from approximately 1.6 miles downstream of the Paynes Creek crossing upstream to near McClure Place on the North Fork, and to Bucks Flat on the South Fork (Klamath Resource Information System Website 2007). However, as previously noted the actual range of steelhead may exceed that of spring-run Chinook due to their smaller size (i.e., ability to navigate instream obstructions and utilize reaches with decreased channel widths).

PASSAGE IMPEDIMENTS/BARRIERS

There are no known passage impediments affecting steelhead spawning.

HARVEST/ANGLING IMPACTS

Recreational fishing is not permitted during the steelhead spawning period.

WATER TEMPERATURE

Water temperatures in the upper reaches of Antelope Creek, where documented steelhead spawning occurs, are sufficiently cold to support steelhead spawning.

WATER QUALITY

Water quality in Antelope Creek is adequate to support steelhead spawning.

FLOW CONDITIONS

Flows in the upper Antelope Creek watershed are unregulated and are not affected during the steelhead spawning period. There have been no flow-habitat relationships developed for salmonids in Antelope Creek.

SPAWNING HABITAT AVAILABILITY

Vanicek (Vanicek 1993) rated spawning habitat as fair to poor in Antelope Creek. There have been no flow habitat relationships developed for Antelope Creek.

PHYSICAL HABITAT ALTERATION

The Antelope Creek watershed is relatively long and narrow with steep slopes. Steep slopes adjacent to the main channel have served as a barrier to human activity and the environment is essentially undisturbed (Klamath Resource Information System Website 2007).

HATCHERY EFFECTS

The last report of hatchery steelhead stocking in Antelope Creek occurred in 1980 (Klamath Resource Information System Website 2007). The current population may occasionally be augmented by hatchery strays.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Recreational fishing in Antelope Creek is not permitted for most of the time when steelhead embryos would be developing in redds.

WATER TEMPERATURE

Water temperatures in Antelope Creek during the winter and early spring months when steelhead embryos are developing are sufficiently cool.

WATER QUALITY

Although little water quality information on Antelope Creek is available, because Antelope Creek habitat in the upstream watershed is basically undisturbed, water quality in the upstream reaches likely have no adverse effects on embryo incubation.

FLOW CONDITIONS

Flow conditions on Antelope Creek during the steelhead embryo incubation period are unaffected by diversions or storage impoundments and are the same as under historic natural conditions.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures within the upper watershed are likely suitable for juvenile steelhead rearing year-round. During summer months, water temperatures in the lower reaches of Mill Creek may become too warm to support steelhead rearing.

WATER QUALITY

Although little water quality information on Antelope Creek is available, because Antelope Creek habitat in the upstream watershed is basically undisturbed, water quality in the upstream reaches likely have no adverse effects on juvenile salmonids.

FLOW CONDITIONS

The downstream migration of juvenile steelhead likely occurs concurrently with peak flows from January through March. The extent to which flow fluctuations from water diversions in Antelope Creek may affect juvenile salmonid habitat availability and cause juvenile stranding is currently unknown. However, there are two diversions in Antelope Creek at the canyon mouth. One is operated by the Edwards Ranch, which has water rights of 50 cfs, and the other by the Los Molinos Water Company which has a water right of 70 cfs. Flows are diverted between April 1 and October 31. The stream is usually dewatered when both diversions operate (Klamath Resource Information System Website 2007).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The Antelope Creek watershed is relatively long and narrow with steep slopes. Steep slopes adjacent to the main channel have served as a barrier to human activity and the environment is essentially undisturbed (Klamath Resource Information System Website 2007).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Because the Antelope Creek watershed is relatively long and narrow, with steep slopes, little natural river function has been lost.

LOSS OF FLOODPLAIN HABITAT

Because Mill Creek is a relatively narrow watershed with steep slopes, there is little natural connection with the floodplain.

ENTRAINMENT

The Antelope Main canal could potentially cause entrainment or impingement of juvenile steelhead. It is unknown how many diversions associated with this canal are equipped with fish screens that meet NMFS and CDFG juvenile fish screen criteria.

PREDATION

Smallmouth bass, brown trout and green sunfish are all non-native predators known to exist in Antelope Creek. The extent of predation that occurs on juvenile steelhead is unknown.

HATCHERY EFFECTS

Central Valley hatchery operations likely do not directly affect juvenile steelhead in Antelope Creek.

4.3.9 BASALT AND POROUS LAVA DIVERSITY GROUP

4.3.9.1 BATTLE CREEK

Battle Creek enters the Sacramento River approximately five miles southeast of the Shasta County town of Cottonwood. It flows into the Sacramento Valley from the east, draining a watershed of approximately 360 square miles.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The mainstem of Battle Creek has three structures that act as potential impediments to adult anadromous fish migration: (1) the CNFH barrier weir that diverts returning hatchery fish into the hatchery for brood stock collection each year from September through early March; (2) the Orwick seasonal gravel diversion dam; and (3) the tailrace from PG&E's Coleman Powerhouse, which had been known to attract steelhead into an area with little spawning habitat, but has currently been improved by the construction of a fish exclusion weir in 2004.

Natural-origin adult steelhead comprise 10 percent of the broodstock for the steelhead artificial propagation program at CNFH. Steelhead produced at the CNFH are part of the Central Valley steelhead DPS. As of 2005, only natural steelhead (non-clipped) adults are intentionally bypassed into upper Battle Creek as part of the Battle Creek Restoration Project (**Table 4-2**). Based upon parental genotyping, the progeny of bypassed natural steelhead have shown a statistically significant higher adult return rate than that of bypassed hatchery steelhead stock, within one generation (K. Niemela, USFWS, pers. comm.).

HARVEST/ANGLING IMPACTS

Battle Creek supports a popular recreational fishery (e.g., fall-run Chinook salmon, steelhead). As a result, some level of poaching likely occurs. Current fishing regulations do not allow any fishing from the mouth of Battle Creek to 250 feet upstream of the weir at the CNFH. Upstream of that point, catch and release fishing with artificial lures and barbless hooks is allowed from the last Saturday in April to November 15. These regulations likely limit potential adverse effects on immigrating adult steelhead.

Table 4-2. Steelhead Passage Above Coleman National Fish Hatchery Barrier Weir, 2001-2006.

Methodology		2001	2002	2003	2004	2005	2006
Weir Trap	Non-clipped	61	103	62	62	44	126
	Clipped	25	13	1	7	0	0
Video	Non-clipped	33	80	56	63	30	63

Bypassed	Non-clipped	225	420	546	304	344	431
	Clipped	1,382	1,643	772	329	0	2
Total Bypassed		1,607	2,063	1,318	633	344	433

Source: Newton *et al.* 2007; and Alston *et al.* 2007;

WATER TEMPERATURE

Water temperatures in Battle Creek during the late fall and winter months are suitable for adult steelhead immigration.

WATER QUALITY

Little information on water quality in Battle Creek is available. However, it is assumed to be quite good as Battle Creek also provides water to the CNFH.

FLOW CONDITIONS

Two studies were conducted to determine the flows necessary to facilitate fish passage within the Battle Creek watershed (Kier and Assoc 1999). The results of these two studies were used to

develop instream flow alternatives for the *Battle Creek Salmon and Steelhead Restoration Project* (SDEIR 2005).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Prime quality spawning, holding, and rearing habitat for steelhead, winter-run, and spring-run Chinook is upstream of Wildcat and Coleman dams on the north and south forks of Battle Creek, respectively.

HARVEST/ANGLING IMPACTS

Battle Creek is closed year-round from the mouth to the CNFH. 250 feet upstream of that point, catch and release fishing with artificial lures and barbless hooks is allowed from the last Saturday in April to November 15. These regulations basically serve to close the recreational fishery during the steelhead spawning period.

WATER TEMPERATURE

Water temperatures in Battle Creek have not been explicitly evaluated for the steelhead life stage given that the majority of steelhead returning to Battle Creek are of hatchery-origin. However, water temperatures in Battle Creek during the late-fall and spring are likely suitable for adult steelhead spawning.

WATER QUALITY

Little information on water quality in Battle Creek is available. However, it is assumed to be quite good as Battle Creek also provides water to the CNFH.

FLOW CONDITIONS

There have been no flow habitat relationships developed for steelhead in Battle Creek. However, protective flow regulations exist to protect steelhead spawning.

SPAWNING HABITAT AVAILABILITY

Brown and Kimmerer (Brown and Kimmerer 2004) report that areas suitable for salmonid spawning – based on substrate particle size – are relatively scarce. However, they also report that in-river conditions are likely not a limiting factor due to the current low population numbers of targeted species.

PHYSICAL HABITAT ALTERATION

Stream channel conditions in Battle Creek during the late 20th century have been considered suitable for salmonid production. Key stream habitat conditions appear to be of sufficient quality such that the abundance of threatened or endangered salmonid populations could be increased by increasing instream flows and constructing fish passage facilities at the Battle Creek Hydroelectric Project diversion dams. Land management activities currently occurring in the watershed appear to have little impact on the potential to restore anadromous salmonids to this watershed (Battle Creek Watershed Conservancy 2004).

HATCHERY EFFECTS

A technical review panel determined that CNFH may pose a significant risk to steelhead recovery in Battle Creek through increased adverse effects of interbreeding as well as increased pathogen exposure (CALFED Bay-Delta Program 2004). The effects of interbreeding may include a reduction in productivity and viability of the wild stock (CALFED Bay-Delta Program 2004). The Battle Creek technical review team also identified several ecological risks to wild steelhead associated with CNFH steelhead introduction in Battle Creek, including increased competition and predation, in addition to CNFH operation related risks, including stranding and isolation, as well as screen entrainment. Currently, hatchery production is dominating the Battle Creek system as indicated by the technical review panel findings of approximately 65 percent of the steelhead passing above CNFH are of hatchery-origin (CALFED Bay-Delta Program 2004).

CNFH releases spent hatchery steelhead adults upon completion of the hatchery spawning season; natural steelhead broodstock are released immediately after their utilization as broodstock. The use of kelts for repeat spawning in the hatchery program diversifies the age structure within the stock and population; kelts are more fecund and contribute larger eggs and subsequently, larger fish, to the population.

CNFH steelhead are residualizing in the upper Sacramento River, and may be the dominant component of the Sacramento River population. Effects of integrating the two populations include possible loss of unique genetic complexes and diversity with homogenization of the gene pool, and increased rates of straying between Battle Creek and the upper Sacramento River. The primary source stock of the current Battle Creek steelhead population is the upper Sacramento River population (Nielsen *et al.* 2003), and continuing supplementation by CNFH may counter natural selection in the Sacramento River population.

CNFH has developed a late fall Chinook salmon run to the hatchery for artificial propagation purposes, and may be maintaining this component of the fall/late fall-run ESU to a great extent. Many of the CNFH late fall-run are raised exclusively for monitoring studies. CNFH annually releases 12 million fall-run Chinook salmon juveniles into the upper Sacramento River, with possible consequences of the “pied piper” effect and habitat/prey competition with natural salmonids in the system. CNFH fall-run exhibit a high degree of homing back to Battle Creek.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Currently, recreational fishing during most of the time period when steelhead embryos are developing is not allowed.

WATER TEMPERATURE

Water temperatures in the upper stream reaches of Battle Creek when the majority of steelhead spawning period are reportedly excellent for all life stages (DWR 2005a).

WATER QUALITY

Little information on water quality in Battle Creek is available. However, it is assumed to be quite good as Battle Creek also provides water to the CNFH.

FLOW CONDITIONS

The operations of the Battle Creek Hydroelectric Project causes water level changes in some reaches of Battle Creek that are more frequent and rapid than those which occur naturally. The effects of these flow changes on steelhead redds have not been the direct focus of any study to date. As part of the Battle Creek Salmon and Steelhead Restoration Project, PG&E in cooperation with the resource agencies, has agreed to adaptively manage instream flows in Battle Creek by adjusting flows at diversion dams to prevent redd dewatering events (Reclamation *et al.* 2004).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperature problems may occur during some years due to the diversion of coldwater springs into canals away from adjacent stream channels on the North Fork and South Fork of Battle Creek. However, it is unknown the degree to which these operations would potentially affect the steelhead the juvenile rearing and outmigration life stages (Reclamation *et al.* 2004).

WATER QUALITY

Little information on water quality in Battle Creek is available. However, it is assumed to be quite good as Battle Creek also provides water to the CNFH.

FLOW CONDITIONS

Powerhouse operations cause flow fluctuations of up to 200 cfs in some reaches of the Battle Creek watershed which could potentially lead to juvenile stranding events. It has been estimated that powerhouse diversions on the North Fork and South Fork of Battle Creek divert up to 97 percent of the natural unimpaired flow (Reclamation *et al.* 2004).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Land management activities currently occurring in the watershed appear to have little impact on the potential to restore anadromous salmonids to this watershed (Battle Creek Watershed Conservancy 2004). Restoration of riparian corridors in lower Battle Creek are currently underway (Battle Creek Working Group 1999).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Stream channel conditions (e.g., gravel distribution and abundance, sedimentation, channel morphology) in Battle Creek are considered to be suitable for salmonid production (Battle Creek Watershed Conservancy 2004). Similarly, land management activities in the watershed are assumed to have little impact on the potential to restore anadromous salmonids to the system (Battle Creek Watershed Conservancy 2004).

LOSS OF FLOODPLAIN HABITAT

Flood control measures have resulted in less frequent high flow events and resulted in a loss of connectivity with the river and historic floodplain.

ENTRAINMENT

The high volume of surface water diverted from unscreened agricultural and hydroelectric diversions in Battle Creek constitutes a substantial threat to rearing and emigrating juvenile salmonids. However, it is anticipated the installation of positive fish barrier screens in the near future as part of the proposed water management strategy for the Battle Creek watershed will reduce the amount of juvenile entrainment at water diversions (Reclamation *et al.* 2004).

PREDATION

USFWS has identified predation as one of the ways that juvenile salmonids released from the CNFH may affect natural populations of salmonids (Battle Creek Working Group 1999). However, the actual extent of predation on natural populations by steelhead and Chinook salmon on natural populations is not known (Battle Creek Working Group 1999).

HATCHERY EFFECTS

USFWS has expressed concern that predation, disease transmission and competition/displacement are ways in which juvenile salmonids released from the CNFH may affect natural salmonid populations (Battle Creek Working Group 1999). The actual extent of these potential impacts is not known, although there is speculation that these factors are minimal or non-existent (Battle Creek Working Group 1999). However, these conclusions were not based on completed investigations. Furthermore, these conclusions that suggest minimal impact were derived during a period when Chinook salmon and steelhead populations were depressed. As restoration of Battle Creek salmonid populations proceed, increased interactions between hatchery operations and natural fish populations are expected, suggesting that more investigations of possible impacts are required (Battle Creek Working Group 1999).

4.3.9.2 COW CREEK

The Cow Creek watershed encompasses approximately 430 square miles and drains the base and foothills of Mt. Lassen. Cow Creek joins the Sacramento River 23 miles downstream of Shasta Dam.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Natural barriers restrict anadromous salmonids to the low elevation portions of the Cow Creek Basin. These barriers (waterfalls) occur on all five of the main Cow Creek tributaries (Hannaford 2000). Agricultural diversions likely present partial barriers to upstream migration during low flows.

HARVEST/ANGLING IMPACTS

Recreational catch-and-release fishing is permitted in Cow Creek from the last Saturday in April through November 15. These regulations are protective of immigrating adult steelhead in that the fishery is closed during the time of peak immigration.

WATER TEMPERATURE

Water temperatures in the mainstem of Cow Creek generally fall below 60°F in the beginning of October and are likely suitable for immigrating adult steelhead (Hannaford 2000).

WATER QUALITY

Water quality in Cow Creek is generally good. Dissolved oxygen concentrations are normally near saturation. Hannaford (2000) found high fecal coliform concentrations in three of nine sites sampled in the Cow Creek Basin. Samples taken near the Afterthought Mine on Little Cow Creek have shown high concentrations of heavy metals but these concentrations appear to be quickly diluted downstream on Little Cow Creek (Hannaford 2000) and should not adversely affect adult steelhead.

FLOW CONDITIONS

Flows in the Cow Creek watershed are not controlled, yet is heavily diverted and likely does not mimic historic conditions during the steelhead adult immigration period.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Natural barriers restrict anadromous salmonids to the low elevation portions of the Cow Creek Basin. These barriers (waterfalls) occur on all five of the main Cow Creek tributaries (Hannaford 2000).

HARVEST/ANGLING IMPACTS

Recreational catch-and-release fishing is permitted in Cow Creek from the last Saturday in April through November 15. The fishery is closed during the time that steelhead would be spawning.

WATER TEMPERATURE

Water temperatures in Cow Creek are generally below 55°F from December through March and are suitable for steelhead spawning (Hannaford 2000).

WATER QUALITY

Water quality in Cow Creek is generally good and should not adversely affect steelhead spawning.

FLOW CONDITIONS

Flows in the Cow Creek watershed are not controlled and mimic historic conditions during most of the steelhead spawning period.

SPAWNING HABITAT AVAILABILITY

Steelhead populations have not been estimated in Cow Creek. No specific studies have been conducted on Cow Creek to estimate the size of the steelhead spawning run, although CDFG (1965) estimated that Cow Creek supported annual spawning runs of 500 steelhead (current estimates would be much lower). Adult steelhead have been observed in North Cow, Old Cow and South Cow creeks; however, it is unknown what percentage of the steelhead run utilizes the other tributaries. Most steelhead spawning in South Cow Creek probably occurs above South Cow Creek diversion. The best spawning habitat occurs in the 5-mile reach of stream extending from about 1.5 miles below South Cow Creek Diversion Dam to 3.5 miles above the diversion dam. Additional spawning habitat occurs upstream of this reach, but it is much less abundant. Sightings of adult steelhead have been made at the South Cow Creek Campground

(approximately 8.5 miles upstream of the South Cow Creek Diversion Dam) and in Atkins Creek, located just upstream from the campground (SHN 2001).

The *Working Paper on Restoration Needs*, compiled by the AFRP Core Group in 1995, identified Cow Creek and its tributaries as in “relatively good condition” related to salmon and steelhead spawning habitat (SHN 2001).

PHYSICAL HABITAT ALTERATION

Substrate composition is a critical factor in spawning suitability. It is vitally important that spawning gravels percolate to deliver fresh oxygen to the eggs and developing embryos. Fine sediment reduces oxygen flow; therefore, adequate substrate crust has low proportions of sand and fine sediment. Water quality in Cow Creek has been significantly affected by siltation and erosion in the upper watershed. Stream banks have been eroded by excessive livestock grazing along Cow Creek and its principal tributaries. The resulting soil erosion and stream channel siltation have degraded salmon and steelhead spawning substrate in Cow Creek and its tributaries (SHN 2001).

HATCHERY EFFECTS

The extent of hatchery fish interaction with wild steelhead that may be present in Cow Creek is unknown. However, because of the proximity of the CNFH to Cow Creek, some interaction is likely.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Recreational fishing is permitted in Cow Creek from the last Saturday in April through November 15. This schedule is protective of steelhead embryos as most embryo development would occur while the fishery is closed.

WATER TEMPERATURE

Water temperatures in Cow Creek are generally below 55°F from December through March and are suitable for steelhead embryo incubation, but warm rapidly in April and are likely marginal for this life stage (Hannaford 2000).

WATER QUALITY

Water quality in Cow Creek is generally good. Dissolved oxygen concentrations are normally near saturation. Hannaford (2000) found high fecal coliform concentrations in three of nine sites sampled in the Cow Creek Basin. Samples taken near the Afterthought Mine on Little Cow Creek have shown high concentrations of heavy metals but these concentrations appear to be quickly diluted downstream on Little Cow Creek (Hannaford 2000).

FLOW CONDITIONS

Flows in the Cow Creek watershed are not controlled and mimic historic conditions during most of the steelhead embryo incubation period. Once irrigation season begins, typically in April, flows may be somewhat diminished by water diversions.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in Cow Creek may warm to above 77°F from June through September which may be lethal to juvenile steelhead that cannot find coldwater refuge (Hannaford 2000).

WATER QUALITY

Water quality in Cow Creek is generally good. Dissolved oxygen concentrations are normally near saturation. Hannaford (2000) found high fecal coliform concentrations in three of nine sites sampled in the Cow Creek Basin. Samples taken near the Afterthought Mine on Little Cow Creek have shown high concentrations of heavy metals but these concentrations appear to be quickly diluted downstream on Little Cow Creek (Hannaford 2000).

FLOW CONDITIONS

Although flows in the Cow Creek watershed are not controlled, in that there are no major storage facilities, diversions during the irrigation season diminish flows and likely lead to increased water temperatures (Western Shasta Resource Conservation District and Cow Creek Watershed Management Group 2001).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Extensive livestock grazing in the Cow Creek watershed has resulted in significant loss of riparian habitat and instream cover (Western Shasta Resource Conservation District and Cow Creek Watershed Management Group 2001). No detailed riparian inventory or damage assessment has been conducted in the watershed.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Because flows in Cow Creek have not been constrained and basically mimic historic conditions, there has been little loss of natural river morphology and function.

ENTRAINMENT

Habitat surveys conducted by CDFG identified 14 unscreened permanent and temporary water diversions in the reaches of the main stem of Cow Creek (Hannaford 2000). Water diversions normally extend from April through October, during which time juvenile steelhead may become entrained in the unscreened diversions.

A loss of juvenile migrating fish to water diversions and entrainment of juvenile salmon and steelhead is assumed to occur in Cow Creek and the tributaries. Only the PG&E diversions have fish screens that comply with CDFG fish screen design criteria (Western Shasta Resource Conservation District and Cow Creek Watershed Management Group 2001).

PREDATION

Largemouth and smallmouth bass have been identified in Cow Creek (Thompson *et al.* 2006). Both of these species likely prey on juvenile steelhead. Additionally, brown trout were introduced to Cow Creek in 1931 (Western Shasta Resource Conservation District and Cow Creek Watershed Management Group 2001) and a self-sustaining population now exists. Brown trout are also a likely predator on juvenile salmonids.

HATCHERY EFFECTS

From 1991 to present, North Cow, Clover, Old Cow and South Cow creeks have been planted with a total of 49,492 catchable rainbow trout. Darrah Springs Hatchery also planted Eagle Lake trout in Clover Creek in the early 1990s. The CNFH planted steelhead in North Cow, Old Cow, and South Cow creeks, as well as the mainstem of Cow Creek. Buckhorn Lake and Kilarc Reservoir are also planted twice a year with catchable trout for sportfishing purposes (Western Shasta Resource Conservation District and Cow Creek Watershed Management Group 2001). These planted species may be significant predators on naturally spawned salmonids in Cow Creek.

4.3.9.3 UPPER SACRAMENTO RIVER TRIBUTARIES¹⁰

Steelhead utilization of upper Sacramento River tributaries including Stillwater, Churn, Sulphur, Olney and Paynes creeks is not well documented. However, it is likely that those same factors that may affect steelhead in the upper Sacramento River as discussed in Section 4.3.7 would apply to these fish.

Extensive mining, road building, railroad construction and sewer line construction in the Sulphur Creek watershed has resulted in large bedload, extreme bank erosion and loss of riparian vegetation, however, Sulphur Creek reportedly supports anadromous salmonids, including steelhead (Sacramento Watersheds Action Group 1998). The Churn Creek watershed reportedly exhibited high rates of erosion and subsequent sedimentation, loss of riparian vegetation and chemical and nutrient water pollution in the early 1990s (Churn Creek Task Force 1991). Extensive spawning by Chinook salmon and large rainbow trout/steelhead has been noted on Salt Creek below Highway 299; however, there is no evidence of identified steelhead in Salt Creek (Vestra Resources, Inc. 2005). Spawning Chinook salmon and steelhead have been documented in Olney Creek (Vestra Resources, Inc. 2005). Suitable spawning gravel has been identified up to approximately four miles upstream of the mouth of Olney Creek (Vestra Resources, Inc. 2005).

4.3.10 NORTHWESTERN CALIFORNIA DIVERSITY GROUP

4.3.10.1 STONY CREEK

Stony Creek is a westside stream originating in the Coast Range and draining into the Sacramento River south of Hamilton City. There are three storage reservoirs in the watershed. The lowermost dam, Black Butte, is a barrier to anadromous fish. The GCID canal crosses Stony Creek downstream of Black Butte Dam and consists of a seasonal gravel dam constructed across the creek on the downstream side of the canal. This crossing not only allows the canal to

¹⁰ This population includes steelhead utilizing the small tributaries in the Redding area including Stillwater, Churn, Sulphur, Salt, Olney, and Paynes creeks.

continue flowing south but it also allows capture of Stony Creek water and is a complete barrier to salmon migration. The GCID berm was removed in 1999. Although steelhead spawning has not been documented in Stony Creek in recent years, there is now access to suitable spawning habitat for steelhead in the creek, following the removal of the GCID berm, and it is reasonable to assume that water management can and will have an effect on steelhead numbers, distribution and reproduction in Stony Creek (NMFS 2002b).

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

From the confluence with the Sacramento River, Stony Creek extends 24.6 miles upstream to Black Butte Lake, impounded by the Black Butte Dam. Black Butte Dam presents an impassable barrier to anadromous fish migration and marks the upstream extent of currently accessible steelhead habitat (NMFS 2002b). Four miles downstream of Black Butte Dam is the North Side Diversion Dam that operates during the irrigation season and also for flood control. The Diversion Dam may present a partial obstacle to upstream migration.

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids (5 per day, 10 in possession except the portion of Stony Creek Middle Fork from Red Bridge upstream, only 2 per day) in Stony Creek is permitted from the last Saturday in April through November 15. For the remainder of the year, catch and release fishing with barbless hooks is allowed.

WATER TEMPERATURE

During the winter months, if flows permit access to upstream areas, water temperatures are likely suitable for steelhead immigration.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life. Total phosphorus concentrations are at stimulatory levels for algae (DWR Website 2007b).

FLOW CONDITIONS

A minimum flow of 30 cfs is required to be released from Black Butte Dam year round.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Black Butte Dam represents the upstream extent of currently accessible steelhead habitat. Most of the habitat in Stony Creek that may be suitable to steelhead spawning occurs in the four mile

reach upstream of the Northside Diversion Dam (NDD). In most years, diversions at the NDD have ceased by mid-November, prior to the initiation of steelhead spawning migrations, and do not resume until late March. During periods of non diversion at NDD, flashboards are removed from the crest of the dam and a large drum gate on the east side of the dam is often raised to allow creek flows to pass through this section of the dam. The level of obstruction caused by the dam during the periods when flashboards are removed is unknown, however a cursory visual inspection of the dam by a NMFS engineer has indicated that the dam is unlikely to pose a significant passage barrier for adult steelhead (NMFS 2000b).

HARVEST/ANGLING IMPACTS

Harvest of steelhead in Stony Creek is permitted up to November 15 which may affect early spawning steelhead.

WATER TEMPERATURE

During the winter months, when steelhead spawning in Stony Creek would occur, water temperatures are cool enough to support spawning steelhead without adverse effects. However, water temperatures can rise quickly in the spring, potentially leading to mortality of late spawned embryos. Water temperature data collected at the Black Butte gage indicate that conditions for juvenile steelhead or developing embryos may become too warm as early as mid-April suggesting that successful steelhead spawning could only continue until mid-February (NMFS 2002b).

WATER QUALITY

See the discussion on water quality above in the adult immigration section.

FLOW CONDITIONS

The Stony Creek watershed is characterized by cool, wet winters with high flows during the steelhead spawning period.

SPAWNING HABITAT AVAILABILITY

Current habitat conditions in Stony Creek are at best, marginal (NMFS 2002b). Although in recent years, steelhead spawning has not been documented in Stony Creek, some salmon spawning has been observed near the confluence with the Sacramento River (NMFS 2002b). The construction of Black Butte Dam has blocked the recruitment of spawning gravel to downstream areas. A substrate study conducted in 1998 concluded that “nearly all samples possessed a level of fine particles (sand) within the level of concern for salmonid reproduction” (NMFS 2002b).

PHYSICAL HABITAT ALTERATION

Construction of dams and subsequent water diversions have depleted streamflows and contributed to higher water temperatures, lower dissolved oxygen levels, and decreased gravel and large woody debris recruitment. The existing streamflow conditions downstream of Black Butte Dam are highly dependent on flood control operations and water diversions.

HATCHERY EFFECTS

Because Stony Creek likely does not support a persistent population of steelhead, it is likely that hatchery steelhead compose a significant portion of any spawning population that may exist.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Stony Creek is open to recreational fishing year round. Some disruption of redds could occur as a result of wading anglers.

WATER TEMPERATURE

Water temperatures in Stony Creek during the winter and early spring months are cool enough to support steelhead embryo incubation. Late spawning would likely result in embryos experiencing unsuitable to lethal conditions.

WATER QUALITY

See the discussion on water quality above in the adult immigration section.

FLOW CONDITIONS

Flows in Stony Creek during the embryo incubation period are highly dependant on flood control and water storage operations which may lead to of redd dewatering during drier years. Day-to-day flow fluctuations due to flood control operations can be large, on the order of 100 to 1300 percent of the previous days flow, and range in magnitude of from several hundred to 6,000 cfs.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in lower Stony Creek during the summer months are likely too warm to support juvenile steelhead rearing.

WATER QUALITY

See the discussion on water quality above in the Adult Immigration section.

FLOW CONDITIONS

Flows in Stony Creek during the summer months are maintained at a minimum of 30 cfs, however, because of often lethal water temperatures during the summer months steelhead juveniles are likely not present.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The lower reach of Stony Creek has been significantly altered by the construction of flood-control levees and bank protection measures (i.e., riprapping). These measures have resulted in reduced habitat for juvenile steelhead. Additionally, Stony Creek is heavily inundated with arundo (*Arundo donax*) and tamarisk (*Tamarix parviflora*), one of the worst infestations in a watershed in the north state. This impairs native riparian vegetation recruitment.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Channel modification projects designed to prevent flood-related damage (e.g., levee construction and bank riprapping) have degraded natural processes which serve to recruit gravel, provide instream cover and forage, and provide habitat diversity in lower Stony Creek. In addition to the levee construction, Stony Creek's heavily braided reach is partly due to instream gravel removal

practices, and in part due to arundo (*Arundo donax*) and tamarisk (*Tamarix parviflora*) infestation, along with the disruption of natural sediment routing processes due to dams. These affect the natural channel migration patterns and morphology, thus affecting migration (*i.e.*, stranding, entrainment, etc.) of both adults and juveniles.

LOSS OF FLOODPLAIN HABITAT

The construction of levees bank riprapping, instream gravel removal practices and infestation of arundo (*Arundo donax*) and tamarisk (*Tamarix parviflora*) in the of lower Stony Creek have disconnected the channel from its historic floodplain thereby preventing the recruitment of large woody debris and natural processes associated with periodic floodplain inundation.

ENTRAINMENT

If adult steelhead are able to pass the NDD and successfully spawn in the reach above the dam, operation of the NDD and North Canal are likely to adversely affect juveniles hatched above the structure. Throughout much of the irrigation season the majority of the water flowing down Stony Creek is diverted into the unscreened North Canal where they are unlikely to survive (NMFS 2002b).

PREDATION

Sacramento pikeminnow is likely the most important predator of juvenile salmonids in Stony Creek. While the pikeminnow is native to these waters, habitat alteration may have changed the predator prey dynamics in the system conferring an advantage to pikeminnow.

HATCHERY EFFECTS

It is possible that some hatchery steelhead released at the CNFH, enter Stony Creek and may compete with naturally spawned steelhead for resources or prey on smaller outmigrating juvenile steelhead.

4.3.10.2 THOMES CREEK

ADULT IMMIGRATION AND HOLDING

Thomes Creek enters the Sacramento River four miles north of the town of Corning. It flows into the Sacramento Valley from the west, draining a watershed of approximately 188 square miles. There are no significant dams on the stream other than two seasonal diversion dams, one near Paskenta and the other near Henleyville. Several small pump diversions are seasonally operated in the stream. The stream is usually dry or intermittent below the USGS stream gage near Paskenta until the first heavy fall rains occur.

PASSAGE IMPEDIMENTS/BARRIERS

There are no significant dams on Thomes Creek other than two seasonal diversion dams, one near Paskenta and the other near Henleyville. Several small pump diversions are seasonally operated in the stream (DWR Website 2007b). These dams would not be in place during the time when steelhead would be immigrating to upstream areas and likely not present obstacles to upstream immigration. Additionally, gravel mining downstream of the Tehama-Colusa Canal

siphon crossing has reportedly resulted in a partial barrier to salmonids returning to Thomes Creek to spawn (Vestra Resources, Inc. 2006).

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Thomes Creek is not permitted. Angling is permitted but restricted to catch-and-release with barbless hooks and artificial flies and lures only.

WATER TEMPERATURE

During the winter months, if flows permit access to upstream areas, water temperatures are likely suitable for steelhead immigration.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life. Water is generally warm in streams flowing through the proposed reservoir sites. Total phosphorus concentrations are at stimulatory levels for algae (DWR Website 2007b).

FLOW CONDITIONS

Thomes Creek has an unimpaired natural pattern of flashy winter and spring flows and very low summer and fall flows creating an environment of fairly inconsistent habitat (CALFED 2000d). These conditions are not conducive to supporting a persistent population of steelhead. However, during wet years some steelhead may migrate into Thomes Creek and limited spawning may occur.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

There are no identified manmade barriers to upstream migrations during the steelhead spawning season.

HARVEST/ANGLING IMPACTS

Harvest of steelhead in Thomes Creek by recreational anglers is not permitted.

WATER TEMPERATURE

During the winter months, when steelhead spawning in Thomes Creek would occur, water temperatures are cool enough to support spawning steelhead without adverse effects.

WATER QUALITY

See the discussion on water quality above in the adult immigration section.

FLOW CONDITIONS

Flows in Thomes Creek are not regulated and mimic historic conditions. It is not likely that flows in Thomes Creek are consistent enough over the years to support a self-sustaining population of steelhead. More likely, during wet years, Thomes Creek supports sporadic steelhead spawning by either hatchery strays or upstream migrating adults attracted into Thomes Creek by high flow events.

SPAWNING HABITAT AVAILABILITY

Historically, there was about 30 river miles of potential steelhead habitat available in Thomes Creek, of which only the lower 4 miles are currently available (NMFS Website 2005).

PHYSICAL HABITAT ALTERATION

Channel modification projects designed to prevent flood-related damage (e.g., levee construction and bank riprapping) have degraded natural processes which serve to recruit gravel suitable for steelhead spawning.

HATCHERY EFFECTS

Because Thomes Creek likely does not support a persistent population of steelhead, it is likely that hatchery steelhead compose a significant portion of the spawning population.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Thomes Creek is closed to recreational fishing during most of the steelhead embryo incubation time period.

WATER TEMPERATURE

Water temperatures in Thomes Creek during the winter and early spring months are cool enough to support steelhead embryo incubation.

WATER QUALITY

See the discussion on water quality above in the adult immigration section.

FLOW CONDITIONS

Flows in Thomes Creek are not controlled and are described as flashy. These conditions likely lead to some level of redd dewatering during drier years.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in lower Thomes Creek during the summer months are likely too warm to support juvenile steelhead rearing.

WATER QUALITY

See the discussion on water quality above in the Adult Immigration section.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The lower reach of Thames Creek has been significantly altered by the construction of flood-control levees and bank protection measures (i.e., riprapping) (CALFED 2000d). These measures have resulted in reduced habitat for juvenile Chinook salmon.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Channel modification projects designed to prevent flood-related damage (e.g., levee construction and bank riprapping) have degraded natural processes which serve to recruit gravel, provide instream cover and forage, and provide habitat diversity in lower Thames Creek.

LOSS OF FLOODPLAIN HABITAT

The construction of levees and bank riprapping of lower Thames Creek have disconnected the channel from its historic floodplain thereby preventing the recruitment of large woody debris and natural processes associated with periodic floodplain inundation.

ENTRAINMENT

Agricultural diversions on Thames Creek are unscreened and any outmigrating salmonids likely are susceptible to entrainment in the diversions.

PREDATION

Sacramento pikeminnow is likely the most important predator of juvenile salmonids in Thames Creek. While the pikeminnow is native to these waters, habitat alteration may have changed the predator prey dynamics in the system conferring an advantage to pikeminnow.

HATCHERY EFFECTS

It is possible that some hatchery steelhead released at the CNFH enter Thames Creek and may compete with naturally spawned steelhead for resources or prey on smaller outmigrating juvenile steelhead.

4.3.10.3 COTTONWOOD/BEEGUM CREEK

Cottonwood Creek drains the west side of the Central Valley and enters the Sacramento River a short distance downstream from the Redding-Anderson area.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

There are several irrigation diversions but no storage reservoirs on Cottonwood Creek. These diversions likely present passage obstacles to most areas of Cottonwood Creek other than Beegum Creek.

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Cottonwood Creek and its tributaries is not permitted. Angling is permitted but restricted to catch-and-release with barbless hooks and artificial flies and lures only. Additionally, angling is not permitted from November 15 through the end of April; therefore the fishery is closed during most of the steelhead immigration time period.

WATER TEMPERATURE

Water temperatures in Cottonwood and Beegum creeks are likely suitable for supporting steelhead adult immigration during the winter months.

WATER QUALITY

Water quality in Cottonwood Creek does not like adversely affect immigrating adult salmonids.

FLOW CONDITIONS

Flow conditions in Cottonwood Creek during the late fall and winter months likely do not impede steelhead upstream migration.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

See discussion above under Adult Immigration and Holding.

HARVEST/ANGLING IMPACTS

Recreational angling is not permitted from November 15 through the end of April; therefore the fishery is closed during most of the steelhead spawning time period.

WATER TEMPERATURE

Water temperatures in Cottonwood Creek and its tributaries are sufficiently cool during the winter and early spring months to support steelhead spawning.

WATER QUALITY

Two major instream gravel extraction projects operate in Cottonwood Creek below the Interstate 5 bridge (CALFED 2000d) which likely degrade water quality for a short distance downstream. However, these activities occur downstream of where steelhead would be expected to be spawning.

FLOW CONDITIONS

Flows in Cottonwood and Beegum creeks likely mimic historic conditions.

SPAWNING HABITAT AVAILABILITY

Gravel mining in Cottonwood Creek has reduced gravel recruitment leading to channel armoring and reduced spawning habitat.

PHYSICAL HABITAT ALTERATION

There are no large water development projects or comprehensive flood control measures in the Cottonwood Creek drainage. Habitat alteration has arisen from timber harvest in the upper watershed, grazing in the middle watershed and extensive gravel mining in the lower watershed.

HATCHERY EFFECTS

There is a potential for native steelhead to interact with strays from the Coleman National Fish Hatchery.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Cottonwood Creek and tributaries are closed to fishing during the steelhead embryo incubation period.

WATER TEMPERATURE

Water temperatures in Cottonwood and Beegum creeks are likely suitable for supporting steelhead embryo incubation.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life.

FLOW CONDITIONS

Flows in Cottonwood and Beegum creeks likely mimic historic conditions during the steelhead embryo incubation life stage.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in the lower reaches of Cottonwood Creek are likely too warm to support steelhead in the summer months.

WATER QUALITY

See discussion presented above under Embryo Incubation.

FLOW CONDITIONS

Flows in Cottonwood and Beegum creeks likely mimic historic conditions and likely do not adversely affect juvenile steelhead.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Extensive gravel mining occurs in lower Cottonwood Creek, which has resulted in a loss of riparian habitat. The remaining portion of the watershed is primarily rural which has helped avoid adverse impacts to the riparian areas.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

There has been little development in the Cottonwood Creek watershed. This has resulted in Cottonwood Creek maintaining most of its historic characteristics and function.

LOSS OF FLOODPLAIN HABITAT

No comprehensive flood control measures have occurred in the Cottonwood Creek drainage resulting in the creek retaining its connection to the floodplain.

ENTRAINMENT

There are irrigation diversions but no storage reservoirs on the Cottonwood Creek. Outmigrating juvenile spring-run Chinook salmon could potentially be entrained at unscreened diversions.

PREDATION

Sacramento pikeminnow is likely the most important predator of juvenile salmonids in Cottonwood/Beegum Creek system. While the pikeminnow is native to these waters, habitat alteration may have changed the predator prey dynamics in the system conferring an advantage to pikeminnow.

HATCHERY EFFECTS

It is possible that juvenile steelhead released from the CNFH may enter Cottonwood Creek for rearing purposes and compete with naturally spawned steelhead.

4.3.10.4 CLEAR CREEK

Clear Creek, a westside tributary to the upper Sacramento River, enters the mainstem Sacramento River at RM 289 near the south Redding city limits in Shasta County, California. Whiskeytown Dam is a complete barrier to fish passage and is the uppermost boundary of habitat available to anadromous salmon and steelhead. The stream channel below Whiskeytown Dam can be divided into two predominant types at Clear Creek Road Bridge (RM 8.5). Upstream, the creek is mainly confined by steep canyon walls and is characterized by falls, high gradient riffles, and deep pools. The substrate is mainly bedrock, large boulders, and fine sand. Downstream from RM 8.5 is the alluvial reach with a much lower gradient and a much wider valley relatively unconstrained by bedrock. Substrate is mainly a mixture of cobble, gravel, and sand.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Whiskeytown Dam, at RM 18.1, is a complete barrier to fish migration and represents the upstream extent of currently accessible anadromous salmonid habitat.

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Clear Creek and its tributaries is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only from last Saturday in April through November 15.

WATER TEMPERATURE

Water temperatures during the late fall and winter months when steelhead would be immigrating to upstream spawning areas are maintained under 60°F and are suitable for this life stage.

WATER QUALITY

The impact of significant accumulations of mercury is an issue in Clear Creek. Mercury contamination is the result of historic gold mining practices in the watershed (CDFG 2004b).

FLOW CONDITIONS

A flow schedule for Clear Creek has been incorporated into the CVPIA Anadromous Fisheries Restoration Program Plan that is designed to maintain flows in Clear Creek that will allow cool water temperatures conducive to all salmonid life stages. Currently the release schedule call for maintenance of 200 cfs flows from October 1 to June 1 and 150 cfs, or less, from July through September in order to maintain water temperatures below 60°F (USFWS 2003b). These flows are adequate to support steelhead adult immigration and holding.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Whiskeytown Dam, at RM 18.1, is a complete barrier to fish migration and represents the upstream extent of currently accessible anadromous salmonid habitat.

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Clear Creek and its tributaries is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only from last Saturday in April through November 15.

WATER TEMPERATURE

Water temperatures in Clear Creek during the winter months when steelhead would be spawning are suitable.

WATER QUALITY

See above section under adult immigration and holding.

FLOW CONDITIONS

See above section under adult immigration and holding. The flow schedule described is supportive of steelhead spawning.

SPAWNING HABITAT AVAILABILITY

The construction of Whiskeytown Dam and significant gravel mining in the Clear Creek watershed has diminished suitable spawning gravel substrate. Currently, gravel replacement projects are being conducted in the watershed (CDFG 2004b).

PHYSICAL HABITAT ALTERATION

The Clear Creek watershed has undergone extensive modification because of Whiskeytown Dam, gold mining, dredger mining, and gravel removal projects. Currently, Whiskeytown Dam diverts most of the Clear Creek natural streamflow to Spring Creek. However, extensive watershed rehabilitation efforts are currently underway in the watershed.

HATCHERY EFFECTS

Steelhead released from the Coleman National Fish Hatchery may have some interaction with native Clear Creek steelhead.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Clear Creek and its tributaries is not permitted. Angling is not permitted during winter months when most steelhead embryo incubation would be occurring.

WATER TEMPERATURE

Water temperatures in Clear Creek during the winter and early spring months are suitable for steelhead embryo incubation.

WATER QUALITY

See above section under adult immigration and holding.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures during the summer months are kept relatively cool by controlling flows at Whiskeytown dam and are generally suitable year-round for juvenile steelhead rearing.

WATER QUALITY

See above section under adult immigration and holding.

FLOW CONDITIONS

In 1999, streamflows in Clear Creek were increased to a minimum of 150 cfs to provide adequate habitat for juvenile steelhead (USFWS 2004).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Over 30 years of gravel mining in Clear Creek has led to a reduction in riparian habitat along the lower sections (CDFG 2004b). Riparian habitat provides cover for rearing juveniles as well as insect habitat that serves as an important food source.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Whiskeytown Dam diverts most of the historic flow from Clear Creek into Spring Creek and also regulates flows in Clear Creek such that natural flow regimes no longer occur.

LOSS OF FLOODPLAIN HABITAT

Because Clear Creek flows are regulated, the channel has become incised and some connection to the historic floodplain has been lost.

ENTRAINMENT

The level of potential entrainment in Clear Creek has not been investigated.

PREDATION

Sacramento pikeminnow is likely the most important predator of juvenile salmonids in Clear Creek. While the pikeminnow is native to these waters, habitat alteration may have changed the predator-prey dynamics in the system conferring an advantage to pikeminnow.

HATCHERY EFFECTS

Juvenile steelhead in Clear Creek are likely not affected by steelhead released from the Coleman National Fish Hatchery.

4.3.10.5 PUTAH CREEK

Putah Creek drains an area of approximately 576 square miles. It is the southernmost major drainage entering the Sacramento Valley from the west. Lower Putah Creek is located in the southwestern corner of the Sacramento Valley and flows 26 miles across the valley floor from the Putah Diversion Dam to the Toe Drain in the Yolo Bypass. Putah Diversion Dam is a reregulating reservoir below Monticello Dam, which controls runoff from 90 percent of the watershed and impounds Lake Berryessa. Steelhead are reported to have historically spawned in the upper tributaries of Putah Creek above the Berryessa Valley (now Lake Berryessa) but there have been no recently confirmed reports of steelhead in Putah Creek (EDAW 2005).

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Monticello Dam, located at river mile 30 presents an absolute barrier to upstream anadromous salmonid migration. There are three other dams and one road crossing on lower Putah Creek which impede migration at certain flows. The bypass dam and the road crossing are seasonal barriers, which are only impediments to migration when they are in the creek, but they are normally removed by the time upstream migration of steelhead begins (DWR 2005a). The town of Winters Percolation Dam is the unused remains of an old dam. This dam is passable at certain flows but it is not clear what those flows are (DWR 2005a).

HARVEST/ANGLING IMPACTS

Lower Putah Creek has no special fishing regulations. The potential anadromous waters of lower Putah Creek allow fishing all year but no fish may be harvested.

WATER TEMPERATURE

Water temperatures in Putah Creek during the late fall and winter months are suitable for steelhead immigration.

WATER QUALITY

Water quality in lower Putah Creek is monitored by the Solano Irrigation District, the Bureau of Reclamation and the State Water Resources Control Board. Water quality in lower Putah Creek is of sufficient quality to not adversely affect adult immigrating salmonids in the creek.

FLOW CONDITIONS

Water flow has been the biggest deterrent to anadromous fish in Putah Creek since 1957 when the Solano Project dams were built. In May of 2000, as a result of several law suits, an agreement was reached whereby required flows from Monticello Dam were established and are

specified by month. The purpose of the required flows is to benefit the fish and habitat of lower Putah Creek (DWR 2005a).

The instream flows and water releases from Monticello Dam became regulated through the May 2000 Putah Creek Accord (Accord) (Solano County Superior Court 2000, *as cited in* EDAW 2005). The purpose of the Accord is to create as natural of a flow regime as feasible (EDAW 2005). Four functional flow requirements are contained in the Accord pertaining to rearing flows, spawning flows for native resident fishes, supplemental flows for anadromous fishes, and drought-year flows (EDAW 2005). **Table 4-3** shows the basic required flow regimes specified by the Accord as prescribed for “normal” and “drought” conditions (EDAW 2005).

Table 4-3. Putah Creek flow summaries before and after construction of the Solano Project.

Summary of Flows at or Near Putah Diversion Dam Before and After Construction of the Solano Project												
Variable	Flow (cfs)											
	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

See section above describing barriers to upstream migration.

HARVEST/ANGLING IMPACTS

Lower Putah Creek has no special fishing regulations. The potential anadromous waters of lower Putah Creek allow fishing all year but no fish may be harvested.

WATER TEMPERATURE

Water temperatures in lower Putah Creek during the winter months are suitable for steelhead spawning.

WATER QUALITY

See section above describing water quality for upstream migration.

FLOW CONDITIONS

In addition to the flow agreements described above under adult immigration, the agreement also specifies spawning flows to be released from the diversion dam for a three day period between February 15 and March 31 each year. These flows are 150 cfs for the first day, 100 cfs on the second and 80 cfs on the third. For the following 30 days, flows must be at least 50 cfs (DWR 2005a).

SPAWNING HABITAT AVAILABILITY

Overall, gravel is not scarce along lower Putah Creek, however, recent gravel surveys indicate that gravel substrate size is generally smaller than that preferred by salmonids for spawning (Yates 2003). Additionally, both Monticello Dam and the Putah Diversion Dam block the transport of gravel from upstream reaches to potential spawning reaches downstream of the Putah Diversion Dam.

PHYSICAL HABITAT ALTERATION

Habitat in Putah Creek has been drastically altered by human activities over the past 120 years. Construction of levees, channel excavation, gravel mining and groundwater extraction have all led to a deeper, narrower creek channel. This has led to a disconnection with the floodplain. Additionally, construction of the Solano Project dams has resulted in reduced gravel and sediment recruitment, decreasing the natural dynamics of the creek.

HATCHERY EFFECTS

Because Putah Creek does not currently support a persistent unique population of steelhead, it is unlikely that hatchery effects (e.g., straying) would have adverse effects.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because recreational fishing is allowed year-round; it is possible that steelhead redds could be disturbed by wading anglers.

WATER TEMPERATURE

Water temperatures during the winter and early spring months are suitable for steelhead embryo incubation. Any late developing embryos (i.e., after April) may experience warmer water temperatures that could potentially reduce survival.

WATER QUALITY

See section above describing water quality for adult upstream migration in Putah Creek.

FLOW CONDITIONS

Flow regimes in Putah Creek are described above under adult immigration and spawning.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in Putah Creek normally remain below 60°F rear round just below the Putah Diversion Dam, but during the summer months, water temperatures increase rapidly downstream. For example, water temperatures at the I-505 Bridge normally begin exceeding 70°F in mid-May.

WATER QUALITY

See section above describing water quality for adult upstream migration in Putah Creek.

FLOW CONDITIONS

Flow regimes in Putah Creek are described above under adult immigration and spawning.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The riparian zone surrounding Putah Creek has been changed drastically from historic conditions. Human activities related to levee construction, flood control, agricultural encroachment into the riparian zone, burning and dumping of trash have all negatively affected riparian habitat. Currently, the riparian forest is dominated by valley oak, black walnut and eucalyptus.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

The flow regime in lower Putah Creek is highly regulated because Monticello Dam controls a large percentage of the watershed, and because the capacity of Lake Berryessa is much larger than the annual watershed runoff. In particular, high flows that formerly sustained much of the geomorphic processes along the creek have been greatly decreased.

LOSS OF FLOODPLAIN HABITAT

Controlled flows in lower Putah Creek have significantly decreased connectivity with the floodplain. For example, the estimated 100-year peak flow in lower Putah Creek is now only about one-third of pre-dam natural flow (Yates 2003).

ENTRAINMENT

The level of entrainment into unscreened water diversions is unknown at this time.

PREDATION

The level of predation on native anadromous salmonids is unknown. However, Putah Creek is a popular recreational fishery that supports non-native brown trout, a known predator on juvenile salmonids.

HATCHERY EFFECTS

Because Putah Creek does not currently support a persistent unique population of steelhead, it is unlikely that hatchery effects (e.g., straying) would have adverse effects.

4.3.11 SOUTHERN SIERRA NEVADA DIVERSITY GROUP

All steelhead that comprise the Southern Sierra Nevada Diversity group utilize the lower San Joaquin River as a migration corridor. A potential threat common to these steelhead is presented by the operation, usage and maintenance of the Stockton Deep Water Ship Channel (DWSC). Required periodic dredging of the DWSC creates noise pollution that could adversely affect salmonid populations in close proximity to dredging operations. Additionally, dredging would create sediment plumes potentially harmful to juvenile salmonids, mobilize heavy metal pollutants in the sediments, and there is a possibility of entrainment of juveniles in the dredging equipment. Potential threats created by DWSC usage by large ships include both noise pollution and propeller entrainment. Additionally, maintenance of the DWSC requires bank stabilization activities that negatively affect the riparian zone, further disconnect the river from its historic floodplain resulting in a loss of natural river morphology and function. The potentially adverse effects and mitigation measures associated with the DWSC are described in the NMFS 2006 Biological and Conference Opinion for the Stockton Deep Water Ship Channel Maintenance Dredging and Levee Stabilization Project (NMFS 2006b).

Another factor influencing steelhead production in the Southern Sierra Nevada Diversity Group is the different water management practices used in the San Joaquin drainage as opposed to the Sacramento River drainage. Brown and Bauer (2008) compared estimates of full natural runoff before construction of major foothill storage reservoirs with measured discharge after construction. In the Sacramento drainage, pre-dam and post-dam mean annual discharges were within 10 percent and the hydrograph was flattened. In the San Joaquin River drainage, post-dam mean annual discharges were 42 to 62 percent less than pre-dam values and mean discharges declined in most months, especially during the spring. Brown and Bauer (2008) conclude that when considered with species life history characteristics, these results support the hypothesis that water management has a major influence on the relative success of native and invasive fish species and that water deliveries through natural channels in the Sacramento River drainage appear to favor native species while water diversions in the San Joaquin River drainage appear to favor invasive species.

4.3.11.1 MOKELUMNE RIVER

The Mokelumne River drains an area of approximately 661 square miles with headwaters at an elevation of over 10,000 feet. The lower Mokelumne flows from Camanche Dam, at RM 64, to

its confluence with the San Joaquin River. Camanche Dam is an impassable barrier and marks the upstream extent of currently accessible steelhead habitat.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Camanche Dam, constructed in 1963 at RM 63.7, presents an impassable barrier to upstream migration and marks the upstream extent of currently accessible steelhead habitat in the Mokelumne River. A potential low flow migration barrier occurs at Thornton just upstream of tidal influence. The potential barrier extends over a 600-foot section of the river and is characterized by shallow water over a sandy bottom. The channel thalweg shifts continuously through this reach (CDFG 1991a). Woodbridge Dam creates Lodi Lake and supplies water to the Woodbridge Canal during the irrigation season. Woodbridge Dam may present an upstream migration barrier at low flows. CDFG suggests that flows of about 300 cfs are necessary to provide passage over the Woodbridge Dam (CDFG 1991a). Woodbridge Dam impounds Lodi Lake which extends upstream for about 8.5 miles. At low flows, there is no dominant flow pattern within the lake which probably delays upstream migration (CDFG 1991a).

HARVEST/ANGLING IMPACTS

The lower Mokelumne River is open to recreational fishing during most of the year and the taking of hatchery steelhead (identified by an adipose fin clip) is allowed. The reach from the confluence upstream to Peltier Road is open year-round and the reach upstream of Peltier Road to Camanche Dam is open from January 1 through March 31 and again from the fourth Saturday in May through October 15.

WATER TEMPERATURE

Upstream adult immigration of steelhead in the Mokelumne River occurs from August through March. Water temperatures in August can be as high as 68°F but normally lower to below 60°F by October (CDFG 1991a).

WATER QUALITY

Dissolved oxygen levels lethal to salmonids frequently occur in the Mokelumne River (CDFG 1991a). High levels of turbidity have also been observed. Additionally, heavy metals and hydrogen sulfide in concentrations toxic to aquatic life have been shown to cause fish kills in the Mokelumne River. Copper and zinc from Penn Mine were identified as the main metals causing fish kills. Recently, hazardous levels of cadmium have been determined to be present from Penn Mine as well as from the base of Camanche Dam (CDFG 1991a).

FLOW CONDITIONS

During dry years flows in the Mokelumne River near Woodbridge can be well under 100 cfs from August through the beginning of November while flows just below Camanche Reservoir typically are fairly constant at 200 to 300 cfs.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Comanche Dam, constructed in 1963 at RM 63.7, presents an impassable barrier to upstream migration and marks the upstream extent of currently accessible steelhead habitat in the Mokelumne River. A potential low flow migration barrier occurs at Thornton just upstream of tidal influence. The potential barrier extends over a 600-foot section of the river and is characterized by shallow water over a sandy bottom. The channel thalweg shifts continuously through this reach (CDFG 1991a). Woodbridge Dam creates Lodi Lake and supplies water to the Woodbridge Canal during the irrigation season. Woodbridge Dam may present an upstream migration barrier at low flows. CDFG suggests that flows of about 300 cfs are necessary to provide passage over the Woodbridge Dam (CDFG 1991a). Woodbridge Dam impounds Lodi Lake which extends upstream for about 8.5 miles. At low flows, there is no dominant flow pattern within the lake which probably delays upstream migration (CDFG 1991a).

HARVEST/ANGLING IMPACTS

The lower Mokelumne River is open to recreational fishing during most of the year and the taking of hatchery steelhead (identified by an adipose fin clip) is allowed. The reach from the confluence upstream to Peltier Road is open year-round and the reach upstream of Peltier Road to Comanche Dam is open from January 1 through March 31 and again from the fourth Saturday in May through October 15. This time period in the reach above Peltier Road is likely protective of most steelhead natural spawning.

WATER TEMPERATURE

Steelhead spawning in the Mokelumne River occurs from December through April. Water temperatures during this time period are generally below 54°F (CDFG 1991a) which is near the upper temperature limit for successful steelhead spawning (Humpesch 1985; Timoshina 1972).

WATER QUALITY

Dissolved oxygen levels lethal to salmonids frequently occur in the Mokelumne River (CDFG 1991a). High levels of turbidity have also been observed. Additionally, heavy metals and hydrogen sulfide in concentrations toxic to aquatic life have been shown to cause fish kills in the Mokelumne River. Copper and Zinc from Penn Mine were identified as the main metals causing fish kills. Recently, hazardous levels of cadmium have been determined to be present from Penn Mine as well as from the base of Comanche Dam (CDFG 1991a).

FLOW CONDITIONS

Based on IFIM studies, maximum steelhead spawning habitat availability occurs at flows ranging from 100 to 500 cfs (CDFG 1991a). Flows are generally in this range during dry years. During wet years, flows are much more variable and range from about 200 cfs to 1,800 cfs during the steelhead spawning season (CDFG 1991a). CDFG (1991a) suggests that during normal water years, maintaining a flow of about 300 cfs during the mid-October through February time period at Woodbridge will provide maximum spawning habitat for steelhead and Chinook salmon.

SPAWNING HABITAT AVAILABILITY

Potential spawning habitat for salmonids extends approximately nine miles downstream of Comanche Dam (Heady 2008). Recruitment of suitable spawning gravels downstream of Comanche Dam is minimal. The dam blocks the downstream movement of gravel from

upstream areas. Also, there have been several gravel mining operations along the river. Although most gravel mining now occurs off channel behind levees, mined gravel has not been replaced (CDFG 1991a).

PHYSICAL HABITAT ALTERATION

Water developments and diversions, mining activities, and discharge of waste material have had significant adverse effects on aquatic resources in the Mokelumne River. As a result, flows in the river have been substantially reduced and temperature and water quality have deteriorated from conditions that occurred naturally (CDFG 1991a).

HATCHERY EFFECTS

The Mokelumne River Fish Hatchery (MRFH) steelhead program has been founded and heavily supplemented by out-of-DPS (Eel River) or out-of-basin (Feather and American River) stock, and currently is not part of the DPS by lack of genetic confirmation. Steelhead returns back to the hatchery have been poor; experimental releases of CWT marked hatchery stock were conducted from 2004 through 2006 to determine the cause but insufficient recovery of data has hampered this effort. Recently, hydroacoustic-tagged MRFH steelhead adult releases have been found in the American River, indicating straying as one possible factor for poor escapement back to the MRFH, with a high degree of residualization being another. Possible effects of MRFH straying include genetic introgression of native steelhead stocks with the Eel River and Feather River genome, loss of genetic structure of the DPS, competition over spawning habitat and redd superimposition.

The MRFH carries out a number of release protocols: volitional, trucking and release within the watershed, trucking and release into San Pablo Bay, and the Delta. Effects of out-of-basin releases include a high degree of straying of adult returns into other streams in the Central Valley and California coast, with implications to native spring and fall Chinook salmon of competition over habitat. Genetic integrity of the Central Valley steelhead DPS is threatened by high straying rates. For example, straying of fall-run has resulted in the homogeneity of the fall-run component of the Central Valley fall-/late fall-run ESU.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The lower Mokelumne River is open to recreational fishing during most of the year. The reach from the confluence upstream to Peltier Road is open year-round and the reach upstream of Peltier Road to Comanche Dam is open from January 1 through March 31 and again from the fourth Saturday in May through October 15. This time period overlaps with the embryo incubation life stage and some disruption of redds by wading anglers may occur.

WATER TEMPERATURE

Steelhead spawning in the Mokelumne River occurs from December through April. Therefore, some embryo incubation may extend into June. Water temperatures during this time period are generally below 54°F (CDFG 1991a) which is adequate for steelhead embryo incubation.

WATER QUALITY

See discussion above under adult immigration and holding.

FLOW CONDITIONS

Based on IFIM studies, maximum steelhead spawning habitat availability occurs at flows ranging from 100 to 500 cfs (CDFG 1991a). Flows are generally in this range during dry years. During wet years, flows are much more variable and range from about 200 cfs to 1,800 cfs during the steelhead spawning season (CDFG 1991a). CDFG (1991a) suggests that during normal water years, maintaining a flow of about 300 cfs during the mid-October through February time period at Woodbridge will provide maximum spawning habitat for steelhead and Chinook salmon. Variable flows during the embryo incubation life stage may lead to some redd dewatering.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Juvenile steelhead rear in the Mokelumne River year-round. Smolt outmigration normally occurs from January through June. Peak water temperatures normally occur in July and August and can reach 68°F. Water temperatures fall below 60°F by October and remain near 54°F from November through May (CDFG 1991a). Steelhead can be found where daytime water temperatures range from nearly 32°F to 81°F in the summer (Moyle 2002). However, an upper water temperature limit of 65°F is preferred for growth and development of Sacramento River and American River juvenile steelhead (NMFS 2002a).

WATER QUALITY

Dissolved oxygen levels lethal to salmonids frequently occur in the Mokelumne River (CDFG 1991a). High levels of turbidity have also been observed. Additionally, heavy metals and hydrogen sulfide in concentrations toxic to aquatic life have been shown to cause fish kills in the Mokelumne River. Copper and zinc from Penn Mine were identified as the main metals causing fish kills. Recently, hazardous levels of cadmium have been determined to be present from Penn Mine as well as from the base of Comanche Dam (CDFG 1991a).

FLOW CONDITIONS

CDFG (1991a) suggests that maintaining flows between 350 and 400 cfs at the Woodbridge gage during March and April will prevent the stranding of juvenile steelhead and facilitate movement through Lodi Lake to the Delta. Woodbridge Dam also impounds Lodi Lake and at low flows, dominant flow patterns in Lodi Lake may be difficult to detect. Downstream migrants have their progress slowed considerably upon reaching the lake. These outmigrants may reside in the lake for considerable periods of time during which they are subject to increased predation and warm water conditions (CDFG 1991a).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Riparian vegetation is found along most of both banks of the lower Mokelumne River. However, there is no regeneration along the relatively thin riparian corridor in many areas. It is subject to erosion, as well as removal for housing, agriculture, flood control, levee maintenance and gravel mining (CDFG 1991a).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

The river tends to be wider the first six miles downstream of Camanche Reservoir and with the exception of Lodi Lake tends to be much narrower downstream. Because flows have been substantially reduced in this section of the river, the river characteristics are quite different than those that occurred historically and much side channel habitat has been lost.

In 2005, EBMUD, in cooperation with CDFG and USFWS, acquired funds to engineer 1,915 m² of side channel habitat. Monitoring of the engineered habitat has shown usage by both juvenile Chinook salmon and steelhead (Heady 2008). Heady (2008) reports that juvenile salmonids seem to respond to preferred diet items made available by the engineered habitat.

LOSS OF FLOODPLAIN HABITAT

Much of the narrowing of the river channel in the downstream reaches of the lower Mokelumne River can be attributed to flood control levees built to protect homes and agriculture on the historic floodplain. There are approximately 40 miles of levees on the lower Mokelumne River downstream of Camanche Dam (CDFG 1991a).

ENTRAINMENT

The diversion at Woodbridge Dam into Woodbridge Canal during the irrigation season (April 15 through October 15) averages 128 cfs but can be as high as 400 cfs. The diversion was screened in 1968. The screens do not meet CDFG or NMFS standards and some entrainment of juvenile steelhead is likely (CDFG 1991a). Another smaller diversion occurs below Camanche Dam and is operated by the North San Joaquin Water Conservation District. Losses of juveniles at this diversion are unknown. At the diversion, the north pump is unscreened and the south pump is screened but the screen is in disrepair. Observations indicate that there are few losses of juvenile salmonids at this site (CDFG 1991a).

PREDATION

Non-native largemouth and smallmouth bass have been introduced to the lower Mokelumne River. Both species are likely predators on juvenile salmonids, particularly as outmigrants are slowed in Lodi Lake. Additionally, introduced striped bass likely prey on juvenile native salmonids in the Mokelumne River downstream of the Woodbridge Dam.

HATCHERY EFFECTS

Because early attempts to create a natural run of steelhead in the Mokelumne River were unsuccessful, the fishery is currently managed by CDFG as a catchable rainbow trout fishery. Steelhead averaging three to a pound are released annually. These fish likely prey on juvenile salmonids in the lower river (EBMUD 1992).

4.3.11.2 CALAVERAS RIVER

The Calaveras River, a tributary to the San Joaquin River, is a relatively small, low elevation Central Valley drainage that receives runoff mainly from winter rainfall. Flow in the Calaveras River is regulated by New Hogan Dam, located approximately 38 miles upstream from the river's mouth at Stockton, where it meets the San Joaquin River. New Hogan Dam marks the upstream extent of currently accessible steelhead habitat in the Calaveras River.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Currently, New Hogan Dam at RM 36 presents an impassable barrier to upstream migration and marks the upper extent of currently accessible steelhead habitat in the Calaveras River. Bellota Weir at RM 18 can be a barrier to upstream migration at low flows (Marsh 2007). At Bellota weir, the river is split into two channels, the old Calaveras River channel and Mormon Slough. Mormon Slough, converted to a flood control channel in the 1960s, now typically has more flow than the old Calaveras River channel. In recent years, steelhead have been documented using winter and spring flows from rain, runoff and occasional reservoir flood releases to migrate up the river, though barriers such as Bellotta Dam can stop steelhead once flows recede after a storm. Additionally, numerous in-channel migration barriers and dry reaches during low flows present complete or partial barriers to upstream migration below Bellota Weir (Fishery Foundation of California 2004).

HARVEST/ANGLING IMPACTS

Recreational angling is allowed in the Calaveras River from the fourth Saturday in May through March 31 of the following year. Current regulations allow for the taking of hatchery trout or steelhead (identified by an adipose fin clip).

WATER TEMPERATURE

A water temperature study was conducted from the spring of 2002 through the winter of 2003. During this study, water temperatures between New Hogan Dam and the Bellota Weir were found to be well within the acceptable limits for steelhead (Fishery Foundation of California 2004).

WATER QUALITY

Environmental conditions such as high water temperatures and low dissolved oxygen concentrations may be a problem for migrating adult salmonids below Bellota Weir (Fishery Foundation of California 2004).

FLOW CONDITIONS

Currently, adult steelhead have two potential migration routes to upstream spawning habitat: (1) the old Calaveras River channel downstream of the town of Bellota, and 2) Mormon Slough via the Stockton Diverting Canal. The majority of steelhead migrate through Mormon Slough because there is typically more water in this route. However, in many years, the timing and magnitude of flows below Bellota Weir are not sufficient to allow steelhead to migrate upstream during winter months (Fishery Foundation of California 2004).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Currently, New Hogan Dam at RM 36 presents an impassable barrier to upstream migration and marks the upper extent of currently accessible steelhead habitat in the Calaveras River. Bellota Weir at RM 18 can be a barrier to upstream migration at low flows (Marsh 2007). At Bellota weir, the river is split into two channels, the old Calaveras River channel and Mormon Slough.

Mormon Slough, converted to a flood control channel in the 1960s, now typically has more flow than the old Calaveras River channel. In recent years, steelhead have been documented using winter and spring flows from rain, runoff and occasional reservoir flood releases to migrate up the river, though barriers such as Bellotta Dam can stop steelhead once flows recede after a storm.

HARVEST/ANGLING IMPACTS

Recreational angling is allowed in the Calaveras River from the fourth Saturday in May through March 31 of the following year. Current regulations allow for the taking of hatchery trout or steelhead (identified by an adipose fin clip).

WATER TEMPERATURE

During a water temperature study that was conducted from the spring of 2002 through the winter of 2003, water temperatures between New Hogan Dam and the Bellota Weir were found to be well within the acceptable limits for steelhead (Fishery Foundation of California 2004).

WATER QUALITY

Water quality appears to be adequate to support steelhead spawning upstream of Bellota Weir.

FLOW CONDITIONS

After construction of New Hogan Dam, and subsequent river regulation, barriers in the lower river became serious impediments to upstream migration causing stranding when flows high enough to pass fish over the barriers drops (Marsh 2007).

SPAWNING HABITAT AVAILABILITY

Spawning habitat upstream of Mormon Slough is considered adequate (Marsh 2007). However, the increased shear stress caused by tailing piles and the associated river channel confinement have resulted in the mobilization of spawning size gravel resulting in some loss of spawning habitat (Fishery Foundation of California 2004).

PHYSICAL HABITAT ALTERATION

A reconnaissance survey, conducted in 2002, indicated the extensive nature of gold dredging activities in the basin and encroachment of the river channel by tailings piles, resulting in the confinement of the river channel (Fishery Foundation of California 2004).

HATCHERY EFFECTS

Because Calaveras River does not support a persistent population of steelhead at this time, there are no likely hatchery effects.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Recreational angling is allowed in the Calaveras River from the fourth Saturday in May through March 31 of the following year. Current regulations allow for the taking of hatchery trout or steelhead (identified by an adipose fin clip). Therefore, it is possible that redds could be inadvertently disturbed by wading anglers.

WATER TEMPERATURE

During a water temperature study that was conducted from the spring of 2002 through the winter of 2003, water temperatures between New Hogan Dam and the Bellota Weir were found to be well within the acceptable limits for steelhead (Fishery Foundation of California 2004).

WATER QUALITY

Water quality appears to be adequate to support egg development and embryo incubation upstream of Bellota Weir.

FLOW CONDITIONS

Flows between New Hogan Reservoir and the Bellota Weir are fairly constant throughout the steelhead embryo incubation period (Fishery Foundation of California 2004).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

During a water temperature study that was conducted from the spring of 2002 through the winter of 2003, water temperatures between New Hogan Dam and the Bellota Weir were found to be well within the acceptable limits for steelhead (Fishery Foundation of California 2004). However, water temperatures below Bellota Weir often rise above suitable levels for juvenile salmonids (Fishery Foundation of California 2004).

WATER QUALITY

There is no evidence that water quality, other than temperature, may limit juvenile rearing (Fishery Foundation of California 2004).

FLOW CONDITIONS

Significant obstacles impede smolt outmigration in the fall and winter when low or no flow conditions are common and smolts can become stranded (Marsh 2007). From late-winter to the middle of April, flows sufficient to carry smolts from spawning and rearing areas to the San Joaquin River are infrequent (Fishery Foundation of California 2004). Under current flow management practices, before the beginning of the irrigation season, full connection of flows in Mormon Slough between Bellota Weir and the San Joaquin River occurs only when storm runoff below New Hogan Dam results in uncontrolled spill over the top of Bellota Weir. Diversion of flows away from the mouth of the old Calaveras channel and development of extensive irrigation infrastructure in Mormon Slough has likely blocked smolt outmigration to a large degree (Fishery Foundation of California 2004).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Dewatering of the Old Calaveras River channel and simplification and reduction of riparian cover in Mormon Slough have resulted in higher water temperatures that would not be expected to support significant numbers of rearing juvenile salmonids (Fishery Foundation of California 2004). In contrast to conditions below Bellota Weir, a great deal of rearing habitat is available upstream (Fishery Foundation of California 2004).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

A reconnaissance survey, conducted in 2002, indicated the extensive nature of gold dredging activities in the basin and encroachment of the river channel by tailings piles, resulting in the confinement of the river channel (Fishery Foundation of California 2004).

LOSS OF FLOODPLAIN HABITAT

According to historical accounts, the Calaveras River's valley reach downstream of Bellota was a large floodplain with many braided streams during times of high flows. This reach has changed from an uncontrolled floodplain of sloughs and oak groves to a system of controlled channels, dams, and levees (Marsh 2007).

ENTRAINMENT

Juvenile steelhead can become entrained at the Bellota Weir (Marsh 2007).

PREDATION

Reconnaissance surveys indicate the presence of large run pools between Jenny Lind Bridge and Shelton Road that may support warmwater prey species such as largemouth and smallmouth bass. Brown (2000) suggests that introduced species found in the lower reaches of tributaries to the San Joaquin River and the lower mainstem San Joaquin River likely compete with and predate upon downstream migrants.

HATCHERY EFFECTS

It is not likely that juvenile steelhead rearing in the Calaveras River are affected by hatchery production.

4.3.11.3 STANISLAUS RIVER

The Stanislaus River is one of the largest tributaries of the San Joaquin River. The river is 65 miles long and has north, middle and south forks. The north and south forks meet several miles upstream from New Melones Lake and the middle fork joins the north fork a few miles before that. The Stanislaus River is extensively dammed and diverted. Donnell's Dam on the middle fork forms Donnell Lake, high in the Sierra Nevada. Downstream is Beardsley Dam, which forms Beardsley Lake. McKays' Point Diversion Dam diverts water on the north fork for hydroelectricity production and domestic use. The New Melones Dam blocks the river after the confluence of all three forks. Downstream from New Melones Lake, there is Tulloch Dam, which forms Tulloch Reservoir, and Goodwin Dam, which is the first major barrier for anadromous fish on the Stanislaus River. The Stanislaus River historically supported a large population of spring-run Chinook salmon which was extirpated with the construction of Goodwin Dam. Below Goodwin Dam, the Stanislaus eventually meets the San Joaquin River and flows into the Delta.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Goodwin Dam, at RM 58.4 presents an impassable barrier to anadromous salmonids and marks the upstream extent of currently accessible steelhead habitat on the Stanislaus River.

HARVEST/ANGLING IMPACTS

There is a catch and release steelhead fishery in the lower Stanislaus River from January 1 through October 15. Artificial lures with barbless hooks are required from Goodwin Dam downstream to the Highway 120 Bridge in Oakdale. Below the bridge, bait fishing is permitted. Poaching and illegal fishing methods are reported to be problems for steelhead in the Stanislaus River (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

WATER TEMPERATURE

Because steelhead immigration to the Stanislaus River primarily occurs during the winter months, water temperature downstream of Goodwin Dam is likely suitable for steelhead adult immigration. During the steelhead migration period, maximum average daily water temperatures at Caswell are generally below 55°F from the end of November through early March, are between 55 and 65°F through the end of May, and are above 65°F through the end of summer. These temperatures during the majority of the steelhead upstream migrating period are not expected to adversely impact adults. However, any adults attempting to migrate during the summer months may experience reduced egg viability.

WATER QUALITY

Water quality in the Stanislaus River is adequate to support steelhead adult immigration and holding.

FLOW CONDITIONS

It is likely that flow conditions in the Stanislaus River are adequate to support steelhead adult immigration during the winter months.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Goodwin Dam, at RM 58.4 presents an impassable barrier to anadromous salmonids and marks the upstream extent of currently accessible steelhead habitat on the Stanislaus River.

HARVEST/ANGLING IMPACTS

There is a catch and release steelhead fishery in the lower Stanislaus River from January 1 through October 15. Artificial lures with barbless hooks are required from Goodwin Dam downstream to the Highway 120 Bridge in Oakdale. Below the bridge, bait fishing is permitted. Poaching and illegal fishing methods are reported to be problems for steelhead in the Stanislaus River (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

WATER TEMPERATURE

Because steelhead spawning in the Stanislaus River occurs primarily during the winter months, water temperatures are likely suitable for this life stage in downstream of Goodwin Dam.

WATER QUALITY

Gravel mining and the subsequent production of pits and long flowing ditches have led to reduced dissolved oxygen concentrations in the lower river (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

FLOW CONDITIONS

Reclamation is required to release up to 98,000 acre-feet of water each year from the New Melones Reservoir to the Stanislaus River on a distribution pattern to be specified each year by CDFG for fish and wildlife purposes (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

SPAWNING HABITAT AVAILABILITY

There has been extensive gravel mining in the Stanislaus River. Increased encroachment and reduced gravel recruitment has led to the coarsening of the bed material, particularly in spawning habitat in the unmined reaches of the river below Goodwin Dam (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

PHYSICAL HABITAT ALTERATION

Habitat downstream of Goodwin Dam has been substantially altered by gravel mining. Drag lines were used to dredge the gravel and the spawning habitat from several reaches of the active riverbed. The dredged channels are now either large instream pits or long, uniform ditches that provide almost no spawning habitat (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

HATCHERY EFFECTS

A genetic analysis of steelhead smolts captured in the Stanislaus River indicates that they are closely related to upper Sacramento River steelhead, but not steelhead from the MRFH or the Nimbus Hatchery on the American River and so they appear to be a natural population (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

There is a catch and release steelhead fishery in the lower Stanislaus River from January 1 through October 15. Artificial lures with barbless hooks are required from Goodwin Dam downstream to the Highway 120 Bridge in Oakdale. Below the bridge, bait fishing is permitted. It is likely that there is some disturbance of steelhead redds by wading anglers during the embryo incubation life stage.

WATER TEMPERATURE

Because embryo incubation of steelhead eggs in the Stanislaus River primarily occurs during the winter and spring months, water temperatures are suitable for this life stage downstream of Goodwin Dam.

WATER QUALITY

Gravel mining and the subsequent production of pits and long flowing ditches have led to reduced dissolved oxygen concentrations in the lower river (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

FLOW CONDITIONS

Flow conditions in the Stanislaus River downstream of Goodwin Dam are likely adequate to support embryo incubation of steelhead. However, turbidity from storm events during January and February have been shown to mobilize fine sediment which may decrease oxygen availability to redds (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures reach critical levels during the summer months between Goodwin Dam and the Orange Blossom Bridge (where most steelhead juvenile rearing occurs) (Carl Mesick Consultants and S.P. Cramer & Associates 2002). However, because of hypolimnetic releases of cold water from Goodwin Dam, water temperatures are likely suitable for a short distance downstream of Goodwin Dam even during summer months (Carl Mesick Consultants and S.P. Cramer & Associates 2002). Temperatures may not be low enough (<14 C) to optimize smoltification within the Stanislaus River and increase survival to the ocean (Myrick and Cech 2001).

WATER QUALITY

Dissolved oxygen concentration reach critical levels during the summer months between Goodwin Dam and the Orange Blossom Bridge (where most steelhead juvenile rearing occurs) (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

FLOW CONDITIONS

Stream flow releases from Goodwin Dam are probably adequate to support juvenile rearing of steelhead except under the driest of conditions. Even during relatively hot spells, releases from the dam provide adequate cooling to the river downstream to about Orange Blossom Bridge (Carl Mesick Consultants and S.P. Cramer & Associates 2002). The magnitude, duration, and frequency of elevated spring flows in the Stanislaus River has been altered by operations of New Melones and Goodwin Dam which may negatively impact migrating juvenile steelhead. A strong correlation has been established between annual spring flow magnitude and the production of salmon smolt outmigrants from the a tributary, survival of smolts in the Delta and the production of adults in the escapement and ocean harvest (Mesick 2008, Mesick and Marston 2007).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

No analyses have been conducted to assess the amount of riparian habitat along the lower Stanislaus River that has been converted for agricultural use or commercial gravel mining. CDFG conducted analyses of aerial photographs taken in 1958 and 1965 that indicated that there were approximately 3,300 acres of riparian habitat between Knights Ferry Bridge and the San Joaquin River in 1958, but only 2,550 acres in 1965 as a result of conversion for agricultural uses

and commercial gravel mining (Carl Mesick Consultants and S.P. Cramer & Associates 2002). The amount of riparian habitat appears to have stabilized since 1965 based on a third analysis conducted by the USFWS in 1998 (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

It is speculated that the construction and subsequent operation of the New Melones Dam has reduced channel diversity and the channel has become incised (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

LOSS OF FLOODPLAIN HABITAT

A study of aerial photographs and field observations indicate that the Stanislaus River has changed from a dynamic river system, characterized by depositional and scour features, to a relatively static and entrenched system. Changes since the construction of New Melones Dam include: (1) large scale vegetation encroachment in the active channel; (2) reduced reproduction of cottonwoods; and (3) substantial encroachment by urban and agricultural development, particularly orchards, in floodplain areas thereby altering the natural river floodplain connection (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

ENTRAINMENT

There are 44 unscreened diversions in the Stanislaus River downstream of Goodwin Dam. However, entrainment rates at these sites have not been studied (Carl Mesick Consultants and S.P. Cramer & Associates 2002).

PREDATION

Dredged channels and pits from gravel mining operations have reduced turbulence and thereby providing habitat for potential predators of juvenile salmonids. Concentrations of predators in slow flowing ditches that lack cover may result in high rates of juvenile mortality through predation (Carl Mesick Consultants and S.P. Cramer & Associates 2002). Brown (2000) suggests that introduced species found in the lower reaches of tributaries to the San Joaquin River and the lower mainstem San Joaquin River likely compete with and predate upon downstream migrants.

HATCHERY EFFECTS

Juvenile steelhead rearing in the Stanislaus River are not likely affected by hatchery production.

4.3.11.4 TUOLUMNE RIVER

The Tuolumne River is the largest tributary of the San Joaquin River. It drains a 1,900-square mile water shed that includes the northern portion of Yosemite National Park. La Grange Dam marks the upstream extent of currently accessible anadromous salmonid habitat. From La Grange Dam, the Tuolumne River flows in a westerly direction for approximately 50 miles before entering the mainstem San Joaquin River. Although some steelhead reportedly persist in the Tuolumne River, debate over historical distribution and less emphasis on commercial value have shifted the primary focus of restoration efforts from steelhead to fall-run Chinook salmon in the Tuolumne Basin (McBain and Trush 2000).

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The La Grange Dam at RM 52.2 presents an impassable barrier to upstream migrating anadromous salmonids and marks the upstream extent of currently accessible steelhead habitat in the Tuolumne River.

HARVEST/ANGLING IMPACTS

The Tuolumne River, from La Grange Dam downstream to the confluence with the San Joaquin River supports a catch and release recreational trout fishery from January 1 through October 15. Therefore, it is possible that redds could be inadvertently disrupted by wading anglers.

WATER TEMPERATURE

Because steelhead immigration to the Tuolumne River primarily occurs during the winter months, water temperature downstream of La Grange Dam is likely suitable for steelhead adult immigration. However, any adults attempting to migrate during the fall and summer months may experience reduced egg viability.

WATER QUALITY

Water quality in the Tuolumne River is adequate to support steelhead adult immigration and holding.

FLOW CONDITIONS

Prescribed baseflows for October 1 through May 15 range from between 100 cfs and 200 cfs for the drier 50 percent exceedance water years, and 300 cfs for the wetter 50 percent exceedance years (McBain and Trush 2000). Minimum instream flows during summer are 50 cfs and 250 cfs for critically dry and normal-wet years respectively (McBain and Trush 2000).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

The La Grange Dam at RM 52.2 presents an impassable barrier to upstream migrating anadromous salmonids and marks the upstream extent of currently accessible steelhead habitat in the Tuolumne River.

HARVEST/ANGLING IMPACTS

The Tuolumne River, from La Grange Dam downstream to the confluence with the San Joaquin River supports a catch and release recreational trout fishery from January 1 through October 15.

WATER TEMPERATURE

Water temperatures in the Tuolumne River during winter months are likely suitable for steelhead spawning.

WATER QUALITY

Water quality in the Tuolumne River likely does not adversely affect steelhead spawning.

FLOW CONDITIONS

Flow standards for the protection of steelhead in the Tuolumne River were implemented in 1991.

SPAWNING HABITAT AVAILABILITY

Habitat suitable for spawning on the Tuolumne River is finite, such that there is an absolute limit on production. A 1986 estimate of spawning habitat enumerated 72 riffles and 2.9 million square feet of riffle area at a flow of 230 cfs (McBain & Trush 1998). Studies on spawning habitat conducted in the 1980s concluded that spawning habitat availability was a significant factor in limiting salmon production in the Tuolumne River.

PHYSICAL HABITAT ALTERATION

Dams, aggregate extraction, agricultural and urban encroachment, and other land uses have caused sediment imbalances in the channel. Reduced magnitude, duration and frequency of high flows has allowed fine sediment to accumulate in the Tuolumne River. Additionally, the elimination of coarse sediment from upstream reaches has degraded salmonid spawning habitat (McBain & Trush 1998).

HATCHERY EFFECTS

The extent of interaction with steelhead spawning in the Tuolumne River with hatchery produced steelhead is unknown. Genetic studies indicate that Tuolumne River steelhead are closely related to other populations in the San Joaquin Basin.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The Tuolumne River, from La Grange Dam downstream to the confluence with the San Joaquin River supports a catch and release recreational trout fishery from January 1 through October 15. Therefore, it is possible that redds could be inadvertently disrupted by wading anglers.

WATER TEMPERATURE

Water temperatures in the Tuolumne River during the time period when most steelhead embryos are incubating are likely suitable. However, water temperatures in the Tuolumne River begin rising in the spring and may become unsuitable within redds that were constructed later in the spawning season (DWR 2007).

WATER QUALITY

Water quality in the Tuolumne River likely does not adversely affect steelhead embryo incubation.

FLOW CONDITIONS

Flow standards for the protection of steelhead in the Tuolumne River were implemented in 1991.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

High water temperatures during summer months are likely a limiting factor for steelhead rearing in the lower Tuolumne River. Water temperatures are particularly problematic at low flows.

High daily fluctuations in water temperature at low flows have been observed in the lower river (ranging from 12°F to 14°F daily) (McBain & Trush 1998). Current FERC flow schedules appear to provide suitable rearing habitat for the first 15 miles downstream of La Grange Dam during non-dry years (McBain & Trush 1998). Temperatures may not be low enough (<14 C) to optimize smoltification within the Tuolumne River and increase survival to the ocean (Myrick and Cech 2001).

WATER QUALITY

Water quality in the Tuolumne River likely does not adversely affect juvenile steelhead.

FLOW CONDITIONS

The magnitude, duration, and frequency of elevated spring flows in the Tuolumne River has been altered by operations of LaGrange Dam which may negatively impact migrating juvenile steelhead. A strong correlation has been established between annual spring flow magnitude and the production of salmon smolt outmigrants from the a tributary, survival of smolts in the Delta and the production of adults in the escapement and ocean harvest (Mesick 2008, Mesick and Marston 2007).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

An area of management concern in the Tuolumne River is the health of the riparian vegetation along the entire river corridor. The primary concern is that many of the riparian forests on the Tuolumne River consist of mature trees that are not being replaced with new growth (Mesick et al. 2007).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Controlled flows in the Tuolumne River have reduced the magnitude and frequency of high flow events that are part of the natural flow regime thereby decreasing habitat diversity and complexity in the lower river.

LOSS OF FLOODPLAIN HABITAT

Attenuation of peak flows in the Tuolumne River have reduced the frequency of floodplain inundation and severed the frequency of river connection to the floodplain.

ENTRAINMENT

The extent of entrainment in water diversions occurring on the Tuolumne River has not been well studied and no data is available to assess effects.

PREDATION

Predation by introduced species of bass may be a dominant source of mortality under low-flow conditions for juvenile salmonids in the Tuolumne River. In-channel aggregate extraction pits appear to provide ideal habitat for predators. The largemouth bass population in the lower Tuolumne River was estimated to be between 10,000 and 11,000 fish in 1992 (McBain & Trush 1998). Brown (2000) suggests that introduced species found in the lower reaches of tributaries to the San Joaquin River and the lower mainstem San Joaquin River likely compete with and predate upon downstream migrants.

HATCHERY EFFECTS

Juvenile steelhead rearing in the Tuolumne River are not likely affected by hatchery production.

4.3.11.5 MERCED RIVER

The Merced River is a tributary to the San Joaquin River in the southern portion of California's Central Valley. The river, which drains an area of 1,276 square miles, originates in Yosemite National Park and flows southwest through the Sierra Nevada, where it joins the San Joaquin River 87 miles south of Sacramento.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The confluence of the Merced and San Joaquin Rivers is at RM 113 of the San Joaquin River. The first 51 miles of the Merced River is accessible to anadromous salmonids. The Crocker-Huffman Dam at RM 51 presents an impassable barrier to upstream migration and marks the upstream extent of currently accessible steelhead habitat.

HARVEST/ANGLING IMPACTS

The Merced River supports a catch and release fishery from January 1 through October 31. Only artificial lures with barbless hooks are allowed from Crocker-Huffman Dam downstream to the Schaffer Bridge on Oakdale road. From that point downstream to the confluence with the San Joaquin River, bait may be used but with restrictions on hook size.

WATER TEMPERATURE

Water temperatures during the steelhead adult immigration life stage normally range from 50°F to 55°F (Vogel 2003).

WATER QUALITY

The effects on aquatic life from water quality conditions in the Merced River have not been well studied. Factors that may affect aquatic life include nutrients, point source discharges from wastewater treatment facilities and non-point source contaminants from agricultural runoff. For example, the Merced River has been identified as impaired for the agricultural pesticides diazinon, chlorpyrifos, and Group A pesticides. It is not likely that water quality parameters are at a level to adversely affect adult steelhead.

FLOW CONDITIONS

Minimum instream flow requirements in the Merced River are defined under Merced Irrigation District's current licenses and agreements and are attended to provide adequate flows for anadromous salmonids and for the Merced River Riparian Water Users Association diversions (Stillwater Sciences 2001). Flows vary by month but typically range from about 230 cfs to 270 cfs during the steelhead adult immigration life stage (Stillwater Sciences 2001).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

The confluence of the Merced and San Joaquin Rivers is at RM 113 of the San Joaquin River. The first 51 miles of the Merced River, ending at the impassable Crocker-Huffman Dam, is accessible to anadromous salmonids.

HARVEST/ANGLING IMPACTS

The Merced River supports a catch and release fishery from January 1 through October 31. Only artificial lures with barbless hooks are allowed from Crocker-Huffman Dam downstream to the Schaffer Bridge on Oakdale road. From that point downstream to the confluence with the San Joaquin River, bait may be used but with restrictions on hook size.

WATER TEMPERATURE

Water temperatures during the steelhead spawning life stage normally range from 50°F to 55°F (Vogel 2003).

WATER QUALITY

Water quality is discussed above under Adult Immigration. Agricultural runoff likely occurs downstream of steelhead spawning and likely does not adversely affect steelhead spawning.

FLOW CONDITIONS

Minimum instream flow requirements in the Merced River are defined under Merced Irrigation District's current licenses and agreements and are intended to provide adequate flows for anadromous salmonids and for the Merced River Riparian Water Users Association diversions (Stillwater Sciences 2001). Flows vary by month but typically range from about 230 cfs to 270 cfs during the steelhead spawning life stage (Stillwater Sciences 2001).

SPAWNING HABITAT AVAILABILITY

Accumulation and retention of coarse sediment suitable for steelhead spawning has been prevented by flow regulation and sediment capture by dams, likely reducing the quantity and quality of spawning habitat.

PHYSICAL HABITAT ALTERATION

The lower Merced River has been altered substantially by gravel mining and dredging activities. This has resulted in channelization of the river as well as substrate armoring.

HATCHERY EFFECTS

Recent genetic analysis of the Merced River Hatchery (MRH) fall-run stock (Garza *et al.* 2007) found the hatchery stock to be the most divergent of the fall-run populations examined for the

study, and genetically distinct from the Merced River fall-run population. Its genetic dichotomy is conjectured as a product of either hybridization with a fall-run genome not found in the Central Valley ESU, or strong natural selection acting on the hatchery stock, although this is questionable as some number of in-river fish are likely incorporated into the broodstock for the program.

MRH fall-run are primarily utilized for the VAMP mark-recapture monitoring activities, and otherwise propagated for recreational purposes. VAMP releases all occur in the Delta, with some component of fish releases never recovered and therefore having the potential to stray as adult returns into streams other than the Merced River. Recent habitat and disease problems in the Merced River have resulted in fewer fish returning to the hatchery and forcing the downsizing or adaptive management of the VAMP study, which would decrease the effects of straying by virtue of smaller release numbers.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The Merced River supports a catch and release fishery from January 1 through October 31. It is possible that redds may be disturbed by wading anglers during the embryo incubation life stage.

WATER TEMPERATURE

Water temperatures during the steelhead embryo incubation life stage normally range from 50°F to 55°F (Vogel 2003).

WATER QUALITY

Water quality is discussed above under Adult Immigration. Agricultural runoff likely occurs downstream of where steelhead spawning occurs and likely does not adversely affect embryo incubation.

FLOW CONDITIONS

Minimum instream flow requirements in the Merced River are defined under Merced Irrigation District's current licenses and agreements and are attended to provide adequate flows for anadromous salmonids and for the Merced River Riparian Water Users Association diversions (Stillwater Sciences 2001). Flows vary by month but typically range from about 230 cfs to 270 cfs during the steelhead embryo incubation life stage (Stillwater Sciences 2001).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in the Merced River, measured at Crocker-Huffman Dam are normally below 60°F year-round other than September and October when temperatures near 63°F (Vogel 2003). In the spring when Crocker-Huffman Dam release flows are reduced (less than 569cfs) warmer water temperatures result (71° F), in comparison to when Crocker-Huffman Dam flows are increased (about 4500 cfs) water temperature during the spring is reduced substantially (59° F). Excessive water temperatures were recorded during the summer period in the primary steelhead rearing area of the lower Merced River (Marston 2007).

WATER QUALITY

Water quality is discussed above under Adult Immigration. Agricultural runoff and pollutants from wastewater treatment facilities likely occur downstream of where most steelhead rearing occurs. However, outmigrating juvenile would be exposed and may exhibit decreased survival particularly during the irrigation season.

FLOW CONDITIONS

Minimum instream flow requirements in the Merced River are defined under Merced Irrigation District's current licenses and agreements and are attended to provide adequate flows for anadromous salmonids and for the Merced River Riparian Water Users Association diversions (Stillwater Sciences 2001). Flows vary by month but typically range from about 230 cfs to 270 cfs during the winter months, increase to about 300 cfs during the spring and begin decreasing in August. Low flows of 65 cfs to 75 cfs occur in October (Stillwater Sciences 2001). The magnitude, duration, and frequency of elevated spring flows in the Merced River has been altered by operations of Crocker-Huffman Dam which may negatively impact migrating juvenile steelhead. A strong correlation has been established between annual spring flow magnitude and the production of salmon smolt outmigrants from the a tributary, survival of smolts in the Delta and the production of adults in the escapement and ocean harvest (Mesick 2008, Mesick and Marston 2007).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Gravel mining along the Merced River has resulted in significant loss of riparian vegetation, particularly in the seven-mile reach downstream from Crocker Huffman Dam. Farther downstream the riparian zone ranges in width from 100 to 300 feet.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Since the completion of New Exchequer Dam in 1967, mean annual flood discharge has been reduced by 80 percent (based on records from WY 1968 to 2000 at the Snelling gage) (Stillwater Sciences 2003). Operating rules for the Merced Irrigation District imposed by the USACE currently limit releases from New Exchequer Dam to 6,000 cfs. The lower flows reduce the incidence of flow events believed to be geomorphically effective for maintaining properly functioning stream channels and associated riparian and floodplain habitats (Stillwater Sciences (2003).

LOSS OF FLOODPLAIN HABITAT

No state or federal levee system has been constructed on the Merced River and existing levees are limited to privately owned structures. The levee system is, however, extensive, especially downstream of the State Route 99 Bridge at RM 20.5. Private landowners have constructed and maintain these levees which protect agricultural lands and houses. These levees confine the river and floodplain width and isolate the river from its former floodplain (Stillwater Sciences 2001).

ENTRAINMENT

The extent of entrainment in water diversions occurring on the Merced River has not been well studied and no data is available to assess effects.

PREDATION

Extensive gravel mining in the lower Merced River has resulted in deep instream pits in the river and has also led to a decrease in riffles and riparian cover. These factors likely change predator-prey dynamics in the system likely favoring predators. Brown (2000) suggests that introduced species found in the lower reaches of tributaries to the San Joaquin River and the lower mainstem San Joaquin River likely compete with and predate upon downstream migrants.

HATCHERY EFFECTS

The MRH is located immediately downstream of the Crocker-Huffman Dam. The hatchery raises and releases Chinook salmon to supplement natural production in the Merced River. Although most of the production is released on-site, the hatchery likely has little effect on steelhead juveniles as hatchery Chinook likely migrate downstream upon release.

4.3.11.6 UPPER SAN JOAQUIN RIVER

The San Joaquin River drains the southern portion of California's Central Valley. The river basin is bounded by the Sierra Nevada to the east and the Coast Ranges to the west. The southern boundary of the drainage is the divide that separates it from the Tulare Lake basin, and its northern boundary is the Delta near Stockton. The river, which drains a 13,536-square-mile watershed, originates in the Sierra Nevada and flows for approximately 350 miles before joining the Delta. Elevations in the watershed range from 11,000 feet at the headwaters to sea level at the Delta. Friant Dam (RM 267), which impounds Lake Millerton, is the primary mainstem dam controlling flows on the San Joaquin River. Friant Dam also marks the currently accessible upstream extent of anadromous salmonid habitat.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The San Joaquin River upstream of the confluence with the Merced River has no remaining significant native fishery (USACE and Reclamation Board 1999). Although Friant Dam presents an upstream migration barrier to anadromous salmonids, flows released from Friant Dam are insufficient to provide year-round flow except during high flow events (USACE and Reclamation Board 1999).

HARVEST/ANGLING IMPACTS

The upper San Joaquin River, from Friant Dam downstream to the Highway 140 Bridge is open for trout fishing year-round and the taking of five trout is allowed. From the Highway 140 Bridge downstream to the Interstate 5 Bridge, the fishery is open year-round but trout must be released.

WATER TEMPERATURE

During the winter months, water temperatures in the San Joaquin River are likely low enough to support steelhead upstream migration.

WATER QUALITY

Water quality in the San Joaquin River varies seasonally, but in periods of low flow is generally degraded due to high temperatures, heavy metals, and pesticides from drainage. During the irrigation season (March through October) and occasionally following the flushing of the drainage water from duck clubs (January and February), degraded quality drainage water makes up a significant portion of the total San Joaquin River flow (USDI *et al.* 1999).

FLOW CONDITIONS

Flow releases from Friant Dam are maintained year-round, but the required 5 cfs measured at Gravelly Ford rapidly infiltrates into the gravel substrate near Gravelly Ford. The net result is no flow from Gravelly Ford to Mendota Pool, except during high flow events. The river channel often does not have water again until agricultural return flows begin to make up the majority of flow around Madera Pool (USACE and Reclamation Board 1999).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

The San Joaquin River upstream of the confluence with the Merced River has no remaining significant native fishery (USACE and Reclamation Board 1999). Although Friant Dam presents an upstream migration barrier to anadromous salmonids, flows released from Friant Dam are insufficient to provide year-round flow except during high flow events (USACE and Reclamation Board 1999).

HARVEST/ANGLING IMPACTS

The upper San Joaquin River, from Friant Dam downstream to the Highway 140 Bridge is open for trout fishing year-round and the taking of five trout is allowed. From the Highway 140 Bridge downstream to the Interstate 5 Bridge, the fishery is open year-round but trout must be released.

WATER TEMPERATURE

During the winter months, water temperatures in the San Joaquin River are likely low enough to support steelhead spawning.

WATER QUALITY

Water quality in the San Joaquin River varies seasonally, but in periods of low flow is generally degraded due to high temperatures, heavy metals, and pesticides from drainage. During the irrigation season (March through October) and occasionally following the flushing of the

drainage water from duck clubs (January and February), degraded quality drainage water makes up a significant portion of the total San Joaquin River flow (USDI *et al.* 1999).

FLOW CONDITIONS

Flow releases from Friant Dam are maintained year-round, but the required 5 cfs measured at Gravelly Ford rapidly infiltrates into the gravel substrate near Gravelly Ford. The net result is no flow from Gravelly Ford to Mendota Pool, except during high flow events. The river channel often does not have water again until agricultural return flows begin to make up the majority of flow around Madera Pool (USACE and Reclamation Board 1999).

SPAWNING HABITAT AVAILABILITY

Only limited spawning habitat is available in the San Joaquin River and low flows likely make that habitat unusable. It is likely that the San Joaquin River is utilized only as a migration corridor to habitat in the Stanislaus, Tuolumne and Merced rivers.

PHYSICAL HABITAT ALTERATION

The construction of dams and resultant controlled flows and extensive gravel mining have likely destroyed almost all potential spawning habitat in the San Joaquin River.

HATCHERY EFFECTS

Hatchery effects on spawning steelhead in the San Joaquin River are not well known.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The upper San Joaquin River, from Friant Dam downstream to the Highway 140 Bridge, is open for trout fishing year-round and the taking of five trout is allowed. From the Highway 140 Bridge downstream to the Interstate 5 Bridge, the fishery is open year-round but trout must be released. If any steelhead spawning were to occur in the San Joaquin River, redd disruption by wading anglers is likely.

WATER TEMPERATURE

Water temperatures in the San Joaquin River downstream of Friant Dam are likely cold enough to support steelhead embryo incubation but it is likely that the lack of spawning habitat and low flows preclude the San Joaquin River from steelhead spawning.

WATER QUALITY

Water quality in the San Joaquin River varies seasonally, but in periods of low flow is generally degraded due to high temperatures, heavy metals, and pesticides from drainage. During the irrigation season (March through October) and occasionally following the flushing of the drainage water from duck clubs (January and February), degraded quality drainage water makes up a significant portion of the total San Joaquin River flow (USDI *et al.* 1999).

FLOW CONDITIONS

It is not likely that any significant steelhead spawning activity occurs in the San Joaquin River and it is used only as a migration corridor.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in the late spring, summer and early fall are likely too warm to support use of the San Joaquin River by steelhead for anything other than a migration corridor.

WATER QUALITY

Water quality in the San Joaquin River varies seasonally, but in periods of low flow is generally degraded due to high temperatures, heavy metals, and pesticides from drainage. During the irrigation season (March through October) and occasionally following the flushing of the drainage water from duck clubs (January and February), degraded quality drainage water makes up a significant portion of the total San Joaquin River flow (USDI *et al.* 1999).

FLOW CONDITIONS

During periods of low flow, the San Joaquin River likely provides poor to marginal habitat for steelhead juveniles. Currently, the San Joaquin River is probably only utilized as a migration corridor.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Only about eight to ten percent of riparian forests in the San Joaquin Valley still remain; most were converted to agricultural land. At present, urbanization, recreational development, aggregate mining and road construction are considered to be the main stressors, in addition to continuing agricultural encroachment in the floodplain, to the remaining riparian vegetation (USACE and Reclamation Board 1999; USDI *et al.* 1999).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Confining flood flows in reservoirs and between levees has caused the loss of natural hydrologic and geomorphic processes. Habitat for fish and wildlife has been lost or severely degraded as a result of loss of natural processes (USACE and Reclamation Board 1999; USDI *et al.* 1999).

LOSS OF FLOODPLAIN HABITAT

The combination of controlled flow regimes and agricultural encroachment has severed most of the connection between the San Joaquin River and its historical floodplain (USACE and Reclamation Board 1999; USDI *et al.* 1999).

ENTRAINMENT

The level of entrainment of juvenile steelhead in the San Joaquin River is not documented.

PREDATION

The San Joaquin River supports a variety of introduced warmwater fish including black bass species known to prey on juvenile salmonids. Additionally, in-river gravel mining and other disturbances have likely altered habitat and affected predator-prey dynamics likely favoring predators. Brown (2000) suggests that introduced species found in the lower reaches of tributaries to the San Joaquin River and the lower mainstem San Joaquin River likely compete with and predate upon downstream migrants.

HATCHERY EFFECTS

Hatchery production of steelhead likely does not affect juveniles in the San Joaquin River.

4.4 STRESSOR PRIORITIZATION

4.4.1 STRESSOR MATRIX DEVELOPMENT

4.4.1.1 STRESSOR MATRIX OVERVIEW

Stressor matrices, in the form of Microsoft Excel spreadsheets, were developed to structure the steelhead diversity group, population, life stage, and stressor information into hierarchically related tiers so that stressors within each diversity group and population in the DPS could be prioritized. The individual tiers within the matrices, from highest to lowest, are: (1) diversity group; (2) population; (3) life stage; (4) primary stressor category; and (5) specific stressor. These individual tiers were related hierarchically so that each variable within a tier had several associated variables at the next lower tier, except at the lowest tier. The four diversity groups were equally weighted in order to be consistent with the recovery criteria described in this recovery plan, which were, in-part, based on the “representation and redundancy” rule described in Lindley *et al.* (2007). This rule reflects the importance of having multiple diversity groups comprised of multiple independent populations in order to recover the DPS (Lindley *et al.* 2007).

The general steps required to develop and utilize the steelhead matrices are identical to those of spring-run Chinook salmon. Please see Section 3.4.1.1 for a description of those steps.

The completed stressor matrix sorted by normalized weight is a prioritized list of the life stage-specific stressors affecting the DPS. For steelhead, threats were prioritized within each diversity group as well as within each population. Specific information explaining the individual steps taken to generate these prioritized lists is provided in the following sections.

4.4.1.2 POPULATION IDENTIFICATION AND RANKING

The threats assessments for the Central Valley steelhead DPS included rivers that both historically supported, and currently support steelhead populations. For the Central Valley steelhead threats assessment, 26 individual rivers/watersheds that historically supported and currently support populations of steelhead were identified using literature describing the historical population structure of steelhead in the Central Valley (Lindley *et al.* 2006) and by using the best professional knowledge of biologists on the current distribution of steelhead. These 26 steelhead populations were categorized into four diversity groups based on the geographical structure described in Lindley *et al.* (2007) (**Table 4-4**).

Table 4-4. Extant Central Valley Steelhead Populations Included in the Threats Assessment Categorized by Diversity Group

Northern Sierra Nevada Diversity Group	Basalt and Porous Lava Diversity Group	Northwestern California Diversity Group	Southern Sierra Nevada Diversity Group
American River	Battle Creek	Stony Creek	Mokelumne River
Auburn/Coon Creek	Cow Creek	Thomes Creek	Calaveras River
Dry Creek	Upper Sacramento River	Cottonwood/Beegum Creek	Stanislaus River
Feather River	Tributaries ¹¹	Clear Creek	Tuolumne River
Bear River	Upper Sacramento River (mainstem)	Putah Creek	Merced River
Yuba River			San Joaquin River (mainstem)
Butte Creek			
Big Chico Creek			
Deer Creek			
Mill Creek			
Antelope Creek			

Source: (Lindley *et al.* 2007)

It is recognized that more than 26 rivers/watersheds that historically supported and currently support steelhead exist in the Central Valley, however it is assumed that recovery of the Central Valley steelhead DPS is primarily dependent on the 26 populations included in the threats assessment.

The steelhead population ranking procedure was identical to that of spring-run Chinook salmon. Please see Section 3.4.1.2 for a description of the population ranking procedure. The population weight is intended to reflect the relative importance of a population to the viability of the diversity group to which it is categorized. The weighting characteristic scores and population weights for each steelhead population in each of the four diversity groups are presented in **Tables 4-5, 4-6, 4-7, and 4-8.**

Table 4-5. Weighting Characteristic Scores and Population Weights for Each Steelhead Population in the Northern Sierra Nevada Diversity Group

4.4.1.3 LIFE STAGE IDENTIFICATION AND RANKING

The life stage identification and ranking procedures for steelhead were identical to that of winter-run Chinook salmon. Please see Section 2.4.1.3 for a description of those procedures. The life stage weightings for each steelhead population are presented in Attachment C.

4.4.1.4 STRESSOR IDENTIFICATION AND RANKING

The stressor identification and ranking procedures for steelhead were identical to that of winter-run Chinook salmon. Please see Section 2.4.1.4 for a description of those procedures.

4.4.2 STRESSOR MATRIX RESULTS

4.4.2.1 NORTHERN SIERRA NEVADA DIVERSITY GROUP

The northern Sierra Nevada diversity group is comprised of the American, Feather, Bear, and Yuba rivers, and Auburn/Coon, Dry, Butte, Big Chico, Deer, Mill, and Antelope creeks. Stressors of high importance were identified for all populations and life stages in this diversity group including:

- ❑ Passage impediments and/or barriers affecting adult immigration in all of the rivers and creeks, except for Bear River¹² and Big Chico Creek;
- ❑ High water temperatures during the adult immigration and holding life stage in Bear River, and Antelope, Deer, Mill, Big Chico, Butte, and Dry creeks;
- ❑ The Nimbus and Folsom dams on the American River, the Fish Barrier Dam and Oroville Dam on the Feather River, and Englebright Dam on the Yuba River as barriers blocking access to historic holding and spawning habitats;
- ❑ The existence trout fisheries supplemented through stocking in the upper sections of Deer, Mill, and Antelope creeks, which likely affects the genetic integrity of anadromous steelhead;

¹² Camp Far West Dam on the Bear River was built at the site of a natural barrier that historically blocked access to upstream habitats.

- ❑ Sedimentation in Mill and Deer creeks, and the potential for hazardous spills in Deer Creek¹³ affecting the embryo incubation life stage;
- ❑ Entrainment of juvenile steelhead in Antelope and Auburn/Coon creeks, and in the Yuba and Bear rivers; and
- ❑ Numerous factors affecting the juvenile rearing and outmigration life stage in the Delta and lower Sacramento River such as loss of floodplain habitat, loss of natural river morphology and function, loss of riparian habitat and instream cover, and predation.

Additional stressors were identified as having a very importance to the northern Sierra Nevada steelhead diversity group. The complete prioritized list of life-stage specific stressors to this diversity group is displayed in Attachment C.

4.4.2.2 BASALT AND POROUS LAVA DIVERSITY GROUP

For the purposes of this threats assessment, the basalt and porous lava diversity group is comprised of four populations: Battle and Cow creeks, the mainstem Upper Sacramento River, and the Upper Sacramento River tributaries including Stillwater, Churn, Sulphur, Salt, Olney, and Paynes creeks. Stressors of high importance were identified for all populations and life stages in this diversity group including:

- ❑ Passage impediments and/or barriers affecting adult immigration in all of the rivers and creeks;
- ❑ High water temperatures during the adult immigration and holding life stage in all of the rivers and creeks;
- ❑ Keswick Dam as a barrier blocking access of the mainstem Sacramento River population to historic holding and spawning habitats;
- ❑ CNFH-origin steelhead spawning with natural-origin steelhead, potentially affecting the genetic and biological diversity of the Battle Creek population;
- ❑ The existence of a trout fishery supplemented through stocking in the upper sections of Cow Creek, which likely affects the genetic integrity of anadromous steelhead;
- ❑ Releases of yearling steelhead produced at CNFH competing with and preying on naturally spawned juvenile steelhead in Battle Creek;
- ❑ High water temperatures in and poor water quality during the embryo incubation life stage in Cow Creek;
- ❑ Entrainment of juvenile steelhead in Cow Creek and the upper Sacramento River tributaries, and entrainment in the Delta, lower Sacramento River, and middle Sacramento River; and
- ❑ Numerous factors affecting the juvenile rearing and outmigration life stage in the Delta and lower Sacramento River such as loss of floodplain habitat, loss of natural river morphology and function, loss of riparian habitat and instream cover, and predation.

Additional stressors were identified as having a high importance to the basalt and porous lava steelhead diversity group. The complete prioritized list of life-stage specific stressors to this diversity group is displayed in Attachment C.

¹³ Highway 32, a major truck route for petroleum distribution, runs parallel and adjacent to Deer Creek for several miles. During winter, road conditions along this section of the highway are poor and accidents are common.

4.4.2.3 NORTHWESTERN CALIFORNIA DIVERSITY GROUP

For the purposes of this threats assessment, the Northwestern California steelhead diversity group is comprised of Stony, Thomes, Beegum, Clear, and Putah creeks. Stressors of very high importance were identified for all populations and life stages in this diversity group including:

- ❑ Passage impediments and/or barriers affecting adult immigration in all of the creeks, including Black Butte Dam on Stony Creek, Solano and Monticello dams on Putah Creek, Whiskeytown Dam on Clear Creek, and Red Bluff Diversion Dam on the Sacramento River;
- ❑ High water temperatures during the adult immigration and holding life stage in all of the creeks, except for Putah Creek;
- ❑ Limited spawning habitat availability in all of the creeks, except for Putah Creek;
- ❑ Sedimentation, flow fluctuations, and high water temperatures affecting embryo incubation in Clear Creek, sedimentation affecting this life stage in Beegum Creek, and high water temperatures affecting this life stage in Thomes Creek;
- ❑ Numerous factors affecting the juvenile rearing and outmigration life stage in the Delta and Sacramento River such as entrainment, loss of floodplain habitat, loss of natural river morphology and function, loss of riparian habitat and instream cover, and predation.

Additional stressors were identified as having a high importance to the Northwestern California diversity group. The complete prioritized list of life stage-specific stressors to this diversity group is displayed in Attachment C.

4.4.2.4 SOUTHERN SIERRA NEVADA DIVERSITY GROUP

For the purposes of this threats assessment, the Southern Sierra Nevada steelhead diversity group is comprised of the Mokelumne, Calaveras, Stanislaus, Tuolumne, Merced, and San Joaquin rivers. Stressors of high importance were identified for all populations and life stages in this diversity group including:

- ❑ Passage impediments and/or barriers affecting adult immigration in all of the rivers, including Sack Dam, Mendota Pool, and Friant Dam on the San Joaquin River, Bellota Weir and flashboard dams on the Calaveras River, Don Pedro and La Grange dams on the Tuolumne River, Tulloch, Goodwin and New Melones dams on the Stanislaus River, Camanche and Pardee dams on the Mokelumne River, and Crocker Huffman, McSwain, and New Exchequer dams on the Merced River;
- ❑ High water temperatures and low-flow conditions during the adult immigration and holding life stage in all of the rivers;
- ❑ Limited spawning habitat availability in all of the rivers and limited instream gravel supply in all of the rivers except for the San Joaquin River;
- ❑ Flow fluctuations affecting the embryo incubation life stage in the Calaveras, Stanislaus, Tuolumne, Mokelumne, and Merced rivers;
- ❑ Low flows limiting juvenile rearing habitat availability in the San Joaquin, Calaveras, Merced, Stanislaus, and Tuolumne rivers; and
- ❑ Numerous factors affecting the juvenile rearing and outmigration life stage in the Delta and San Joaquin River such as entrainment, loss of floodplain habitat, loss of natural river morphology and function, loss of riparian habitat and instream cover, predation, and poor water quality.

Additional stressors were identified as having a high importance to the Southern Sierra Nevada steelhead diversity group. The complete prioritized list of life stage-specific stressors to this diversity group is displayed in Attachment C.

VSP	Viable Salmonid Population
WSRCD	Western Shasta Resource Conservation District

1.0 INTRODUCTION

This Recovery Plan maintains a consistent strategic framework for the establishment of recovery goals and criteria, the identification and prioritization of threats, and the identification of recovery actions. As described in Chapter 4, the framework for ESU or DPS recovery includes goals and criteria directed at the diversity group (recovery units) and population (management units) levels. Similarly, the threats assessment framework for each ESU or DPS also was organized by diversity groups and populations. For winter-run Chinook salmon, threats were prioritized within the Sacramento River population, whereas for spring-run Chinook salmon and steelhead, threats were prioritized within each diversity group as well as within each population.

Results from the threats assessment and prioritization process (described in Appendix B) were used to guide the identification of watershed- and site-specific recovery actions for each diversity group and population. In that process, threat/stressor matrices were used to structure diversity group, population, life stage, and stressor information into hierarchically-related tiers so that stressors to each ESU or DPS could be prioritized. Although the matrices provide a semi-quantitative means of comparatively ranking individual stressors within a diversity group or population, it is important to avoid attributing unwarranted specificity to the prioritized stressor list. As such, the prioritized stressor list was distributed into four separate quartiles which represent four tiers of stressor importance, identified as “Very High”, “High”, “Medium”, or “Low” importance.

In an effort to focus and direct energy at the most significant threats (i.e., threats in the “Very High” or “High” quartiles) to the Sacramento River winter-run Chinook salmon ESU, the Central Valley spring-run Chinook salmon ESU, and the Central Valley steelhead DPS, watershed- or site-specific recovery actions for the threats ranked in the “Medium” or “Low” quartiles have not been described in this recovery plan. Although such actions would certainly contribute to ESU or DPS recovery, considering the number of specific threats that ranked in the “Very High” or “High” quartiles for each diversity group¹, we believe an efficient recovery strategy should address the most important threats first.

An additional effort to prioritize recovery actions was undertaken through consideration of specific actions that benefit multiple species and populations. The initial step in this prioritization process was to organize recovery actions according to prioritized identified threats by geographic location throughout the Central Valley Domain.

The geographic locations are organized by specific areas that are most commonly used by multiple species and populations for some part of their life-history, specifically including juvenile rearing, juvenile emigration, and adult upstream migration. For example, the Delta is used by all anadromous salmonid populations at some stage(s) of their life cycles. Therefore, recovery actions in the Delta would have the highest priority in terms of providing multiple species and populations benefits because they affect all species and populations. Consequently, in consideration of potential benefits to multiple species and populations resulting from implementation of a specific recovery action, the descending order of geographic prioritization includes the Delta, lower Sacramento River, middle Sacramento River, upper Sacramento River, and the individual diversity groups (i.e., Northern Sierra Nevada, Basalt and Porous Lava, Northwestern California and Southern Sierra Nevada).

¹ Nearly 250 specific threats were identified in the “Very High” quartile for the Northern Sierra Nevada steelhead diversity group alone.

For each geographic area, recovery actions are organized in descending order of priority for species based on the priority assigned to Sacramento River winter-run Chinook salmon, Central Valley spring-run Chinook salmon, and Central Valley steelhead. Therefore, because winter-run Chinook salmon is identified as having the highest priority, recovery actions associated with winter-run Chinook salmon are given highest priority in Tables 2-1 through 2-6. Although spring-run Chinook salmon and steelhead are considered to have the same priority, spring-run Chinook salmon were assigned the next highest priority because only three remaining natural populations with consistent spawning exist, and they are in geographic proximity to each other. Consequently, due to the geographic and ESU/DPS-specific prioritization format, there are some occasions when a “very high” and “high” priority action for a given species/population also addresses a “low” or “medium” action identified for an additional species/population, and therefore are incorporated into the recovery action prioritization matrices.

A cross-referencing procedure was developed so that the relationship between prioritized threats, recovery actions, and threat abatement recovery criteria addressed by recovery actions could be tracked. This cross-referencing procedure is represented in matrix format in Tables 2-1 through 2-10, described as follows.

Species and populations were identified for each prioritized threat. A number was assigned to each threat so that individual prioritized threats could be identified. Recovery actions addressing each individually identified (numbered) threat were specified, and numerically differentiated corresponding to the identified threat. For example, if a threat was numerically identified as 2.1.1, then the recovery action corresponding to that threat would be identified as 2.1.1.1, and if more than one recovery action corresponded to a numerical threat then it would be sequentially numerically represented (e.g., 2.1.1.2, 2.1.1.3, 2.1.1.4, etc). Further, Chapter 4 of this Recovery Plan numerically identified individual threat abatement recovery criteria associated with specific listing factors and threats for winter-run Chinook salmon, spring-run Chinook salmon and steelhead. The threat abatement criteria associated with each identified threat and numbered recovery actions also were specified in Tables 2-1 through 2-10.

By linking specific recovery actions to the highest ranked threats, those recovery actions also become prioritized in importance to the diversity group or population. This structure provides the opportunity to consider recovery actions at multiple levels. Hence, recovery actions can be examined for the Central Valley Domain in its entirety, or for specific geographic areas, diversity groups or populations. For example, if a stakeholder or project proponent were interested in identifying recovery actions for a particular species/population in a given stream or watershed, the Stressor Matrix (Attachment A of Appendix B) and Appendix C could be used in combination to identify recovery actions for a specific area of interest (e.g., an individual stream or population). While Appendix C can be used to identify threats and associated recovery actions prioritized by species within each geographic area or diversity group, as described above, Attachment A of Appendix B could be used to identify the suite of life-stage specific stressors (i.e., characterized as threats in Appendix C) for a particular population or diversity group. Information contained in Attachment A and Appendix C could be used to cross-reference prioritized stressors identified in Attachment A with associated threats and recovery actions identified in Appendix C for a “priority of interest”.

According to NMFS’ 1990 Endangered and Threatened Species Listing and Recovery Priority Guidelines (55 FR 24296), recovery actions identified in a Recovery Plan are to be assigned priorities of 1 to 3, as follows.

Priority 1 – An action that must be taken to prevent extinction or to identify those actions necessary to prevent extinction

Priority 2 – An action that must be taken to prevent a significant decline in population numbers, habitat quality, or other significant negative impacts short of extinction

Priority 3 – All other actions necessary to provide for full recovery of the species

Priority 1 actions are described in Chapter 6 (Recovery Actions) and an implementation schedule for those critical actions is presented in Chapter 8 (Implementation). All of the remaining recovery actions identified in this Recovery Plan are considered Priority 2 actions, because they were identified to alleviate threats that ranked as “High” or “Very High” in the threats assessment and can be considered necessary to prevent a significant decline in population numbers, habitat quality or other significant negative impacts, directly or indirectly (e.g., through public outreach). Priority 2 actions are described in Tables 2-1 through 2-10 below. No Priority 3 recovery actions have been identified because there are numerous Priority 1 and Priority 2 actions that should be implemented first. As these higher priority actions are implemented over time and the status of winter-run Chinook salmon, spring-run Chinook salmon, and/or steelhead improves, it may be necessary to identify and prioritize remaining threats and associated actions, including actions necessary to provide full recovery (i.e., Priority 3 actions). However, at this time, recovery efforts should be directed at implementing the Priority 1 and Priority 2 actions.

The status of the recovery actions identified in Tables 2-1 through 2-10 will be assessed periodically through the adaptive management program of the recovery plan. During these assessments, the threats identification and prioritization process could be re-initiated to account for threats that have been alleviated and for changes in environmental and biotic conditions, which may have altered the distribution of stressors in terms of importance. Such alterations would result in a re-prioritization of recovery actions. Nonetheless, implementation of the prioritized recovery actions presented herein represent the first step at eliminating or alleviating the factors believed to be most detrimental to the viability of the Sacramento River winter-run Chinook salmon and Central Valley spring-run Chinook salmon ESUs, and the Central Valley steelhead DPS.

Tables 2-1 through 2-10 function to describe the site- and watershed- specific recovery actions that were developed to alleviate threats identified and prioritized during the threats assessment process (Appendix B) and the implementation schedule associated with those actions, including involved parties, time frames, and cost estimates.

The cost of many of the actions in Tables 2-1 through 2-10 was not estimated due to a lack of information upon which to base the estimates. It is anticipated that recovery action implementation costs that are not yet determinable will be periodically assessed and updated through the Recovery Plan’s adaptive management program. The cost of certain habitat restoration actions was based on information presented in a NOAA Tech Memo titled, “*Habitat Restoration Cost References for Salmon Recovery Planning*” (Thomson and Pinkerton 2008). That Tech Memo is included in this Recovery Plan as Appendix E.

Because: (1) the threats assessment was focused on watersheds and areas where winter-run, spring-run, or steelhead currently occur; and (2) the development of watershed- and site-specific recovery actions was limited to actions that address those threats, detailed threats information and associated recovery actions have not been identified in this Recovery Plan for watersheds that are currently unoccupied by those species. As described in Chapter 3, one component of the recovery strategy is to explore opportunities to reintroduce winter-run, spring-run, and steelhead into historic holding, spawning, and rearing habitats above large dams. This will involve detailed habitat assessments that will subsequently allow for the identification and prioritization of threats and associated recovery actions.

2.0 Priority 2 Recovery Actions

2.1 Ocean Recovery Actions

Table 2-1. Ocean Threats and Associated Recovery Actions

Species	Population(s)	Threat	Recovery Action(s)	Threat Abatement Recovery Criteria Addressed	Duration	Involved Parties			Estimated Cost (\$)				Comments	
						Federal	State	Other Parties	Cost Per Unit	Year 1	Year 2	Year 3		
Winter-run Chinook Salmon	Sacramento River.	2.1.1 Poor water quality in the ocean	2.1.1.1 Enhance water quality in the ocean, and along the coast by promoting and implementing sustainable practices on land in ways that will improve the health of ocean water quality	2.1: Threats to water quality	Long-term	NMFS, USFWS	CDFG, WDFW, ODFW	Pacific Fisheries Management Council	N/A	TBD	TBD	TBD		
	2.1.1.2 CDFG and National Marine Sanctuary Program should consider the ecological requirements of salmon and steelhead when designating sanctuaries													
Spring-run Chinook Salmon	Mill Creek, Deer Creek, Yuba River, Butte Creek, Feather River, Antelope Creek, Big Chico Creek, Battle Creek, Sacramento River, Beegum Creek, Thomes Creek, Clear Creek.		2.1.1.3 Establish and implement an integrated ecosystem protection and restoration strategy that is science-based and aligns conservation and restoration goals at the Federal, state, tribal, local, and regional levels.											
Steelhead	Beegum Creek, Thomes Creek, Stony Creek, Clear Creek, Big Chico Creek, Antelope Creek, Feather River, Yuba River, Mill Creek, Deer Creek, Sacramento River, Battle Creek, Upper Sacramento River tributaries, Cow Creek, San Joaquin River, Tuolumne River, Merced River, Calaveras River, Stanislaus River, Mokelumne River, Putah Creek.		2.1.1.4 Implement recommended actions from the White House Council on Environmental Quality, Interim Report of the Interagency Ocean Policy Task Force, September, 10, 2009.

2.7 Northern Sierra Nevada Diversity Group Recovery Actions

Table 2-7 Northern Sierra Nevada Diversity Group Threats and Associated Recovery Actions

Spring-run Chinook Salmon	Deer Creek.	2.7.1 Agricultural diversion dams in Deer Creek impeding and/or blocking adult immigration.	2.7.1.1 Permit and construct a state-of-the-art fish ladder that meets NMFS' adult fish passage criteria and install a new apron at the Cone-Kimball Diversion (AFRP Website 2005).	1.1: Threats to Spawning Habitat	5 Years	NMFS	CDFG	Deer Creek Watershed Conservancy, Deer Creek Irrigation District	N/A	2-3 million	TBD	TBD	One fish ladder project on the Sacramento River cost \$2.28 million (1999 \$). Source: Thomson and Pinkerton 2008.
Steelhead	Deer Creek.		2.7.1.2 Install state-of-the-art fish ladder and jump pool enhancement at Stanford-Vina Dam (AFRP Website 2005, NMFS 2007b).		5 Years	NMFS	CDFG	Deer Creek Watershed Conservancy, Deer Creek Irrigation District	N/A	2-3 million	TBD	TBD	One fish ladder project on the Sacramento River cost \$2.28 million (1999 \$). Source: Thomson and Pinkerton 2008.
			2.7.1.3 Conduct fish passage evaluation at all agricultural diversions in Deer Creek to determine if they meet NMFS' fish passage criteria (AFRP Website 2005). Design install, and maintain state-of-the-art fish passage facilities at diversions that currently do not meet the passage criteria.		5 Years	NMFS	CDFG	Deer Creek Watershed Conservancy, Deer Creek Irrigation District	N/A	TBD	TBD	TBD	Cost would be project-specific (e.g., the engineering investigation of anadromous fish passage (for adults and juveniles) in upper battle creek was estimated to cost \$790,000). Source: DWR 1997a.
			2.7.1.4 Study feasibility of consolidating diversion points to minimize the number of diversions on Deer Creek. Based on this study, consolidate diversions where feasible.		5 Years	NMFS	CDFG	Deer Creek Watershed Conservancy, Deer Creek Irrigation District	N/A	TBD	TBD	TBD	
			2.7.1.5 Assess the feasibility and need for modifying the lower Deer Creek falls fish ladder, to improve its function for allowing upstream passage to the upper six miles of anadromous habitat. Implement modifications as needed.		5 Years	NMFS	CDFG	Deer Creek Watershed Conservancy	N/A	TBD	TBD	TBD

The Central Valley Technical Recovery Team has published five reports that provide scientific guidance for planning the recovery of listed Chinook salmon and steelhead in the Central Valley. Those five reports appear in this appendix in the following order:

- ❑ Population structure of threatened and endangered Chinook salmon ESU in California's Central Valley basin.
- ❑ Historical population structure of Central Valley steelhead and its alteration by dams.
- ❑ Monitoring and research needed to manage the recovery of threatened and endangered Chinook and steelhead in the Sacramento-San Joaquin basin.
- ❑ Framework for assessing viability of threatened and endangered Chinook salmon and steelhead in the Sacramento-San Joaquin Basin.
- ❑ Directed connectivity among fish populations in a riverine network.

NOAA Technical Memorandum NMFS

This TM series is used for documentation and timely communication of preliminary results, interim reports, or special purpose information. The TMs have not received complete formal review, editorial control, or detailed editing.

Abstract

This report describes the historical structure of spring- and winter-run chinook salmon populations in the Sacramento-San Joaquin watershed based on historical distributional information, geography, hydrography, ecology, population genetics, life history information, and trends in abundance. For the purposes of technical recovery planning, there are potentially two levels of organization within the evolutionarily significant unit (ESU) that are of interest: populations and population groups. In future documents, we will describe ESU viability goals in terms of viable independent populations spread among population groups that will maintain the evolutionary potential and ensure the persistence of the ESU.

We divided the spring-run chinook salmon ESU into four geographic groups. Members of the groups inhabit similar environments, according to a principle components analysis of environmental variables. The groups are southern Cascades, northern Sierra, southern Sierra, and Coast Range. There were historically at least 18 independent populations of spring-run chinook salmon spread among these four groups, plus an additional seven spring-run chinook salmon populations that may have been strongly influenced by an adjacent population. Three of the 18 independent spring-run chinook salmon populations are extant (Mill, Deer and Butte Creek populations). Several of the seven dependent populations still have intermittent runs of spring-run chinook salmon, including Big Chico, Antelope, and Beegum creeks.

The winter-run chinook salmon ESU historically contained at least four independent populations. These populations all spawned in the southern Cascades, and have been extirpated from their historic spawning areas. The single extant population of winter-run chinook salmon spawns in habitat outside of this range (spawning below Keswick Dam on the floor of the Central Valley), and was founded by some unknown combination of fish from the original populations. The distribution and diversity of winter- and spring-run chinook salmon has been strongly altered by habitat modifications, especially the placement of impassable dams at low elevations throughout the Central Valley basin.

1 Introduction

1.1 Background

A major goal of the Central Valley Technical Recovery Team (TRT) is production of criteria that describe viable salmonid populations in terms of abundance, productivity, diversity and spatial structure (McElhany et al., 2000) for listed evolutionarily significant units (ESUs) in the Central Valley ¹. These viability factors can be assessed at various levels of biological organization, ranging from independent populations, through population groups experiencing similar environments and sharing life history traits, to the ESU. Viability assessments and viability criteria therefore require definition of population structure.

In this document, we delineate the historical population structure of the listed evolutionarily significant units of chinook salmon ² in the Central Valley domain (Plate 1), based on available evidence. We seek to describe the historical structure of ESUs because we are relatively certain that these structures were viable, i.e., capable of persisting for long periods of time. An ESU may not need to be at its historical levels of abundance, productivity, diversity and spatial structure in order to be viable, but the further it is from its historical structure, the less likely it is to be viable. We describe the population structure in terms of geographically-based population groups composed of independent and dependent populations.

Population groups are components of an ESU that partition genetic diversity. These groups might share common life history traits (e.g., early run timing cued to snow melt) or reside in the same region (e.g., a certain mountain range with environmental conditions different from other regions with the ESU boundaries). Identifying these population groups may be useful for several reasons. The first is that such groups represent genetic diversity within the ESU, and maintenance of this diversity is important for ESU persistence (McElhany et al., 2000). Second, if it is necessary or desirable to reintroduce salmonids to areas where they were extirpated, it would be best to use a founder from the same group.

Population groups are composed of independent and dependent populations. In this report, we follow the independent population definition of McElhany et al. (2000):

An independent population is any collection of one or more local breeding units whose population dynamics or extinction risk over a 100-

¹The endangered Sacramento River winter-run chinook salmon, threatened Central Valley spring-run chinook salmon and threatened Central Valley steelhead.

²Steelhead population structure will be described in a separate document.

year time period is not substantially altered by exchanges of individuals with other populations.

The focus on breeding units suggests that we define the boundaries of salmon populations by watershed boundaries, since salmon have high fidelity to the watershed where they were born. In most (but not all) cases, ESUs will be composed of multiple independent populations. Note that under *current* conditions, a population need not be viable to be considered independent.

1.2 Processes creating population structure

Geographic and behavioral isolation are major drivers of population divergence (Mayr, 1993; Barlow, 1995). Anadromous salmonids have a strong propensity to return to their natal stream upon maturation (Candy and Beacham, 2000; Hard and Heard, 1999; Pascual and Quinn, 1995; Quinn and Fresh, 1984; Quinn et al., 1991), and this homing isolates breeding groups. Isolation of breeding groups allows adaptation to local environmental conditions, creating phenotypic divergence and further reinforcing isolation (Healey and Prince, 1995; Quinn et al., 2001). The behavior and life history of winter-run chinook salmon and spring-run chinook salmon, in combination with the structure of the Central Valley stream network, make these mechanisms especially strong in our study area.

The life history of spring-run chinook salmon allows for exploitation of high-elevation spawning and rearing habitats. To reach these habitats, chinook salmon must migrate during high flow periods in the spring—later in the summer and fall, stream flows are too low for fish to pass higher gradient reaches. Once spring-run chinook salmon reach elevations high enough to maintain suitably cool water temperatures, they hold over the summer in pools. When temperatures drop in the fall, they move out of the pools (sometimes back downstream) and spawn. The low stream flows during the fall spawning season prevent fall-run chinook salmon from spawning with spring-run chinook salmon. Furthermore, eggs and juveniles of spring-run chinook salmon experience cooler waters than fall-run chinook salmon, which delays maturation such that some (possibly large) fraction of the juveniles do not emigrate from high elevation rearing areas until a full year of life has passed.

Winter-run chinook salmon, like spring-run chinook salmon, used to spawn at high elevations, but were restricted to the spring-fed headwaters of the southern Cascades. Winter-run chinook salmon were reproductively isolated from sympatric populations of spring-run chinook salmon because of their different spawning times.

Historically, winter-run chinook salmon entered freshwater in the winter and reached headwater areas in the spring. Rather than hold over the summer, as spring-run chinook salmon do, winter-run chinook salmon spawn during the summer (which isolates them reproductively from sympatric spring-run chinook salmon populations). This strategy is only successful in spring-fed streams with adequate summer flows and relatively low water temperatures. Fry emerge from the gravel in the late summer, and begin emigrating from upriver areas as water temperatures become suitable in the fall, entering the ocean the following spring.

The high elevation spawning areas used by spring-run and winter-run chinook salmon are isolated from each other by large distances, and during the summer, by low flows and high temperatures. Our initial assumption, on the basis of the isolation of spawning groups in different tributaries, and in the absence of other information, is that major basins (i.e., tributaries to the Sacramento and San Joaquin rivers) historically supported at least one independent population, and that larger basins may have supported several independent populations. In the following section, we review various kinds of information that might allow us to refine this hypothesis.

2 Conceptual approach to identifying populations

As discussed in the preceding section, population structure arises through isolation of breeding groups and adaptation to local conditions, which further reduces their tendency to breed with other groups. Clues to population structure therefore come from information about the physical isolation of spawning groups, environmental differences between habitats used by spawning groups, and evidence of reproductive isolation in the form of phenotypic and genotypic differences between populations. In this section, we discuss in detail the types of information that might provide insight into the population structure of Pacific salmonids.

2.1 Geography

We expect that the internal structure of an ESU will be related to the geography of that ESU because salmon usually spawn in their natal streams. The amount of straying between basins is inversely related to the distance between the basins (Candy and Beacham, 2000; Hard and Heard, 1999; Pascual and Quinn, 1995; Quinn and Fresh, 1984; Quinn et al., 1991). Geographic analysis can therefore provide insight into the population structure of Cen-

tral Valley winter-run and spring-run chinook salmon. In order to more carefully examine the hypothesis that major basins supported at least one independent population, we considered the distances between watersheds (as the fish swims) that historically supported spawning and rearing of spring-run chinook salmon (as reported by Yoshiyama et al. (1996)). In the absence of detailed information on the distribution of spawners for most streams, we identified the intersection of streams and the 500 m elevation contour line, assuming that most spring-run chinook salmon spawning and rearing occurred above this elevation (Yoshiyama et al., 1996).

In addition to the spatial arrangement of basins, the basin size provides some information on whether a basin could have supported an independent population. Population ecology theory tells us that, due to demographic and environmental stochasticity, populations below a critical minimum size are unlikely to persist without immigration (Goodman, 1987). Because carrying capacity is related to habitat area, it is therefore plausible that watersheds smaller than some critical size are unable to support independent populations of chinook salmon. Currens et al. (2002) found that in the Puget Sound, the smallest watershed containing an independent population of chinook salmon is the Nooksack River, with an area of 477 km². The largest watershed containing a single independent population is the upper Skagit River basin, with an area of 2600 km²; larger watersheds contained at least two independent populations. The Puget Sound results are of limited utility for the Central Valley due to the significant environmental differences between the regions, but nonetheless, provide a standard for comparison.

2.2 Migration rates

The extent to which adults move between sites affects the degree of reproductive isolation and, therefore, demographic independence between sites. Migration rate can be estimated in two ways: direct observation based on mark-recapture, and indirect inference based on population genetics. Mark-recapture estimates depend on few assumptions, but migrants may not necessarily contribute equally to reproduction (Tallman and Healey, 1994), and the estimates might vary over time. Genetic approaches are sensitive only to successful reproduction and integrate over longer time scales, but are dependent on several assumptions that are frequently violated in real studies.

2.3 Genetic attributes

The existence of genetic differences between reasonably large and stable populations indicates that these popu-

lations are independent, because low rates of gene flow between populations will rapidly erase such differences. There are many considerations that should be kept in mind when interpreting the results of population genetics studies, and these are described in detail Appendix A.

2.4 Patterns of life history and phenotypic characteristics

Chinook salmon have a remarkably flexible life history and variable phenotypes, and much variation has been observed among populations (Adkison, 1995; Healey, 1994; Healey and Prince, 1995). Some of this among-population variability is heritable, presumably reflecting adaptation to local conditions (Healey and Prince, 1995; Quinn et al., 2000, 2001) (although genetic drift and phenotypic plasticity lead to differences among populations (Adkison, 1995)). Because local adaptation is easily overcome by immigration, phenotypic differences between populations indicate that the populations are independent of one another, or at least that the selective environments of the populations are different.

2.5 Environmental and habitat characteristics

The distribution of lotic organisms is determined in part by their adaptation to their physical habitat “template,” which is in turn created by biogeoclimatic processes (Poff and Ward, 1990). The life history characteristics that promote survival under one template may preclude survival under another, if the other template exceeds the tolerance or behavioral range of the organism. Poff and Ward (1990) emphasize substratum, thermal regime and stream-flow pattern as minimal representations of the physical habitat template. Streams that differ markedly in these attributes are more likely to harbor populations that are independent of one another, because gene flow would be selected against. Chinook salmon have flexible life histories that can be tuned by adaptation to local conditions, presumably leading to optimal timing of adult entry to freshwater, migration to spawning areas, spawning, emergence, migration to rearing habitat, and emigration to the sea (but all within the constraints of development). Figure 1 illustrates some of the complex interactions among environmental effects and salmon life history events.

There is relatively abundant information on various aspects of the environment inhabited by chinook salmon in the Central Valley. In this report, we examine floristic ecoregions, geology, elevation, stream flow (magnitude, seasonal patterns, and interannual variation), and air temperature (a proxy for water temperature). There are strong correlations among these variables, leading us

Figure 1. A simplified conceptual model of how aspects of the environment interact to influence the optimal timing of life history events such as spawning and juvenile emigration. Arrows indicate direct effects of one variable on another.

to use principle components analysis (PCA) to reduce the dimensionality of the information. PCA results can be potentially helpful in identifying population groups sharing similar environments (especially if they form discrete clusters) and in quantifying the similarity of environments experienced by different putative independent populations.

2.5.1 Ecoregional setting

Because the distribution of plants is controlled by climate, geology, and hydrology (among other factors), floristic regions are useful indicators of biogeography. Streams in different floristic ecoregions likely present chinook salmon with different selective environments, leading to local adaptation and reduction in gene flow between populations in different ecoregions.

2.5.2 Geology

Geology acts in several ways to determine characteristics of the environment faced by migrating and rearing salmon. Geologic processes determine many physical aspects of watersheds, including rock types, slope, aspect, and elevation. The interaction of these physical attributes with large-scale climate patterns determines the supply of water and sediments to stream channels on shorter time scales, and the nature of the stream channels themselves at longer timescales. We therefore expect that areas with different geological histories present salmonids with different selective regimes. However, geological attributes important to salmon habitats can be highly variable within as well as among different types of rock, depending on the extent of weathering and fracturing, particular chemical composition, and other factors.

2.5.3 Elevation

Except at extremes, elevation has little or no direct effect on organisms, but it strongly affects temperature and precipitation, and has been shown to be a primary determinant of ecological variability (Kratz et al., 1991). The elevation profile of a basin is therefore a useful proxy for streamflow and temperature. The effects of stream flow and temperature are discussed below.

2.5.4 Hydrography and thermal regime

By itself, stream flow variability has direct effects on stream-dwelling organisms as well as indirect effects on structural attributes of streams, and is therefore a useful indicator of environmental variability in lotic systems (Poff and Ward, 1989). Flow and temperature are often related in streams, and exert interacting effects on salmonids. The pattern of flow and temperature variation in rivers sets windows of opportunities for various stages of the salmonid life cycle, which combined with the developmental limits of salmonids, dictates when certain life history events and transitions must occur.

Fish that migrate to headwaters for spawning (e.g., Central Valley spring-run chinook salmon) tend to take advantage of high flows in the spring and summer while valley-floor spawners that migrate shorter distances tend to delay migration until after the peak flows (Healey, 1991). Adult upstream migration is thought to be blocked by temperatures above 21°C (McCullough, 1999), and temperatures below this level can stress fish, increasing their susceptibility to disease (Berman, 1990) and elevating their metabolism (Brett, 1979). The summer must be spent at high elevations to avoid negative impacts from

high temperatures on egg viability (Hinze, 1959). Spawning can occur only when temperatures drop to acceptable levels (Murray and Beacham, 1987). The initiation of spawning is thought to be strongly influenced by temperature; spawning has been observed over a wide range of temperatures (2.2°C-18.9°C) but spawning of chinook salmon typically occurs below 13.9 °C (McCullough, 1999). Temperature controls the development rate of eggs in the gravel and the size of emerging alevins (Beer and Anderson, 1997; McCullough, 1999), and high temperatures reduce survival of eggs (Aldering and Velsen, 1978). Alevins must leave the gravel before scouring spring floods occur, or risk high rates of mortality (Montgomery et al., 1996; Beer and Anderson, 2001). Successful smolt emigration can occur only when temperatures are suitable (Brett, 1979). It is unlikely that chinook adapted to the hydrographic and thermal regime of a certain river can reproduce as effectively in a different stream with a substantially different regime.

Support for these ideas comes from comparing the results of model predictions and the observed pattern of adult migration and juvenile emergence in Mill Creek (Figure 2). Adults must move into the streams prior to the onset of high summer temperatures (> 21 °C) (Stage I in Figure 2). The adults hold over the summer either far upstream or in cool water refugia where the temperatures are below 16°C (Stage II in Figure 2). Cool water refugia are often several degrees cooler than the river temperature so fish might also hold over at lower elevations. If the fish are exposed to higher temperatures in this stage, high prespawning mortality is likely which can impact population productivity. Since temperatures above 14°C are generally lethal to the eggs, spawning should only begin below this level. We assume for illustration that spawning occurs between 12° and 14°C. Because isotherms move from high to low elevations in the autumn, the beginning of spawning can be protracted, beginning in August at the high elevations and in late October at low elevations (Stage III in Figure 2). However, as a result of the non-linear relationship between egg development and temperature, the pattern of fry emergence with elevation does not necessarily match the pattern of spawning with elevation (Beer and Anderson, 2001). Because eggs deposited at lower elevations would experience higher incubation temperatures than eggs deposited at higher elevations, the low elevation fry could in fact emerge prior to high elevation fry that spawned two months earlier. The result is likely to protract the fry emergence period, with fish emerging at all elevations over the winter and spring. This is the pattern observed for spring-run chinook salmon in Mill, Deer and Butte creeks (Figure 24). A model-derived pattern of

Figure 2. Effect of temperature on timing of spawning migration and fry emergence. Upper Panel shows the isotherm ($^{\circ}\text{C}$) contours representative of northern Sierra Nevada streams. Line I depicts the thermal boundary for upstream adult migration. Line II depicts the thermally derived elevation where adults can safely hold prior to spawning, Area III depicts the 12 and 14°C isotherms, which are assumed to identify the spawning temperatures. IV depicts the resulting fry emergence distribution. Lower Panel: the relative upstream migrations of spring chinook adults and downstream migrations of 35 mm fry in Mill Creek.

emergence for fish spawning between 12° and 14°C is illustrated as Stage IV in Figure 2 using an egg development model (Beer and Anderson, 1997)³. Area IV depicts the fry emergence between maximum alevin weight and absorption of the yolk-sack. The observed patterns of adult immigration into Mill Creek in the spring and the downstream capture of their offspring as 35 mm fry eight months later (lower panel of Figure 2) comport with the modeled spawning and emergence pattern.

While there are reasonable flow data for Central Valley streams, water temperature data are not widely available. Studies have found that stream temperatures are closely related to air temperature. Langan et al. (2001) determined that the stream temperature from the Girnock burn in Scotland was 0.8°C warmer than the air temperature over a range 0° to 14°C . Mohseni et al. (1998) determined the air-water relationship from hundreds of streams could be described by an S-shaped function in which the river is warmer at air temperatures near freezing and is cooler than the air above 20°C . In between the extremes, water and air temperatures are essentially linearly related. Therefore, air temperature, in a linear function or S-function, can be used to estimate the water temperature and to a first approximation the water temperature is about equal to the air temperature. We therefore use the air temperature climatology to explore temporal and

spatial variation in the thermal regimes at large scales.

2.6 Population dynamics

Abundance data can be used to explore the degree to which demographic trajectories of two groups of fish are independent of one another. All else being equal, the less correlated time series of abundance are between two groups of fish, the less likely they are to be part of the same population. Complicating the interpretation of correlations in abundance is the potentially confounding influence of correlated environmental variation. When groups of fish that are in close proximity are not correlated in abundance over time, it is likely that they are not linked demographically. The reverse is not always the case—when correlations in abundance between groups of fish are detected, more work is needed to rule out confounding sources of correlation.

2.7 Synthesis and decision making

2.7.1 Population groups

Other TRTs have identified groups of salmon within large (in the spatial sense) ESUs sharing common life history characteristics, environments, and genetics. It is assumed that conservation of the ESU depends on conservation of these groups because it is in these groups that significant genetic variation is contained. In the case of the Central Valley, such population groups might be defined largely on the basis of common environmental characteristics, because most populations are extirpated (making genetic analysis difficult) and run-timing differences were partitioned in the delineation of ESUs. We initially identified historical population groups through a qualitative analysis of geography, hydrography, and ecoregional information. The TRT quickly reached consensus on these groups, probably because the different types of information all seemed to point to the same conclusion. We performed a quantitative analysis (principle components analysis) of a wider suite of environmental information to check the reasonableness of the qualitative assessment.

2.7.2 Independent populations

The TRT followed a three-step process to identify independent populations:

1. identify watersheds that historically contained spawning groups of spring-run chinook salmon or winter-run chinook salmon.

³Available at http://www.cbr.washington.edu/egg_growth

2. group together watersheds within a critical dispersal distance (50 km) and in the same ecoregion to produce a list of hypothesized independent populations.
3. examine any other available data to test the population hypotheses.

3 Review of data

In the case of Central Valley spring-run chinook salmon and winter-run chinook salmon, we have at least some data on all of the above-described categories except direct estimates of migration rates among populations, although for many basins, only basic geographic and environmental information are available. In this section, we review the available data and discuss its implications for population structure. In the final sections of the report we list the independent populations of spring-run chinook salmon and winter-run chinook salmon and discuss how the data support the delineations.

3.1 Historical distribution

Yoshiyama et al. (1996) reviewed a variety of historical information, including reports by early fisheries scientists, journals of miners and explorers, and ethnographic sources, to reconstruct the historical distribution of spring-run chinook salmon and winter-run chinook salmon in the Central Valley. Plates 2 and 3 summarize this information. Spring-run chinook salmon appear to have occurred in all rivers with drainages reaching the crest of the Sierra Nevada (except for the Kern River) or southern Cascades, as well as some other streams draining the coast range and southern Klamath Mountains (Plate 2). With few exceptions, these watersheds have extensive areas above the 500 m elevation contour. Winter-run chinook salmon spawned only in the larger spring-fed streams of the southern Cascades region⁴(Plate 3).

3.2 Geography

3.2.1 Distance among basins

We assume that most spawning of spring-run chinook salmon and winter-run chinook salmon occurred above 500 m elevation, and that the straying rate between spawning areas is inversely proportional to the distance along

⁴CDFG suggested in several memos to their files (cited in Yoshiyama et al. (1996)) that winter-run chinook salmon were found in the Calaveras River, but given the lack of suitable spawning and rearing habitat in this low-elevation, rain-driven basin, it is most likely that the fish observed in the winter in the Calaveras were late-fall-run chinook salmon (Yoshiyama et al., 1996).

Figure 3. Neighbor-joining tree, based on distance along streams between 500 m elevation points, of watersheds that historically contained spring-run chinook salmon.

the streams separating the areas. Plate 4 shows the points where spring-run chinook salmon and winter-run chinook salmon streams cross the 500 m elevation contour. Figure 3 shows a neighbor-joining tree constructed from the distances among 500 m points. Distances to nearest neighbors among tributaries to San Joaquin and lower Sacramento rivers are longer than those of the upper Sacramento River.

If distance between areas was the only information available, populations can be identified from Figure 3 by examining the population groups that form below a critical migration distance (x_c). Following the Interior Columbia Basin Technical Recovery Team (2003) and Quinn and Fresh (1984), we set x_c to 50 km, beyond which populations are probably independent. Other values of x_c might be reasonable, so we examined the sensitivity of the results to different values of x_c (Figure 4). The number of populations identified declines roughly exponentially with increasing x_c .

3.2.2 Basin size

Figure 5 shows the size of all basins in the Central Valley that historically supported spawning of spring- and winter-run chinook salmon, according to Yoshiyama et al. (1996). Of watersheds with extant spring-run chinook salmon spawning groups, Butte Creek is the largest at over 2000 km², although much of this area is of very low elevation. Deer and Mill creeks are 563 km² and 342 km², respectively. If we assume that the Puget Sound chinook salmon results (Currens et al., 2002) are roughly applica-

Figure 4. The number of population groups separated by dispersal distances. Distance measure is distance between 500 m elevation along the stream route.

ble to the Central Valley, then most river basins identified in Plate 2 contained at least one independent population, and most of the larger basins (e.g., Feather, American, Yuba, Stanislaus, Merced, Tuolumne, middle-upper San Joaquin rivers) may have contained two or more. As a rule of thumb, we assumed watersheds with an area > 500 km² to be capable of supporting independent populations, if other environmental attributes seemed suitable (especially the magnitude and variability of summer flow).

Other proxies for habitat area are available. Spring-run chinook salmon spawners are more directly limited by the amount of cool-water holding and spawning habitat than watershed area (although these measures are roughly correlated in the Central Valley). Cool-water habitat might be better measured by mean annual discharge or by the amount of high-elevation habitat. Figure 6 shows the relationship between elevation and area for watersheds that historically contained spring-run chinook salmon. Figure 7 shows the mean annual discharge rate for streams that historically supported spring-run chinook salmon or winter-run chinook salmon.

3.3 Population genetics

In this subsection we discuss the principle refereed papers and agency reports that provide molecular genetic data on Central Valley chinook salmon populations. Earlier works are cited in some of these papers. The results are structured by data type. Subsequently, we present a synthesis of these results and discuss their implications for the via-

bility of Central Valley chinook salmon. See Appendix A for background information on population genetics.

3.3.1 Allozyme studies

Waples et al. (2004) examined patterns of genetic and life history diversity in 118 chinook salmon populations from British Columbia to California. The genetic data were derived from variation at 32 polymorphic allozyme loci. This comprehensive survey included 10 samples from the Central Valley representing fall, late-fall, spring, and winter runs. A salient feature of this study was that all Central Valley populations constituted a single taxonomic entity genetically distinct from all other populations, including those geographically proximate along the coast or in the Klamath/Trinity drainage (see Figures 8 and 9). This result indicates a more recent derivation of life history forms within the Central Valley or a greater recent gene flow rate among the Central Valley run types. Similar separation of Central Valley chinook from coastal populations was shown by Gall et al. (1991) using 47 polymorphic loci. An extension of the Waples et al. (2004) dataset has been used to show relationships among Central Valley chinook (Figure 10)⁵. Fall, late-fall, and Feather River spring-run chinook salmon formed one cluster, as did winter-run fish. Allele frequencies in Spring-run chinook salmon from Deer Creek, Butte Creek, Feather River hatchery, and Yuba River were not significantly different from each other.

3.3.2 Major histocompatibility complex (MHC) genes

Kim et al. (1999) describe results for MHC Class II exon variation among nine samples of spawning adults drawn from the Sacramento River (winter run (1991, N=18; 1992, N=27; 1993, N=9; 1994, N=23; 1995, N=33), spring run from the main stem (1995, N=13), spring run from Butte creek (1995, N=13), fall run (1993, N=19), and late fall run (1995, N=20)). The fish were taken at either the Red Bluff diversion dam or the Keswick dam. Four alleles were observed to be segregating at this locus. Figure 11 is a phenogram based on neighbor joining of Nei's genetic distance. The figure reveals the relationships among the samples with main clusters of winter-run chinook salmon samples, fall- and late-fall-run chinook salmon, and the spring-run chinook salmon samples. While the 1991 through 1994 winter-run chinook salmon samples show a high degree of temporal stability, the 1995 sample does not. The authors argue that this sample may

Figure 8. Populations sampled for genetic and life history data in Waples et al. (2004). Populations are coded by adult run time: closed circle = spring; open square = summer; open circle = fall; asterisk = winter. Twelve geographical provinces (A-L) used in the analysis of genetic and life history data are outlined in bold.

have some admixture with spring-run chinook salmon. The limited number of populations sampled and the use of a single locus would urge some caution in drawing strong conclusions from these data.

3.3.3 Microsatellites

Banks et al. (2000) used 10 microsatellite loci to examine the distribution of genetic variation within and among 41 wild and hatchery populations of Central Valley chinook salmon from 1991 to 1997, including representatives of winter, spring, fall and late fall runs. The number of loci examined in each of the 41 populations ranged from five to 10 loci. After initial genotyping of all individuals they adjusted their data sets in three ways. First, individuals were removed from the data set if they were missing one of five loci or two of eight or nine loci. Second, the four

Figure 9. UPGMA phenogram of genetic distances (Cavalli-Sforza and Edwards) among 118 chinook salmon populations. Bold letters and numbers indicate provinces and areas, respectively, identified in Figure 8. Population symbols indicate adult run timing: closed circle = spring; open square = summer; open circle = fall; asterisk = winter. Genetic outliers (populations not closely affiliated with other nearby populations) are identified by their population identification number next to their symbol. Pie diagrams show the range of other life history trait values (upper: percent subyearling smolts; lower: marine harvest rate). Numbers at branch points indicate bootstrap support > 70%. Strong bootstrap support also exists for branch points within some labeled clusters but is not shown. From Waples et al. (2004).

Unlabeled branches are various fall-run chinook populations. CNFH = Coleman National Fish Hatchery; FRH = Feather River hatchery.

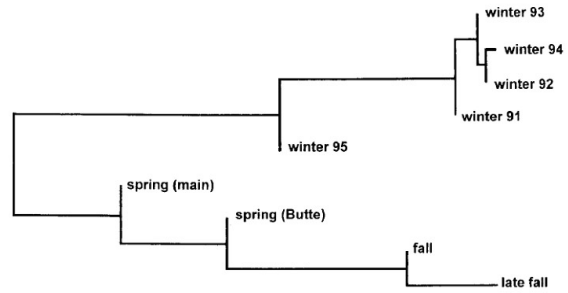

Figure 11. Phenogram based on Nei's genetic distance (D) demonstrating the relationships of Central Valley chinook runs.

populations from Butte, Mill, and Deer that involved juveniles were adjusted for apparent relatedness of individual genotypes. This procedure involved determining apparent full siblings and replacing them with putative parental genotypes. Third, winter run samples from 1991 through 1995 were determined to be admixtures of winter run and spring run. The suspect individuals were removed from the data set. After these adjustments were made, sample sizes varied from 11 to 144 with a mean of 64 individuals per population. An unweighted pair group method with arithmetic mean (UPGMA) dendrogram based on Cavalli-Sforza and Edwards chord distances from five loci showing the relationships of the 41 populations is shown in Figure 12. Four principle groupings are shown, winter run, Mill and Deer creek spring run, Butte creek spring run, and fall and late-fall. The three collections over two years of Upper Sacramento late fall run fish cluster closest to each other suggesting that they may constitute a distinct lineage.

While allele frequencies of spring-run chinook salmon in Deer, Mill, and Butte creeks appear statistically different from fall, late-fall, or winter-run populations, spring-run chinook salmon in the Feather and Yuba were not shown to be differentiated from fall-run chinook salmon by the allozyme data from Teel et al. (unpublished data) or the microsatellite data in Banks et al. (2000). A more detailed examination of putative spring-run chinook salmon adults using 12 microsatellite loci was conducted by Hedgecock (2002). Putative spring run hatchery samples from 1994, 1995, 1996 and 1999 and wild fish from 1996 and 2000 in the Feather were compared to Feather River fall run hatchery fish from 1995 and 1996, wild fish from Butte and Deer creeks, and a composite fall run sample from multiple locations. Eleven of fifteen pairwise comparisons among putative Feather River spring run samples were not significantly different from zero where only one

Figure 12. UPGMA dendrogram of Cavalli-Sforza and Edwards chord distances based on 5 microsatellite loci. Numbers at branch points indicate bootstrap percentages. Figure adapted from Banks et al. (2000).

of twelve pairwise comparisons of these six samples with the two Feather River hatchery samples were not significantly different from zero. It should be pointed out that all but one of these twelve pairwise comparisons have F_{ST} values less than 0.01 (i.e., they are very similar). Also, the 1995 fall run hatchery sample is significantly different from the composite fall run sample and the F_{ST} for this comparison exceeds that for nine of the twelve comparisons between putative spring run and fall run samples within the Feather River. This latter point underscores how tenuous the significance levels are in these comparisons. That being said, all of these putative spring-run samples in the Feather River show a very close genetic similarity with the fall-run fish and little similarity to spring-run fish from Butte, Mill, or Deer creeks. In fact tagging studies of hatchery fish in the Feather River hatchery show that progeny from spring- and fall-run matings can return at either time and progeny from fall-run matings have been used in subsequent spring-run matings and vice versa (California Department of Fish and Game, 1998). Hedgcock (2002) show an UPGMA tree that combines related populations into six major groupings of Central Valley chinook salmon (Figure 13).

Williamson and May (2003) developed new microsatellite markers with more alleles per locus than those used previously in the Central Valley and used them to look for differences between fall-run chinook salmon from the

Figure 13. Neighbor joining tree (Cavalli-Sforza and Edwards chord distances) for Central Valley chinook populations, based on 12 microsatellite loci. D&M = Deer and Mill Creek; BC = Butte Creek; FR = Feather River; Sp= spring chinook; L Fall = late-fall chinook; Winter = winter-run chinook salmon. The tree was constructed using Cavalli-Sforza and Edwards measure of genetic distance and the unweighted pair-group method arithmetic averaging. The numbers at branch points indicate the number of times that these neighbors were joined together in 1000 bootstrap samples.

Sacramento basin and fall-run chinook salmon from the San Joaquin basin. They used seven loci to examine variation within and among spawning adults from 23 samplings across three years, including four hatcheries and nine natural spawning populations. Seventeen to 75 alleles per locus were found supporting the view that a large amount of variation is present within these populations. However, limited differentiation was observed among the populations, far less than observed for chinook salmon in other regions of north America.

3.3.4 mtDNA

Nielsen et al. (1997) present data on the distribution of seven mitochondrial haplotypes among fall (nine locations, 479 individuals), late-fall (two locations, 56 individuals), spring (two locations, 113 individuals), and winter (one location, 46 individuals) runs of chinook salmon from 1992-1995. Fall- and late-fall-run fish revealed one rare and four common haplotypes. Of the four common haplotypes in fall-run fish, three were found in spring-run fish and only one in winter-run fish. The missing haplotype in the spring-run fish is the least common among the fall- and late-fall-run fish. Winter-run fish showed one rare haplotype as well. Nielsen et al. (1997) question whether several of the samples (1994 Deer Creek and both Butte Creek samples) were actually spring-run fish. If not, then the spring run may only possess two of the common fall and late-fall haplotypes. These results support the view of winter-run fish being differentiated from the other runs, and that Deer Creek spring-run chinook

salmon are genetically distinct from spring-run chinook salmon in Butte Creek and the Feather River.

3.3.5 Synthesis and conclusions

How are we to interpret the above results? Each of the described studies suffers from various weaknesses in experimental design and violates several of the assumptions discussed in Appendix A. One common theme among many of the studies is probable violation of the sampling accuracy assumption. Whenever a juvenile sample is taken, there is the possibility of overlap of some run types and an overrepresentation of only a few families. Samples taken at weirs and fish ladders may represent multiple spawning populations. It is also doubtful that today's distribution of genetic variation within and among extant populations of chinook salmon in the Central Valley is very similar to the distribution 50, let alone 200, years ago. Nevertheless, a synthesis of the extant genetic data reveals the following picture.

1. Central Valley chinook salmon, including all run types, represent a separate lineage from other chinook salmon, specifically from California coastal chinook salmon (Waples et al., 2004).
2. Within the Central Valley and its currently available natural spawning habitat and hatcheries, there are four principle groupings that might form the basis of separate meta-population structures: (1) all winter-run chinook salmon, (2) Butte Creek spring-run chinook salmon, (3) Deer and Mill Creek spring-run chinook salmon, and (4) fall-, late-fall-, and Feather/Yuba spring-run chinook. The fourth group is represented by at least a dozen discrete spawning areas (i.e., major rivers). The first three groups are perilously close to extirpation since the first group (winter-run chinook salmon) is represented by only a single natural population and one hatchery population, the second (Butte Creek spring-run chinook salmon) is supported by a single spawning area and the third (Deer and Mill creek spring-run chinook salmon) is represented by just two discrete spawning areas. The data in Banks et al. (2000) suggest that the late fall run represents a fifth lineage.
3. Fall-run chinook salmon populations and spring-run chinook salmon in the Feather and Yuba rivers are very similar genetically to each other, probably because of the extensive movement of eggs among facilities and smolts to downstream areas (Williamson and May (2003), Teel, unpublished data; Hedgecock

(2002)). This movement has included trucking of smolts downstream and transport of eggs from one hatchery to another. While the phenotype for early entrance into freshwater still persists in the Yuba and Feather rivers, the mixing of gametes of these fish with fall run fish has almost certainly led to homogenization of these runs. The genetic results from Hedgecock (2002), the existence of springtime freshwater entry, and the possible segregational natural spawning of spring-run fish in the Feather River system suggest that rescue of a spring run in the Feather may be possible, even though there has been extensive introgression of the fall run gene pool into that of the spring run. Further, the capacity of salmonid fishes to rapidly establish different run timings may make reestablishing discrete temporal runs in rivers possible if separate spawning habitats can be made available. It is doubtful that this phenotype will persist without immediate and direct intervention to preserve the genetic basis of spring run timing.

4. No data exist and therefore no conclusions are available for spring-run chinook salmon that exist in Big Chico, Antelope, Clear, Thomes, and Beegum creeks.

3.4 Life history diversity

While CDFG has recently been collecting life history information on spring-run chinook salmon in Mill, Deer and Butte creeks, limitations in the sampling prevent assessment of whether there are significant differences among spring-run chinook salmon in these streams. Interested readers can go to Appendix B, which summarizes the available data.

3.5 Population dynamics

Time series of population abundance are available only for the extant spring-run chinook salmon spawning groups in Butte, Deer and Mill creeks and the Feather River. Given the strong genetic divergence of Butte Creek spring-run chinook salmon from the Mill and Deer groups, and the close relationship of Feather River spring-run chinook salmon to Feather River fall chinook, the main question is whether Mill Creek and Deer Creek form a single population.

Inspection of the time series of spawner abundance (Figure 14) shows that spring-run chinook salmon in Deer and Mill creeks have had roughly similar patterns of abundance, with relatively high abundance in the late 1950s and 1970s (not shown), and a recent upturn in abundance

Figure 14. Estimated escapement of spring-run chinook in Mill, Deer, Butte creeks and the Feather River.

in beginning in the late 1990s. Big Chico creek has shown a similar pattern, but the extended periods of no spawners indicates that this is not an independent population. Butte Creek also had peaks of abundance around 1960, but abundance was low throughout the 1970s and the recent increase in abundance has been much larger than in the other streams. A major caveat in interpreting the spring-run chinook salmon spawning escapement data is that population estimation techniques were not standardized until the 1990s.

The population dynamics of Mill and Deer creeks can be compared quantitatively in several ways. The simplest way is to compare estimates of the parameters that describe the population time series. The simplest model that can capture the observed dynamics is the random-walk-with-drift (RWWD) model (Dennis et al., 1991). In the RWWD model, population dynamics are governed by exponential growth (drift) with random variation (the random walk). Measurement error in the population estimates can be accounted for by recasting the RWWD model as a state-space model (Lindley, 2003), which reduces the bias in estimates of the process error variation. Table 1 shows the parameter estimates of the state-space RWWD model when applied to the spawner escapement data. Parameter estimates for both populations are similar, with broadly overlapping probability intervals for parameter estimates.

A potentially more informative approach is to fit models that describe various levels of interaction among populations, and evaluate the relative performance of the models with some metric, such as Akaike's information crite-

tion (AIC) (Burnham and Anderson, 1998). We fit three models: the simple RWWD model where Mill Creek and Deer Creek are independent, a model where there is no migration between the populations but there is correlation in the environment (expressed as covariation in the process variation), and a model where migration is allowed between the populations. The models are described in more detail in Appendix C.

The best model, in terms of AIC, is the model with no migration and uncorrelated process variation. The other models do fit the data slightly better, but not enough to justify their additional parameters. The model with correlated errors is not very compelling— AIC is higher and the estimate of the covariance is biologically insignificant. The migration model is more compelling— while it had the highest AIC (and was thus the least supported by the data), the estimates for migration rates were biologically significant, with a little more than half of the probability mass below the 0.10 migration rate thought to indicate demographic dependence (McElhany et al., 2000). In summary, the population trends in Mill and Deer creeks suggest that these populations have independent dynamics, although the evidence for independence from this analysis of population dynamics is not overwhelming.

3.6 Environmental characteristics

3.6.1 Ecoregional setting

The Sacramento-San Joaquin basin spans several major floristic ecoregions (as defined by Hickman (1993)), including the Great Central Valley, the Sierra Nevada, the southern Cascades, northwestern California, and the Modoc Plateau (Plate 5). Spring-run chinook salmon pass through the alluvial plains of the Great Valley during their migrations to and from the ocean. Spring-run chinook salmon spawning and rearing occurred mainly in the southern Cascades and the Sierra Nevada ecoregions, with some populations using basins in the Modoc plateau and northwestern California ecoregions.

3.6.2 Hydrographic variation

Precipitation generally declines from north to south along the Central Valley, but orographic effects are an extremely important source of variation in precipitation⁶ (Plate 6). West-facing, high-elevation basins generally receive more total precipitation and more precipitation as snow. The basins draining into the Sacramento River are generally

⁶Precipitation climatology data obtained from The Climate Source Inc., Corvallis, OR.

Table 1. Parameter estimates for random-walk-with-drift model. Numbers in parentheses are 90% central probability intervals.

Stream	population growth rate	variance of growth rate
Deer Creek	0.112 (-0.097, 0.307)	0.346 (0.122, 0.699)
Mill Creek	0.042 (-0.200, 0.273)	0.439 (0.197, 0.730)

lower in elevation than those draining into the San Joaquin, and are more driven by rainfall than the snow-melt driven San Joaquin basin streams. Stream discharge is further influenced by the geology of the basin (shown in Plate 7). Highly fractured basalts and lavas found more commonly in the southern Cascades can store water and release it through springs, dampening variation in discharge and maintaining relatively high and cool flows during summer months.

Spring-run chinook salmon evolved in the pre-dam period, and we must therefore examine the unimpaired⁷ hydrography of the Central Valley to understand how hydrographic variation might have driven population differentiation. Fortunately for the Central Valley TRT, the U. S. Army Corps of Engineers and State of California Reclamation Board estimated the unimpaired hydrography of the Central Valley as part of a comprehensive study of Central Valley hydrography (USACOE, 2002). As described by California Department of Water Resources (CDWR) (1994), “unimpaired” flow (the flow that would have occurred if dams and major diversions were not in place) was computed from various flow gauges. Prehistoric conditions were probably somewhat different, since other anthropogenic factors also influence flow, and these were not accounted for in the calculation of unimpaired flow. Such effects include consumptive use of water by riparian vegetation that is no longer present, reduced groundwater accretion due to groundwater withdrawals, the effects of floodplains that are no longer connected to channels, and the episodic outflow from the Tulare Lake basin.

Figure 15 shows the mean monthly unimpaired discharge for 28 hydrologic units, and Figure 16 shows the month of peak discharge for these same units. In general, Sacramento River tributaries draining lower elevation basins of the southern Cascades (e.g., Sacramento Valley eastside tributaries such as Mill, Deer and Butte creeks) have peak discharges in February, and Sacramento and San Joaquin tributaries draining high elevation basins in the Sierra Nevada (e.g., Feather, Yuba, Tuolumne rivers) have peak discharges in May. Tributaries to the

**Figure 16.** Month of peak discharge for the Sacramento and San Joaquin rivers and assorted tributaries, prior to development of on-stream reservoirs.

Sacramento arising in the Cascades (“Sac. Valley E. Side Streams” and “Sac. R. Near Red Bluff” in Figure 15) maintain relatively high flows with low interannual variability over the late summer compared to streams that historically supported spring-run chinook salmon in the southern Sierra (e.g., Stanislaus River).

3.6.3 Thermal variation

There are some major differences in thermal regime among Central Valley subbasins. Plate 8 shows the average high air temperature in August in the Sacramento-San Joaquin basin, Plate 9 shows the average low temperature in January, and Plate 10 shows the range between

⁷“Unimpaired” in the sense of USACOE (2002).

Figure 15. Estimated monthly discharge of the Sacramento and San Joaquin rivers and assorted tributaries, prior to development of on-stream reservoirs. Center of notch indicates median; notch represents standard error of median; box covers interquartile range; whiskers cover $1.5 \times$ interquartile range; outliers are represented by dots. Year of record is water year, 1 October-30 September, and discharge is $\log_e \text{m}^3 \text{s}^{-1}$.

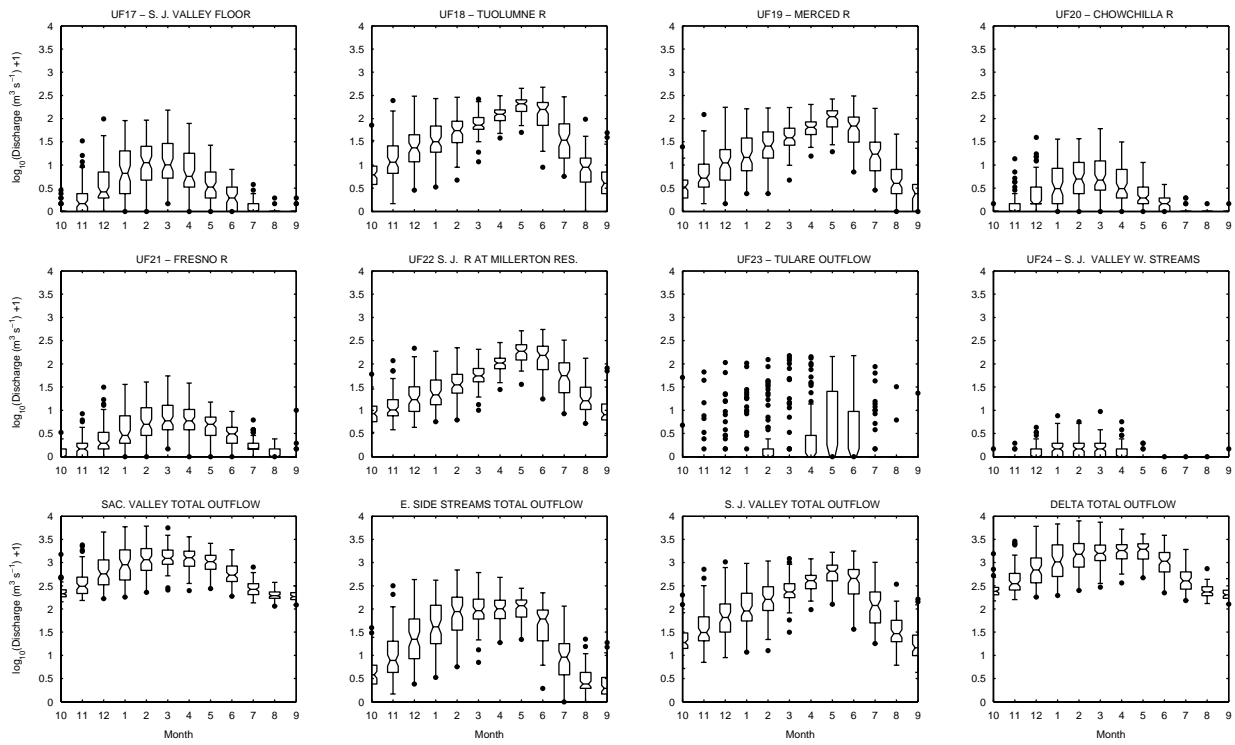

Figure 15. Continued. Estimated monthly discharge of the Sacramento and San Joaquin rivers and assorted tributaries, prior to development of on-stream reservoirs. Center of notch indicates median; notch represents standard error of median; box covers interquartile range; whiskers cover $1.5 \times$ interquartile range; outliers are represented by dots. Year of record is water year, 1 October-30 September, and discharge is $\log_e m^3 s^{-1}$.

these values⁸. Not surprisingly, temperature decreases with increasing elevation and latitude. Among drainages that historically supported spring-run chinook salmon, the Feather and Pit drainages stand out as being particularly warm in summer and highly variable over the year. This contrasts with the central and southern Sierra drainages, which are cool in the summer and show minimal seasonal variation.

3.7 Synthesis of environmental information

We conducted a principle components analysis of the environmental data described above to see how watersheds relate to each other in multivariate space and to identify common patterns of variation. The analysis is described in detail in Appendix D; the most important results are presented here.

The first two principle components, describing 55% of the variance, strongly delineate the upper Sacramento basins (southern Cascades and Coast Range drainages) from the lower Sacramento-San Joaquin basins (Sierra Nevada drainages), largely on the basis of their different geology, ecoregion, timing of peak flow, elevation, and temperature (Figure 17). The PCA does not reveal a strong split between northern and southern Sierra drainages, but with the exception of Butte Creek, the southern Cascades and Coast Range basins are well-separated. Butte Creek clusters with Coast Range streams due to its relatively low altitude and warm temperature. Some pairs of watersheds group very closely together in both the multivariate space defined by the PCA and actual geographic space, including Mill-Deer, Pit-McCloud, North and Middle Fork Feather, North and Middle Fork American, and Mokelumne-Stanislaus.

4 Structure of the Central Valley spring-run chinook ESU

In this section, we describe the structure of the Central Valley spring-run chinook salmon ESU in terms of geographic groups, independent populations, and dependent populations. Although there are differences in physical habitat among streams within the groups there are also general similarities regarding climate, topography and geology that make them useful categories for discussion of the spatial structure of Central Valley spring-run chinook. These groups should be considered in the assessment of ESU-level viability, because spatial diversity is directly

⁸Temperature climatology data obtained from The Climate Source Inc., Corvallis, OR

Figure 17. Principle components analysis of environmental attributes. Symbols denote regions: ○—Southern Cascades; □—Northern Sierra; △—Coast range; ▽—Southern Sierra. Numbers indicate stream: 1—Upper Sacramento; 2—Lower Pit; 3—Fall; 4—Hat; 5—McCloud; 6—Battle; 7—Mill; 8—Deer; 9—Butte; 10—Big Chico; 11—Antelope; 12—Clear; 13—Cottonwood; 14—Thomes; 15—Stony; 16—NF Feather; 17—MF Feather; 18—SF Feather; 19—WB Feather; 20—Yuba; 21—N&MF American; 22—SF American; 23—Mokelumne; 24—Stanislaus; 25—Tuolumne; 26—Merced; 27—San Joaquin; 28—Kings.

related to these units, and genetic diversity is likely to be so as well.

4.1 Population groups

We initially delineated population groups on the basis of geography as defined by mountain ranges (Coast Range, southern Cascades, northern Sierra and southern Sierra) and associated thermal and hydrographic conditions (Figure 18). The geographically-based grouping is well-supported by the PCA results (Figure 17). We retained the split between the northern and southern Sierra because these basins drain into different major rivers and because although they did not form well-separated groups in multivariate space, the groups did not overlap.

The geology, elevation and aspect of the basins in the different groups causes hydrology to vary among the regions. Streams in the southern Cascades group are influenced by springs that maintain relatively high summer flows and lower interannual variability in summer flow. The Coast Range group encompasses streams that enter the Sacramento River from the west. These streams originate in the rain shadow of the coast range, and appear to be marginally suitable for spring-run chinook salmon under current climate conditions. These streams are strongly influenced by rainfall, with relatively small annual discharge and high interannual variability. The northern Sierra group is composed of the Feather and American River drainages, which are tributaries to the Sacramento with high annual discharge and predominately granitic geologies. Rivers in the southern Sierra group drain into the San Joaquin River (or directly into the delta, in the case of the Mokelumne River), and have hydrologies dominated by snowmelt.

Figure 18. Historical structure of the Central Valley spring-run chinook salmon ESU. Independent populations are in regular type; dependent populations are in italics. In this figure, Mill and Deer creek spring-run chinook salmon populations are indicated as independent, although the TRT will also consider the possibility that spring-run chinook salmon in these two streams form a single population.

4.2 Independent populations

If we assume that spawning groups in different geographic groups are independent, the question then becomes which populations or groups of populations within these groupings formed independent populations. Several characteristics were used to decide whether populations were independent: distance from a basin to its nearest neighbor (at least 50km), the basin size (generally at least 500 km²), and significant environmental differences between basins inside of the distance criterion. It is likely that his-

torically there was significant population structure within these basins associated with various tributaries. Contemporary data on population genetics and dynamics were also used directly, where available, and indirectly to substantiate the isolation rule of thumb. Table 2 summarizes the independent and dependent populations of spring-run chinook salmon that historically existed in the Central Valley. The remainder of this section consists of discussions of these populations.

4.2.1 Little Sacramento River

The Little, or Upper, Sacramento is a spring-fed river draining Mt. Shasta. The river itself divides the volcanic southern Cascades ecoregion from the granitic northwestern California ecoregion. It is a moderate-size basin (2370 km²), well-isolated from its nearest neighbor, the McCloud River (83 km between 500m points). It, unlike the McCloud, is not known to have supported bull trout (Moyle et al., 1982), but did support winter-run chinook salmon as well as spring-run chinook salmon (Yoshiyama et al., 1996). We concluded the the Little Sacramento was large enough and well-isolated enough to have supported an independent population of spring-run chinook salmon. Access to the Little Sacramento is presently blocked by Keswick and Shasta dams.

4.2.2 Pit River–Fall River–Hat Creek

It is not clear whether the middle Pit River itself actually supported spawning spring-run chinook salmon, but the Fall River and Hat Creek (its major tributaries) are documented to have contained spring-run chinook salmon (Yoshiyama et al., 1996). The middle and upper Pit is relatively low gradient, meandering across a flat valley floor, and is warm and turbid (Moyle et al., 1982). Large falls block access shortly above the confluence of the Fall River (Yoshiyama et al., 1996). The Fall River arises from springs at the edge of a lava field, and subsequently has a fairly large discharge of clear water. Hat Creek is similar to the Fall River. The whole region is above 500 m, and Hat Creek and the Fall River are within 50 km of each other. Based on the similarity and proximity of Hat Creek and the Fall River, and the fairly short lengths of accessible habitat within the tributaries, we decided that this area probably was occupied by a single population that had significant substructure. Access to this watershed is presently blocked by Keswick and Shasta dams.

Table 2. Historical populations of spring-run chinook salmon in the Central Valley. Criteria for independence include isolation (I), minimum basin size (S), and substantial genetic differentiation (G). See text for detailed discussion.

Independent Populations	Criteria met	Notes
Little Sacramento River	I, S	
Pit–Fall–Hat rivers	I, S	
McCloud River	I, S	only basin to support bull trout
Battle Creek	I, S	
Butte Creek	I, S, G	
Mill and Deer creeks	I, S, G	TRT will analyze as one or two populations
NF Feather River	I, S	
WB Feather River	I, S	
MF Feather River	I, S	
SF Feather River	I, S	
Yuba R	I, S	relationship between historical and current populations unknown
N & MF American River	I, S	
SF American River	I, S	
Mokelumne R	I, S	
Stanislaus River	I, S	
Tuolumne River	I, S	
Merced River	I, S	
San Joaquin River	I, S	
Dependent Populations		
Kings River		basin frequently inaccessible to anadromous fish
Big Chico, Antelope, Clear, Thomes, Cottonwood, Beegum and Stony creeks		not enough habitat to persist in isolation

4.2.3 McCloud River

The McCloud River, a spring-fed tributary to the Pit River, drains Mt. Shasta, and was swift, cold and tumultuous before hydropower development (Moyle et al., 1982). The McCloud River is the only Central Valley river known to have supported bull trout (*Salvelinus confluentus*), extirpated from the McCloud in the 1970s (Moyle et al., 1982), and it also supported winter-run chinook salmon. The area above 500 m elevation is isolated from other areas historically used by spring-run chinook salmon, being over 100 km from Hat Creek, Battle Creek, Fall River, and the mainstem Pit River. We concluded that the McCloud River was large enough and well-isolated enough to have supported an independent population of spring-run chinook salmon. Access to this watershed is now blocked by Keswick and Shasta dams.

4.2.4 Battle Creek

Battle Creek is a spring-fed stream draining Mt. Lassen, a Cascadian volcano. It is known to have supported winter-run, spring-run, and fall-run chinook salmon. Its nearest neighbors are rather distant (>80 km) west-side streams (Clear and Beegum creeks) that have quite different hydrologies and offer marginal habitat for spring-run chinook salmon. The more ecologically-similar McCloud and Little Sacramento rivers are well over 100 km away. We concluded that Battle Creek historically contained an independent population of spring-run chinook salmon. It is possible, however, that Battle Creek received significant numbers of strays from the major upper Sacramento River tributary populations. Very large numbers of spring-run chinook salmon migrated past Battle Creek, and if only a small fraction strayed into Battle Creek, this might have had a significant impact on the Battle Creek population. Presently, hydropower operations and water diversions prevent access to areas suitable for spring-run chinook salmon spawning and rearing, but there are no large impassable barriers in Battle Creek.

4.2.5 Butte Creek

Butte Creek and its spring-run chinook salmon appear to be unique. The fish are genetically distinct from spring-run chinook salmon from Mill and Deer creeks. Banks et al. (2000) and Hedgecock (2002), using microsatellites, Kim et al. (1999), using MHCII, and Teel (unpublished), using allozymes, found Butte Creek spring-run chinook salmon to be quite distinct from spring-run chinook salmon in Mill and Deer creeks as well as spring-run chinook salmon from the Feather River and other chi-

nook salmon groups in the Central Valley. Such genetic distinctiveness indicates nearly complete isolation from other chinook populations. Butte Creek spring-run chinook salmon have an earlier spawning run timing than other extant Cascadian populations. Physically, the Butte Creek watershed is unusual for a spring-run chinook salmon stream, being low elevation (all spawning occurs below 300 m) and having rather warm summer water temperatures (exceeding 20°C in 2002 in the uppermost and coolest reach). Such warm temperatures are observed only in the lower reaches of Mill and Deer creeks. It appears that Butte Creek spring-run chinook salmon regularly survive temperatures above the incipient lethal limit reported for chinook salmon, suggesting that they may be adapted to warmer temperatures than most chinook stocks, although spring-run in Beegum Creek apparently survive in similar temperatures⁹, and spring-run in the San Joaquin River were reported to do so as well (Clark, 1943; Yoshiyama et al., 2001). While the headwaters of Butte, Deer and Mill creeks are close together, Butte Creek joins the Sacramento River quite far downstream from Mill and Deer, having a long run across the valley floor. We concluded that Butte Creek contains an independent population of spring-run chinook salmon. Access to Butte Creek is presently adequate, although during drought years in recent decades, water diversions have caused the lower reaches to run dry during the spring-run chinook salmon migration period (California Department of Fish and Game, 1998).

4.2.6 Mill and Deer creeks

The question of whether Mill and Deer creeks support two independent populations or a single panmictic population of spring-run chinook salmon is a thorny one. Evidence supporting the panmictic hypothesis includes information on population genetic structure, life history, and habitat attributes. The frequencies of microsatellite alleles in Mill and Deer creeks are not significantly different (Banks et al., 2000; Hedgecock, 2002), although the small sample sizes in these studies provide limited statistical power. Habitat attributes of these adjacent basins are remarkably similar in terms of watershed area, elevation, precipitation, and geology, and the two streams clustered closely together in the PCA. Basin areas are small—the Mill Creek watershed is smaller than any watershed occupied by an independent chinook population in the Puget Sound (Currens et al., 2002). The best available information suggests that Mill and Deer creek spring-run chinook salmon populations were never very large historically; (Hanson

⁹public communication, D. Killam, CDFG, Red Bluff, CA.

et al., 1940) estimated that Mill Creek could support about 3000 and Deer Creek about 7500 spring-run chinook salmon spawners. Furthermore, large numbers of spring-run chinook salmon once migrated past Mill and Deer creeks on their way to upper Sacramento tributaries, and Mill and Deer creeks may have received significant numbers of strays, causing their dynamics to be linked to that of the up-river tributary populations.

Evidence supporting the independent populations hypothesis includes spatial isolation and population dynamics. The distance between the 500 m isopleths in Mill and Deer creeks is 89 km, longer than the 50 km cutoff used to distinguish independent chinook populations in the upper Columbia domain (Interior Columbia Basin Technical Recovery Team, 2003). The mouths of the two creeks, however, are much closer together, roughly 25 km. Analysis of contemporary spawning escapement trends supports the independence hypothesis, but not overwhelmingly so (See Appendix C for the analysis).

We could reach no conclusion as to whether Mill and Deer creeks are independent of one another, although we did conclude that spring-run chinook salmon in these streams are currently independent from other spring-run chinook salmon populations. The TRT will conduct viability analyses that consider the streams as independent populations and as a panmictic population. Given that these two streams represent a significant lineage within Central Valley chinook and are a major component of the extant ESU, we suggest that parties implementing recovery actions choose results from the more precautionary alternative.

4.2.7 North Fork Feather River

The North Fork Feather River is well-isolated from other higher-elevation areas of the Feather River, and is in the southern Cascades while the other subbasins of the Feather are in the Sierra Nevada ecoregion. The headwaters are fed by rainfall and by snowmelt from Mt. Lassen, and rocks are predominately of volcanic origin. Spring-run chinook salmon could ascend quite high in this river (Yoshiyama et al., 1996). The TRT concluded that the North Fork Feather River likely contained an independent population of spring-run chinook salmon. Access to this watershed was blocked by Oroville Dam in the 1968; habitat above Oroville is thought to be in good condition¹⁰.

¹⁰E. Thiess, NOAA Fisheries SWRO, Sacramento, CA, personal communication.

4.2.8 West Branch Feather River

The West Branch of the Feather River is a tributary to the North Fork of the Feather River that drains a fairly small basin (430 km²), but according to Yoshiyama et al. (1996), spring-run chinook salmon moved quite far up into the basin. The 500-m contour crossing of the West Branch is about 63 km from the 500-m crossing of the North Fork and 69 km from the Middle Fork of the Feather. The West Branch of the Feather River, unlike other tributaries of the Feather, is completely within the southern Cascades ecoregion. Given the large amount of the west branch that was historically used by spring-run chinook salmon, its position in the Cascades ecoregion, and its isolation from other systems, the TRT concluded that the West Branch of the Feather River contained an independent population of spring-run chinook salmon, in spite of the small area of the basin. An alternative hypothesis is that the West Branch and North Fork together supported an independent population with significant internal structure. Like other tributaries of the Feather River, access to the West Branch is presently blocked by Oroville Dam.

4.2.9 Middle Fork Feather River

The Middle Fork Feather River is a large basin (> 3000 km²), and is quite different than the adjacent North Fork Feather River. The Middle Fork is entirely within the Sierra Nevada ecoregion, although the watershed is lower in elevation compared to more southerly Sierra basins. The Middle Fork is over 100 km from its nearest neighbor, the South Fork Feather River. Such a distance between suitable spawning and rearing environments suggests that migration between these rivers was low in demographic terms. The TRT concluded that the Middle Fork Feather River historically contained an independent population of spring-run chinook salmon. Access to this watershed is blocked by Oroville Dam.

4.2.10 South Fork Feather River

As discussed in the preceding section, the South Fork of the Feather River probably was home to an independent population of spring-run chinook salmon. Access to this watershed is blocked by Oroville Dam.

4.2.11 Yuba River

The Yuba River is a tributary to the Feather River, joining the Feather River on the floor of the Central Valley. The Yuba River basin as a whole is fairly large (3500 km²) and well-isolated from the American and Feather rivers

(\approx 250 km and 150 km, respectively). Peak discharge in the Yuba River occurs somewhat later than in the Feather River. Within the basin, the north, middle and south forks of the Yuba River cross the 500 m elevation line within 11-37 km of each other, suggesting that some exchange among these basins was likely, but that there may have been significant structuring of the population within these tributaries. In the absence of further information, we will treat the entire Yuba River as a single independent population, while recognizing that there may have been significant population structure within the Yuba River basin. Access to much of the areas historically utilized for spawning and rearing is now blocked by Englebright Dam.

4.2.12 North and Middle Fork American River

The American River basin, as a whole, is the third largest sub-basin in the Central Valley that historically supported spring-run chinook salmon, and its spawning areas are well-isolated from the adjoining Yuba and Mokelumne rivers. Clearly, spring-run chinook salmon populations in the American River would have been independent from those in other basins; the question then is whether sub-basins within the American might have contained independent populations.

The North Fork of the American River has an area of roughly 1000 km² and the Middle Fork's area is about 1600 km². Both basins extend to the crest of the Sierra Nevada. Yoshiyama et al. (1996) documents the presence of spring-run chinook salmon in both basins. The 500-m crossings of the two rivers are only 10 km apart. Following the isolation rule of thumb, we concluded that together, the North and Middle Forks of American River supported an independent population of spring-run chinook salmon. It is possible that each of the basins may have contained independent populations. Access to these watersheds is blocked by Nimbus Dam.

4.2.13 South Fork American River

The South Fork of the American is the largest sub-basin in the American (area = 2200 km²), and it is fairly isolated from the other American River tributaries, being about 120 km from the North and Middle forks. We concluded, from the large size and relative isolation, that the South Fork of the American River contained an independent population of spring-run chinook salmon. Access to this watershed is blocked by Nimbus Dam.

4.2.14 Mokelumne River

The Mokelumne River is unique among historical spring-run chinook salmon basins in that it drains directly into the Delta rather than into the Sacramento or San Joaquin rivers. The basin as a whole is of moderate size (2700 km²) and it is well isolated from adjacent rivers—the Mokelumne's nearest neighbor, the American River, is about 280 km away. According to Yoshiyama et al. (1996), spring-run chinook salmon were present in the Mokelumne River, but only in the mainstem below the confluence of the various forks. The upstream limit was thought to be near the present-day location of the Electra Powerhouse (elev. 205 m). The actual amount of accessible spawning habitat was probably relatively small compared to other Sacramento and San Joaquin tributaries. We concluded that the Mokelumne River contained an independent population of spring-run chinook salmon. Access to much of this watershed is now blocked by Camanche Dam.

4.2.15 Stanislaus River

The Stanislaus River is the northernmost spring-run chinook salmon-bearing tributary to the San Joaquin River. It has an area of 2840 km², and is about 250 km from its nearest neighbor, the Tuolumne River. According to Yoshiyama et al. (1996), spring-run chinook salmon entered all of the forks of the Stanislaus for "considerable" distances (reaching as high as 1030 m elevation on the Middle Fork). The forks themselves enter the mainstem Stanislaus not far below the 500-m contour (distances among 500-m crossings range from 6 to 28 km). We concluded that the Stanislaus contained at least one independent population, and may have had substantial structure within the basin. Access to this watershed is presently blocked by New Melones and Tulloch dams.

4.2.16 Tuolumne River

The Tuolumne River basin has an area of nearly 4900 km², with much of this area at high elevation. It is 250 km from the Stanislaus River and 320 km from the Merced River. Yoshiyama et al. (1996) state that spring-run chinook salmon had access to over 80 km of the mainstem Tuolumne River, reaching nearly to the boundary of Yosemite National Park. Access to the major tributaries to the Tuolumne River, such as the Clavey River and South and Middle Forks, may have been limited by steep sections near their mouths. We concluded that the Tuolumne River contained an independent population of spring-run chinook salmon. Access to habitat suitable for spring-run

chinook salmon spawning and rearing is currently blocked by La Grange and Don Pedro dams.

4.2.17 Merced River

The Merced River basin, as a whole, has an area of roughly 3250 km². The major tributaries join in above the 500-m contour line, suggesting little barrier to movement among spawning and rearing locations within the basin. The lowest major tributary is the North Fork, which has a substantial falls 2 km upstream from its mouth and drains a low-elevation area. According to Yoshiyama et al. (1996), spring-run chinook salmon could access at least the lower 11 km of the South Fork, and possibly significantly more if spring-run chinook salmon could pass the waterfall near Peach Tree Bar. In the mainstem, spring-run chinook salmon reached to the area of El Portal (elev. 700 m) and perhaps nearly to Yosemite Valley (Yoshiyama et al., 1996). The Merced's nearest neighbor is the Tuolumne River, over 300 km away. We concluded that the Merced River contained at least one independent population of spring-run chinook salmon, and probably had significant structure corresponding to the mainstem and South Fork. Access to habitat suitable for spring-run chinook salmon spawning and rearing is now blocked by McSwain and New Exchequer dams.

4.2.18 Middle and Upper San Joaquin River

The Middle and Upper San Joaquin basin (area above the valley floor) is a large basin (4700 km²) and it is more than 300 km from its nearest neighbors, the Merced and Kings rivers. According to Yoshiyama et al. (1996), spring-run chinook salmon ascended as far as Mammoth Pool (elev. 1000 m), which is well below the confluence of the North, Middle and South forks. Anecdotal accounts reported by Yoshiyama et al. (1996) suggest that the population in the San Joaquin was quite large, perhaps exceeding 200,000 spawners per year. Additionally, San Joaquin spring-run chinook salmon may have been adapted to warm temperatures, like those in Butte Creek and perhaps Beegum Creek; Clark (1943) reported spring-run chinook salmon successfully holding over the summer at temperatures of 22°C. We concluded that the middle and upper San Joaquin River contained an independent population of spring-run chinook salmon. Access to habitat suitable for spring-run chinook salmon spawning and rearing is now blocked by lack of flow below Friant Dam, by Friant Dam itself, and above that, by a series of hydroelectric dams. Access to the San Joaquin had already been greatly reduced by various weirs and diversions prior to the construction of Friant Dam.

4.3 Dependent populations

In this section, we describe groups of spring-run chinook salmon that we believe were not historically independent of other populations in the Central Valley. We term them "dependent" populations because they probably would not have persisted without immigration from other streams (either because they are sink populations or part of a metapopulation). Note that dependent populations may play a role in ESU viability, and populations labeled dependent are not necessarily expendable.

4.3.1 Kings River

Yoshiyama et al. (1996) presents information indicating that spring chinook salmon spawned in the Kings River, and the Kings River basin is quite large, with substantial high-elevation areas. The Kings River drains into the Tulare Lake Basin, which in turn drains episodically into the San Joaquin basin. According to the calculations of California Department of Water Resources (CDWR) (1994), if the water storage and diversion system had not been in place during the 1921-1994 period, outflow from the Tulare Lake basin would have happened in only 38 of the 74 years, with stretches of up to 8 years without outflow. It seems that an independent population of spring-run chinook salmon would not be able to survive by spawning in the Kings River, since in many years, neither juveniles or adults could complete their migrations. However, details of the historical connection between the Kings River and San Joaquin River are not well documented (The Bay Institute, 1998), and passage for salmon may have been possible. We hypothesize that under favorable flow conditions, spring-run chinook salmon from the San Joaquin and its tributaries spawned in the Kings River, and therefore we concluded the the Kings River did not contain an independent population of spring-run chinook salmon. On the other hand, it is hard to reconcile the reports of large abundances of spring-run chinook salmon in the Kings River with its extreme isolation and its frequent inaccessibility. Perhaps, in actuality, the Kings River may have been connected to the San Joaquin basin frequently enough to support an independent spring-run chinook salmon population. Access to the Kings River is now blocked by frequently dry streambeds upstream of the confluence of the Merced and San Joaquin rivers, the now-dry Tulare Lake bed, a series of irrigation weirs, and Pine Flat Dam.

4.3.2 Big Chico, Antelope, Clear, Thomes, Beegum and Stony creeks

All of these streams appear to offer habitat of marginal suitability to spring-run chinook salmon, having limited area at higher elevations and being highly dependent on rainfall. Records reviewed by Yoshiyama et al. (1996) do not suggest that spring-run chinook salmon were historically abundant in these streams. We acknowledge that the sparse historical record of fish in Beegum Creek may reflect its extreme remoteness. However, the small area of available habitat argues against the existence of an independent population.

We hypothesize that the persistence of spring-run chinook salmon population in these streams is dependent on the input of migrants from nearby streams, such as Mill, Deer and Butte creeks, and historically, spring-run chinook salmon from the extirpated populations in the upper Sacramento basin. An alternative hypothesis is that this group of streams operates as a metapopulation (Hanski and Gilpin, 1991), i.e., member populations may not be viable on their own, but migration among members of the group maintains persistence of the whole group.

The classification of these populations as dependent does not mean that they have no role to play in the persistence or recovery of the Central Valley spring-run chinook salmon ESU. If these populations are adapted to their unusual spawning and rearing habitats, they may contain a valuable genetic resource (perhaps being more tolerant of high temperatures than other spring-run chinook salmon). These habitats and populations may also serve to link other populations in ways that increase ESU viability over longer time scales.

4.4 Other spring-run chinook salmon populations

In this subsection, we discuss the status of extant spring-run chinook salmon stocks that we believe do not represent historical entities.

4.4.1 Feather River below Oroville Dam

Historically, spring-run chinook salmon probably did not spawn below the location of Oroville Dam. The dam releases cold water from its base, and this creates conditions that support an early run of chinook salmon, which are called spring-run chinook salmon by CDFG (although CDFG does not consider this population to be true spring-run chinook salmon (California Department of Fish and Game, 1998)). Presumably, this run-timing attribute is a

legacy from spring-run chinook salmon populations that once spawned above Oroville Dam.

Spring-run chinook salmon currently in the Feather River are clearly independent from the spring-run chinook salmon populations in southern Cascade streams, as indicated by several genetic studies (Banks et al., 2000; Kim et al., 1999; Hedgecock, 2002). What is less clear is whether this population is independent from the Feather River Hatchery spring-run chinook salmon, or Feather River fall-run chinook.

Hedgecock (2002) found small but statistically significant allele frequency differences between Feather River spring-run chinook salmon and fall-run chinook salmon, suggesting minimal exchange between these groups (certainly much less than 10%). Hedgecock (2002) found that spring-run chinook salmon captured in the river formed a homogeneous group with spring-run chinook salmon captured in the hatchery, which suggests that the naturally-spawning population may not be independent from the hatchery spawners. California Department of Fish and Game (1998), however, reported that fish released as spring-run chinook salmon returned in the fall run at high rates, and vice-versa, suggesting that the two groups are integrated. The TRT, while perplexed by this information, believes that Feather River spring-run chinook salmon should be conserved because it may be all that is left of an important component of the ESU, and we will continue to consider this population in future analyses.

4.4.2 Mainstem Sacramento River, below Keswick Dam

It is highly doubtful that spring-run chinook salmon historically used the mainstem of the Sacramento River for spawning. Spring-run chinook salmon apparently began using the mainstem Sacramento River below Keswick Dam following the construction of Shasta and Keswick Dams. Recently, very few spring-run chinook salmon have been observed passing RBDD. There is no physical or obvious behavioral barrier to separate fall-run chinook from spawning with spring-run chinook below Keswick. CDFG biologists believe that serious hybridization has occurred between the runs (California Department of Fish and Game, 1998), and that spring-run chinook salmon have nearly disappeared from this stretch of the Sacramento River.

5 Structure of the Sacramento River winter-run chinook ESU

The population structure of winter-run chinook salmon was probably much simpler than that of spring-run chinook salmon. Winter-run chinook salmon were found historically only in the southern Cascades region, and the TRT found no basis for subdividing the ESU into units other than independent populations (Figure 19, Table 3). Following the logic and evidence laid out for spring-run chinook salmon in the southern Cascades region, we reached parallel conclusions: there were historically four independent populations of winter-run chinook salmon (Little Sacramento, Pit-Fall-Hat, McCloud River, and Battle Creek). The first three of these areas are blocked by Shasta and Keswick dams, and access to Battle Creek has been blocked by the Coleman National Fish Hatchery weir and various hydropower dams and diversions. Currently, there is one independent population of winter-run chinook salmon inhabiting the area of cool water between Keswick Dam and Red Bluff. Unlike spring-run chinook salmon, winter-run chinook salmon have persisted in this area due to their temporal isolation from the highly abundant fall-run chinook salmon. This area was not historically utilized by winter-run chinook salmon for spawning.

6 Acknowledgments

We thank Colleen Harvey-Arrison, Tracy McReynolds and Paul Ward for life history information and data on Mill, Deer and Butte Creek spring-run chinook. Arwen Edsall, Aditya Agrawal and Matthew Goslin provided GIS support. Qinqin Liu, Tracy McReynolds, Mike Lacy, Colleen Harvey-Arrison, Tommy Williams and David Boughton reviewed earlier drafts of the manuscript.

A The use of population genetics for determining population structure

In this Appendix, we review common methods and concerns that should be considered in the interpretation of the results. More thorough explanations of some of this material can be found in Hallerman (2003) and references therein.

A.1 Quantitative trait loci vs. Mendelian markers

Most of the molecular markers used in population genetic studies are inherited in a simple Mendelian fashion and, with exception of the major histocompatibility complex (MHC) loci, are essentially selectively neutral. They have little or no effect on successful reproduction, and therefore the frequency of these markers does not change as a result of natural selection. Quantitative trait loci (QTLs) are those loci which code for phenotypic characters (e.g., growth rate, behavior, swimming speed, etc.). Many quantitative traits are under natural selection, and can be expected to change frequency when the population is exposed to different selective forces.

A.2 Types of molecular data

Below we discuss some of the principle types of molecular variation that have been used to gather data for chinook populations. These data come from two principle forms of analysis, separation of DNA sequences in matrices or gels (e.g., starch, agarose, acrylamide; Figure 20) or direct determination of DNA sequences (Figure 21).

Figure 20. Microsatellite variation where each allele is portrayed by two bands, each representing one of the two strands of a DNA molecule. Vertical sets of bands are derived from single individuals. Individuals with two bands are homozygous for the same allele, receiving the same from both parents and individuals with two sets of bands are heterozygous receiving different alleles from each parent. Starting on the left side, the first individual is homozygous and the second is heterozygous, both sharing one allele in common. Three alleles are revealed on this gel.

Figure 21. DNA sequence variation. The principle type of DNA variation is in the sequence of nucleotides found at some location (locus) in the genome. Mutations give rise to the replacement of one of the four nucleotides (guanine - G, adenine - A, cytosine - C, and thymine - T) with another. In this case the two DNA sequences or alleles differ in having an A or a G (at point of arrow).

A.2.1 Allozymes

Allozymes are different forms of protein (usually catalytic enzymes, e.g., lactate dehydrogenase) encoded by a single Mendelian locus. Variation in DNA sequence (e.g., substitution of a G for a T) leads to changes in the DNA triplet code for the amino acids that make up enzymes. Thirty percent of these changes in amino acids involve a change in charge of the amino acid (e.g., a negatively charged amino acid is replaced with one with a neutral charge). These changes in charge may lead to the change in overall charge on the enzyme molecule. This change in charge can lead to differences in mobility in an electric field. One can detect these differences in migration by staining for specific enzymes, employing their substrate specificity.

A.2.2 MHC

The major histocompatibility complex (MHC) consists of several classes of genes that encode proteins involved in the immune response. Each class may consist of several loci. MHC genes are highly polymorphic and under intense selective pressure. MHC genes have been implicated in mate selection (Aeschlimann et al., 2003), such that individuals choose mates with divergent MHC types thereby maintaining variation at these loci in populations that go through bottlenecks. MHC variation is usually detected as sequence variation, either through direct sequencing or some form of gel separation that can detect changes in sequence rather than length of sequence (e.g., single strand conformational polymorphism, denaturing gradient (DGGE) or temperature gradient gel electrophoresis (TGGE)).

A.2.3 Microsatellites

Microsatellites are a class of repetitive DNA, consisting of variable numbers of 2-6 bp repeats (e.g., TATATATATA). The repeating units may be simple repeats of the same unit, a complex of several repeats (e.g., TATATATA-CATCATCATCAT), or an interrupted sequence (e.g., TATATATATA-GAATAC-CATCATCAT-CAT). Surrounding the repeat are anonymous DNA sequences from which primers are designed to amplify the repeat region. These surrounding or flanking sequences evolve slowly and can often permit primers from a related taxon to amplify (e.g., chinook salmon primers will often work in cutthroat trout).

A.2.4 mtDNA

Mitochondrial DNA is found in tens to hundreds of copies in each mitochondrion and a given cell can have hundreds of mitochondria. The mitochondrial genome in fish ranges from 15 to 20 kbp (Billington and Hebert, 1991). The principle features of this type of DNA are (1) relatively strict maternal inheritance, (2) no recombination, and (3) a higher rate of mutation than most nuclear DNAs. Usually all mtDNA molecules in an individual are identical. Occasionally paternal leakage can occur and lead to sequence heteroplasmy (presence of different types of mtDNAs in the same individual) and some instances of length heteroplasmy may occur. Mitochondrial DNA molecules that differ in sequence are considered haplotypes (only one form per individual). In reality mtDNA can be thought of as a single locus that experiences no recombination. Each haplotype is a single allele at the mtDNA locus.

A.3 Allele frequencies

The principle data for use in studying populations are the frequencies of alleles at individual genetic loci. Evolutionary similarity of populations is judged based on similarities in allele frequencies, that is two populations with very dissimilar sets of frequencies for a group of loci are said to be reproductively isolated and to have been isolated for a longer time than populations with more similar allele frequencies.

A.4 Mutations and mutation rates

Changes in DNA sequence (mutations) are constantly occurring over time. Most mutations are lost from a population in the first few generations, while a few increase in frequency, even to the point of completely replacing other forms (alleles) of that sequence (allelic substitution).

Different types of DNA experience substantially different rates of mutation or substitution. Mutation rate is often directly related to the number of alleles segregating in the population. For the markers used in work on chinook salmon, allozymes exhibit the lowest level of mutation, MHC and mtDNA intermediate (five to 10 times that of most nuclear genes) and microsatellites the highest (100 fold increase over allozymes).

A.5 Populations and gene pools

Populations are collections of individuals that have the potential to reproduce with each other and not to reproduce with individuals from other populations. The distinction of populations is easy to understand for fish in two lakes with no corridors for migration. The distinction is harder to draw for anadromous fish that inhabit rivers with many sub-drainages.

Gene pools consist of all of the genetic variation held by a population. In essence, a gene pool can be described by the allele frequencies of a given population over the entire genome. Gene pools under assumptive models of no selection, no immigration or selective emigration, large population size, no mutation, and random mating are expected to remain constant: one generation passes its gene pool intact on to the next generation. Obviously, reality violates many of the assumptions of the model and these violations must be weighed in interpreting the results from molecular genetic studies.

A.6 Genetic drift

A common assumption in population genetic studies is that a gene pool stays the same from generation to generation, that is, the same allele frequencies at each locus will be observed in the spawning adults each generation (or each year assuming overlapping generations). This assumption is based on having thousands of spawners that have an equal probability of mating with each and producing the same number of offspring per family. Obviously, reality shows there are uneven family sizes and often small numbers of spawners in many tributary streams. Thus, there is some variation in allele frequencies from one generation to the next, termed "genetic drift." Genetic drift is expected to be greatest for those loci with larger numbers of alleles and those populations with the smallest number of breeders.

A.7 Gene flow

While salmonid fish are noted for their fidelity to return to their natal streams (homing), they do at times stray to

other streams. This straying is often called migration from one population to another and not to be confused with the migration pattern of salmonids to the ocean and back to their natal stream. There are two types of straying, emigration (out of the population) or immigration (into the population). Straying/migration is not equivalent to gene flow or introgression. It only matters for competition for habitat resources whether a fish simply enters or immigrates into a non-natal population. For that immigrant to effect evolutionary change it must leave its gametes in the non-natal population. That a non-natal fish appears in a population is not in and of itself sufficient for gene flow; however, transferring eggs from one hatchery to another likely is. We usually term this exchange of genes *gene flow* for intraspecific exchange, and *introgression* where the flow is across a species boundary from hybridization and subsequent backcross events.

A.8 Data analysis

A.8.1 Is this a single population and is it genetically stable?

There are several tests that can be done to establish the genetic integrity and genetic health of a population. The first test is whether the population is in Hardy-Weinberg equilibrium. If the mutation, selection, genetic drift, and immigration are minimal and mating is basically random, then there is an expectation of frequencies of single locus genotypes based on the allelic frequencies at that locus. Departures from Hardy-Weinberg equilibrium at multiple single loci imply deviations from the aforementioned basic assumptions. Non-random mating within the presumptive population (e.g., mating between native and out-of-basin hatchery fish or multiple sub-populations within the drainage system) is often the cause of departure from Hardy-Weinberg equilibrium.

A more sensitive measure of genetic integrity of a population is the test for linkage disequilibrium. This test examines pairs of loci at a time and seeks to determine if the observed gamete frequencies in the population fit the expected distribution of gametes based on allele frequencies. Again, departures from the basic population assumptions can be detected by linkage disequilibrium and more importantly the signature from past generational disruptions in equilibrium last for multiple generations, unlike Hardy-Weinberg equilibrium which can be returned in a single generation.

A.8.2 Are these populations reproductively isolated?

Once allele frequencies are calculated for sample sets, they can be compared to determine if the allele frequency arrays for two populations are significantly different. Alternatively, could the samples be drawn from a common population? Determination that the samples could not come from a single random mating population implies that there must be at least two populations and that they should be managed separately. There are a variety of means of testing for significantly different allele frequency arrays (Hallerman, 2003).

A.8.3 How is the diversity partitioned among the populations?

The distribution of allelic variation within and among populations can be evaluated with the genetic statistic F_{ST} . This statistic compares the levels of heterozygosity found in component populations relative to an imaginary pooled population of all the component populations. An F_{ST} of 0.07 for a pair of populations would suggest that 7% of the total variation is between the populations. Values below 0.005 are often not significant, such that the populations might not in fact be reproductively isolated.

A.8.4 Pairwise genetic distance values

Arithmetic measures of the similarity of allele frequencies between a pair of populations can be calculated using a number of different algorithms. Today most of these measures give dissimilarity measures (termed “genetic distance”) rather than similarities. Thus, a pair of populations with a lower genetic distance value is considered more related than a pair of populations with a higher genetic distance value. Some common measures used today include Nei (1972, 1978), Goldstein’s $(d_u)^2$, and Cavalli-Sforza and Edwards chord distances (1967).

A.8.5 Clustering or ordination - putting the genetic distance values together

Gaining a feel for the overall relationships for a group of populations can be accomplished by combining the information from the pairwise population comparisons into an overall graphical representation. Many approaches are available including: unweighted pair-group method using arithmetic averages (UPGMA), multidimensional scaling (MDS), principal component analysis (PCA), minimum spanning tree, neighbor joining, etc. Some of these methods ordinate the populations in two or three dimensions, some draw lines of linkage with shortest lines indicating

those pairs of populations with the most similarity, while others position the populations in space without any lines linking populations.

Several methods are available to test the robustness of particular ordinations. Maximum likelihood compares probabilities for different trees to choose the best tree. Bootstrapping generates pseudo replicates of the original data set by random sampling with replacement.

A.8.6 Concerns in interpreting the results

The clarity in scoring of Mendelian loci coupled with a rich history of theoretical population genetics can lead to overconfidence in accepting the seemingly obvious conclusions from interpreting the results. However, in the following paragraphs we discuss a number of concerns or cautions that should be addressed because they may alter the meaning of the results. Most of these concerns cannot be overcome and we tend to ignore them based on assumptions that may be erroneous. There are obvious overlaps among these concerns.

A.8.7 Sampling accuracy

Assumption: The sample of fish analyzed reflect the population being examined.

Discussion: While we often use the mouths of rivers to designate major populations from one another, the complexity of each individual river will dictate how the fish that spawn in that river are broken into subsets of populations that have varying levels of gene flow among them. Temporal and spatial spawning separations may lead to reproductive isolation of populations within rivers. We need to know how a sample was taken in order to feel confident that the sample is a true reflection of the population in question? This assumption of sampling accuracy is probably often violated and the literature is rife with statements that apparently aberrant samples may be combinations of populations (e.g., “The wild population . . . from Butte Creek that may have been contaminated with a few fall-run fish” (Hedgecock et al., 2001) or “It seems likely that the spring run is mixed into the 1995 winter run because the run is most similar to spring” (Kim et al., 1999).)

A.8.8 Temporal stability

Assumption: The results for one year will be replicable in the next year.

Discussion: While evolutionary change is expected, relatively stable gene pools over several generations are a requisite to comparisons of data sets taken in different years. Admixture, low spawner, and sampling inaccuracy can lead to temporal variation that may equal spatial variation (see Williamson and May (2003)).

A.8.9 Historical reflection

Assumption: The population in the stream today is nearly the same as the population 200 years before.

Discussion: We know that populations are constantly changing due to new mutations, random drift, changes in environment, and immigration. These changes would be expected to be relatively small over 200 years. However, there have been drastic anthropogenic changes in the environment, and immigration from transplants and straying has increased many fold. Contaminants may have increased mutation rates. Small numbers of spawners in some years have led to gross change in allele frequencies from random drift.

A.8.10 Admixture

Assumption: The population has not experienced admixture of genes from other populations (e.g. transplants or straying leading to hybridization with out-of-basin stocks or other temporal runs).

Discussion: The current population is a reflection of the contributions of previous generations. Since most wild spawning goes unobserved, the number of non-natal fish that spawn is unknown. While data suggest that hatchery fish contribute less to a gene pool, any contribution of gametes to the gene pool will alter the composition of that gene pool over time. The data for fall-run chinook salmon in the Central Valley strongly support the conclusion that admixture from transplants and straying has reduced an historical tapestry of different populations to essentially one panmictic population (Williamson and May, 2003).

A.8.11 Genetic uniqueness

Assumption: Statistical differences in molecular markers among populations are reflective of substantial gene pool differences among the populations.

Discussion: Are these fish sufficiently different from other geographically proximate runs to warrant independent status? Beyond run timing what quantitative traits distinguish one population from another such that each should be managed separately?

A.8.12 Genetic variability

Assumption: The molecular marker variability rates are reflective of the variability in important survival traits.

Discussion: Can we ascertain whether the levels of variability for a few dozen molecular markers are predictive of the genetic health of a population for 100 years?

B Life history diversity of Central Valley spring-run chinook salmon

Life history information is available for the spring-run chinook salmon spawning groups in Mill, Deer and Butte creeks. Biologists at CDFG have collected and compiled information on adult migration timing, the size distribution of spawners, the timing of juvenile emigration, and the size of juvenile emigrants. In general, periods of high flow cause gaps in the sampling, and it is likely that significant numbers of fish move during these high-flow periods. No attempt has been made to account for the effects of these gaps on the information presented here.

B.1 Adult migration

The Butte Creek spring-run chinook salmon enter their natal stream roughly six weeks earlier, on average, and have a more protracted migration than spring-run chinook salmon in Mill and Deer creeks (Figure 22). Run timing in Mill and Deer creeks looks quite similar. This size distribution of spawners looks quite similar in all three streams, with perhaps fewer < 60 cm fish (typically two-year-old) in Butte Creek (Fig 23), although this difference may be an artifact of sampling differences rather than the result of biological differences.

B.2 Juvenile emigration

In all three streams, the peak of juvenile emigration occurs in January or February (Figure 24). Emigration of young-of-the-year (YOY) juveniles appears to be somewhat later, and yearlings somewhat earlier, in Mill and Deer creeks than in Butte Creek, consistent with the latter spawning timing and colder water temperatures in Mill and Deer creeks. Figure 25 shows the size distribution of emigrants from all three streams. In October, all outmigrants are yearlings. In November, YOY begin to be observed, but only in substantial numbers in Butte Creek. YOY migrants are abundant in all three streams from December through May. In the December through April period, the modal size of migrants is constant at around 40 mm, presumably reflecting the prolonged emergence of fry from the gravel. As the outmigration season progresses, the upper tail of the distribution broadens, reflecting the growth of juveniles in areas above the traps. Modal size increases in May and June. Overall, the patterns look very similar among the streams, with only the early and prolonged emigration from Butte Creek standing out as different (and this may be an artifact of the different sampling regimes in the streams).

C Population dynamics of Mill and Deer Creek spring chinook

Summary: A model comparison approach is used to test whether Mill and Deer creek spring-run chinook form a single population. Three models, based on random-walk-with-drift dynamics, are compared: completely independent dynamics, correlated process variation, and a simple metapopulation model allowing for migration between populations. According to Akaike's Information Criterion, the model ignoring correlated process variation and migration is the most parsimonious explanation for the observed time series of abundances. The metapopulation model is not implausible, however, and the estimated rates of migration are biologically significant.

C.1 Model formulations

Three hypotheses describe the possible relationship between two spawning groups:

1. completely independent dynamics
2. correlated environment causing correlations in abundance
3. migrations between populations causing correlation in abundance

These hypotheses can be tested by fitting corresponding models to population abundance data and comparing the fits with Akaike's Information Criterion (AIC) (Burnham and Anderson, 1998). The model with the lowest AIC is the most parsimonious model of the data. Three models are sketched below, corresponding to the three hypotheses above. models are cast in state-space form to account for observation error in abundance.

Let N_t denote the size of a population of chinook. Total population size is not typically measured in salmon populations, rather, only mature individuals are available for counting in freshwater. N_t is therefore estimated from a running sum of spawning escapements:

$$N_t = S_t + S_{t+1} + S_{t+2}. \quad (1)$$

The summation is taken over three years because most chinook salmon spawn by age 3 in the Central Valley. A similar approach to estimating population size from observations of breeding adults has been used in studies of a variety of vertebrates (Dennis et al., 1991; Holmes, 2001).

C.1.1 Model 1: independent populations

A state-space model for two independent populations is described by

$$N_{t+1,a} = \alpha_a N_{t,a} + \eta_{t,a} \quad (2)$$

$$N_{t+1,b} = \alpha_b N_{t,b} + \eta_{t,b} \quad (3)$$

$$y_{t,a} = N_{t,a} + \epsilon_{t,a} \quad (4)$$

$$y_{t,b} = N_{t,b} + \epsilon_{t,b}, \quad (5)$$

where α_a is the population growth rate of population a , $\eta_{t,a}$ is a random change in population size caused by the environment, $y_{t,a}$ is the observation of population size at time t , and $\epsilon_{t,a}$ is an observation error. Both η_t and ϵ_t are assumed to be normal and independent, with means = 0 and standard deviations proportional to N_t^2 . This is an approximation to lognormal errors, which could easily be used for this model but not for the migration model described below without leaving the normal linear setting (which allows use of the Kalman filter, greatly simplifying computations).

C.1.2 Model 2: correlated environment

Model 1 can be extended to incorporate correlated environmental variation simply by treating the η_t s as arising from a bivariate normal distribution with mean = 0 and with covariance Σ :

$$\Sigma = \begin{bmatrix} c_p N_{t,a}^2 & c_{a,b} N_{t,a} N_{t,b} \\ c_{a,b} N_{t,a} N_{t,b} & c_p N_{t,b}^2 \end{bmatrix}, \quad (6)$$

where c_p and c_{ab} are proportionality constants (roughly, coefficients of variation).

C.1.3 Model 3: migration between populations

Model 1 can also be extended by adding movement between populations to the state equations, creating a simple metapopulation model:

$$N_{t+1,a} = (1 - s_{ab})\alpha_a N_{t,a} + (1 - s_{ab})\eta_{t,a} + s_{ba}\alpha_b N_{t,b} + s_{ba}\eta_{t,b} \quad (7)$$

$$N_{t+1,b} = (1 - s_{ba})\alpha_b N_{t,b} + (1 - s_{ba})\eta_{t,b} + s_{ab}\alpha_a N_{t,a} + s_{ab}\eta_{t,a}, \quad (8)$$

where s_{ab} is the fraction of group a moving into spawning area b .

C.2 Model fitting and comparison

Maximum likelihood estimates of unknown parameters were obtained by minimizing the negative loglikelihood

with the Nelder-Mead algorithm for multidimensional unconstrained minimization. Variances and probabilities were log and logit transformed, respectively, so that they would fall on the real line. The likelihood of the data was found with the Kalman filter (Harvey, 1989; Lindley, 2003). To explore the issue of parameter uncertainty, a Bayesian approach was taken by simulating from the joint posterior distribution of the parameters using the Metropolis-Hastings algorithm (Metropolis et al., 1953; Hastings, 1970).

C.3 Results and discussion

Table 4 summarizes parameter estimates and the AIC of the three models as applied to Mill (*a*) and Deer (*b*) Creek spawner data. According to AIC, Model 1 is the best approximation to the data, followed by Model 3 and Model 2. This means that there is no *need* to invoke migration between populations or correlated environments to explain the population dynamics of Mill and Deer Creek spring-run chinook salmon. AIC differences of $< 2 - 3$ relative to the best model, however, indicate that models 2 and 3 are not unreasonable approximations to the data. The estimate of the covariance of process errors for Model 2 is positive but small, indicating that most of the variation in population size is independent: even though the covariation is statistically significant, it is not significant in the biological sense.

According to the point estimates of the parameters of Model 3, no fish move from Mill to Deer creek, but around 9% of the production of Deer Creek returns to Mill Creek. This level of migration is biologically significant, and is near the VSP criteria of 10% migration (McElhany et al., 2000). In order to assess the precision of the estimate of s_{ba} , I computed the profile likelihood of this parameter (shown in Figure 26). According to Model 3, estimates of s_{ba} in the range of 0–0.2 would be expected from repeated observations of the system.

The uncertainty in parameter estimated is most easily conveyed with univariate and bivariate plots of parameter densities (Figure 27). Growth rate and emigration rate are positively correlated within populations, and growth rates and emigration rates are negatively correlated between populations. The probability that $s_{ab} < 0.10$ is 0.52, and the probability that $s_{ba} < 0.10$ is 0.57, i.e., it is slightly more likely than not that migration rates between Mill and Deer creeks are less than 0.10.

Table 4. Summary of parameter estimates and AIC for three models describing dynamics of two salmon populations

parameter	Model 1	Model 2	Model 3
α_a	1.15	1.16	1.04
α_b	1.12	1.12	1.19
c	0.105	0.105	0.071
c_{ab}	NA	9.54×10^{-3}	NA
s_{ab}	NA	NA	0.000
s_{ba}	NA	NA	0.107
δAIC	0	1.91	2.29

D Multivariate analysis of spring-run Chinook watersheds in the Central Valley

The Central Valley Technical Recovery Team (TRT) is tasked with identifying the structure of historic independent populations. As part of this effort we created an initial classification scheme (see Figure 18) for spring-run chinook salmon watersheds in the Central Valley. This gestalt delineation was based loosely on the following variables: ecoregions, geology, elevation, hydrography, several climatological variables, and timing of peak flow. In order to quantitatively test whether this initial structure was valid and concordant with available environmental data, we ran a series of multivariate analyses on the watershed-level environmental data.

D.1 Methods

D.1.1 Data

We delineated watersheds across the entire Central Valley Basin, and used these polygons as the basis for extracting environmental data and constructing an $m \times n$ database for ordination. To complete this database we used two different types of joins in ArcInfo GIS (ArcGIS 8.3, Environmental Systems Research Institute, Redlands, CA): a spatial join between two polygon coverages; and a spatial join between one polygon coverage and one raster coverage. ArcInfo splits its data types into two main categories: vector (points, lines & polygons) and raster (a grid-cell based representation of a surface). We use the term coverage to refer to any of the three vector data-types and grid or raster interchangeably to refer to the raster data type.)

Using GIS, we first joined the watershed coverage with the other two polygon coverages: Jepson Ecoregion (Table 5), and Dominant Geology (Table 6). The output of these two joins were summarized by type by watershed. For the second join, we intersected the watershed coverage with several raster layers (Table 7). In addition to these spatial joins, the month of peak flow and the area of each watershed was added to each watershed in the database.

D.2 Data Analysis

We exported the complete database to R (Ihaka and Gentleman, 1996) for statistical analysis. We investigated the use of Non-Metric Multidimensional Scaling (NMMDS) (Shepard, 1962; Kruskal, 1964), but we chose Principal Components Analysis (PCA) (Pearson, 1901; Hotelling,

1933) for the ordination of these data because its easier conceptual underpinnings and because NMMDS lacks an analytical solution. Because PCA makes assumptions about linearity and normality, we scaled and centered the data before analysis.

We ran the PCA on the standard covariance matrix, and explored the output using 2D and 3D plots. Additionally, we produced biplots using the principal component biplot (*sensu* Gabriel (1971)). This type of biplot shows the descriptors on top of the 2D plots, and allows for visual interpretation of the environmental correlation within the ordination space. For example, if a certain group of watersheds are all high in granitic soil, and are in the Sierra Nevada Ecoregion, then these two vectors will show up along this axis or along this dimension in multivariate space.

While examining the initial biplots we noted several of the environmental descriptors were closely correlated in multivariate space. Because this biplot is a scaled representation of their (the descriptors) relative positions (Legendre and Legendre, 1998), we removed highly correlated (> 80%) descriptors. To do this, we examined the correlation matrix prior to removing one of a correlated pair of descriptors, e.g. remove min January temp from the min annual temp and min January temp pair.

Table 5. Jepson Ecoregion Codes

Item Name	Item Definition
nwca	% (by area) Northwestern California Ecoregion
cwca	% (by area) Central Western California Ecoregion
swca	% (by area) South Western California Ecoregion
gcv	% (by area) Great Central Valley Ecoregion

Historical Population Structure of Central Valley Steelhead and its Alteration by Dams

ABSTRACT

Effective conservation and recovery planning for Central Valley steelhead requires an understanding of historical population structure. We describe the historical structure of the Central Valley steelhead evolutionarily significant unit using a multi-phase modeling approach. In the first phase, we identify stream reaches possibly suitable for steelhead spawning and rearing using a habitat model based on environmental envelopes (stream discharge, gradient, and temperature) that takes a digital elevation model and climate data as inputs. We identified 151 patches of potentially suitable habitat with more than 10 km of stream habitat, with a total of 25,500 km of suitable habitat. We then measured the distances among habitat patches, and clustered together patches within 35 km of each other into 81 distinct habitat patches. Groups of fish using these 81 patches are hypothesized to be (or to have been) independent populations for recovery planning purposes. Consideration of climate and elevation differences among the 81 habitat areas suggests that there are at least four major subdivisions within the Central Valley steelhead ESU that correspond to geographic regions defined by the Sacramento River basin, Suisun Bay area tributaries, San Joaquin tributaries draining the Sierra Nevada, and lower-elevation streams draining to the Buena Vista and Tulare basins, upstream of the San Joaquin River. Of these, it appears that the Sacramento River basin was the main source of steelhead production. Presently, impassable dams block access to 80% of historically available habitat, and block access to all historical spawning habitat for about 38% of the historical populations of steelhead.

INTRODUCTION

Steelhead (*O. mykiss*) in California's Central Valley were identified as an evolutionarily significant unit (ESU) and listed in 1998 as a threatened species under the U.S. Endangered Species Act (1973). Myriad problems afflict steelhead in the Central Valley: impassable dams block access to much of the historically available spawning and rearing habitat (Yoshiyama and others 1996), and water diversions and withdrawals, conversion of riparian zones to agriculture, introduced species, water pollution, disruption of gravel supply, and other factors have degraded much of the habitat below the dams (McEwan 2001). Recovering Central Valley *O. mykiss* presumably will require some mix of improved access to historically available habitat and restoration of degraded habitat. A better understanding of the current and historical distribution and population structure of *O. mykiss* in the Central Valley will be critical for guiding such restoration actions, but currently available information deals with changes in distribution at a fairly coarse level and does not address population structure.

Detailed distribution data at the population level are fundamental to planning effective restoration and protection activities. In the short term, one must know where a species occurs in order to efficiently safeguard its existence. In the longer term, an understanding of historical distribution is important because it gives insight into how the species might have survived catastrophic disturbances. Prior to the era of intensive anthropogenic impacts, the Central Valley steelhead ESU apparently survived prolonged droughts (Ingram and others 1996), catastrophic volcanic eruptions (Kerr 1984), landslides triggered by fires, floods and earthquakes (Keefer 1994), and other devastating events, although individual populations of Central Valley steelhead

probably were extirpated from time to time. Following recovery from disturbance, catastrophically disturbed areas likely were recolonized by neighboring populations whose members were adapted to similar environmental conditions. Understanding the historical distribution of populations within an ESU is therefore important to understanding how the ESU persisted in the past and how an altered ESU might or might not persist in the future.

To the extent that environmental conditions vary across the range of an ESU, population structure could influence the ability of the ESU to respond to climate or other sources of ecological change, as well as its resilience to catastrophic disturbances. McEwan (2001) concluded that steelhead were widely distributed in the Central Valley, ranging from the Pit River in the north to perhaps the Kings River in the south, a distribution spanning multiple ecoregions and climate zones. This wide distribution across diverse ecological conditions should have provided Central Valley *O. mykiss* with substantial opportunities for adaptation to local conditions, creating the genetic variation required for adaptation to changing conditions (Darwin 1859). While such variation would be important for ESU persistence, it also limits the ability of some populations to rescue others because the fitness of a locally adapted population would be expected to be lower in other environments (Taylor 1991). Knowing which populations might have members that are ecologically exchangeable would help guide reintroductions, should currently empty and degraded habitats be restored, and help to prioritize populations for conservation.

Habitat modeling is often used to extrapolate from and interpolate between observations of species occurrence to provide

the comprehensive picture of the distribution of species that is needed to guide conservation and restoration. Ideally, habitat units are sampled randomly for the presence of the species and various qualities of the habitat are measured, allowing resource selection functions to be estimated (Manly and others 2002). These resource selection functions can then be used to characterize the suitability of habitat units that were not sampled for the occurrence of the species but for which the habitat information is available. A related but simpler approach is to characterize environmental attributes associated with specimen collections in terms of envelopes that characterize habitat as either suitable or unsuitable. The edges of these envelopes are defined by the most extreme conditions under which the organism has been commonly observed. Once defined, the envelopes can be used with appropriate environmental data to predict the distributional limits of the species. Within these distributional limits, the species may or may not be found, depending on the effects of other factors not characterized by the envelopes, but the species is not expected to be found outside of this distribution. Originally developed for predicting the distribution of agricultural pests (Cook 1929), such models are increasingly used in conservation planning for many species (e.g., Johnson and others 2004; Argáez and others 2005; Chéfaoui and others 2005), including fish (Burnett and others 2003; Valavanis and others 2004; Wall and others 2004; Quist and others 2005).

In this paper, we use habitat models to describe the historical structure of the Central Valley *O. mykiss* ESU and assess how impassable dams have altered this structure. We start with a model of steelhead habitat to identify stream reaches within the Central Valley that were likely to have supported *O. mykiss* during summer months. We then analyze the spatial distribution of these stream reaches to identify clusters of reaches that are

isolated from other clusters. These isolated clusters of stream reaches are presumed to have supported independent populations of *O. mykiss*. We assess the degree to which populations may be exchangeable by quantifying differences in climatic conditions experienced by the populations. Finally, we assess how man-made impassable barriers have reduced the amount of habitat available to steelhead, and how this reduction in habitat has altered the structure of the ESU.

METHODS

Modeling the Distribution of *O. mykiss*

O. mykiss habitat was predicted using two models. The first model predicts the spatial location of stream reaches, along with their mean annual discharge and gradient, using a digital elevation model (DEM) and precipitation (the PRISM data set (Daly and others 2002)) as inputs (Burnett and others 2003). Where available, we used the USGS 10-m DEM; where this was not available, we created a 10-m DEM by interpolating the USGS 30-m DEM to 10 m using a regularized spline procedure (SPLINE function, ArcGIS Ver. 9, ESRI, Redlands, CA). We recalibrated the precipitation-discharge equations in Burnett and others' (2003) model with data from the Central Valley (Appendix A).

The second model is a set of simple rules, or environmental envelopes, that define whether a given stream segment is suitable for steelhead. The envelopes include mean annual discharge (suitable if $>0.028 \text{ m}^3\text{s}^{-1}$), gradient (suitable if $<12\%$), and mean August air temperature (suitable if $<24^\circ\text{C}$), and whether the area was considered by Knapp (1996) to be fishless prior to anthropogenic introductions. We are aware of no published data suitable for identifying a lower discharge limit for steelhead, but Harvey and others (2002) found that the density of age one-year-old-or-older steelhead was lower in streams

with lower discharge in tributaries to the Eel River. A discharge of $0.028 \text{ m}^3 \text{ s}^{-1}$ (or 1 cubic foot per second) was taken as a lower bound, although data of Harvey and others (2002) suggest that steelhead occasionally occur in streams with somewhat lower discharge. Steelhead are commonly found in stream reaches with gradients less than 6% (Burnett 2001; Harvey and others 2002; Hicks and Hall 2003), but in some systems they are not uncommon in reaches with gradients of up to 12% (and occasionally higher) (Engle 2002). Stream temperature is linearly related to air temperature between 0 and 24°C (Mohseni and others 1998). Steelhead in southern California are almost never found in areas where mean August air temperatures exceed 24°C (D. Boughton, NOAA Fisheries Santa Cruz Lab, in preparation). Schmidt and others (1979) reviewed available information on thermal tolerance of *O. mykiss*, and found that 24°C was the highest reported maximum temperature for *O. mykiss* rearing. More recently, Nielsen and others (1994) found that 24°C was the upper lethal temperature for juvenile steelhead in northern California. In the Eel River, steelhead were not found in streams with maximum weekly average summer temperatures greater than 22°C (Harvey and others 2002). Knapp (1996) developed a GIS coverage of historical fish distributions through a survey of published papers and unpublished reports. Most areas of the western Sierra Nevada above 1500-m elevation were historically fishless due to Pleistocene glaciation and numerous migration barriers (Moyle and Randall 1998). The final output of this stage of the analysis was a GIS dataset describing a collection of stream segments suitable for *O. mykiss*, connected by unsuitable stream segments.

Identification of Independent Populations

Following McElhany and others (2000), we define independent populations as “any collection of one or more local breeding units

whose population dynamics or extinction risk over a 100-year time period is not substantially altered by exchanges of individuals with other populations.” Within a basin such as the Central Valley, high summer temperatures at lower elevations fragment otherwise acceptable and continuous habitat into enclaves of interconnected habitats isolated from one another by downstream regions of thermally unsuitable habitat (Rahel and others 1996). If these enclaves are far enough apart, we expect that the enclaves will function as independent populations. We therefore intersected the 24°C mean August air temperature isotherm with the stream network to identify downstream boundaries of habitat patches. We assume implicitly that while discharge, gradient, and temperature all affect the suitability of a habitat, only temperature restricts movement between habitat patches. We computed the distance along the stream network among these downstream edges with the NODEDISTANCE function in the Network Module of ArcInfo, creating a matrix of distances among habitat patches. We used hierarchical clustering with a simple distance-based rule to group nearby patches into independent populations using the LINKAGE function (with the single linkage algorithm) in Matlab (Version 6.5.1, The Mathworks, Natick, MA). Following the Interior Columbia Basin Technical Recovery Team (2003), who reviewed available information on straying of Pacific salmonids, we chose 35 km as the critical dispersal distance: patches that link at 35 km were grouped together as independent populations. The sensitivity of the population delineation to the distance criterion was examined by calculating how the number of clusters declines with increasing linkage distance. If the total length of suitable stream habitat was less than 10 km, we ignored these small areas in subsequent analyses, on the assumption that isolated populations with less than 10 km of habitat would be unlikely to

persist for long periods without immigration (Bjorkstedt and others 2005).

Quantification of Habitat Similarities

In most basins, spawning by salmonids can be successful only if it occurs at certain times, such that development and migration can occur before temperature or flow conditions become unsuitable (Montgomery and others 1996; Beer and Anderson 2001). Thus, climate, through its effects on stream temperature and flow regime, is thought to be an important selective force leading to local adaptation in salmonids (Burger and others 1985; Konecki and others 1995; Brannon and others 2004; Lytle and Poff 2004). As proxies for water temperature and flow, we characterized mean elevation (from the USGS DEM), mean annual precipitation and the temperature regime (annual mean, maximum monthly mean, minimum monthly mean and range of air temperature (all from PRISM)) over the watersheds containing the spawning and rearing habitats of each of the independent populations identified with the procedure above. Watershed boundaries were based on the CalWater 2.2 watershed map¹ of 1999, but in cases where CalWater boundaries follow political rather than geomorphic boundaries, we delineated boundaries by hand, following the DEM. We characterized the similarity of watersheds by calculating the Mahalanobis (1936) distance among the centroids of watersheds using the PDIST function in Matlab. The Mahalanobis distance reduces the effect of variables that are highly correlated with each other, and is equal to the normalized Euclidean distance between the centroids if variables are uncorrelated. We then used hierarchical clustering based on the average distance to join groups (using the LINKAGE function in Matlab), and plotted the results as a

tree (with the DENDROGRAM function in Matlab).

Quantification of Habitat Loss to Dams

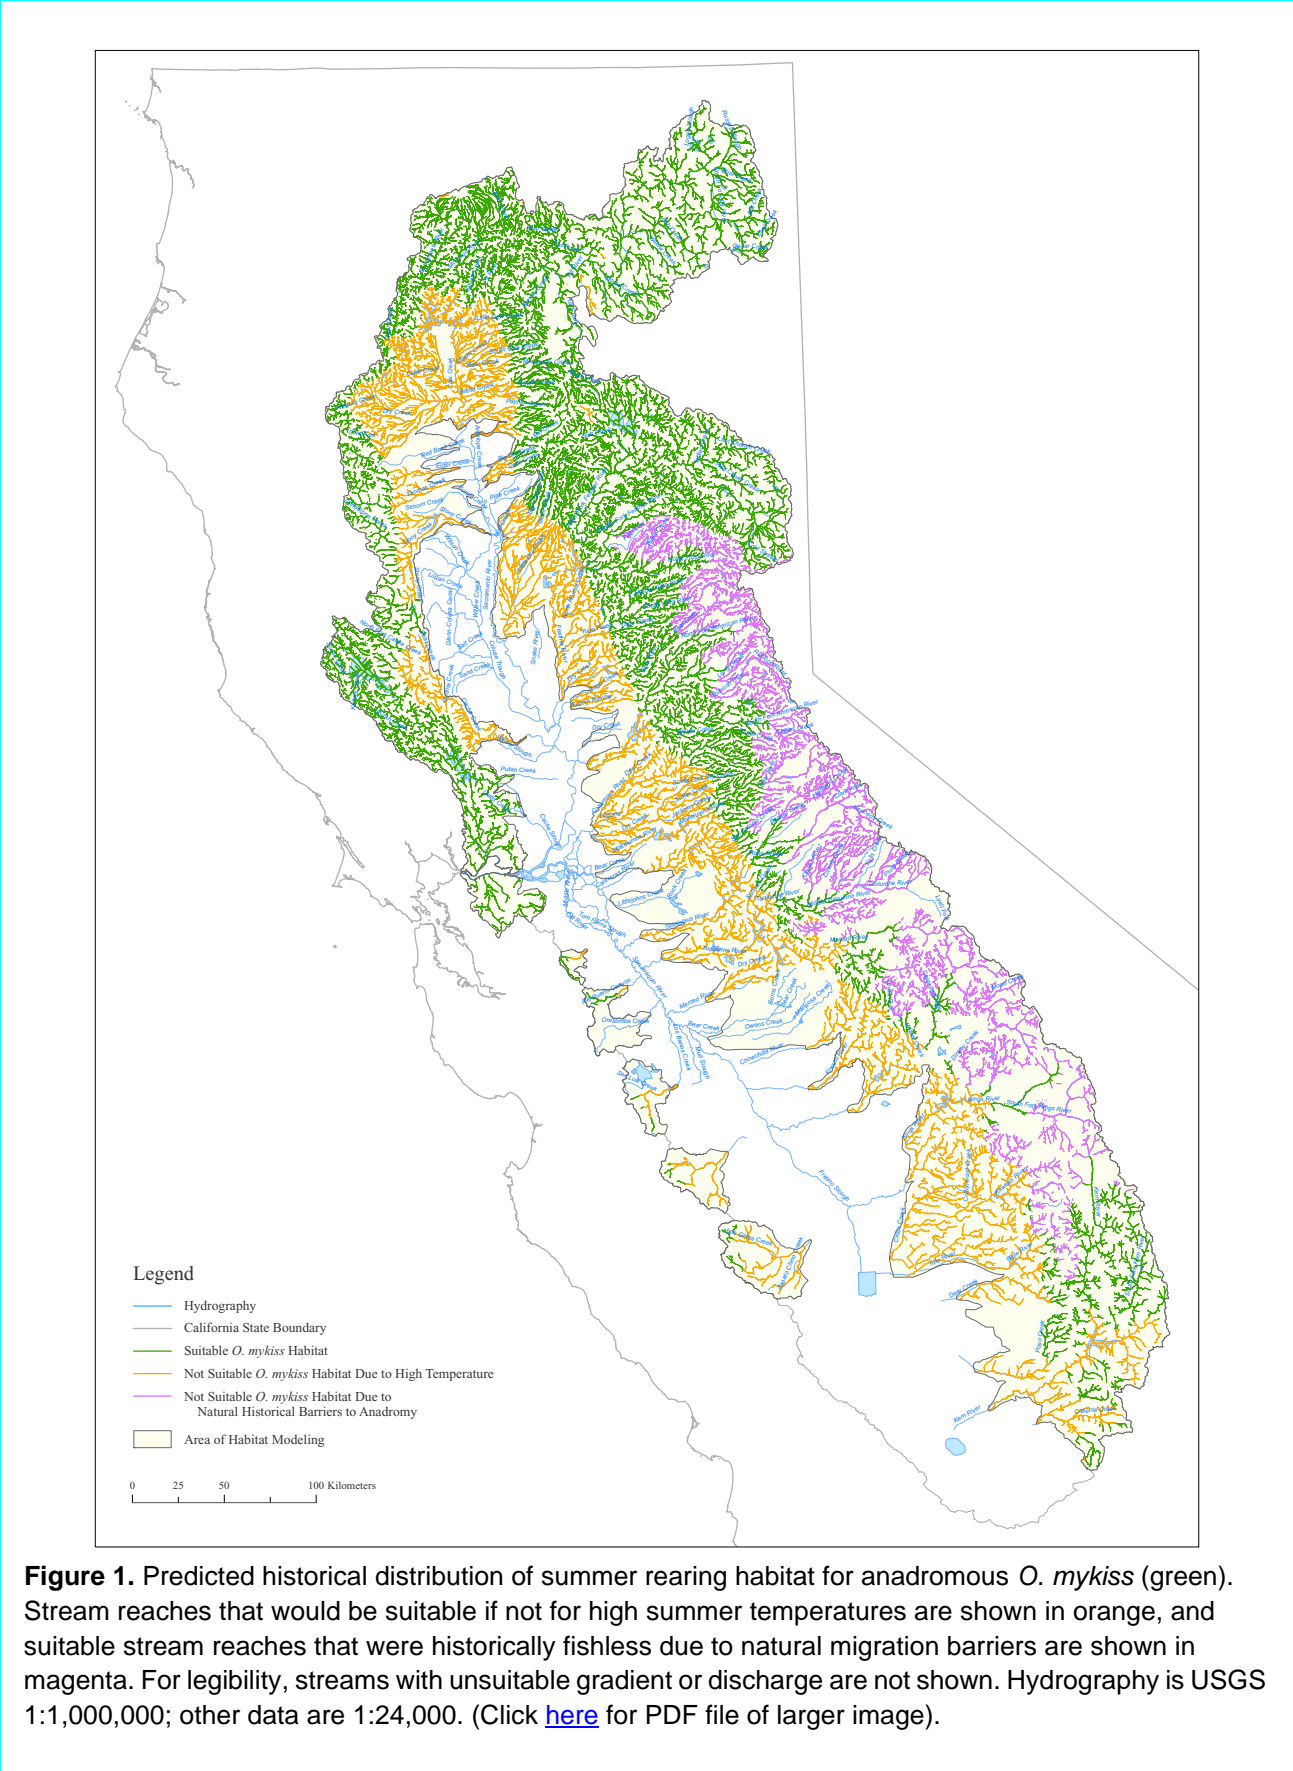

Goslin (2005) prepared a nearly comprehensive database of dams for California, using data from the Coastal Conservancy, McEwan (2001), USGS and the U.S. Army Corps of Engineers. We intersected these dams with our stream layer, and computed the amount of suitable habitat within each watershed that was above and below the lower-most dam that was impassable to anadromous fish, using the TRACE function in the network module of ArcInfo.

RESULTS

Distribution of *O. mykiss* Habitat

Our model identifies 25,500 km of stream habitat suitable for *O. mykiss*, broken up into 151 discrete habitat patches, each having at least 10 km of stream habitat (Figure 1). Rivers and streams on the valley floor are largely rated as unsuitable for spawning and rearing because of high summer temperatures. The exception to this are tributaries around Suisun Bay, where summer temperatures are moderated by the marine influence of the nearby San Francisco Bay and Pacific Ocean. Large portions of the upper watersheds draining the central Sierra are ruled out because they were historically fishless according to Moyle and Randall (1998). At intermediate elevations, many small tributaries to the major San Joaquin River tributaries are of too high gradient or too low flow to support *O. mykiss*, and *O. mykiss* are restricted to the mainstems and larger tributaries. Streams in the southern Cascades, coast range and northern Sierra, in contrast, appear to have much more *O. mykiss* habitat due to their lower elevation and more moderate stream gradients.

1. The CalWater data can be obtained from the California Spatial Information Library, 900 N Street, Sacramento, CA 95814.

Independent Populations

Most subbasins of the Central Valley contain multiple discrete habitat patches, because high temperatures make the lower reaches of tributaries unsuitable in summer months. At a dispersal distance of 35 km, there are 81 clusters of habitat patches, suggesting 81 independent populations of steelhead in the Central Valley (Figure 2, Table 1). The geometry of a watershed and its relationship to the 24°C August isotherm has a strong effect on the number of clusters within it: Cottonwood Creek, with its highly dendritic form and low elevation, has 6 isolated clusters, while the larger but more pinnate Tuolumne River contains a single cluster, as does the Pit River, which is entirely above the 24°C isotherm. The sizes of clusters are highly variable, with a few large clusters and many small ones (Table 1).

The choice of dispersal distance criterion has a strong effect on the number of independent populations identified by the clustering algorithm. There are only a few obvious breaks in the relationship between the number of clusters and the along-stream distance between them, occurring around 140, 225 and 280 km (Figure 3), corresponding roughly to the distance among the major subbasins of the Central Valley.

Similarity of Habitats

Figure 4 shows the similarity of the habitats occupied by the 81 independent populations of *O. mykiss* as a neighbor-joining tree based on Mahalanobis distance. As expected, nearby streams with similar mean elevations clustered together, although some San Joaquin tributaries clustered with Sacramento tributaries. Well-resolved clusters include the tributaries near Suisun Bay (including Sweany and Marsh creeks), the upper San Joaquin and its major tributaries draining the Sierra Nevada, the small west-side tributaries to the San Joaquin, tributaries to the now-dry Buena Vista

and Tulare lakes, and a large group of Sacramento River tributaries. Within the large group of Sacramento tributaries are a few small tributaries that ultimately drain to the San Joaquin, including most notably the Calaveras River, but also smaller tributaries to the Merced, Kings and Mokelumne rivers. Some of the groupings shown in Figure 4 may be artifacts of representing the multidimensional environmental data as a neighbor-joining tree: the cophenetic coefficient (Sokal and Rohlf 1962) relating the tree to the underlying matrix of Mahalanobis distances is only 0.73 (an accurate representation would have a cophenetic coefficient close to 1.0).

Habitat Loss to Dams

About 80% of habitat identified by our model that was historically available to anadromous *O. mykiss* is now behind impassable dams, and 38% of the populations identified by the model have lost all of their habitat (Figure 5). Anadromous *O. mykiss* populations may have been extirpated from their entire historical range in the San Joaquin Valley and most of the larger basins of the Sacramento River. The roughly 52% of watersheds with at least half of their historical area below impassable dams are all small, low elevation systems. Of the eight population clusters that form at a Mahalanobis distance of 2 (Figure 4), for example, only two clusters contain watersheds with habitat that remains accessible to anadromous *O. mykiss*, suggesting that there has been a significant reduction in the diversity of habitats available to Central Valley *O. mykiss*.

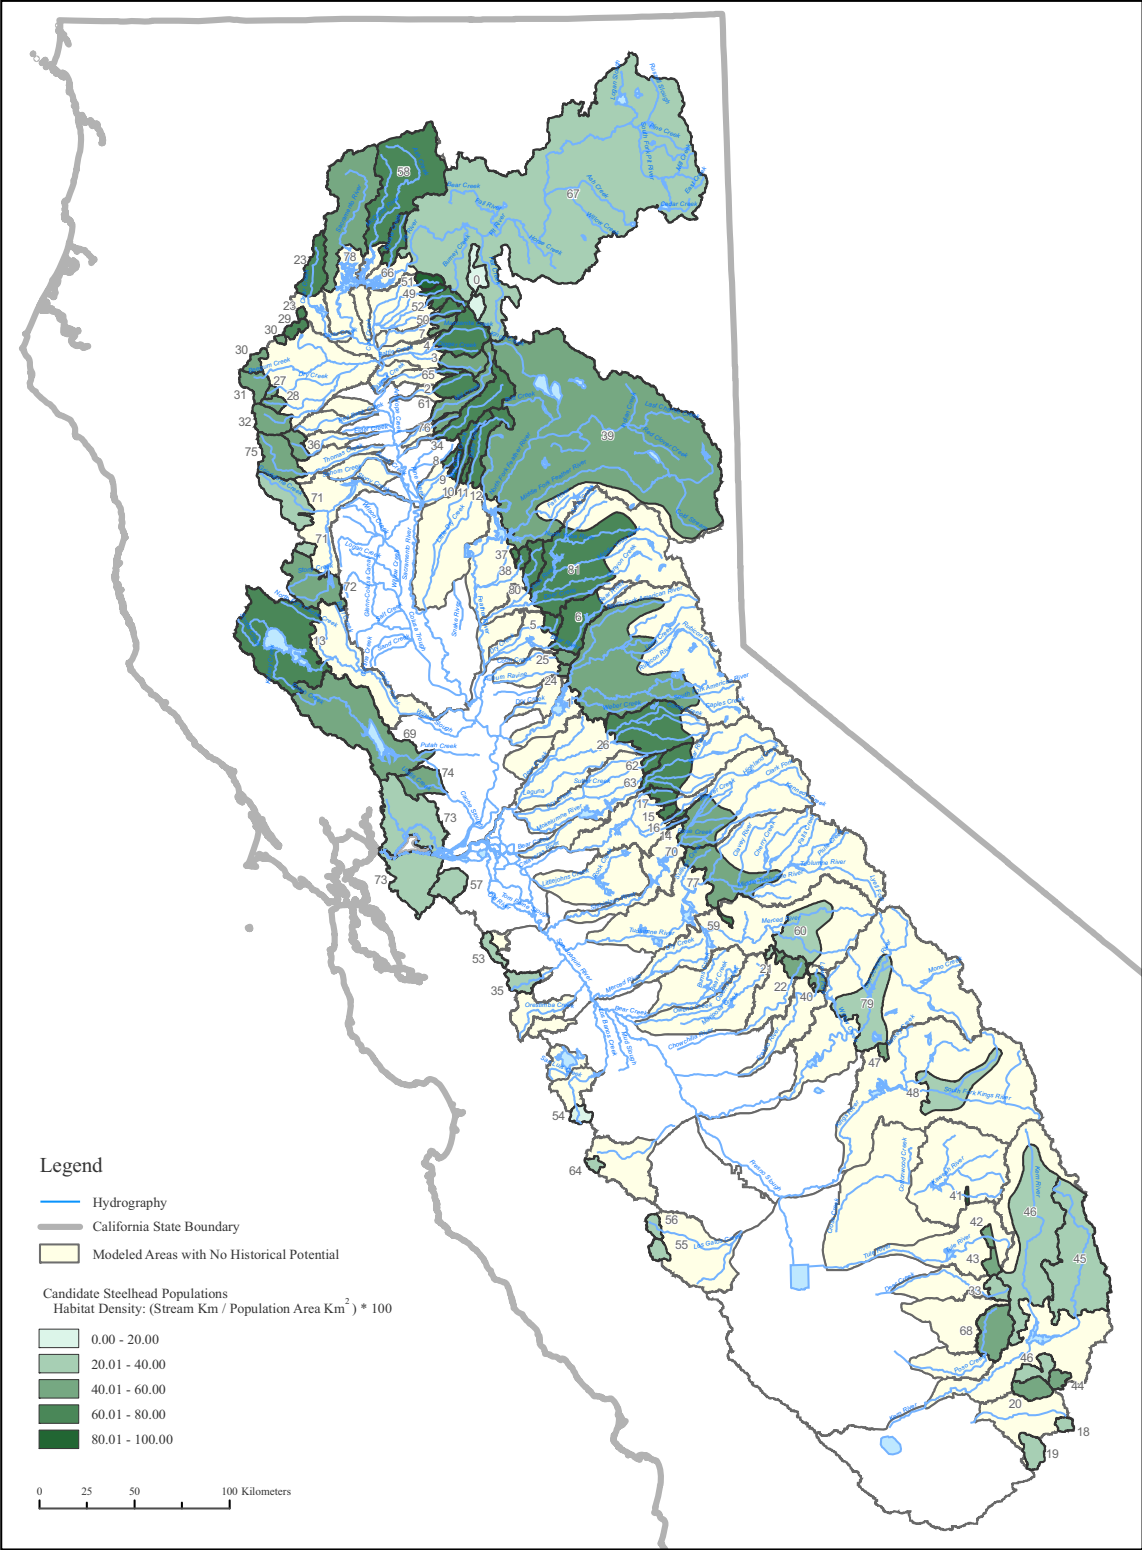

Figure 2. Spawning and rearing habitat areas of independent *O. mykiss* populations. Green polygons indicate habitat boundaries; color intensity indicates the density of habitat ($\text{km stream habitat km}^{-2} \times 100$). (Click [here](#) for PDF file of larger image).

DISCUSSION

We used a simple habitat model and readily available environmental information to predict the historical distribution of *O. mykiss* spawning and rearing habitat in the Central Valley. In agreement with the suggestions of McEwan (2001) and Yoshiyama and others (1996), our results suggest that *O. mykiss* was widespread throughout the Central Valley, but indicate that *O. mykiss* was relatively less abundant in San Joaquin tributaries than Sacramento River tributaries due to natural migration barriers. Due largely to high summer temperatures on the valley floor, *O. mykiss* habitat is patchily distributed, with 81 discrete patches isolated by >35 km of unsuitable stream habitat. The posited existence of 81 independent populations is likely to be an underestimate because large watersheds that span a variety of hydrological and environmental conditions, such as the Pit River, probably contained multiple populations.

High summer temperature on the valley floor is one important driver of habitat fragmentation, and thus population structure, in our model. At cooler times of the year, *O. mykiss* could potentially move freely among habitat patches. If fish commonly moved from where they were born to distant habitat patches for spawning, then the real population structure could be much simpler than that predicted by our model. It is well known that adult anadromous salmonids are capable of dispersing long distances, but this occurs at a low rate under natural conditions (Quinn 2005). Resident *O. mykiss* in the Kern River basin (Matthews 1996) and other systems (Bartrand and others 1994; Young and others 1997; Meka and others 2003) have small home ranges, on order of a few kilometers or less, suggesting that few juveniles regularly move more than a few kilometers except during their migration to sea. The other main driver of population structure in our model is our choice

of 35 km as a threshold for delineating populations. While we believe that 35 km is a reasonable value, 25 or 50 km might also be reasonable, and the number of independent populations identified by our model changes significantly if these alternatives are used (Figure 3). Users of our model results should bear in mind that specific population boundaries are uncertain, and consider how different but still plausible delineations might influence their results.

The distribution of many discrete populations across a wide variety of environmental conditions implies that the Central Valley steelhead ESU contained biologically significant amounts of spatially structured genetic diversity. This hypothesis is bolstered by the presence of distinct subspecies of non-anadromous *O. mykiss* in several regions of the basin (Behnke 2002). According to Behnke's map (his p. 78), coastal rainbow trout (which include Central Valley steelhead) are distributed throughout the Central Valley, with the exception of the Pit and upper Kern rivers. Golden trout were historically found in the mainstem Kern River (*O. mykiss gilberti*), the South Fork Kern and Golden Trout Creek (*O. mykiss aquabonita*), and the Little Kern River (*O. mykiss whitei*). Similarly, redband trout (*O. mykiss stonei*) inhabit the upper Sacramento, including the McCloud, Pit, North and Middle Fork Feather rivers, and Butte Creek. Another implication of these observations is that not all of the *O. mykiss* habitat identified by our model may have been used by Central Valley steelhead, because coastal *O. mykiss* can interbreed with golden and redband trout, yet introgression appears to be a recent phenomenon.

It appears that much of the historical diversity within Central Valley *O. mykiss* has been lost or is threatened by dams. Figure 5 shows that dams have heavily altered the distribution and population structure of

steelhead in the Central Valley. Our estimate of steelhead habitat loss is somewhat larger than the 70% habitat loss of Chinook salmon reported by Yoshiyama and others (2001), but quite similar to the 80% loss reported by Clark (1929). The loss is not spread evenly among populations, however. About 38% of the discrete habitat patches are no longer accessible to anadromous *O. mykiss*. For most anadromous fish, such an impact would generally mean extirpation of the affected population, but the life-history flexibility of *O. mykiss* means that formerly anadromous *O. mykiss* populations may persist as resident trout above the dams. Rainbow trout are indeed common in streams above reservoirs in the Central Valley (Knapp 1996; Moyle and others 1996). It is not at all clear, however, whether these populations are the residualized descendants of native anadromous populations, or are the descendants of rainbow trout that have been widely planted throughout California to enhance recreational trout fisheries. Nielsen and others (2005) found that fish from areas above barriers were more similar to other above-barrier populations than to fish from the same river downstream of the barrier. This could indicate a separate phylogenetic origin for these above-barrier populations (in particular, derivation from a common hatchery strain), or may be a case of long-branch attraction (Felsenstein 1978), an artifact of tree construction where widely divergent populations cluster together, away from the more closely-related populations.

The extensive loss of habitat historically available to anadromous *O. mykiss* supports the status of *O. mykiss* as a species threatened with extinction. An important next step is to identify and secure the sources of current natural production of steelhead, limited as they may be. Our model identifies those few streams where historical habitat may still be accessible (e.g., Mill, Deer, Butte and Cottonwood creeks) as likely candidates.

Tailwater areas below dams with hypolimnetic releases, while not identified by our model, may also produce steelhead. Natural areas that continue to produce steelhead should be a top priority for conservation. Tailwater and above-barrier populations in the San Joaquin basin could also be important targets for conservation, because any such populations could be the only representatives of a presumably ecologically distinct segment of the ESU, assuming that they are descended from native anadromous populations. The value of these populations for recovering anadromous runs may be reduced due to the selective effects of the dams. Obviously, for populations above dams, reproductive effort devoted to producing anadromous offspring is completely lost to that population. More subtly, water releases from dams like Shasta change the thermal regime and food web structure of the river below (Lieberman and others 2001) in ways that may provide fitness advantages to resident forms. Clearly, the current state of the Central Valley landscape presents a very different selective regime than any faced by *O. mykiss* before, posing thorny issues for conservation of Central Valley steelhead.

In this report, we assess whether existing monitoring activities in the Central Valley are sufficient to determine if biological recovery goals are being met, and make recommendations for monitoring and research that could provide critically-needed information for effective management of Chinook salmon and steelhead beyond simple viability assessments. Assessing population status requires, at a minimum, estimates of abundance on the spawning grounds and the fraction of naturally-spawning fish that are of hatchery origin. We find that such data are generally available for independent populations of Chinook salmon, but are almost entirely unavailable for steelhead populations. Effective monitoring of steelhead run sizes at the population scale is needed urgently.

Effective management of listed salmonids requires more information than simply whether populations and ESUs are achieving viability targets. We anticipate that managers will need information on the response of salmonid populations to regional climate change, the use of freshwater habitat, mechanisms and magnitude of mortality in freshwater and the ocean, age- and stock-specific harvest rates, trends in effective population size and genetic diversity within and among populations, the effects of hatchery operations on naturally-spawning populations, how to go about reintroducing fish to reconnected or restored habitats, and the factors controlling and the implications of variable life history tactics of steelhead. We discuss why these information gaps need to be filled, and offer some suggestions on promising approaches to filling them. Finally, we recommend that new and existing data should be made accessible to researchers and managers through a central data portal that can aggregate information from the many existing databases.

1 Background

A key contribution of science to recovery planning is to ensure that recovery plans specify adequate monitoring of species status (Clark et al., 2002). Lindley et al. (in press.) laid out viability criteria for populations and evolutionarily significant units (ESUs) in the Central Valley recovery domain. Populations are assumed to be viable if they satisfy criteria relating to population size, trends in abundance, incidence of catastrophic disturbance, and hatchery impacts. ESUs are assumed to be viable if enough viable are distributed throughout the ESU. Monitoring ESU viability depends on monitoring the viability of populations. The first part of this report discusses the monitoring needed to determine if populations are satisfying viability criteria. Successful recovery of salmonid ESUs, however, will require more detailed information than that needed to merely assess their viability. In the second part of this report, we discuss the kinds of monitoring and research that are needed to guide recovery and management of Central Valley salmonids listed under the Endangered Species Act.

2 Monitoring for viability

Criteria for assessing the viability of threatened and endangered Chinook and steelhead in the Sacramento-San Joaquin basin are presented and discussed in Lindley et al. (in press.), and the populations, population groups, and ESUs to which they are to be applied are described by Lindley et al. (2004) and Lindley et al. (2006). The criteria and associated data requirement are summarized in Tables 1 and 2 (reproduced from Lindley et al. (in press.)). The criteria in Table 1 were modeled after IUCN (1994) as modified for Pacific salmon by Allendorf et al. (1997), and are designed for use with the data that are practical to collect, rather than the data that one might like to have for the purpose. Accordingly, use of the criteria imposes only modest requirements for monitoring: the abundance of returning adults, and the percentage of hatchery fish among the returning adults. High accuracy in these estimates may not be required, if the population clearly is not near the threshold values that separate risk categories. It is also important to note that abundance estimates need to correspond to specific populations. For example, if a simple weir count is to be used, the weir must be below the spawning grounds of a single population.

2.1 Existing monitoring programs

Existing monitoring programs for listed *Oncorhynchus* in the Central Valley are comprehensively described by Pipal (2005), and monitoring programs for all Central Valley *Oncorhynchus* are described by Low (2005); the programs are described only briefly here.

2.1.1 Spring-run Chinook salmon

Estimates of adult returns are routinely made on all Central Valley streams with extant independent populations of listed Chinook salmon, as well as on some streams with historically dependent populations. These data are available from CDFG's Grand Tab database¹, which is produced annually as part of the ocean salmon fishery assessment.

Various methods are used to estimate adult returns, including counts at ladders and weirs, snorkel surveys, and carcass surveys (Pipal, 2005; Low, 2005). Generally, estimates of adult returns in the Central Valley are given without confidence intervals or standard errors, so the accuracy of the estimates is uncertain and the statistical power of trend detection tests is unknown. A joint CDFG-NMFS review (CDFG and NMFS, 2001) noted that "The accuracy and variance of most Central Valley escapement estimates are currently unknown and may not be sufficient to meet management

¹Grand Tab can be obtained from Robert Kano, Wildlife and Habitat Data Analysis Branch, CDFG, Sacramento, CA. or from <http://www.delta.dfg.ca.gov/AFRP/>

Table 1: Criteria for assessing the level of risk of extinction for populations of Pacific salmonids. Overall risk is determined by the highest risk score for any category. Reproduced from Lindley et al. (in press.) based on Allendorf et al. (1997).

Criterion	Risk of Extinction		
	High	Moderate	Low
Extinction risk from PVA	> 20% within 20 years – or any ONE of –	> 5% within 100 years – or any ONE of –	< 5% within 100 years – or ALL of –
Population size ^a	$N_e \leq 50$ –or– $N \leq 250$	$50 < N_e \leq 500$ –or– $250 < N \leq 2500$	$N_e > 500$ –or– $N > 2500$
Population decline	Precipitous decline ^b	Chronic decline or depression ^c	No decline apparent or probable
Catastrophe, rate and effect ^d	Order of magnitude decline within one generation	Smaller but significant decline ^e	not apparent
Hatchery influence ^f	High	Moderate	Low

^a Census size N can be used if direct estimates of effective size N_e are not available, assuming $N_e/N = 0.2$.

^b Decline within last two generations to annual run size ≤ 500 spawners, or run size > 500 but declining at $\geq 10\%$ per year. Historically small but stable population not included.

^c Run size has declined to ≤ 500 , but now stable.

^d Catastrophes occurring within the last 10 years.

^e Decline $< 90\%$ but biologically significant.

^f See Figure 1 of Lindley et al. (in press) for assessing hatchery impacts.

Table 2: Estimation methods and data requirements for population metrics. S_t denotes the number of spawners in year t ; g is mean generation time, which we take as 3 years for California salmon.

Metric	Estimator	Data	Criterion
\hat{S}_t	$\sum_{i=t-g+1}^t S_i/g$	≥ 3 years spawning run estimates	Population decline
N_e	$N \times 0.2$ or other	varies	Population size
N	$\hat{S}_t \times g$	≥ 3 years spawning run estimates	Population size
Population growth rate (% per year)	slope of $\log(S_t)$ v. time $\times 100$	10 years S_t	Population decline
c	$100 \times (1 - \min(N_{t+g}/N_t))$	time series of N	Catastrophe
h	average fraction of natural spawners of hatchery origin	mean of 1-4 generations	Hatchery influence

needs, ..." However, as noted above, use of Table 1 does not necessarily require that abundance estimates be highly accurate (although standard errors for abundance estimates would be extremely useful).

In response to the need to review and improve escapement monitoring programs in the Central Valley, the CALFED Ecosystem Restoration Program approved funding in 2005 to develop a comprehensive Central Valley Chinook Salmon Escapement Monitoring Plan². From January 2007 through June 2008, a project team consisting of a biostatistician, biologist, and database expert, will evaluate existing monitoring programs and make recommendations for new or revised programs, in coordination with the Central Valley Salmonid Escapement Project Work Team. The Plan is intended to improve monitoring programs for winter-run Chinook salmon and spring-run Chinook salmon, and make the data more relevant to recovery planning for these stocks. The Plan will include the design of a consistent, integrated database and data reporting and communication system for Central Valley salmon escapement monitoring data.

Currently, all spring-run Chinook salmon produced at Feather River Hatchery are marked with adipose fin clips and coded-wire tags, so that tracking the percentage of hatchery fish among spawning adults is relatively straightforward in principal. Available information indicates that the spring-run Chinook salmon population in the Feather River is clearly dominated by hatchery-origin fish. One serious complication arises from the fact that early run timing (a defining characteristic of spring Chinook salmon) appears in the progeny of FRH fall-run Chinook salmon. This raises the possibility that unmarked, early-running Chinook salmon from the FRH could stray to natural populations, where they would be difficult to detect. Ideally, all hatchery fish, or at least a constant fraction of every release group, would be marked in some way so that statistically defensible estimates of their straying rates into natural populations could be made.

Although the rugged terrain typically surrounding spring-run Chinook salmon holding and spawning habitat makes estimating the number or returning adults difficult, existing programs seem generally satisfactory for the narrow purpose of assessing population viability using Table 1. Further valuable information comes from monitoring programs for emigrating juveniles. Except for Clear Creek and the Feather River, current spring-run Chinook salmon populations fall either well below or well above the risk criteria for hatchery influence, so for the narrow purpose of applying Table 1 the accuracy of the estimates of hatchery influence for these populations is sufficient.

2.1.2 Winter-run Chinook salmon

Abundance estimates are generated from carcass surveys conducted in the area most heavily used for spawning by winter-run Chinook salmon, and by expanding counts of winter-run Chinook salmon made at Red Bluff Diversion Dam as the last portion of the run ascends seasonally-operated fish ladders. Resource managers use the carcass-based estimates for management purposes. The accuracy and precision of the mark-recapture estimates is uncertain, largely due to uncertainties surrounding how well the survey method meets the assumptions of the Jolly-Seber model used to estimate abundance. However, recent population estimates are

much greater than the criterion for low risk in Table 1, and there is no apparent or probable population decline. At current abundance levels, estimates have sufficient accuracy and precision for assessing extinction risk using Table 1. For assessing the effectiveness of restoration actions, however, more accurate estimates may be needed.

In terms of Table 1, the hatchery influence criterion is more critical for winter-run Chinook salmon than the population criteria, since the rising proportion of hatchery fish among returning adults threatens to shift the population from low to moderate risk of extinction (Lindley et al., in press.). If the status of the winter-run Chinook salmon population is downgraded due to hatchery influence, the accuracy of the estimates of hatchery influence may become contentious. Bias may arise if hatchery fish differ from naturally-spawned fish in their distribution within the river, size or sex ratio. This possibility, and its effect on the estimate of hatchery contribution to natural spawning, should be examined.

2.1.3 Steelhead

In contrast to the existing monitoring programs for Central Valley Chinook salmon, steelhead monitoring is insufficient to evaluate populations with respect to the criteria in Table 1, except for streams where hatchery operations likely satisfy the high risk criterion for hatchery effects (Lindley et al., in press.). Unfortunately, such information as does exist indicates sharp declines in abundance over the least half-century (McEwan, 2001). There are reasons for the dearth of data on anadromous steelhead. Steelhead spawn in the winter, when conditions for monitoring are difficult, and although many steelhead die after spawning, their carcasses are not concentrated near the spawning areas. There is also the difficulty of distinguishing resident and anadromous forms, because resident fish in the tail waters of dams that release cool water through the summer can attain the size of typical anadromous fish, and juveniles migrating downstream may not continue to the ocean. Moreover, the effectiveness of screw traps declines for larger fish, and many juvenile steelhead are large enough that they may be able to avoid the traps.

Given that the anadromous component of the ESU is critical for its long-term persistence, as made clear by the discussion of anadromous and resident *O. mykiss* in Travis et al. (2004), monitoring of the anadromous form should be substantially increased. Populations of *O. mykiss* in Central Valley streams with hatcheries are at high risk of extinction because of the high proportion of hatchery fish among naturally spawning fish (Lindley et al., in press.). More accurate estimates of adult returns will not change this assessment. Accordingly, priority should go to monitoring steelhead populations in streams without hatcheries that have the potential to support significant populations. These are likely often the same streams that support spring-run Chinook salmon, which suggests that efficiency could be maximized by employing methods capable of counting both Chinook salmon and steelhead. However, basic distributional data are needed to guide future monitoring efforts.

Traps at dams on some of these streams apparently have been effective for monitoring steelhead in the past (e.g., Figure 1). An automatic counting system such as the Vaki RiverWatcher or DIDSON sonar could be used in place of a trap, to avoid stress associated with trapping, and resistance board weirs might be used

²The proposal to CALFED is available online at http://www.delta.dfg.ca.gov/erp/docs/2005grants/Central_Valley_Salmon_Esc_CMP_DA_Proposal.pdf

Figure 1: Total number of steelhead observed passing Clough Dam on Mill Creek, 1953-63. Data from Van Woert (1964). On average, 1,160 fish passed the dam each year. Harvey (1995), cited in Pinal (2005), reported that 34 steelhead were observed passing the dam in 1993-94, along with 76 spring Chinook.

instead of dams. Such monitoring will produce partial counts, because some fish will likely bypass the traps during high flows. These partial counts would need to exceed criteria for low extinction risk before the population could be determined to be at low risk. The same facilities could be used to obtain more accurate estimates of returning spring-run Chinook salmon.

In response to the need to develop monitoring programs for Central Valley steelhead, the CALFED Ecosystem Restoration Program approved funding in 2005 to develop a comprehensive Central Valley Steelhead Monitoring Plan³. From January 2007 through June 2008, a project team consisting of a biostatistician, biologist, and database expert, will design the comprehensive long-term monitoring program, in coordination with the Central Valley Steelhead Project Work Team. The plan will include the design of a consistent, integrated database and data reporting and communication system. We recommend that serious consideration be given to monitoring returning steelhead adults at weirs or traps on streams that do not have steelhead hatcheries.

3 Research and monitoring to assist management

In this section we provide recommendations regarding research that seems particularly important for improving the scientific basis for management and recovery. At the outset, however, we emphasize the close connection between monitoring and research in the context of adaptive management. The essence of adaptive management is treating management as experimental, so that monitoring provides the experimental results, and is part of science as well as part of management (Peterman et al., 1977; Halbert, 1993; Williams, 1999). Roni (2005) provides a recent review of monitoring and evaluation principles, including adaptive management, as applied to restoration of salmonid-bearing watersheds.

We emphasize that the data required for risk assessment (Table 1) are only a subset of the data required for effective management of the populations and recovery planning. Data on spring-run Chinook salmon in Mill Creek (Figure 2) illustrate this point.

³The proposal is available online at http://www.delta.dfg.ca.gov/erp/docs/2005grants/Central_Valley_Steelhead_CMP_DA_Proposal.pdf

Figure 2: Estimated numbers of adult spring-run Chinook salmon returning to Mill Creek. Data from Van Woert (1964) and the CDFG GrandTab data base. For purposes of the tables, the population is the sum of the returns over a generation, i.e., 3 to 4 years.

Spring-run Chinook salmon in Mill Creek are monitored by redd counts, a not particularly precise method for estimating run sizes. From the data, however, it seems clear that the population has been over 2,500 in recent years, and over the last decade is not decreasing (note that for the genetic considerations underlying the population-size criterion, the population includes the adult returns for each year of a generation, which lasts 3 to 4 years; see the legend for Table 2). Because there is no reason to expect a significant hatchery influence, the population can be assigned to the low risk category, despite the considerable uncertainty in the abundance estimates.

For management, however, better data seem needed, as shown by the following example. Spring-run Chinook salmon in Mill Creek were monitored at a dam below the spawning grounds from 1954-63 (Van Woert, 1964), and the resulting information on the temporal distribution of the migration indicates that diversions for irrigation probably hinder late-arriving fish, especially in dry years (Figure 3). Better monitoring than now occurs would be required to confirm this, and to allow an assessment of the benefit to the population that might result from, say, pumping water from the Sacramento River to replace the water currently diverted from the creek a few miles upstream from the confluence. Put differently, abundance data by themselves say little about what might be done to improve conditions for the population. Similarly, although uncertain abundance estimates may be all that is needed to assess the viability of a population using Table 1, more accurate estimates may be needed to test hypotheses regarding the importance of various factors in regulating populations.

In the following subsections, we outline what we believe to be the major questions that need to be addressed in order to effectively manage salmon and steelhead in the Central Valley.

3.1 Climate change and temperature tolerance

Regional climate change (driven by global warming) is a critical issue for Chinook salmon and steelhead in the Central Valley (Lindley et al., in press.), and better information on future water temperatures and on the temperature tolerance of Chinook salmon and steelhead will be important for developing realistic recovery plans. This will require improved understanding at several levels: how temperature and precipitation will change at regional scales; how

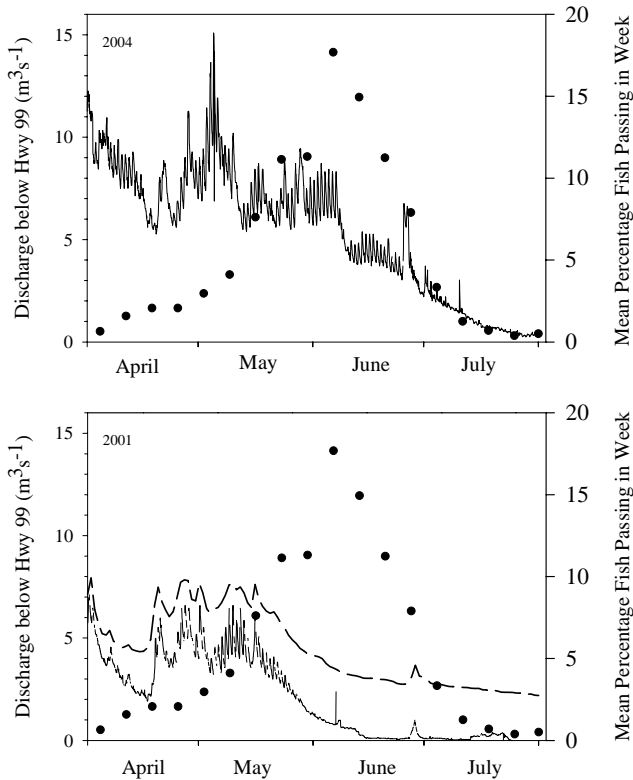

Figure 3: Temporal distribution of adult spring-run Chinook salmon migration for 1954-64 (circles), and discharge in Mill Creek at the DWR gage, downstream from diversions (solid line), and at the USGS gage, upstream from the diversions, 2001 and 2004. Migration data from Van Woert (1964). Copied from Williams (2006).

these regional-scale changes will alter conditions at the scales relevant to individuals and populations; and how individuals and populations will respond to these changes. Recent work has shown that the hierarchical structure linking large-scale climate variation to individual organisms must be understood in order to predict how organisms will respond to climate change (Gilman et al., 2006).

Several climatological studies dealing with warming and subsequent alterations to the hydrologic regime in the Central Valley have been published recently (Wilson, 2003; Dettinger et al., 2004; Hayhoe et al., 2004; Peterson et al., 2005), and we expect that more will be forthcoming. However, more focused efforts will be needed to translate the results of such studies to estimates of actual stream temperatures, which while strongly related to air temperature (Mohseni et al., 1998), are moderated by evapotranspiration, hill shading, groundwater inputs, and hyporheic exchange.

Temperature is a critical determinant of the shifting habitat mosaic (Hauer et al., 2003) that moves in time and space as river temperature isopleths migrate upstream to higher elevations in the spring/summer and downstream to the valley floor in the autumn/winter. For spring-run Chinook salmon the seasonal pattern of temperature is particularly critical. The adults enter in the spring and move to high elevations to avoid the lethal summer temperatures at lower elevations. In the autumn, temperature isopleths move downstream and the adults spread throughout the habitat to spawn. The eggs emerge and the fry move out of the system or seek temperature refugia prior to the next temperature cycle (Lindley et al., 2004).

To understand how climate change and restoration activities

will affect this shifting habitat mosaic, salmon ecologists stress a landscape perspective that emphasizes the connectivity of riparian systems to associated terrestrial and aquatic ecosystems (Wissmar and Bisson, 2003). In particular, the hydrological and geological mechanisms controlling stream habitats and the fish responses to the conditions are important. In the Central Valley the seasonal patterns of precipitation and temperature determine snow accumulation and rainfall patterns which are then filtered through the surface and subsurface water exchanges to produce flow and temperature patterns in the salmon habitats. How fish respond to changes in flow and temperature over their critical life stages will determine their ability to respond and adapt to climate change.

While much information is available on the life-stage-specific temperature ranges of Chinook salmon and steelhead (McCullough, 1999) little is known about the specific responses of Central Valley species to temperature. Anecdotal evidence suggests that some species of Central Valley salmonids are heat tolerant: "The high temperature tolerance of San Joaquin River fall run salmon, which survived temperatures of 80° F, inspired interest in introducing those salmon into the warm rivers of the eastern and southern United States" (Ron Yoshiyama, public communication). The full suite of life-stage and species need not be investigated, but rather it may be sufficient to examine those life stages most vulnerable to warming. For winter-run Chinook salmon, which spawn in summer, the embryonic life stage is at greatest risk from warming. Slater (1963) found in laboratory studies that winter-run Chinook salmon eggs and alevins had almost complete mortality by the time water temperatures reached 17.4°C. For spring-run Chinook salmon, the most vulnerable stages are adults holding over the summer in streams, and the gametes that they contain, although spawners, eggs and fry may also be vulnerable into early fall. For steelhead, and for yearling spring-run Chinook salmon, older juveniles are also subject to high summer temperatures. Some juvenile spring-run Chinook salmon and steelhead may encounter stressfully warm water as they migrate through the lower rivers and Delta in late spring. It may be possible to learn more about the effects of high temperatures under natural conditions by monitoring expression of heat shock proteins (e.g., Viant et al., 2003), viability of gametes, and mortality.

3.2 Use of freshwater habitat

Large numbers of winter-run Chinook salmon fry migrate past the Red Bluff Diversion Dam in late summer and fall (Gaines and Martin, 2002), but little is known about their survival or use of the habitat downstream from the dam. Studying small fish in large rivers is difficult, and it is not obvious how best to proceed, but some combination of exploratory and hypothesis-based research seems in order. A salient question is whether restoring more natural conditions in the Sacramento River upstream from Colusa (the meanderbelt concept) would benefit juvenile winter-run Chinook salmon.

Juvenile spring-run Chinook salmon in Butte Creek have access to a remnant of overbank habitat in the Butte Sinks and the Sutter Bypass, which may help explain the relatively high productivity of this population (Williams, 2006). This hypothesis should be explored, building on earlier Department of Fish and Game studies, because if confirmed it would provide support for the idea of increasing access to the Yolo Bypass for fish moving down the Sacramento River. Microstructural and microchemical analyses of otoliths from returning adults may be a reasonable approach.

The spatial and temporal distribution of fish from various listed ESUs in the Delta is not well known, particularly since the size criteria used to assign juvenile fish to runs are not highly accurate (Hedgecock et al., 2001). How juvenile salmon and steelhead use Delta habitats is also poorly understood, in spite of the long history of sampling in the Delta. This limits the effectiveness of habitat restoration in the Delta. Several management issues of immediate concern involve the effects of water operations on listed runs and whether operations need to be modified to avoid harm to the runs. Better understanding of the spatial and temporal patterns of habitat use by the various runs should allow more effective strategies to balance disruption of water operations and harm to the runs. Such information could be obtained by genetic analysis of tissue samples collected during regular monitoring of juveniles, as well as by more focused studies. To the extent that fish from listed ESUs are sacrificed, it seems appropriate to obtain as much information as is practicable from them; physiologically-based measures of condition, discussed by Williams (2006), should be considered for this purpose.

3.3 Juvenile migration and survival

Low survival of juvenile Chinook salmon during freshwater migration is widely believed to be a serious problem. This belief is based on the propensity of hatchery releases made in San Francisco Bay to yield much higher contribution rates to ocean fisheries than are observed for releases made near the hatchery, at least for the Feather River Hatchery, and on the recognition that river habitats have been highly altered. To date, there has never been a serious attempt to measure the survival of fish migrating down the Sacramento River or to identify locations of unusually high mortality, as has been done for many years on the Columbia River (e.g., Williams et al., 2001; Skalski et al., 2002).

CALFED has funded a collaboration between UC Davis and NOAA to estimate migration and survival patterns of late fall-run Chinook salmon and steelhead smolts as they move from Battle Creek to the ocean in 2007-09. These stocks were selected for logistical reasons, including being large enough to carry the ultrasonic transmitters used by the study, and availability of large numbers of fish. Other agencies will be tagging fish and releasing them in the Delta (USFWS) or Bay (USACOE) in coordinated studies. This study should provide new insights into the magnitude, location and perhaps mechanisms of mortality of salmonids as they migrate through the Sacramento River, Delta and Bay. As tag technology advances and tags become ever smaller, this study design should become feasible for spring-run Chinook salmon and winter-run Chinook salmon.

3.4 Population genetics

Genetic analyses have provided substantial new information about Central Valley Chinook (Banks et al., 2000; Hedgecock et al., 2001; Williamson and May, 2003), and more information will be forthcoming as improved methods for genetic analysis develop. Routine monitoring with population genetics tools can allow detection of population bottlenecks (Garcia and Williamson, 2001), estimation of effective population size (Waples, 2004), and introgression (Aurelle et al., 2002; Cordes et al., 2006). However, the

utility of these methods will depend in large part of the availability of tissue samples from which DNA can be extracted. We suggest that fin samples be routinely taken when fish are handled, and sent to the CDFG Salmonid Tissue Archive. Examples of fish that should be routinely sampled would include: fish used for gamete production in hatcheries, migrating juveniles, resident *O. mykiss*, especially where both resident and anadromous forms occur, and fish used in attempts to initiate new runs.

3.5 Harvest

The harvest of listed Central Valley Chinook has generated little controversy in recent years, because populations have been stable or increasing. It seems likely that good ocean conditions have contributed substantially to this state of affairs, however, and harvest may come under greater scrutiny when ocean conditions change (see the current situation regarding Klamath River fall Chinook for a preview of what may happen when fishery management goals in the Central Valley cannot be easily achieved⁴). Harvest affects not only the number of returning adults but also their age structure, and the effects on age structure may be long-lasting (Williams, 2006). It can be anticipated that models will be used to assess the effects of harvest on populations and their viability (Newman and Lindley, 2006), in terms of effects on age structure as well as abundance. To support these assessments, appropriate sampling needs to occur both in the fisheries and on the spawning grounds.

Existing monitoring of ocean harvest provides estimates of total chinook landings and fishing effort stratified by month and catch area. Direct estimates of stock- and age-specific harvest are routinely available only for hatchery coded-wire tagged release groups, and the harvest rates on these CWT groups are used as a proxy measure of the harvest rates on their natural stock counterparts. These hatchery and natural stock counterparts may or may not be different in ways that would effect ocean harvest rates, but in any event the approach is limited to instances in which there is a suitable hatchery/natural counterpart (e.g. Livingston Stone Hatchery/natural born Sacramento River winter Chinook), and is not applicable otherwise (e.g. Central Valley spring Chinook).

Genetic stock identification (GSI) techniques have advanced significantly in recent years. When coupled with the coast-wide microsatellite database for Chinook salmon recently developed by the Pacific Salmon Commission, GSI analysis of fishery harvests should provide a substantial increase in the information available for stock-specific impact assessment and management, particularly for those stocks that do not have a CWT counterpart (although not all listed Central Valley populations are identifiable to river of origin). GSI assessments in themselves, however, do not provide the corresponding age information for the harvests, which is essential for fishery management and population dynamics modeling purposes. Therefore, existing monitoring of the harvest should be expanded to include not only the collection and processing of tissue for the purpose of stock identification, but also the collection and processing of scales or otoliths for the purpose of aging. This data together with stock- and age-specific freshwater harvest and escapement data will enable the estimation of stock-age-specific ocean harvest rates (stratified by month and catch area), maturation rates, and freshwater harvest rates. These estimates in turn provide the foundation for fishery and population viability modeling. We

⁴A Google search on "Klamath fishery controversy" on 23 January 2007 yielded 51,300 pages that will give the interested reader a sense of what to expect.

note that CDFG has recently begun routine aging of many Chinook salmon runs in the Central Valley⁵

The temporal distributions of adult freshwater migrations makes it easier to avoid harvest of listed ESUs in the freshwater fishery than in the ocean fishery, but analysis of tissue samples collected at appropriate times would serve as a check, and also provide information on the tails of the temporal distributions of the adult migrations of listed ESUs. Better monitoring of freshwater harvest is needed for effective management of fall-run Chinook salmon, and tissue samples could be collected as an adjunct to such monitoring.

3.6 Ocean climate influence

It is now generally recognized that ocean conditions can have strong effects on salmon populations, and better understanding of these effects is important for assessing the effectiveness of recovery efforts. Ocean conditions for salmon are the subject of a growing literature, but Central Valley salmon enter a unique ocean environment, the Gulf of the Farallones, and seem to respond differently to ocean conditions than do salmon farther north (MacFarlane et al., 2005; Williams, 2006). Moreover, ocean conditions probably affect winter-run Chinook salmon and spring-run differently, since most spring-run Chinook salmon enter the ocean as subyearlings in late spring, but winter-run Chinook salmon enter the ocean at larger size, in the winter or early spring. Accordingly, although studies elsewhere may provide useful information, direct assessment of the effects of ocean conditions on Central Valley ESUs seems necessary.

Studies of juvenile fall-run Chinook salmon in the Gulf of the Farallones, such as (MacFarlane et al., 2005), probably are applicable to spring-run Chinook salmon, and should be continued. Capturing juvenile winter-run Chinook salmon in the ocean does not seem feasible, even if it were desirable, and studying the otolith microstructure and microchemistry of winter-run Chinook salmon sampled during carcass counts or taken at the hatchery may offer the best opportunity for assessing year to year differences in growth during early ocean residency. Less intensive microstructural analyses of spring-run Chinook salmon may be in order, to confirm that most juveniles follow a life history pattern similar to that of fall-run Chinook salmon.

3.7 Hatchery influence

There is a broad range of concern regarding the effects of hatchery culture on salmonids (Utter, 1998; Waples, 1999), and issues at either end of the range are most relevant for Chinook salmon in the Central Valley. Regarding winter-run Chinook salmon, the concern is whether negative effects of culture in conservation hatcheries such as the Livingston Stone Hatchery outweigh the demographic benefits. More generally, work is needed on the dynamics of hatchery impacts and recovery from these impacts: the theoretical studies done to date (Goodman, 2005) examine steady-state solutions. Also, more empirical information is needed on the strength of domestication selection in the hatchery, the fitness consequences of this selection, and the strength of natural selection in counteracting domestication selection, in order to better identify the safe limits of hatchery impacts.

⁵The proposal for this project can be found online at http://www.delta.dfg.ca.gov/erp/docs/2005grants/Cohort_Reconstruction_DA_Proposal.pdf.

3.8 Estimating spawning run sizes

Despite their widespread use in the Central Valley, models to estimate in-river spawning escapement based on mark-recapture carcass survey data require a number of assumptions which may not be met in the surveys. A principal assumption of mark-recapture surveys is that the marked animals will distribute randomly among the population during the interval before the recapture sampling. This assumption is often violated for carcasses, with differing consequences on the final escapement estimate depending on the size of the run, the area sampled, and the degree to which random resampling designs are used. Another assumption in carcass mark-recapture sampling is that all fish are either available for marking or are available for recapture sampling. This assumption is likely not met in large streams with deep pools. In these areas, some carcasses may be unavailable to sampling by field crews. This may result in under or over-estimation of the actual run size as it represents an unsampled portion of the run. Research is needed to better understand the degree to which these problems may occur in carcass surveys, the effect that these violations of assumptions have on estimates, and analytical and field strategies to reduce bias.

Data should be gathered on the age and size distributions of returning adults, as well as their numbers. Data on size distributions are important for estimating fecundity, which should be taken into account in estimating the reproductive potential of a given year-class of adults, and data on age are important for assessing the effects of harvest, and more generally are needed for the age-structured population models that could be used in improved harvest and viability models. These data could be obtained during carcass surveys by measuring lengths and collecting otoliths from subsamples of fish. Otoliths could also be used for microstructure analysis to elucidate juvenile life histories, as described above. Scales might also be used to collect age information on adults, but would provide much less information on juvenile life histories.

3.9 Estimating juvenile production

Juvenile production estimates, in combination with adult return data, allow for the effects of ocean and freshwater conditions to be teased apart. Such information is extremely valuable for understanding whether habitat restoration is effective and whether ocean climate anomalies are driving abundance trends. Estimating juvenile abundance is challenging, due to problems of operating sampling gear in highly variable flows, estimating the efficiency, or capture probability, of the gear, identifying juveniles to ESU or population, and accounting for the importance of juvenile age. Advances in all of these areas are needed.

3.10 Life history of *O. mykiss*

As a species, *O. mykiss* exhibit great variation in their tendency to migrate, ranging from non-migratory (resident trout) to strongly migratory (anadromous steelhead moving from rivers to the sub-arctic Pacific). It is now well understood that these two forms represent two distinct life history strategies of the same taxonomic species. In some river systems, it appears that the two forms maintain separate populations; in others there is evidence that they comprise a single interbreeding population where one form can give

rise to the other (Zimmerman and Reeves, 2000). This type of population is said to be “polymorphic” in its life history.

In California, steelhead and resident rainbow trout are often sympatric within stream reaches accessible from the ocean. Resident and anadromous fish could either be two components of a polymorphic and panmictic population, or they might be largely separate breeding populations. In the Central Valley, there is limited evidence that at least some populations are polymorphic (Titus (2000), as cited in McEwan (2001)). How we should think about and manage *O. mykiss* populations depends on the prevalence migratory polymorphism. If it is common, then it is nonsensical to manage one of the morphs without reference to the other, because polymorphic populations should have ecological, demographic and evolutionary properties quite distinct from strictly anadromous or resident populations.

To answer the question of whether steelhead and resident rainbow trout comprise a single interbreeding population, one must determine if the two forms are reproductively isolated from one another. Reproductive isolation may occur through differences in spawning times, differences in spawning habitat, or assortative mating. A particularly attractive approach to this question is based on the ratio of strontium (Sr) to calcium (Ca) within the otolith to identify the migration history of individuals and whether that individual had a resident trout or anadromous steelhead mother. Rainbow trout that have migrated to the ocean retain a Sr/Ca signature in their otoliths. Similarly, a rainbow trout that has a steelhead mother, regardless of its own migratory history, also retains an ocean Sr/Ca signature in the primordia of its otoliths due to the fact that the egg from which it arose was formed while its mother was in the ocean. If anadromous and resident *O. mykiss* interbreed rarely, then this should be detectable as differences in the frequency of neutral genetic markers between the two populations (but such differences will not arise with even limited reproductive exchange).

We suspect that there has been a significant shift in the frequency of resident and anadromous life histories in *O. mykiss* in the Central Valley (Lindley et al., in press.), and this likely has important conservation consequences. A CalFed-funded project⁶ at UCSC, NOAA and CDFG is examining the role that river regulation may have in driving these shifts, but further work is needed in documenting the distribution of life history types throughout the range, identifying the factors driving this shift, assessing the degree to which it is reversible, and evaluating the consequences for population and evolutionary dynamics.

3.11 Reintroductions

When previously blocked or degraded habitat is restored and made accessible to anadromous fish, how exactly should salmonids be reintroduced to habitats? A number of critical decisions will need to be made when new habitats are made accessible, including method of reintroduction (natural colonization, transplanting of natural fish, outplanting of hatchery fish), source population of founding stock, and methods to limit access by undesired populations, species or stocks. These decisions in turn hinge upon complex genetic, demographic and ecological processes and principles. The Southwest Fisheries Science Center is undertaking a literature review to develop a decision analysis tool to guide future reintroductions.

⁶Proposal is available online at https://solicitation.calwater.ca.gov/solicitations/2004.01/reports/public_proposal_compilation?proposal_id=0140

Figure 4: Number of spring Chinook returning to the Sacramento River above the Red Bluff Diversion Dam, as reported in the Grand Tab data base. The decrease after 1990 reflects changes in criteria for assigning fish to runs, not an actual population change.

A related effort is needed to evaluate the prospects for various fish passage technologies that might be employed to allow anadromous fish to move past currently impassable barriers. In concert with this effort, habitat and potential passage opportunities above rim dams in major tributaries of the Central Valley should be assessed.

3.12 Data Management

A good deal of data exist on Central Valley Chinook, steelhead, and their environments, from monitoring programs described by Pipal (2005) and Low (2005), and from other sources. Data are useful to the extent that they are used, however, and by and large the existing data are under used because they are not easily obtained. Worse, some of the data are misleading. Data management is difficult and expensive, but the cost of neglecting data is likely to be greater. Here are some recommendations:

1. Document the the strengths and weaknesses of existing datasets. The quality of existing datasets is highly variable, and sometimes not well documented, although Pipal (2005) provides good preliminary descriptions of many of them. For example, DFG maintains an Excel file, Grand Tab, with historical information on returns of Chinook to Central Valley streams. An apparent decline in returns of spring-run to the upper Sacramento River (above the Red Bluff Diversion Dam) after 1990 reflects a change in the criteria used to allocate fish to runs at the RBDD ladder, rather than an actual change in the population (Williams, 2006). Such problems with existing datasets need to be described before the people who know about them retire, and the descriptions need to be easily available to users of the data. This data about data is called metadata, and using metadata standards is an important step towards making comparisons among datasets feasible.

2. Develop a common portal for basic data on Central Valley salmon and steelhead and related environmental variables, using a common format and data retrieval protocols. A significant number of databases directly connected with ongoing monitoring programs exists for Central Valley fish and habitats. However, the coordination of these databases is weak, in part because the databases

were developed independently by programs and agencies for specific unrelated purposes. For example, CALFISH (<http://www.calfish.org/DesktopDefault.aspx>) provides information on fish migrations and trends, the IEP Data Vault points to the Bay Delta and Tributaries (BDAT) Project data on <http://bdat.ca.gov/> and the California Data Exchange (CDE; <http://cdec.water.ca.gov>) provides information on flows, storage and snow pack. The CALFISH and BDAT databases share some common variables but neither contains water data available at the CDE database and none of these sites has temperature information. Further, they use different data formats, data retrieval protocols, and have different temporal and spatial coverage.

Coordination of essentially independent databases with unique purposes is a major technical and organizational undertaking. However, the Pacific Northwest faces similar challenges and has developed the Northwest Environmental Data Network (NED) (<http://www.nwcouncil.org/ned/Default.asp>), a cooperative effort to improve collection, management and sharing of environmental data and information. The objective of the NED Portal is to direct scientific and resource management users of data to a consistent source of environmental geospatial and tabular data and metadata. In like fashion, Central Valley and related databases should be coordinated through a common data portal so that data and its metadata can be obtained in a common format using a common retrieval protocol.

3. Develop a portal for graphical data presentation. Analysis and synthesis are necessary to convert data into information. Although researchers and some others need data in numerical form, graphical presentations of data are more useful for most purposes. For example, as part of the Environmental Water Account program, DWR prepares graphics synthesizing data on fish and flow for the weekly conference calls of the Data Assessment Team. Other such graphics, designed to present up-to-date information on particular topics or to meet the needs of particular audiences, should be made available. As an example that might be emulated in the Central Valley, the DART data site (<http://www.cbr.washington.edu>) synthesizes data on fish, climate, and river conditions from various monitoring programs and provides graphical and textual information on historical, current, and forecasted fish migrations and trends. In general, if monitoring data are not worth presenting in graphical formats on a regular basis, probably they are not worth collecting. With modern graphical programs, creating such graphics and keeping them up to date would not be difficult.

ABSTRACT

Protected evolutionarily significant units (ESUs) of salmonids require objective and measurable criteria for guiding their recovery. In this report, we develop a method for assessing population viability and two ways to integrate these population-level assessments into an assessment of ESU viability. Population viability is assessed with quantitative extinction models or criteria relating to population size, population growth rate, the occurrence of catastrophic declines, and the degree of hatchery influence. ESU viability is assessed by examining the number and distribution of viable

populations across the landscape and their proximity to sources of catastrophic disturbance.

Central Valley spring-run and winter-run Chinook salmon ESUs are not currently viable, according to the criteria-based assessment. In both ESUs, extant populations may be at low risk of extinction, but these populations represent a small portion of the historical ESUs, and are vulnerable to catastrophic disturbance. The winter-run Chinook salmon ESU, in the extreme case, is represented by a single population that spawns outside of its historical spawning range. We are unable to assess the status of the Central Valley

steelhead ESU with our framework because almost all of its roughly 80 populations are classified as data deficient. The few exceptions are those populations with a closely associated hatchery, and the naturally-spawning fish in these streams are at high risk of extinction. Population monitoring in this ESU is urgently needed.

Global and regional climate change poses an additional risk to the survival of salmonids in the Central Valley. A literature review suggests that by 2100, mean summer temperatures in the Central Valley region may increase by 2–8°C, precipitation will likely shift to more rain and less snow, with significant declines in total precipitation possible, and hydrographs will likely change, especially in the southern Sierra Nevada mountains. Warming at the lower end of the predicted range may allow spring-run Chinook salmon to persist in some streams, while making some currently utilized habitat inhospitable. At the upper end of the range of predicted warming, very little spring-run Chinook salmon habitat is expected to remain suitable.

In spite of the precarious position of Central Valley salmonid ESUs, there are prospects for greatly improving their viability. Recovering Central Valley ESUs may require re-establishing populations where historical populations have been extirpated (e.g., upstream of major dams). Such major efforts should be focused on those watersheds that offer the best possibility of providing suitable habitat in a warmer future.

INTRODUCTION

Numerous evolutionarily significant units (ESUs) of Pacific salmon and steelhead are listed as threatened or endangered species under the US Endangered Species Act (ESA) of 1973. The ESA, as amended in 1988, requires that recovery plans have quantitative, objective criteria that define when a species can be removed from the list, but does not offer detailed guidance on how to define recovery criteria. Logically, some of the recovery criteria should be biological indicators of low extinction risk. Recovery plans prepared since the 1988 amendment typically have about six recovery criteria, but only about half of these are quantitative or clearly related to biological information (Gerber and Hatch 2002). Gerber and Hatch (2002) found a positive relationship between the number of well-defined biological recovery criteria and the trend in abundance for the species. This empirical finding supports our intuition that well-defined recovery goals are important for recovering species.

Recovery planning seeks to ensure the viability of protected species. Viability of populations and ESUs depends on the demographic properties of the population or ESU, such as population size, growth rate, the variation in growth rate, and carrying capacity (e.g., Tuljapurkar and Orzack 1980). In the short term, the demographic properties of a population depend largely on the quality and quantity of habitat. In the longer term, genetic diversity, and the diversity of habitats that support genetic diversity, become increasingly important (McElhany et al. 2000; Kendall and Fox 2002; Williams and Reeves 2003). Consequently, McElhany et al. (2000) suggested that the viability of Pacific salmon populations should be assessed in terms of abundance, productivity, spatial structure, and genetic and life-history diversity. ESUs can be assessed in these same terms. While providing a useful conceptual framework for thinking about viability of Pacific salmon, McElhany et al. (2000) did not provide quantitative criteria that would allow one to assess whether particular populations or ESUs are viable.

Developing objective, quantitative, and biologically meaningful recovery criteria for Pacific salmonid ESUs is difficult. Ideally, these criteria would be population- and ESU-specific, taking into account the constraints

in some factors that influence viability. For example, quantity of suitable habitat will usually set some limit on the size of a population, and populations with less habitat will need to have higher intrinsic growth rates (or less variable growth) than populations with more habitat, if they are to have similar viability. Unfortunately, population-specific information is frequently unavailable. One way out of this problem is to forego population-specific goals and develop biologically relevant criteria that are generic to *Oncorhynchus* species. Conservation biologists have developed a number of such criteria for the related task of identifying and prioritizing species in need of conservation (Mace and Lande 1991; IUCN 1994; Gärdenfors et al. 2001), and these taxonomically general criteria have been modified for application to Pacific salmonids (Allendorf et al. 1997).

If extinction risks of populations were independent, assessing the extinction risk of the ESU would be straightforward—the extinction risk of the ESU would be the product of the extinction risks of all its populations. We expect the extinction risks of populations to be correlated, however, because normal environmental influences affecting the population dynamics of salmonids are spatially correlated. Perhaps even more importantly, the effects of catastrophes (defined as rare environmental perturbations with very strong negative effects on afflicted populations) can be quite widespread. Finally, in cases like the Central Valley, all populations must use certain small areas (e.g., San Pablo Bay) where a single event such as a toxic spill could affect all populations even though they are widely dispersed for most of their life cycle. In some cases, it may be possible to explicitly examine the vulnerability of ESUs to catastrophic risks. We are unlikely to be able to identify all possible sources of risk, however, so we should also think of managing risk by maximizing diversity within ESUs.

In this report, we develop an approach for assessing the viability of Pacific salmonid populations and ESUs, and apply it to listed ESUs in California's Central Valley domain. In the "Assessment Framework" section below, we extend the criteria-based approach of Allendorf et al. (1997) to account for the effects of hatchery fish on the extinction risk of naturally-spawning populations, and explicitly define a "low" extinction risk category. This

low-risk definition can serve as a default goal for recovering populations for which too little data exist for more detailed goals to be developed. ESU viability is addressed in two ways. In the first, risk-spreading is assessed by examining how viable populations are spread among geographically-defined regions within the ESU. In the second, we attempt to account explicitly for the spatial structure of the ESU and the spatial structure of various catastrophic risks, including volcanos, wildfires, and droughts. In the "Application to Central Valley Salmonids" section, we apply the analyses to Central Valley spring-run Chinook salmon (*Oncorhynchus tshawytscha*), Sacramento River winter-run Chinook salmon (*O. tshawytscha*), and Central Valley steelhead (*Oncorhynchus mykiss*). As these methods implicitly assume that the future will be like the recent past, we review the likely effects of climate variation and climate change in "Climate Variability and Change." The "Summary and Recommendations" section summarizes our findings and makes some recommendations for recovery planners.

ASSESSMENT FRAMEWORK

Population Viability

Risk Categories

The goal of our population-level viability assessment is to classify populations into one of six categories, including "extinct," "extinct in the wild," "high," "moderate," and "low" extinction risk, or "data deficient," following the general approach of the IUCN (1994) as modified for Pacific salmonids by Allendorf et al. (1997). The goal of recovery activities should be to achieve at least a low risk of extinction for focal populations. We assume that a 5% risk of extinction in 100 years is an acceptably low extinction risk for populations (Thompson, 1991). Many salmonid populations are capable of achieving much lower risk levels and can provide additional benefits to ecosystems (Schindler et al. 2003) and people (e.g., by providing fishing opportunities) at these higher levels of abundance and productivity.

For Chinook salmon, we infer that populations are extinct if all of their historically utilized spawning habitat is blocked by impassable dams. *O. mykiss* pop-

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

Table 1. Criteria for assessing the level of risk of extinction for populations of Pacific salmonids. Overall risk is determined by the highest risk score for any category. (Modified from Allendorf et al. 1977)

Populations entirely dependent on artificial production (i.e., found only in a captive broodstock program or hatchery) would be considered extinct in the wild.

Criterion	Risk of Extinction		
	High	Moderate	Low
Extinction risk from PVA	> 20% within 20 years – or any ONE of –	> 5% within 100 years – or any ONE of –	< 5% within 100 years – or ALL of –
Population size ^a	$N_e \leq 50$ –or– $N \leq 250$	$50 < N_e \leq 500$ –or– $250 < N \leq 2500$	$N_e > 500$ –or– $N > 2500$
Population decline	Precipitous decline ^b	Chronic decline or depression ^c	No decline apparent or probable
Catastrophe, rate and effect ^d	Order of magnitude decline within one generation	Smaller but significant decline ^e	not apparent
Hatchery influence ^f	High	Moderate	Low

Risk categories from “high” to “low” are defined by various quantitative criteria, and correspond to specific risks of extinction within specific time horizons (Table 1). We extend Allendorf et al.’s (1997) criteria categories and risk levels in two ways (Table 1). First, we define criteria for the “low” risk category, which are implicit in Allendorf et al. (1997) Table 1. To simplify analysis, we collapse Allendorf et al. (1997) “very high” and “high” risk categories into a single “high” risk category. We add a set of criteria to deal with fish produced by hatcheries that spawn in the wild. Allendorf et al. (1997) deal with hatchery fish in their assessment of conservation value, but for our purposes of defining recovery criteria, the influence of hatchery fish must be included in the viability criteria.

Populations are classified as “data deficient” when there are not enough data to classify them otherwise. It is possible to classify a population as “high” risk with incomplete data (e.g., if it is known that $N_e < 50$, but

ulations may persist above migration barriers even if spawning habitat is inaccessible to anadromous fish, so migration barriers can not be taken as evidence of extinction for *O. mykiss*. In some cases, dams create suitable habitat in downstream reaches (typically through regulated discharges of cold water), and may support a population. We assess the status of such populations with the criteria described below, but note that the identity of tailwater populations may differ from populations historically found above the barrier.

trend data and hatchery straying are lacking), but a low risk classification must be met with all criteria.

Risk Criteria

Following Allendorf et al. (1997), the first set of criteria deal with direct estimates of extinction risk from population viability models. If such analyses exist and are deemed reasonable, such assessments may be sufficient for assessing risk; indeed, Allendorf et al. (1997) intended that their other criteria be used when

such analyses were not available. The simplest useful population viability assessments are based on the random-walk-with-drift model (Dennis et al. 1991), and can be extended to account for observation error (Lindley 2003); we use this model where possible in this paper. We note that trying to predict absolute extinction risk is subject to many pitfalls and is viewed with skepticism by many conservation biologists and ecologists (Beissinger and Westphal (1998) provides a review of the various issues). We therefore recommend that population viability analysis (PVA) results be compared to the results of applying the simpler criteria, described below.

The effective population size criteria in the second row of Table 1 relate to loss of genetic diversity. The effective population size, N_e , is smaller than the population census size N due to variation in reproductive success among individuals. For Chinook salmon, N_e/N ranges from 0.06 to 0.29 (Waples et al. 2004). N_e can be estimated from detailed demographic or genetic data (e.g., see Ardren and Kapuscinski 2003). Very small populations, for example with $N_e < 50$, suffer severe inbreeding depression (Franklin 1980; Soulé 1980), and normally outbred populations with such low N_e have a high risk of extinction from this inbreeding.

Somewhat larger, but still small, populations can be expected to lose variation in quantitative traits through genetic drift faster than it can be replaced by mutation. Franklin (1980) and Soulé (1980) used population genetics models to show that such drift is significant when $N_e < 500$. The assumptions behind the $N_e > 500$ rule are problematical in two ways. On one hand, the original models used to derive the 500 rule (Franklin 1980; Soulé 1980) assumed that all mutations were mildly deleterious, but later research showed that only 10% of mutations are mildly deleterious (Lande 1995). This means that mutation effectively introduces new genetic variation at only 10% of the rate previously assumed, so N_e should therefore be > 5000 to attenuate the loss of genetic diversity due to drift. On the other hand, the models of Franklin and Soulé also assume that populations are closed to immigration. Very low levels of immigration, on the order of one individual per generation, can prevent the loss of alleles through drift (Wright 1931). We note

that salmonid populations within ESUs are expected to have immigration at such low rates. Given the countervailing effects of the violations of the assumptions underlying the $N_e > 500$ rule, we apply the Allendorf et al. (1997) criteria as they stand, but note that with future research, it may be possible to define population size targets that conserve genetic variation and account for migration and genetic structuring within ESUs (e.g., Whitlock and Barton 1997).

The population decline criteria are intended to capture demographic risks. The rationale behind the population decline criteria are fairly straightforward—severe and prolonged declines to small run sizes are strong evidence that a population is at risk of extinction. The criteria have two components— a downward trend in abundance and a critical run size (< 500 spawners). Note that spawning run size is distinct from N_e .

Although it is not clear how Allendorf et al. (1997) chose 500 as the threshold spawning run size, we adopt this threshold to maximize consistency with their criteria. We also note that typical salmonid populations near a carrying capacity of 500 spawners require only modest intrinsic growth rates to have low probability of extinction, given typical levels of variation in population growth (D. Boughton, NOAA Fisheries, Santa Cruz, CA; in preparation).

The catastrophe criteria trace back to Mace and Lande (1991), and the underlying theory is further developed by Lande (1993). The overall goal of the catastrophe criteria is to capture a sudden shift from a low risk state to a higher one. Catastrophes are defined as instantaneous declines in population size due to events that occur randomly in time, in contrast to regular environmental variation, which occurs constantly and can have both positive and negative effects on the population. Catastrophes have a qualitatively different effect on the distribution of mean time to extinction than does environmental variation. Because of this, it is sensible to treat catastrophes separately from population declines. We view catastrophes as singular events with an identifiable cause and only negative immediate consequences, as opposed to normal environmental variation which can produce very good as well as very bad conditions. Some examples of catastrophes include disease outbreaks, toxic spills, or vol-

Figure 1. Extinction risk levels corresponding to different amount, duration and source of hatchery strays. Green bars indicate the range of low risk, yellow bars moderate risk, and red areas indicate high risk. Which chart to use depends on the relationship between the source and recipient populations. A: hatchery strays are from a different ESU than the wild population. B: Hatchery strays are from the same ESU but from a different diversity group within the ESU. C: Hatchery strays are from the same ESU and diversity group, but the hatchery does not employ “best management practices.” D: Hatchery strays are from the same ESU and diversity group, and the hatchery employs “best management practices.” Redrawn from Interior Columbia Basin Technical Recovery Team (2005).

canic eruptions. A high risk situation is created by a 90% decline in population size over one generation. A moderate risk event is one that is smaller but biologically significant, such as a year-class failure.

We view the spawning of hatchery fish in the wild as a potentially serious threat to the viability of natural populations. Population genetics theory predicts that fish hatcheries can negatively impact wild populations when hatchery fish spawn in the wild (e.g., Emlen 1991; Lynch and O’Hely 2001; Ford 2002; Goodman 2005). These predictions are supported by mounting empirical evidence (e.g., Reisenbichler and McIntyre 1977; Chilcote et al. 1986; Reisenbichler and Rubin 1999; McLean et al. 2003; Kostow 2004). In assessing the genetic impact of immigration on a population, one must consider the source of the immigrants, how long the impact goes on, the number of immigrants relative to the size of the recipient population, and how divergent the immigrants are from the recipient population. We adopt the approach of the Interior Columbia Basin Technical Recovery Team (TRT) (2005) to define how different scenarios relate to extinction risk for natural populations, summarized in Figure 1. We made one significant change to the Interior Columbia Basin Technical Recovery Team (2005) hatchery introgression criteria, allowing up to 5% of naturally spawning fish to be of hatchery origin while maintaining a low risk, if the hatchery fish are from a hatchery using “best management practices” (see Flagg et al. 2004; Olson et al. 2004; Mobernd et al. 2005, for a description of these practices) using broodstock derived from the wild population. This is consistent with the ICBTRT scheme, which can result in a low-risk classification even with moderate amounts of straying from best-practices hatcheries, so long as other risk measures are acceptable. We note that the risk levels depicted in Figure 1 are based on expert opinion, and that the empirical basis for relating hatchery impacts to extinction risk is currently limited (Bilby et al. 2003).

Allendorf et al. (1997) did not specify how to calculate estimates for the various viability criteria. Table 2 provides estimators that we have used in this paper. The average run size is computed as the mean of up to the three most recent generations, if that much data are available. Mean population size is estimated as the

Table 2. Estimation methods and data requirements for population metrics. S_t denotes the number of spawners in year t ; g is mean generation time, which we take as three years for California salmon.

Metric	Estimator	Data	Criterion
\hat{S}_t	$\sum_{i=t-g+1}^t S_i/g$	≥ 3 years spawning run estimates	Population decline
N_e	$N \times 0.2$ or other	varies	Population size
N	$\hat{S}_t \times g$	≥ 3 years spawning run estimates	Population size
Population growth rate (% per year)	slope of $\log(S_t)$ v. time $\times 100$	10 years S_t	Population decline
c	$100 \times (1 - \min(N_{t+g}/N_t))$	time series of N	Catastrophe
h	average fraction of natural spawners of hatchery origin	mean of 1-4 generations	Hatchery influence

While we will not assess ESU viability in absolute terms, we assume that recovery planners will want ESUs to be likely to persist in the face of environmental variation of the sort we know has occurred over the last 500-1000 years. Such variation has included natural catastrophes such as prolonged drought, volcanic eruptions, large wildfires, and anthropogenic impacts such as the 1991 Cantara metam sodium spill. Such catastrophes could occur at any time in the foreseeable future. Therefore, for ESUs to be considered viable, they should at a minimum be able to persist if challenged by any one of these types of catastrophes.

product of the mean run size and the average generation time. Population growth (or decline) rate is estimated from the slope of the natural logarithm of spawners versus time for the most recent 10 years of spawner count data. The fraction of naturally spawning fish of hatchery origin is the mean fraction over one to four generations.

ESU Viability

ESU viability depends on the number of populations within the ESU, their individual status, their spatial arrangement with respect to each other and sources of catastrophic disturbance, and diversity of the populations and their habitats. In the most general terms, ESU viability increases with the number of populations, the viability of these populations, the diversity of the populations, and the diversity of habitats that they occupy. Under natural conditions, most salmonid ESUs have persisted for at least many centuries, and perhaps much longer, given the observed level of genetic differentiation within and among them. How much can an ESU be altered before it is considered at risk of extinction?

Viability by Representation

We assess ESU viability with two different approaches. The goal of both approaches is to spread risk and maximize future potential for adaptation. The Puget Sound, Willamette/Lower Columbia and Interior Columbia TRTs have used variations on the idea of dividing ESUs into subunits (Myers et al. 2003; Ruckelshaus et al. 2002; Interior Columbia Basin Technical Recovery Team 2003), and requiring representation of all subunits and redundancy within the subunits (which we call the “representation and redundancy” rule). The ESU subunits are intended to capture important components of habitat, life history or genetic diversity that contribute to the viability of salmonid ESUs (Hilborn et al. 2003; Bottom et al. 2005). If extinction risks are not strongly correlated between populations, two populations, each with low risk of extinction, would be extremely unlikely to go extinct simultaneously (McElhany et al. 2003). Should one go extinct, the other could serve as a source of colonists to re-establish the extirpated population. Therefore, at

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

Figure 2. Salmonid ecoregions within the Central Valley. Map A: Central Valley spring-run Chinook salmon. Map B: Central Valley steelhead. Sacramento River Winter-run Chinook salmon not shown because this ESU has only one region (Basalt and porous lava). The numbers identifying steelhead populations correspond to Table 1 in Lindley et al. (2006).

least two viable populations within each ESU subunit are required to ensure viability of the subunit, and hence the ESU. In the cases of large subunits, more than two viable populations may be required to maintain connectivity among populations.

As discussed in Lindley et al. (2004), drainages in the Central Valley basin are characterized by a wide variety of climatological, hydrological, and geological conditions. To a first approximation, floristic ecoregions, such as the Jepson ecoregions defined by Hickman (1993), provide an integrative view of these differences. We use the Jepson ecoregions as a starting point for salmonid ecoregions, but modify them to account for the effect of springs, which are very influential on salmonids, but less influential to upland plants (Figure 2). Instead of the Cascade Ranges

region, we define a “basalt and porous lava” region that comprises the streams that historically supported winter-run Chinook salmon. All of these streams receive large inflows of cold water from springs through the summer, upon which winter-run Chinook salmon depended. This region excludes streams south of Battle Creek, but would include the part of the Upper Sacramento drainage used by winter-run, and part of the Modoc Plateau region. The southern part of the Cascades region (i.e., the drainages of Mill, Deer, and Butte creeks) is added to the Sierra Nevada region, but the Sierra Nevada region is divided into northern and southern parts (split somewhat arbitrarily south of the Mokelumne River). This split reflects the greater importance of snowmelt runoff in the southern part, and distinguishes tributaries to the Sacramento and

San Joaquin rivers. The Central Valley steelhead ESU has two additional salmonid ecoregions: the Suisun Bay region which consists of tributaries to or near Suisun Bay, where summer temperatures are moderated by the marine influence of nearby San Francisco Bay and the Pacific Ocean, and the Central Western California ecoregion, which contains west-side San Joaquin Valley tributaries.

Viability by Assessment of Specific Threats

An alternative to the representation and redundancy rule is to assess the relationship between ESU structure and specific sources of catastrophic risk. For example, one can assess whether a spill of toxic material at a certain point could extirpate all populations of an ESU. The advantage of this approach is that it is explicit: benefits or shortcomings of a particular ESU structure can be seen. The disadvantage is that we are unlikely to foresee all possible catastrophes, and more generally, this approach does not fully consider the value that biocomplexity has for ESUs. With this caution in mind, we assess the present structure of ESUs in relation to volcanic eruptions, wildfire, and drought¹.

Volcanos may seem like an unlikely threat, but the Mt. St. Helens eruptions of 1980 extirpated salmon in the Toutle River (Jones and Salo, 1986). The Cascades Range, of which Mt. St. Helens is a member, forms the northeastern boundary of the Sacramento River basin and is volcanically active. To assess the risk from volcanic eruptions, we obtained data on impact for lava flow, volcanic blast, pyroclastic flows, and debris-lahar flows from Hoblitt et al. (1987). For each volcano and impact type, we computed the percentage of habitat that would be impacted for each population.

While probably less devastating than a major volcanic eruption, fires can cause large injections of fine particles into streams, and fires have been implicated in the extinction of trout populations (e.g., Rinne 1996; Brown et al. 2001). In addition, fire-fighting chemicals are toxic to juvenile salmon (Buhl and Hamilton 1998). Assessing whether two populations might be vulnerable to a single large fire is in part a question of how frequently fires of such size arise. Moritz (1997) provides a way of estimating the relationship between fire size and return frequency from fire size data. We

acquired data on fire sizes within the Central Valley domain from the California Department of Forestry, and created a time series of the largest fire in each year for the period 1908–2003. We then found the maximum diameter of the polygon describing each fire. The probability of the largest fire in a year having a maximum diameter less than some specific size x , $P(X_{\max} \leq x)$, was estimated empirically following Moritz (1997).

Prolonged droughts have been implicated in the extinction of riverine fish species in the southwestern US (Douglas et al. 2003; Matthews and Marsh-Matthews, 2003), and a short drought had severe impacts on Sacramento River winter-run Chinook salmon broods in 1976 and 1977 (National Marine Fisheries Service, 1997). We estimated the correlation scale for drought by computing the correlation among the Palmer drought severity index scores among the grid points within CA presented by Cook et al. (2004) using a spline correlogram, which estimates a non-parametric covariance function (Bjornstad et al. 1999). Of particular interest is whether this characteristic scale is larger or smaller than the scale of ESUs—if it is larger, then drought risk can not be mitigated by maintaining widely-separated populations (although it would reduce the risk of simultaneous drought).

APPLICATION TO CENTRAL VALLEY SALMONIDS

Central Valley Spring-run Chinook Salmon

Perhaps 15 of the 18 or 19 historical populations of Central Valley spring-run Chinook salmon are extinct, with their entire historical spawning habitats behind various impassable dams (Figure 3 and Table 3). Butte Creek and Deer Creek spring-run Chinook salmon are at low risk of extinction, satisfying both the PVA (Figure 4) and other viability criteria (Table 3). Mill Creek is at moderate extinction risk according to the PVA, but appear to satisfy the other viability criteria for low-risk status. Lindley et al. (2004) were uncertain whether Mill and Deer creek populations were each independent or two parts of a single larger population. If viewed as a single population, Mill and Deer Creek spring-run Chinook salmon are at low extinction risk. Early-returning Chinook salmon persist within the

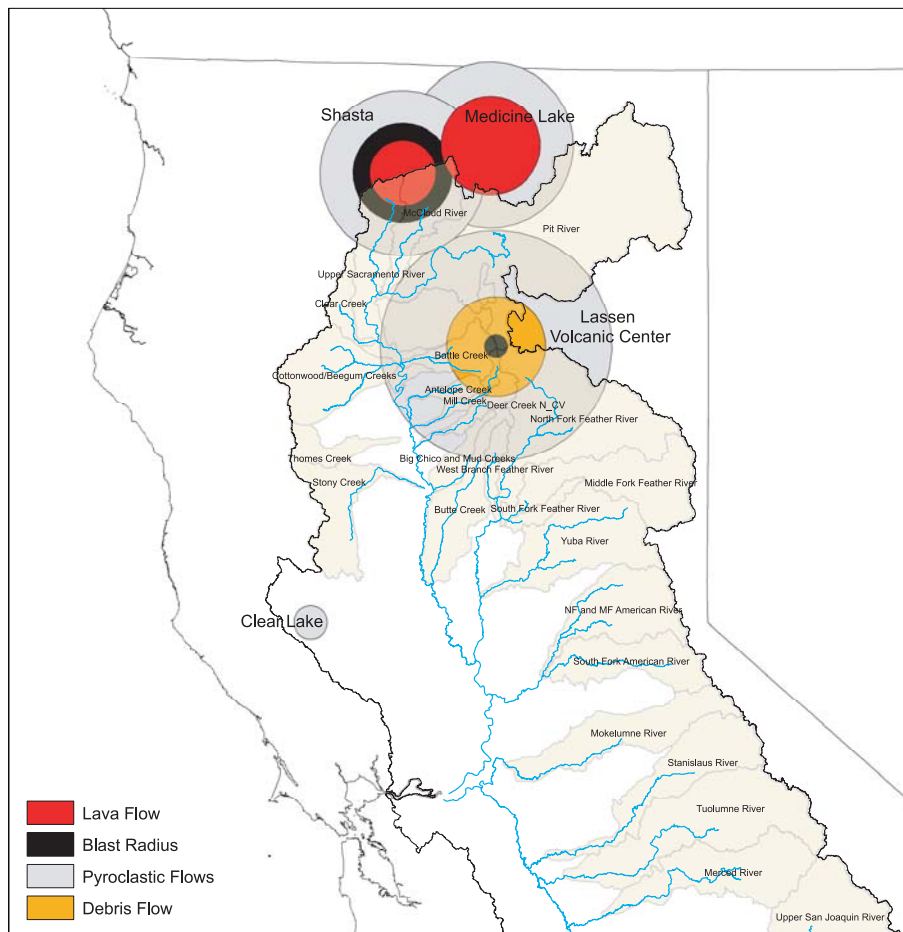

Figure 5. Volcanic hazards affecting the Central Valley recovery domain. Circles indicate the possible spatial extent of various kinds of volcanic effects that could devastate salmonid stream habitat, including lava flow, blast, pyroclastic flow, and debris. Data from Hobblitt et al. (1987)

tained them, Central Valley spring-run Chinook salmon fail the representation and redundancy rule for ESU viability. Historically, the Central Valley spring-run Chinook salmon ESU spanned four ecoregions: the region used by winter-run Chinook salmon plus the northern and southern Sierra Nevada and the northwestern California region. There are two or three viable populations in the northern Sierra Nevada (Mill, Deer and Butte creeks), although these populations were once probably relatively small compared to populations such as the Feather River. A few ephemeral or dependent populations are found in the Northwestern California region (e.g., Beegum and perhaps Clear

creeks). Spring-run Chinook salmon have been entirely extirpated from both the basalt and porous lava region and the southern Sierra Nevada region.

The current distribution of viable populations makes the Central Valley spring-run Chinook salmon ESU vulnerable to catastrophic disturbance. All three extant independent populations are in basins whose headwaters lie within the debris and pyroclastic flow radii of Mt. Lassen (Figure 5), an active volcano that the USGS views as highly dangerous² (Hobblitt et al. 1987). The historical ESU was of such a large scale that neither Mt. Lassen, Mt. Shasta, or Medicine Lake could have extirpated even an entire diversity group, let alone the entire ESU. The current ESU structure is, not surprisingly, vulnerable to drought, which has a correlation scale of approximately 640 km (Figure 6), on order of the length of the historical ESU. Even wildfires, which are of much smaller scale than droughts or large volcanic eruptions, pose a significant threat to the ESU in its current configuration. A fire with a maximum diameter of 30 km, big enough to burn the headwaters of Mill,

Deer and Butte creeks simultaneously, has roughly a 10% chance of occurring somewhere in the Central Valley each year (Figure 7).

We note that the historical Central Valley spring-run Chinook salmon ESU was widespread enough to be invulnerable to all of these catastrophes, except perhaps prolonged drought. The correlation scale of drought is roughly 640 km, and the Central Valley spring-run Chinook salmon ESU is about 500 km from the Pit River to the Kings River. It is possible that Central Valley spring-run Chinook salmon were less vulnerable to drought than might be expected because they once occupied diverse types of watersheds, including those with very high influence from springs. In fact, annual mean stream flow in Southern Cascade streams is less well correlated with annual mean precipitation than in other regions (see Appendix A in Lindley et al. (2006)).

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

Figure 6. Spline correlogram fit to the gridded Palmer drought severity index data for California of Cook et al. (2004). Solid line indicates the estimated correlation function; dashed lines are the 95% confidence interval. Note that the correlation of drought indices declines with distance between locations, with no correlation evident at a distance 640 km.

Sacramento River Winter-run Chinook Salmon

All four historical populations of Sacramento River winter-run Chinook salmon are extinct in their historical spawning range (Table 3). The upper Sacramento, McCloud and Pit River populations had spawning and rearing habitat far upstream of impassable Keswick and Shasta dams, although these populations were apparently in poor condition even before the construction of Shasta dam in the 1940s (Moffett 1949). Winter-run Chinook salmon no longer inhabit Battle Creek as a self-sustaining population, probably because hydropower operations make conditions for eggs and fry unsuitable (National Marine Fisheries Service 1997). Also, until recently access to much of the basin was blocked by the Coleman National Fish Hatchery barrier weir.

The population of Sacramento River winter-run Chinook salmon that now spawns below Keswick

dam is at moderate extinction risk according to the PVA (Figure 4), and at low risk according to the other criteria. Since roughly the mid-1990s, this population has been growing, although its previous precipitous decline to a few hundred spawners per year would have qualified it as high risk at that time, and prior to that, the 1976-77 drought would have qualified as a high-risk catastrophe. At present, the population easily satisfies the low-risk criteria for population size, population decline, and catastrophe, but hatchery influence is a looming concern. Since 2001, hatchery-origin winter-run Chinook salmon from Livingston Stone National Fish Hatchery (LSNFH, perhaps one of the best examples of a “best-management practices” Chinook salmon hatchery) have made up more than 5% of the natural spawning run, and in 2005 it exceeded >18% (K. Niemela, USFWS, Red Bluff CA, unpublished data). If the contribution of LSNFH to natural spawning exceeds 15% in 2006-07, the winter-run Chinook salmon population would be reclassified as moderate risk, and even the lower observed rates will become problematic if they continue for the next decade.

Figure 7. The probability that the largest fire in a year (X_{max}) will be smaller than the critical size x . Based on observed fire sizes for the Central Valley recovery domain during the 1908–2003 period.

The Sacramento River winter-run Chinook salmon ESU does not currently satisfy the representation and redundancy rule because it has only one population, and that population spawns outside of the ecoregion where it evolved. For the Sacramento River winter-run Chinook salmon ESU to satisfy the representation and redundancy rule, at least two populations would need to be re-established in the basalt-and-porous-lava region. This may require passage past Shasta and Keswick dams.

Obviously, an ESU represented by a single population at moderate risk of extinction is at high risk of extinction over the long run. A single catastrophe could extirpate the entire Sacramento River winter-run Chinook salmon ESU, if its effects persisted for four or more years. The entire stretch of the Sacramento River used by winter-run Chinook salmon is within the zone of influence of Mt. Lassen. Some other possible catastrophes include a prolonged drought that depletes the cold water storage of Lake Shasta or some related failure to manage cold water storage, a spill of toxic materials with effects that persist for four years, or a disease outbreak.

Central Valley Steelhead

There are almost no data with which to assess the status of any of the 81 Central Valley steelhead populations described by Lindley et al. (2006). With few exceptions, therefore, Central Valley steelhead populations are classified as data deficient. The exceptions are restricted to streams with long-running hatchery programs: Battle Creek and the Feather, American and Mokelumne rivers. In all cases, hatchery-origin fish likely comprise the majority of the natural spawning run, placing the natural populations at high risk of extinction. In the American River, the natural spawning run appears to be comprised mostly of hatchery-origin spawners (McCracken et al. 2005). The broodstock used by Feather River Hatchery is derived from native fish from the Feather River, but hatchery-origin fish probably play a large role in maintaining the Feather River population (Kindopp et al. 2003). The Coleman National Fish Hatchery steelhead program uses many “best management practices,” but hatchery fish make up substantially more than 15% of the natural spawners in Battle Creek (Campton et al. 2004).

There is no evidence to suggest that the Central Valley steelhead ESU is at low risk of extinction, or that there are viable populations of steelhead anywhere in the ESU. Conversely, there is evidence to suggest that the Central Valley steelhead ESU is at moderate or high risk of extinction (McEwan 2001; Good et al. 2005). Clearly, most of the historical habitat once available to steelhead has been lost (Yoshiyama et al. 1996; McEwan 2001; Lindley et al. 2006). Furthermore, the observation that anadromous *O. mykiss* are becoming rare in areas where they were probably once abundant (California Department of Fish and Game, unpublished data; McEwan (2001)) indicates that an important component of life history diversity is being suppressed or lost. It should be noted, however, that habitat fragmentation, degradation, and loss are likely having a strong negative impact on many resident as well as anadromous *O. mykiss* populations (Hopelain 2003).

Discussion

Population Viability

In this section, we applied viability criteria, and PVA where possible, to assess the status of Sacramento River winter-run Chinook salmon, Central Valley spring-run Chinook salmon, and Central Valley steelhead populations identified by Lindley et al. (2004) and Lindley et al. (2006). For Central Valley steelhead, we were only able to assess the status of populations with a strong hatchery influence, even though the criteria-based approach that we employed has low data requirements compared to some PVA approaches. For extant, independent Chinook salmon populations, we were able to apply a PVA model as well as the simpler criteria (because relatively long time series of spawning run size are available for these populations). In two cases, the PVA gave the same result (Butte Creek and Deer Creek both classified as low risk), and in the other two cases, risk assignments differed by one category (winter-run Chinook salmon and Mill Creek spring-run Chinook salmon classified by the PVA as moderate risk, while the criteria indicate low risk). That populations can satisfy the criteria for low risk while just failing a PVA suggests that the criteria for low risk really are criteria for minimal viability. Recovery planners may want to aim somewhat higher for at least some populations as a precautionary measure.

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

There have been three population-level risk assessments for winter-run Chinook salmon, by Botsford and Brittnacher (1998), Lindley and Mohr (2003), and Good et al. (2005). The analysis of Botsford and Brittnacher (1998) was conducted at a time when it was much less clear that winter-run Chinook salmon were on an upward trend, and not surprisingly, Botsford and Brittnacher (1998) found that winter-run Chinook salmon were certain to go extinct if the trends seen up to the time of their analysis were to continue. Lindley and Mohr (2003) used a model that allowed for a change in population growth rate following initiation of conservation measures in 1989 and density-dependent reproduction. Allowing for the possibility that winter-run Chinook salmon population growth rate increased after 1989 led to a much more optimistic prediction for extinction risk of 24% in 100 years. The analysis in Good et al. (2005), like Lindley and Mohr (2003), allowed for a change in population growth in 1989, but included more recent data and ignored density dependence. Good et al. (2005) found that if the 1989-present growth rate holds into the future, the winter-run Chinook salmon population has essentially no risk of extinction. The varying conclusions of these studies illustrates the sensitivity of PVA results to both data and model assumptions, especially those about future conditions and the effect of density on population growth rate.

ESU Viability

Our assessment of the viability of Central Valley Chinook salmon ESUs is broadly consistent with other recent assessments. Good et al. (2005), based on the combined opinion of an expert panel, considered the Sacramento River winter-run Chinook salmon ESU to be in danger of extinction, and the Central Valley spring-run Chinook salmon ESU to be likely to become endangered in the foreseeable future. These findings were essentially unchanged from the earlier review of Myers et al. (1998). United States Fish and Wildlife Service (1994) suggested that Central Valley spring-run Chinook salmon could be considered “restored” when Mill and Deer creeks both have >500 spawners, and the average total number of spawners in Sacramento tributaries exceeds 8,000, with a minimum of 5,000 spawners, over a 15 year period that includes at least three critically dry years.

Central Valley spring-run Chinook salmon have achieved these abundance levels since about 1998, but are not yet “restored” as defined by United States Fish and Wildlife Service (1994). The restoration goals of United States Fish and Wildlife Service (1994) are based on estimates of what could be attained in Sacramento River tributaries that are still accessible to spring-run Chinook salmon, and do not address issues of viability.

National Marine Fisheries Service (1997) proposed that for Sacramento River winter-run Chinook salmon to be recovered, there would need to be on average 10,000 females spawning naturally in the mainstem Sacramento River, and recommended creation of a second winter-run Chinook salmon population in Battle Creek. Should Sacramento River winter-run Chinook salmon achieve these draft goals, their status would be much improved, but they would still be excluded from much of the apparently unique areas in the upper Sacramento, McCloud, and Pit River tributaries that gave rise to their unique life-history strategy.

Good et al. (2005) found Central Valley steelhead to be in danger of extinction in the foreseeable future, in agreement with an earlier assessment (Busby et al. 1996). We were unable to assess the status of the Central Valley steelhead ESU with the more quantitative approach developed in this paper, because of data limitations. This should not be viewed as a contradictory finding—what little information is available for Central Valley steelhead is not positive (Busby et al. 1996; McEwan, 2001; Good et al. 2005).

Even if there were adequate data on the distribution and abundance of steelhead in the Central Valley, our approaches for assessing population and ESU viability might be problematical because the effect of resident *O. mykiss* on the viability of populations and ESUs is unknown. From one perspective, resident fish may reduce the extinction risk of the ESU through the production of anadromous individuals that can bolster or rescue weak steelhead populations. Such life history diversity also confers risk spreading, in that members of the ESU are spread among habitats that are subject to independent sources of disturbance. For instance, fish in the ocean are unaffected by flooding, while fish in rivers

are immune to poor feeding conditions in the ocean. At the margins of a species' range, where conditions may be more frequently unfavorable, such life history diversity could be an adaptation to the unpredictable environment (Jonsson and Jonsson 1993.)

On the other hand, the apparent dominance of the resident form is a recent and unnatural phenomenon. It is likely that the apparent shift towards the resident life history strategy is partly a response to hypolimnetic releases from reservoirs, which alter trophic, temperature and flow conditions for some distance below the dam (McEwan, 2001). *O. mykiss* may take up residency in these altered areas due to their phenotypic plasticity, or the fitness of *O. mykiss* using these areas may exceed the fitness of anadromous fish, which would drive an evolutionary (i.e., genetic) change if life history strategy is heritable. Another component of the shift is likely the decline of steelhead due to loss of suitable steelhead habitat. Even if the shift in life history strategy is a plastic response, the fitness of steelhead may decline due to relaxed selection pressure. At longer time scales, this is likely to be a problem, because storage reservoirs have finite lifetimes, and when they are filled with sediments, the rivers downstream will be much less suitable for year-round residency.

Both the United States Fish and Wildlife Service (1994) goals for Central Valley spring-run Chinook salmon and the National Marine Fisheries Service (1997) goals for Sacramento River winter-run Chinook salmon are primarily focused on abundance and productivity, a traditional fisheries and natural resource perspective. In light of the mounting failures of that traditional perspective, ecologists are increasingly recognizing the importance of diversity in sustaining ecological processes (e.g., Daily 1999; Pauly et al. 2002; Elmqvist et al. 2003; Fischer et al. 2006). Recent thinking on salmonids (e.g., McElhany et al. 2000; Hilborn et al. 2003; Bottom et al. 2005) highlights the importance of habitat, life history, and genetic diversity as the foundation for productivity (and hence abundance). Our approach to assessing and specifying ESU viability broaden the focus from abundance and trends to include the numbers, diversity, and spatial distribution of populations across the landscape. Restoring and sustaining diverse popula-

tions of salmonids will require restoring and sustaining the habitats and ecological processes upon which they depend.

Summary

In this paper, we have developed a framework for evaluating the viability of salmonid populations and ESUs, based on simple criteria and rules that have modest data requirements. When applied to Chinook salmon ESUs, the framework makes clear that the risk facing these ESUs is not so much the low viability of extant populations, but rather that much of the diversity historically present in these ESUs has been lost. While the criteria and rules that comprise our framework are based in no small part on expert judgment and are subject to considerable uncertainty, our conclusions are not particularly sensitive to the exact values of the criteria.

The utility of our framework can be judged in several ways. It provides quantitative criteria that allow that status of salmonid ESUs to be assessed in an objective way, and it points out areas where things need to improve for ESUs to be removed from the endangered species list. The framework is, however, rather simplistic, and significant improvements, especially at the ESU level, could be made as our understanding of salmonid population biology improves. Perhaps the most significant shortcoming of our framework is the implicit assumption that future will be like the past. In the next section, we evaluate this critical assumption.

CLIMATE VARIABILITY AND CHANGE

Introduction

Viability assessments, including ours, typically attempt to answer the question of whether the population will persist into the future if it continues to experience conditions like it has in the recent past. Future conditions, however, are not likely to be like the recent past. In this section, we briefly review descriptions of natural climate variability, and regional-scale predictions of how climate might change over the next century in response to rising atmospheric greenhouse gas concentrations. Natural climate variation will make it difficult to properly assess whether ESUs are recovering in

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

response to management actions. Anthropogenic climate change may preclude some otherwise attractive recovery strategies, depending on future greenhouse gas emissions and the response of regional climate.

Natural Climate Variability

Fisheries scientists have shown that ocean climate varies strongly at decadal scales (e.g., Beamish 1993; Beamish and Bouillon 1993; Graham, 1994; Miller et al. 1994; Hare and Francis 1995; Mantua et al. 1997; Mueter et al. 2002). In particular, the identification of the Pacific Decadal Oscillation (Mantua et al. 1997) seems to have led to the belief that decadal-scale variation may be cyclical, and thus predictable. As pointed out by Rudnick and Davis (2003) and Hsieh et al. (2005), apparent regime shifts need not be cyclical or predictable, but rather may be the expression of a stochastic process with red noise. If this interpretation is correct, then we should expect future ocean climate conditions to be different than those we have observed in the past few decades.

Terrestrial climate, like ocean climate, appears more variable the longer that it is observed. For example, Ingram et al. (1996) showed that freshwater inputs to San Francisco Bay varied with a period of 200 years, and several extreme and prolonged wet and dry periods occurred over the last 2,000 years. A 7,000-year river-flow reconstruction by Goman and Wells (2000) for the same area shows even longer-lasting periods of extreme conditions. Analysis of tree-ring data show that prolonged and intense droughts were more common during the period 750-1100 before present than in more recent centuries (Cook et al. 2004).

Natural climate variability poses several potential challenges for recovery planners. First, the population viability criteria that we have proposed may not offer sufficient protection in the case of a prolonged period of unfavorable climatic conditions. Second, a prolonged period of unusually favorable climatic conditions could cause populations to grow enough that they satisfy our biological viability criteria even though serious problems with habitat quality remain. In other words, the ESU may temporarily appear to be recovered, but its status would decline as soon as conditions become more typical. Conversely, the effects of

substantial improvements to habitat quality could be masked by poor climatic conditions, possibly eroding society's enthusiasm for doing the hard work of salmon recovery. The key to overcoming these challenges is to consider climate variation in future assessments, hopefully with the benefit of improved understanding of the links between specific populations and regional climate conditions. Research is needed in this area.

Presumably, Central Valley salmonid ESUs are capable of surviving the kinds of climate extremes observed over the past few thousand years if they have functional habitats, because these lineages are on order of a thousand years old or older³. There is rising concern, however, that the future climate will be unlike that seen since perhaps the Pliocene, due to global warming in response to anthropogenic greenhouse gas emissions.

Climate Warming

The consensus of climate scientists is that the Earth's climate is warming, and that the warming is caused in part by the accumulation of greenhouse gases in the atmosphere (McCarthy et al. 2001; Oreskes, 2004). While there is a scientific consensus about global climate change, the effects of global warming at regional scales are generally less certain. Here, we briefly review available regional-scale forecasts relevant to the Central Valley domain, and then speculate on possible impacts on Central Valley salmonids.

Climate forecasts for the Central Valley

Making regional-scale climate forecasts involves choosing an "emissions pathway" and running one of a number of global climate models with an embedded regional-scale model that can capture features, such as mountain ranges, that can significantly modify the global pattern. As in any modeling exercise, there are a number of sources of uncertainty, but particularly important ones in this case are the assumption about future emissions and the choice of climate model. The uncertainties are addressed by examining a number of emissions pathways and by using several models.

The recent paper by Hayhoe et al. (2004) examines multiple emissions pathways using two global models to make regional forecasts for California. Their results

are alarming. The more sensitive Hadley Center Climate Model (HadCM3) predicts that under the high emissions scenario (where CO₂ rises to 970 ppm by 2100, also known as the “business as usual” scenario), average summer temperature would rise 8.3°C and snowpack would be reduced by 89%. The HadCM3 also predicts that the climate will get drier, with possibly a 43% reduction of inflows to southern Sierra reservoirs. At the other extreme, the low-sensitivity Parallel Climate Model (PCM) predicts that average summer temperature would rise slightly more than 2°C if emissions were curtailed such that CO₂ rises to 550 ppm by 2100. The PCM predicts that total precipitation could rise slightly, but snowpack would still be reduced by 28% in this scenario.

Dettinger (2005) analyzed six different climate models under three emissions scenarios to produce distributions of future temperature and precipitation. This analysis showed that uncertainty due to the models was about equal to that due to emission scenario. There was general agreement among the models that temperatures will rise significantly (between 2 and 7 °C by 2100), while total precipitation is expected to decline slightly. Temperature and precipitation predictions were negatively correlated (i.e., warming is associated with drying).

Dettinger et al. (2004) and VanRheenen et al. (2004) used the PCM to investigate in detail how climate change may influence the hydrology of Central Valley rivers. These analyses find that average precipitation will decline over time, while the variation in precipitation is expected to increase substantially. Extreme discharge events are predicted to become more common, as are critically dry water years. Peak monthly mean flows will generally occur earlier in the season due to a decline in the proportion of precipitation falling as snow, and earlier melting of the (reduced) snowpack. By the end of the century, it may be difficult to achieve current operations targets for fish conservation even with substantial decreases in other demands for water. Knowles and Cayan (2002) show that in summer, saline water will intrude farther into the Bay and Delta than it does now. Within some limits, water storage reservoirs might be operated to mitigate changes to the hydrograph

caused by climate change, although water project operations are likely to become even more contentious as temperature rises, snowmelt falls, and population rises.

Possible Effects on Salmon and Steelhead

Regional-scale climate models for California are in broad agreement that temperatures in the future will warm significantly, total precipitation may decline, and snowfall will decline significantly. What are the likely consequences for salmon and steelhead in the Central Valley? Melack et al. (1997) states that predicting the response of salmon to climate warming “requires examination of the responses of all life history stages to the cumulative effects of likely environmental changes in the lakes, rivers and oceans inhabited by the fish.” Such an endeavor is beyond the scope of this paper, and the question of climate change effects on Pacific salmonids has received surprisingly little attention to date. In this subsection, we briefly review the literature and conduct a simple assessment of the effects of warmer summer temperature on the availability of freshwater habitat.

Focusing on freshwater life history phases, Neitzel (1991) reviewed the likely responses of salmonids in the Columbia River basin to climate warming, which he anticipated would affect salmonids through alterations to the timing of discharge and changes in sedimentation rate, temperature, and flow. Effects are predicted to depend on the river and on the species or run. As in the case of many salmonid populations in the Columbia River basin, spring-run Chinook salmon are likely to be negatively impacted by the shift in peak discharge (needed for smolt migration), and juvenile steelhead are likely to be negatively impacted by reduced summer flows. All Central Valley salmonids are likely to be negatively affected by warmer temperatures, especially those that are in freshwater during the summer.

Recent summer mortality of adult spring-run Chinook salmon in Butte Creek offers a case in point. Mean July water temperature in the middle of the spawning reach of Butte Creek is often around 18–20°C in July. In 2002 and 2003, mean water temperature in Butte Creek exceeded 21°C for 10 or more days in July, and 20–30% of adults in 2002 and 65% of adults in 2003 died (reviewed by Williams 2006), primarily from columnaris.

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

Figure 8. Effects of climate warming on availability of over-summer habitat. Mean August air temperatures exceeding 25°C are shown in gray; blue lines indicate the historical distribution of spring-run Chinook salmon.

Less obvious effects, such as reduced viability of gametes, may also have occurred. These data suggest that existing conditions in Butte Creek are close to the thermal tolerance limit for Chinook salmon.

Myrick and Cech (2004) state that juvenile Chinook salmon are unlikely to be capable of rearing for extended periods in temperatures exceeding 24°C, and juvenile steelhead may be able to withstand slightly higher temperatures. Maximum in-stream temperatures of many streams frequently exceed 24°C at lower elevations, which may determine the lower distributional limit of salmonids (Yoshiyama et al. 1996; Lindley et al. 2006).

Distributions at higher elevations were once largely restricted by natural barriers to movement, but are now limited by dams in many streams (Lindley et al. 2006). If these artificial migration barriers are not removed, climate warming is expected to reduce the amount of habitat available to Central Valley salmonids that reside in freshwater during summer months, as the lower distributional limit rises, and the upper limit remains constrained by physical barriers.

A rough view of the consequences for Central Valley spring-run Chinook salmon and Central Valley steelhead can be obtained by adding the regional warming forecasts of Dettinger (2005) to PRISM temperature fields, and overlaying this with the distributional data presented in Lindley et al. (2004). Figure 8 shows how the area with high summer temperatures (mean August air temperature > 25°C) may expand under three warming scenarios. Under current conditions, streams that had major independent populations of spring-run Chinook salmon all have significant amounts of habitat above the 25°C isotherm, although dependent populations generally had little or no habitat above the 25°C isotherm (Figure 8, upper left). By 2100, mean summer air temperatures are expected to rise by at least 2°C. Under this scenario, the amount of habitat above the 25°C isotherm is reduced, but in general, most streams that historically contained habitat above this isotherm would not lose all such habitat. The exceptions are the Tuolumne, Merced, and upper San Joaquin rivers, and Butte Creek, where the 25°C isotherm might just rise to the upper limit of the historical distribution of spring-run Chinook salmon (Figure 8, upper right). Under the expected warming of around 5°C, substantial habitat would be lost, with significant amounts of habitat remaining primarily in the Feather and Yuba rivers, and remnants of habitat in the upper Sacramento, McCloud, and Pit rivers, Battle and Mill creeks, and the Stanislaus River (Figure 8, lower left). Under the less likely but still possible scenario of an 8°C warming, spring-run Chinook salmon habitat would be found only in the upper-most reaches of the north fork Feather River, Battle Creek, and Mill Creek. This simple analysis suggests that Central

Valley salmonids are vulnerable to warming, but more research is needed to evaluate the details of how warming would influence individual populations and subbasins.

The hydrologic effects of climate change are harder to evaluate. Increased frequency of scouring floods might be expected to reduce the productivity of populations, as egg scour becomes a more common occurrence. The timing of various life history events is presumably an adaptation to past climate conditions (temperature and discharge timing), and populations may not be well-adapted to future hydrographs. One concern is that warmer summers will delay spawning, and earlier and more frequent floods will impact eggs and alevins before they emerge from the gravel, a phenomenon thought to limit the productivity of some Chinook salmon stocks (Beer and Anderson 2001), and one that might be impossible for salmonids to adapt to, given fundamental constraints on development.

The flip side of frequent flooding is the possibility of more frequent and severe droughts. Long-term climate records show that warm periods have been associated with droughts in California (Davis 1999; Cook et al. 2004), and the regional climate change models reviewed above hint at the possibility of increasing frequency of droughts. In the Central Valley, low flows during juvenile rearing and outmigration are associated with poor survival (Kjelson and Brandes 1989; Baker and Morhardt 2001; Newman and Rice 2002) and poor returns in subsequent years (Speed 1993).

Climate change may also impact Central Valley salmonids through community effects. For example, warming may increase the activity and metabolic demand of predators, reducing the survival of juvenile salmonids (Vigg and Burley, 1991). Peterson and Kitchell (2001) showed that on the Columbia River, pikeminnow predation on juvenile salmon during the warmest year was 96% higher than during the coldest.

To summarize, climate change may pose new threats to Central Valley salmonids by reducing the quantity and quality of freshwater habitat. Under the worst-case scenario, spring-run Chinook salmon may be driven extinct by warming in this century, while the best-case scenario may allow them to persist in some streams. Uncertainties abound at all levels, however.

First, the composition of Earth's atmosphere is partly under human control, and we cannot predict how it might be managed in the future. Even if the emissions pathway was known, different climate models offer significantly different climate forecasts (although we note that the differences are quantitative, and the models are in qualitative agreement). Finally, we have only the crudest understanding of how salmonid habitats will change and how salmonid populations will respond to those changes, given a certain climate scenario. This is another area where research is needed.

SUMMARY AND RECOMMENDATIONS

For Central Valley steelhead, there are insufficient data to assess the risk of any but a few populations, and therefore, we cannot assess the viability of this ESU using the quantitative approach described in this paper. However, qualitative information does suggest that the Central Valley steelhead ESU is at a moderate or high risk of extinction. Most of the historical habitat once available to steelhead is largely inaccessible and the observation that the anadromous forms of *O. mykiss* are becoming less abundant or rare in areas where they were probably once abundant indicates that an important component of life history diversity is being suppressed or lost. Even in populations that exhibit life-history polymorphism, steelhead are important to viability and long-term persistence and are critical to the conservation of the population (Travis et al. 2004; Bilby et al. 2005).

For the Chinook salmon ESUs, we found that extant populations are now at low or moderate risk of extinction, but the extensive extirpation of historical populations has placed these ESUs in jeopardy of extinction. The proximate problem afflicting these ESUs and the Central Valley steelhead ESU is that their historical spawning and rearing areas are largely inaccessible, due to the direct or indirect effects of dams.

Recovering even a few populations may therefore be a challenging and slow process, although we stress that there appear to be some opportunities that, if successful, would greatly increase the viability of all three ESUs. Some possibilities that are being considered include restoring flows and habitat in the San Joaquin River below Friant Dam and in Battle Creek, and

SAN FRANCISCO ESTUARY & WATERSHED SCIENCE

restoring access to the Yuba River above Englebright Dam. All of these actions, in our view, have the potential to significantly improve the status of affected ESUs, but achieving recovery may require access to additional historically-utilized spawning areas that are currently blocked by dams.

As we pursue the more ambitious and long-term habitat restoration solutions, there are some easier but very important things that should be done as soon as possible. These include the following, in no particular order:

1. Secure all extant populations. All three ESUs are far short of being viable, and extant populations, even if not presently viable, may be needed for recovery. An important lesson to draw from Hilborn et al. (2003) is that tomorrow's most important populations might come from populations that are relatively unimpressive today. We recommend that every extant population be viewed as necessary for the recovery of the ESU. Wherever possible, the status of extant populations should be improved.
2. Begin collecting distribution and abundance data for *O. mykiss* in habitats accessible to anadromous fish. This is fundamental to designing effective recovery actions and eventual delisting. Of equal importance is assessing the relationship of resident and anadromous forms of *O. mykiss*. Any quantitative assessment of population or ESU viability could be inadequate unless we know the role resident fish play in population maintenance and persistence. It has been well-documented that Chinook salmon has been the major focus of anadromous fish monitoring, assessment, and research in the Central Valley (McEwan 2001) and there needs to be a more equitable partitioning of research funds and effort.
3. Minimize straying from hatcheries to natural spawning areas. Even low levels of straying from hatchery populations to wild ones works against the goal of maximizing diversity within ESUs and populations. Current mark and recovery regimes do not generally allow reliable estimation of contributions of hatchery fish to natural spawning, so we recommend that all hatchery fish be marked in some way. A number of actions could reduce straying from

hatcheries to natural areas, including replacing off-site releases with volitional releases from the hatchery, allowing all fish that attempt to return to the hatchery to do so, and reducing the amount of fish released (see CDFG and NMFS 2001, for a review of hatchery issues).

4. Begin conducting critical research on fish passage, reintroductions, and climate change⁴. To recover Central Valley salmon and steelhead ESUs, some populations will need to be established in areas now blocked by dams or insufficient flows. Assuming that most of these dams will remain in place for the foreseeable future, it will be necessary to move fish around the dams. We are unaware of such projects involving dams of the scale typical in the Central Valley. Assuming that a feasible solution to that problem is found, it is necessary to reintroduce fish to the newly available habitat. Should this be allowed to occur naturally, or should a more active approach be taken? If so, which fish should be used as the donors? Finally, in a warmer future, some basins might cease to be suitable for salmon or steelhead. It would be a costly mistake to invest heavily in restoring habitat that will become too warm to support salmonids.
5. Accept the notion that listed salmonid ESUs are likely to be conservation-reliant (Scott et al. 2005). It seems highly unlikely that enough habitat can be restored in the foreseeable future such that Central Valley salmonid ESUs could be expected to persist without continued conservation management. Rather, it may be possible to restore enough habitat such that ESUs can persist with appropriate management, which should focus on maintaining ecological processes at the landscape level. NOAA regulators should begin considering how to implement conservation agreements among agencies and stakeholders that will be acceptable to all parties and ensure the persistence of populations and ESUs.

ENDNOTES

¹We also examined the potential of toxic spills, earthquakes, and landslides to extirpate ESUs, but concluded that these risk sources were generally not a threat to ESUs with more than one population.

²We note that any particular debris flow would cover only a portion of the circle depicted in [Figure 5](#), and that a single flow might not necessarily devastate all three spring-run Chinook salmon streams.

³Using data in Lindley et al. (2004) and relationships in Waples et al. (2004), the F_{st} observed between Sacramento River winter-run Chinook salmon and fall-run Chinook salmon (based on neutral markers) could have arisen in around 780 years if these ESUs were completely isolated from one another.

⁴The CVTRT is preparing a comprehensive list of research recommendations.

Summary

1. The addition of large water storage dams to rivers in California's Central Valley blocked access to spawning habitat and has resulted in a dramatic decline in the distribution and abundance of spring-run chinook salmon *Oncorhynchus tshawytscha* (Walbaum 1792). Successful recovery efforts depend on an understanding of the historical spatial structure of these populations, which heretofore has been lacking.

2. Graph theory was used to examine the spatial structure and demographic connectivity of riverine populations of spring-run chinook salmon. Standard graph theoretic measures, including degree, edge weight and node strength, were used to uncover the role of individual populations in this network, i.e. which populations were sources and which were pseudo-sinks.

3. Larger spatially proximate populations, most notably the Pit River, served as sources in the historic graph. These source populations in the graph were marked by an increased number of stronger outbound connections (edges), and on average had few inbound connections. Of the edges in the current graph, seven of them were outbound from a population supported by a hatchery in the Feather River, which suggests a strong influence of the hatchery on the structure of the current extant populations.

4. We tested how the addition of water storage dams fragmented the graph over time by examining changing patterns in connectivity and demographic isolation of individual populations. Dams constructed in larger spatially proximate populations had a strong impact on the independence of remaining populations. Specifically, the addition of dams resulted in lost connections, weaker remaining connections and an increase in demographic isolation.

5. A simulation exercise that removed populations from the graph under different removal scenarios – random removal, removal by decreasing habitat size and removal by decreasing node strength – revealed a potential approach for restoration of these depleted populations.

6. *Synthesis and applications.* Spatial graphs are drawing the attention of ecologists and managers. Here we have used a directed graph to uncover the historical spatial structure of a threatened species, estimate the connectivity of the current populations, examine how the historical network of populations was fragmented over time and provide a plausible mechanism for ecologically successful restoration. The methods employed here can be applied broadly across taxa and systems, and afford scientists and managers a better understanding of the structure and function of impaired ecosystems.

Key-words: California, chinook salmon, connectivity, dispersal, evolutionarily significant unit (ESU), graph theory, *Oncorhynchus tshawytscha*, population spatial structure, restoration

Journal of Applied Ecology (2007) **44**, 1116–1126

Introduction

Effective management of species requires knowledge of population structure, because this is key to understanding how local impacts may affect the larger entity at both ecological and evolutionary time scales (Kareiva & Wennergren 1995; Wennergren, Ruckelshaus & Kareiva 1995; Tilman & Lehman 1997). For example, a metapopulation may have quite different dynamics than a panmictic population of the same aggregate size, depending on factors such as the dispersal rates among populations and internal dynamics of the metapopulation components (Levins 1969; Kareiva 1990; Hanski & Gilpin 1991). Ignoring spatial structure, especially immigration from nearby populations, can impair the management of protected species, such as incorrectly diagnosing population status or the response to habitat restoration (Cooper & Mangel 1999). At longer time scales, the relationship between the structure and dynamics of populations and landscapes may determine the degree to which populations adapt to local conditions (Sultan & Spencer 2002) and how they respond to disturbance (Pickett & White 1985).

In many cases, species conservation problems can be framed in terms of problems with spatial structure, because impacts to species often take the form of lost habitat patches or dispersal corridors. Restoration is aided with a 'guiding image' (Palmer *et al.* 2005), and the virgin state of the system is often used as such. To be most effective, the guiding image should be in the form of a conceptual model that can show system function, system impairment and restoration strategies (Jansson *et al.* 2005). We propose that graph theory provides the tools needed to construct conceptual models for spatially explicit problems in conservation that allow quantitative comparisons of historical, contemporary and potentially restored population structures.

Graphs have been used across a variety of disciplines to study everything from the structure of the World Wide Web to subcellular protein networks. [See any of the following reviews, listed in approximate order of increasing specificity and mathematical complexity: Hayes (2000a, 2000b); Strogatz (2001); Watts (2004); Albert & Barabási (2002); and Newman (2003).] Graph theory is an appealing tool for analysis of population structure for several reasons. First, it allows us to characterize a complex system with a tractable, but explicitly spatial, mechanism (Urban & Keitt 2001; Brooks 2006; Gastner & Newman 2006). Secondly, using graphs we can assess the importance of individual elements in a graph both backwards in time as we examine how the graph, or network, breaks apart (Keitt, Urban & Milne 1997; Bunn, Urban & Keitt 2000; Urban & Keitt 2001) and forward in time to guide a conservation or restoration effort (Palmer *et al.* 2005). Thirdly, a graph is perhaps the simplest spatially explicit representation of a metapopulation (Urban & Keitt 2001; Brooks 2006). Lastly, there is a wealth of graph tools and algorithms that allow different graphs to be analysed and compared.

While graph theory carries with it its own terminology (Harary 1969), many of the terms have direct ecological interpretations. Nodes can represent a range of things, from individuals to populations to patches on a landscape. Edges are the connections between nodes. Construction of a landscape graph typically requires at least two data structures (Urban & Keitt 2001). The first structure includes information about the node's spatial location and some indicator of size. The second structure is a distance matrix between all of the nodes. The *degree* of a node is the number of edges incident to it. A regular graph is one where the edges are bi-directional, i.e. for nodes a, b the connection is $a \leftrightarrow b$ (Fig. 1a). In contrast, a digraph's edges (also called arcs) have direction, i.e. $a \rightarrow b$ (Fig. 1b). For a digraph, *degree* is slightly different: *outdegree* of a point v is the number of points adjacent from a node; and *indegree* is the number adjacent to a node. Logically, *outdegree* and *indegree* correspond to familiar source-sink dynamics with which most ecologists are familiar (Pulliam 1988). The connection between a pair of nodes in a given graph G is based on an adjacency matrix. The adjacency matrix is comprised simply of 0s and 1s, where 0 indicates no connection between a pair of nodes and 1 indicates that a connection, or edge, exists. [To help avoid confusion, we note that nodes can be adjacent (connected) in a graph theoretic sense even if they are not adjacent in a geographical sense.] Lastly, in most instances, populations and metapopulations can be represented realistically as weighted digraphs (Fig. 1c) with different population sizes and the asymmetric connections between them (Barrat *et al.* 2004; Bascompte, Jordano & Oleson 2006). These cartoon graphs serve as the conceptual basis for the connections in larger, more complicated, and in our case, spatially explicit graphs.

While the role of ecological connectivity in regulating and maintaining population distribution and population persistence has been documented in both the terrestrial (Fahrig & Merriam 1985; Taylor *et al.* 1993) and aquatic realms (Wiens 2002), the direction of the connectivity can have important impacts on a given system (Gustafson & Gardner 1996). Therefore, because regular graphs may not capture completely how connectivity influences population structure, we use weighted digraphs (Barrat *et al.* 2004; Bascompte *et al.* 2006) to examine how directed connectivity and asymmetrical dispersal elucidate population structure. Although directed connectivity has been mentioned previously (Gustafson & Gardner 1996; van Langevelde, van der Knaap & Claassen 1998; Urban & Keitt 2001; Schooley & Wiens 2003), its importance for fish populations has not been fully explored. Furthermore, the influence of the dendritic riverine structure on metapopulation persistence and population vulnerability for fish has only been noted relatively recently (Dunham & Rieman 1999; Gotelli & Taylor 1999; Fagan 2002) and no attempt has been made, to our knowledge, to use graphs to represent fish populations in a riverine

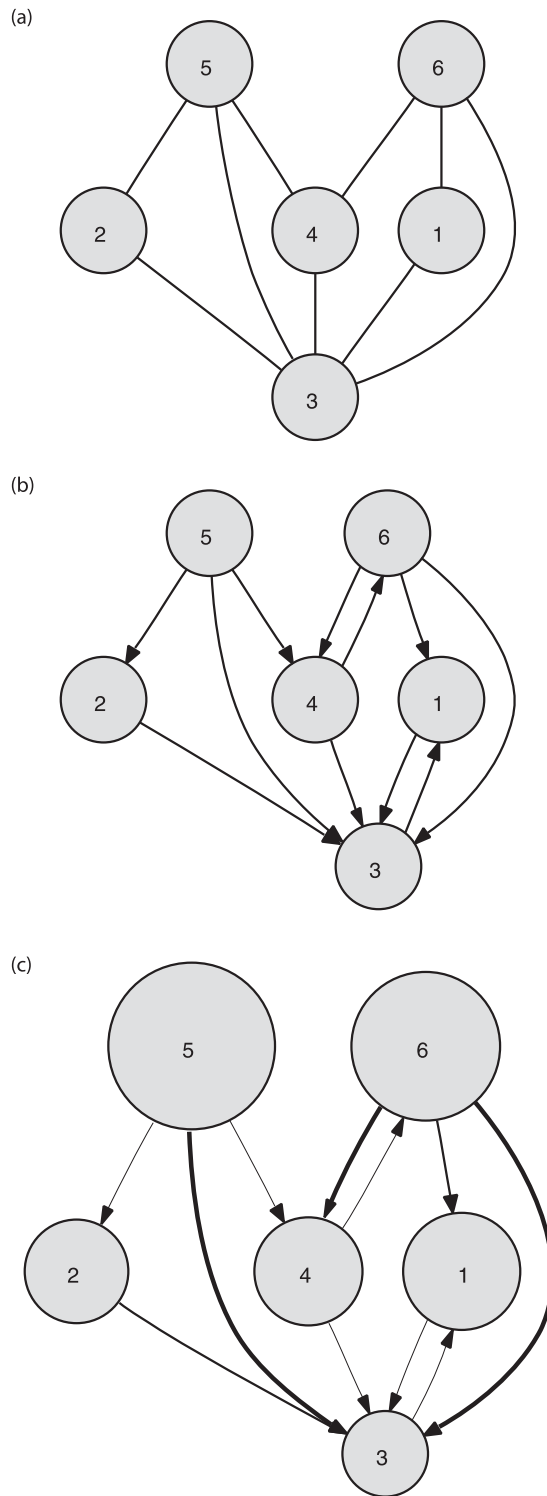

Fig. 1. Panels depict three different types of graphs: a regular unweighted graph (a), a directed unweighted graph or digraph (b), and a weighted digraph (c). Nodes in (a) and (b) are all equal size, while nodes in (c) have different size. Edges in (a) are regular and un-weighted. Edges in (b) are directed, while edges in (c) are both directed and weighted.

setting. The representation of river/stream fish populations as a graph is notably different from most terrestrial graphs, because the dispersal corridors (rivers and streams) are generally fixed and immutable at ecological time scales, i.e. the fish already live in a network.

Endangered salmonid populations are managed as evolutionarily significant units (ESU), which are defined as a salmon population or group of salmon populations that is substantially isolated reproductively from other populations and that contributes substantially to the evolutionary legacy of the species (Waples 1991, 1998). Typically, ESUs are structured internally (Gharrett, Gray & Brykov 2001; Olsen *et al.* 2003; Guthrie & Wilmot 2004) due to the fact that salmon mainly return to their natal rivers after spending several years at sea, but there is some low level of dispersal among the populations that is probably important for ESU persistence. As salmon return to their natal rivers they stray naturally at varying rates (Ricker 1972; Quinn 1993), which allows them to occupy new habitat (Milner & Bailey 1989; Wood 1995) and is the mechanism by which populations are connected. The rate at which salmon stray has proved difficult to quantify, although observed rates in the wild range from 0 to 67% (McElhany *et al.* 2000). Changing the spatial structure through population loss or increased straying must have effects on an ESU, but to date these have not been quantified.

We examine spring-run chinook salmon *Oncorhynchus tshawytscha* (Walbaum 1792) in California's Central Valley (Fig. 2), which are listed as threatened under the United States' Endangered Species Act. Spring-run chinook salmon are high-elevation mainstem spawners that migrate into the watersheds under high flow conditions in springtime (Yoshiyama *et al.* 2001; Lindley *et al.* 2004). They over-summer in cool temperature pools before migrating out of the pools in the fall to spawn (Lindley *et al.* 2004). After spawning the cool water temperatures delay maturation, and juveniles often remain in the system for a full year (Lindley *et al.* 2004). Spring-run chinook salmon occupied much of the Central Valley, although the installation and continued presence of major dams has blocked and restricted access to much of their historical habitat (Yoshiyama *et al.* 2001; Lindley *et al.* 2004) (Fig. 2). The first of 10 'keystone' dams in the Central Valley, i.e. the lowest-elevation dam that completely blocks upstream habitat, was installed in 1894. The addition of such keystone dams proceeded until 1968, removing a total of 19 populations from the ESU. Lindley *et al.* (2004) describe the putative historical structure of the ESU, which forms the basis for our analysis. We presume this was a viable ESU prior to 1894.

We build and test a dispersal model that accounts for directional connectivity between populations within the historic spring-run chinook salmon ESU, and use graph theoretic methods to test how connectivity influences the spatial structure of populations within the ESU. We focus on (a) the organisms' ability to disperse through fixed edges, (b) on the importance of individual fish populations (nodes) and (c) how the installation and continued presence of dams impacted the ESU. In addition, we examine the structure of the current spring-run chinook salmon ESU. Lastly, we use

Fig. 2. Basemap of the study region. Depicted are the two river basins in the Central Valley, California (Sacramento River and San Joaquin River) and the major rivers within those basins that historically contained spring-run chinook salmon. The mainstems of the rivers are drawn up to the historical uppermost extent of spring-run chinook salmon as determined by Yoshiyama *et al.* (2001). Inferred spawning habitat above 500 m is shown in thick black lines. Populations are labelled with the river name and with a numerical ID that will be used in subsequent figures. Keystone dams are depicted as light grey nodes and are labelled with the year they were installed. For clarity, the Sacramento River Delta is omitted from the map.

these results – notably changes in graph metrics and in the role of populations – to discuss the persistence and survival of this threatened species. The graph theoretic methods presented herein have broad application across a variety of ecological systems, and can be used in data limited environments to predict population structure, persistence and synchrony.

Materials and methods

To populate the first graph data structure, we initially identified populations in the spring-run chinook salmon ESU that historically contained spawning groups (Lindley *et al.* 2004). The nodes in our graph represent populations; to identify these populations spatially, we located the intersection of the 500 m elevation contour and the mainstem of each river

within the ESU. (Yoshiyama *et al.* 2001 identify 500 m as the approximate lower extent of the breeding range for spring-run chinook salmon.) This intersection is then the spatial representation of the node. To represent the size of the population (node) in the historical spring-run chinook salmon ESU, we used a habitat proxy: extent of the mainstem spawning range > 500 m elevation (Yoshiyama *et al.* 2001). For populations whose habitat was below 500 m, e.g. several small populations on the western side of the Central Valley, we used estimated ranges from Yoshiyama *et al.* (2001). Previous studies have shown that spawning habitat, as we have defined it here, correlates significantly with effective population size, N_e (Shrimpton & Heath 2003). To represent the size of the population (node) in the current spring-run chinook salmon ESU, we used the mean number of annual spawners since 1980 in lieu of the habitat proxy for the historical ESU (R. M. Kano, California Department of Fish and Game, Sacramento, CA., USA, unpublished data). [We note that these definitions of node size are different, and comparisons between the historic and current graph were made with an appropriate degree of caution. The correlation between habitat length and number of spawners was negative (−0.301); however, a plot of these revealed the relationship between the two was nonlinear and that this negative correlation was driven by an outlier (Butte Creek). Once Butte Creek was removed, the correlation between habitat length and number of spawners was positive (0.65).]

To create the second graph data structure, we used a network module of a commercially available geographical information system (GIS) package (ArcInfo® workstation version 9.0) to estimate ‘as the fish swims’ distance between all identified populations. By ‘as the fish swims’ we mean minimum straight-line distance along the river network, i.e. fish do not explore available tributaries. We used the ArcGIS Network module to estimate this distance between node locations along the river network of the Central Valley (1 : 100 k routed stream layer, version 2003-6, available from CalFish: <http://www.calfish.org/DesktopDefault.aspx?tabId=76>, last accessed 18 August 2006). This yielded a full (upper and lower triangles) distance matrix, which served as the second input to our model.

Any two nodes in the graph were deemed connected by an edge if the proportion of incoming fish from one population exceeds a certain threshold level of the total recruitment (local + incoming) in the target population. The edges in the graph were developed from a migration matrix, N . To construct N we needed the following data structures: (1) a full distance matrix D of all the interpopulation ‘as the fish swims’ distances; (2) a dispersal kernel; (3) a matrix M of dispersal probabilities; and (4) a matrix X of population size.

We assumed in this analysis that a fraction of fish returning to spawn will stray from their natal stream and that the probability p_{ij} of a fish from node i migrating to node j is a function of the distance between the

populations. While this inter-population distance may seem biologically counterintuitive, we repeated the same analysis using a model where salmon return to their natal watershed with some high fidelity, but make 'wrong' decisions with some small probability. Because the results were quite similar, we chose the more parsimonious model for interpopulation distance, because it rested on fewer unverifiable assumptions. (See supporting material for full characterization of this 'wrong-turn' model and results.)

To estimate p_{ij} , we fitted a dispersal kernel to the interpopulation distances. We used the kernel from Clark, Macklin & Wood (1998):

$$p_{ij} = \frac{c}{2\alpha\Gamma(1/c)} \exp\left(-\left|\frac{d_{ij}}{\alpha}\right|^c\right), \quad \text{eqn 1}$$

where α is a dispersion parameter, c a shape parameter, and d_{ij} , an interpopulation distance measured along the stream network (from a full distance matrix D , described above). α is an estimate of a species dispersal capability, while c controls the shape of the tail in the kernel. To parameterize α we used two different studies on chinook dispersal from McClure *et al.* (2003, unpublished data, available at: http://www.nwfsc.noaa.gov/trt/col_docs/independent-popchinsteelsock.pdf, last accessed 23 August 2006). The first was a within-basin movement study of wild spring-run chinook salmon, which indicated an $\alpha = 31.6$ km; the second was a cross-basin study of hatchery fish that indicated an $\alpha = 166$ km. While the first data source is on wild fish, and probably represents a better source, it was limited to one river basin and does not account for basin-to-basin straying. The second estimate of α does account for basin-to-basin straying; however, it is probably biased upwards because of the reduced homing ability of hatchery fish. Therefore we chose the average of the two, or $\alpha = 98$ km. The nature of the tail is controlled by c , whereby $c = 1$ and $c = 1/2$ correspond to a kernel with an exponential tail and a fat tail, respectively (Clark *et al.* 1998; Clark *et al.* 1999). We chose $c = 1$, where the shape of the kernel is exponential and dispersal probability is controlled by the value of α (personal communication, J. S. Clark, Duke University, Durham, NC 27708, USA).

Whether populations were deemed adjacent depended upon the magnitude of migration between them, the magnitude of total recruitment and a threshold for the ratio of the two. If the percentage of a population's total recruitment coming from immigrating fish from another donor population exceeded some value, these populations were deemed connected (Bjorkstedt *et al.* 2005). To find these connections we first created a dispersal probability matrix M comprised of a mixture model composed of two probabilities: (1) m , defined as straying probability and initialized at 5%; and (2) p_{ij} , as defined above. We then set the off-diagonal elements of M to mp_{ij} and the diagonal elements to $1 - m$. Because p_{ij} represented a discrete interpopulation movement, we

normalized the off-diagonal probabilities over all possible movements, i.e.

$$M_{i \neq j} = \frac{p_{ij}}{\sum_j p_{ij}}.$$

We then used the matrix of population sizes X (described in the previous section) in conjunction with M to define a migration matrix $N = XM$. The diagonal elements of N contained the number of fish resulting from self-recruitment, and the column sums of the off-diagonal elements contained the number of fish immigrating to the populations (*sensu* Bjorkstedt *et al.* 2005). The proportion of recruitment in population i that comes from population j was then calculated in order to examine pairwise directed dependence. If this ratio exceeded some threshold, then population i was dependent upon population j . The relationships among all populations were visualized as a directed graph. Independent populations in the graph were populations that are not dependent upon any others indicated either by populations with either no connections to other nodes, or only outbound connections. In our model, populations were adjacent (connected) if the donor population contributes more than 1% of total recruitment to the recipient. In addition, we preserved the strength of the connection to represent the weighted graph fully.

Lastly, we defined the population's independence (Bjorkstedt *et al.* 2005), or ζ , as:

$$\zeta_i = \frac{\delta_{ii}X_i}{\delta_{ii}X_i + \sum_{i \neq j} \delta_{ij}X_j}, \quad \text{eqn 2}$$

where X represents population size, and δ_{ij} is local recruitment. We assessed how the trajectory of population independence changed over time by recalculating ζ for the remaining populations after each dam addition.

We examined the source-sink structure (Pulliam 1988) of the ESU by evaluating the importance of individual populations to the historical graph at the ESU scale (Bunn *et al.* 2000; Urban & Keitt 2001). Specifically, we examined node sensitivity for *outdegree* and *indegree* of a given node. *Outdegree* and *indegree* correspond logically to a qualitative representation of source and sink structure (Pulliam 1988), while *node strength* provides a quantitative representation of this structure (Barrat *et al.* 2004; Bascompte *et al.* 2006). We calculated *outdegree* and *indegree* of a given node by summing the rows and columns of the adjacency matrix $A(D)$, respectively. To calculate *node strength*, we summed the row and column sums of the off diagonal elements of N . Note that we assumed all populations have at least some local recruitment and may be more accurately termed pseudo-sinks (Watkinson & Sutherland 1995).

We combined methods from Bunn *et al.* (2000) and Urban & Keitt (2001) with our digraphs to examine the

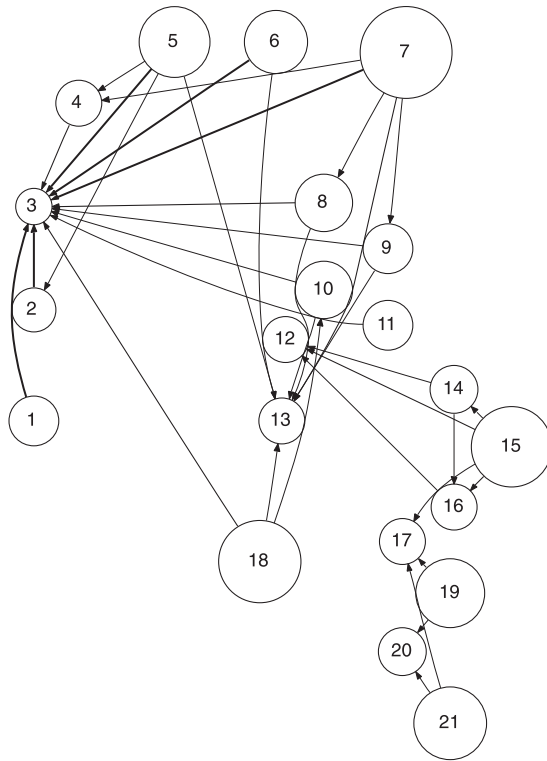

Fig. 3. Digraph for dispersal through the historical spring-run chinook salmon ESU. Because there were no connections into or out of any of the San Joaquin Basin populations (numbers 22–27), they are excluded from the figure. Populations are connected if donor population contributes more than 1% of local recruitment to the receiving population. Increased edge thickness corresponds to increased demographic dependence (1–4.9%, 5–9.9%, > 10%). The size of the nodes corresponds to the amount of habitat present in each watershed (log +1.5 transformed), and the location of the nodes in the figure is an approximation of their true location. Populations are numbered as in Fig. 2.

effect dam addition had on the structure of the ESU. In addition to observing the actual fragmentation of the ESU, we used our model of connectivity and a series of alternate node removal scenarios (random, removal by largest available habitat and removal by largest node strength) to observe what happened to the graph as populations in the ESU went extinct.

We tested the sensitivity of the model to our assumptions by perturbing each of five model parameters by 10% and tallying the percentage change in the total number of edges in the graph. These parameters included: (1) the α parameter in the dispersal kernel; (2) the percentage of fish straying; (3) that migration is proportional to the interpopulation distance; (4) that population size is proportional to historical spawning extent; and (5) that all fish arriving at a new population recruit into that population (i.e. fitness of natives vs. strays).

Results

The historical digraph G_1 based on the dispersal adjacency matrix outlined above exhibited unbalanced

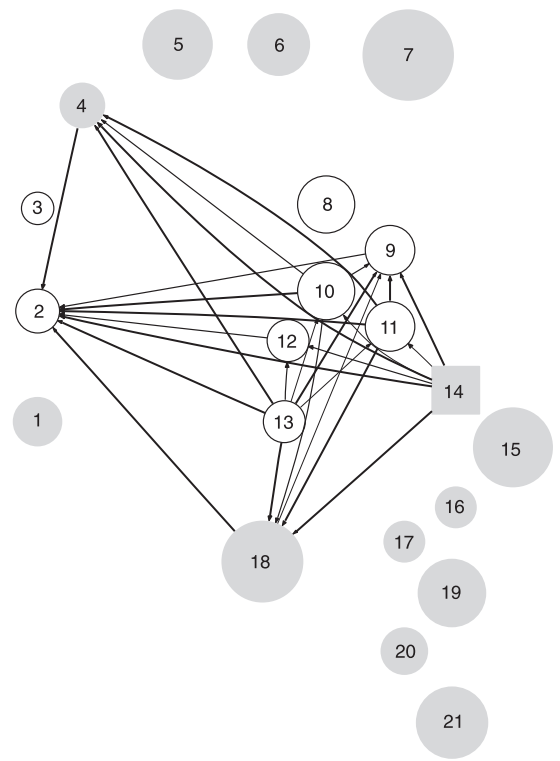

Fig. 4. Digraph for dispersal through the extant populations in the spring-run chinook salmon ESU. In addition the Feather River Hatchery is included in the graph, and is in the same place as the West Branch Feather River (14). Nodes for extinct populations are depicted in grey. Several populations whose historical habitat was blocked by hydropower dams now have some small populations spawning below dams, hence the presence of edges into grey nodes. These include Clear Creek (4) and the Yuba River (18).

indegree and *outdegree*, and contained six entirely disconnected (independent) populations (Fig. 3). All these populations are in the San Joaquin system, where the geography of the river basins is such that the populations are quite far apart (Fig. 2). In addition, the geographically closest of these populations (23–25) are all small enough to preclude outbound/inbound connections (Fig. 2). There are several populations in the Sacramento River Basin whose connections (> 1) were all outbound: Upper Sacramento (5), McCloud (6), Pit (7), Yuba (18), North Fork Feather (15) and the North and South Forks of the American River (19, 21) (Fig. 3). These large source populations, like those in the San Joaquin, are also demographically independent. Stronger demographic connections, on average, exist between nearby populations in which the source population is larger than the pseudo-sink population; as expected, the strength of the connection tends to decay with distance (Fig. 3).

The current graph is smaller than the historic graph, because most spawning habitat for historical populations is now behind dams (Fig. 4). At the ESU scale there are 15 demographic connections above the 10% threshold, four of which are outbound from the Feather River Hatchery (14). Butte Creek (13), a net

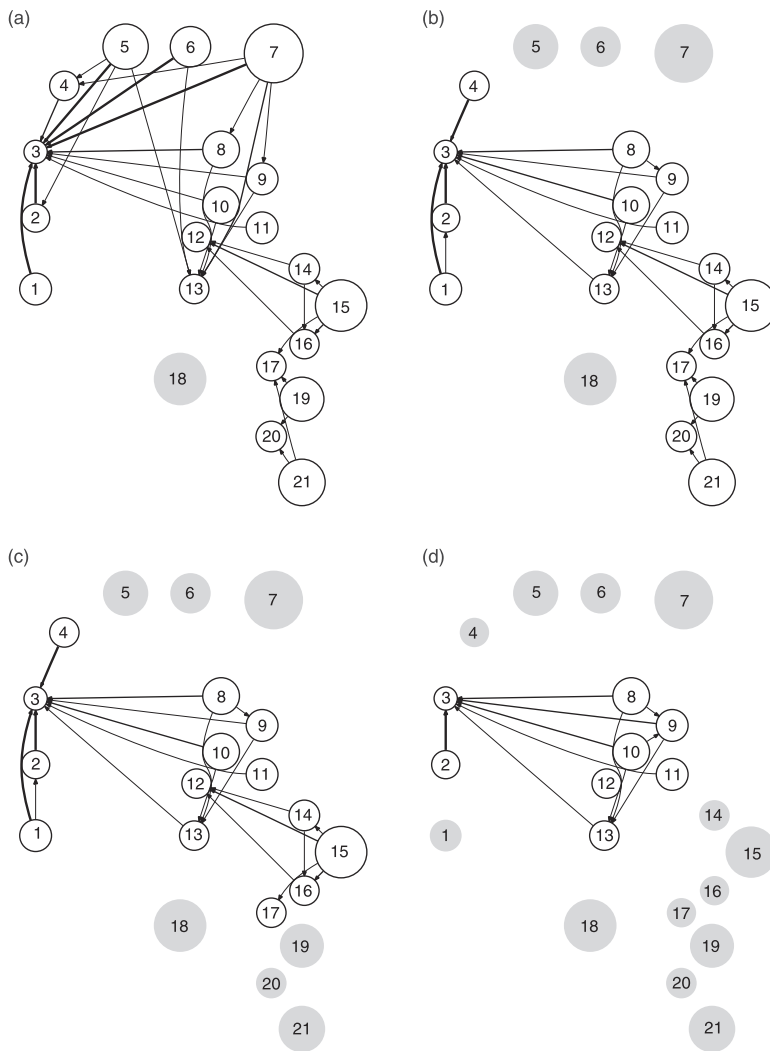

Fig. 5. Four panels depict the addition of dams to certain rivers, and the accompanying change in the graph. Shown are (a) Englebright Dam on the Yuba River (1941), (b) Shasta Dam on the Sacramento River (1945), (c) Nimbus Dam on the American River (1955) and (d) Oroville Dam on the Feather River (1968). Nodes and edges are depicted as in Fig. 3, except for extinct populations whose nodes are in grey.

importer before dam construction (*indegree* = 6, *outdegree* = 1 in Fig. 3), is a net exporter (*indegree* = 0, *outdegree* = 7 in Fig. 4). Both Stony (1) and Beegum Creek (3) had an average of zero reported spawners, hence the lack of connections in either direction (Fig. 4). Lastly, there is only one independent population, Battle Creek (8), in the current graph, while there were nine such populations in the historical graph.

In addition to blocking habitat, dam addition affects the remaining nodes both by increasing demographic independence on average and reducing the strength of the connections between nodes (Fig. 5a–d). As large spatially proximate nodes are removed from the graph, edges with an initial high weight are lost and the weight of certain remaining edges increases as migrants have fewer possible destinations (Fig. 5a–d). For example, when Shasta Dam was constructed in 1945 it blocked access to several major rivers including the Pit, McCloud and the Upper Sacramento (located just

above the northernmost dam in Fig. 2), and the results illustrate what a vital source these three rivers were to the overall graph (Fig. 5b). Each of these nodes (especially the Pit River) had a high outdegree, and the removal of these three nodes results in a loss of 12 edges (Fig. 5b). However, the loss also affected the context of populations such as Battle Creek (8), which had an increase in the number of outbound edges, as well as their weight (Fig. 5b–d). The last two panels depict the loss of the American River and the Feather River populations through the addition of Nimbus Dam and Oroville Dam, respectively (Fig. 5c,d). Any dam that blocked access to anadromous habitat in the San Joaquin system had little effect on the remaining populations, because these populations were all quite isolated (nodes not shown).

Independence of smaller populations increases with the loss of large source populations (Fig. 6), suggesting that recolonization rates are lower under the current structure than they were historically. Some losses are worse than others; the addition of Shasta Dam (1942) not only removed many edges (Fig. 5b), but it also caused a dramatic increase in population independence for many of the populations present in the ESU (Fig. 6). Consider, for example, Butte Creek (13), which progresses from $\zeta = 0.77$ in 1850 to $\zeta = 0.87$ in 1968 (Fig. 6).

The median ζ across the ESU shows markedly different patterns when exposed to different node-removal scenarios (Fig. 7). Under the scenario aimed at removing the nodes with the highest node strength, population independence ζ of the remaining populations increased the fastest. The random removal scenario has the next strongest effect, followed by removal based on the largest habitat size of the remaining populations (Fig. 7). The difference between the node-strength and the random removal scenarios is particularly evident after approximately one-third of the habitat has been removed. Population independence ζ increased faster for all of these scenarios, as compared to actual removal (Fig. 7).

Our model was most sensitive to two parameters: (1) uncertainty about the percentage of fish that stray; and (2) to percentage of straying fish that recruit into the recipient population (Table 1). The model was less sensitive to uncertainty in dispersal capabilities of

Table 1. Results from sensitivity analysis. For each parameter listed, we implemented a 10% perturbation and tallied the absolute change in number of edges in the final historical graph. Noted are the number of edges and the absolute percent change. There were 35 edges in the base historic graph

Parameter	No. of edges	% Change
α	37	5.7
% of fish that stray	38	8.6
Habitat size	35	0
Inter-population distance	33	5.7
% Strays recruiting	38	8.6

Fig. 6. Independence level (ζ) for each extant population in the ESU from 1850 up to the last dam addition in 1968. Population independence increases as populations are removed from the ESU (dam additions denoted by thick tick-marks on the x -axis). ζ -values are logit-transformed for visual clarity; for reference $\zeta = 0.9$ and $\zeta = 0.95$ are included as dashed and dash-dot lines, respectively. A dramatic change in population independence is seen after 1945, when the construction of Shasta Dam blocked access to the Pit, McCloud and Upper Sacramento Rivers. Populations are labelled as in Fig. 2.

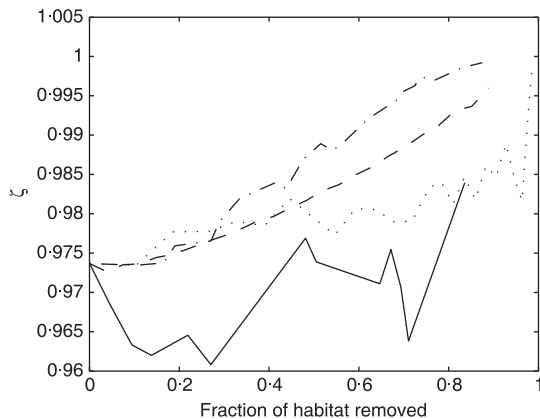

Fig. 7. Effect of node removal on median independence (ζ) of remaining populations in the ESU for four different removal scenarios: actual (solid line), random (dashed line), largest population first (dotted line), population with largest node strength first (dashed-dotted line). Random line represents the mean of 1000 iterations.

chinook and interpopulation distance. The model was not sensitive to our definition of population size. While we present only results for the historical graph (Table 1), these results hold as the graph fragments and the relative impacts of dams are the same as the unaltered empirical graph.

Discussion

Weighted digraphs have enabled us to understand more clearly the population context in the spring-run

chinook salmon ESU, because they have shown whether populations are importers, exporters, or functionally independent. The historical digraph had both source and pseudo-sink populations, and a range of demographic connections between populations. The current graph has fewer source populations and fewer independent populations. Additionally, the current graph has populations that switch context from their position in the historical graph, and has more and stronger demographic connections between populations. While the impact of dams on fish populations has long been known, our examination of the sequential dam addition in the Central Valley showed clearly how a single dam can impact almost the entire ESU. This impact meant a loss of source populations to the ESU, resulting in fewer edges and increased isolation for the remaining nodes. This translates to decreased opportunity for recolonization after extinction or disturbance events.

Previous graph theoretic attempts to model how organisms perceive their landscape have relied mainly on regular graphs (Bunn *et al.* 2000; Urban & Keitt 2001; Brooks 2006) (although see Fortuna *et al.* 2006 for a recent example of the utility and strength of a digraph application). Here we have accounted for the strength and directionality of the connections in the graph, and while this is an obvious and intuitive extension of graph theoretic applications that has been mentioned several times in the literature (Gustafson & Gardner 1996; van Langevelde *et al.* 1998; Urban & Keitt 2001; Fagan 2002), we stress its importance in this and future applications. Imagine, for example, the different interpretation of Butte Creek (13) in a regular graph. There Butte Creek might jump out as a stepping-stone population (*sensu* Urban & Keitt 2001); however, it is clear from the digraph that this, in fact, is a pseudo-sink population whose demographic trajectory is influenced by several populations in the graph. Lastly, by accounting for recruitment as a measure of connectivity (*sensu* Bjorkstedt *et al.* 2005), we have extended the purely spatial application of graph theoretic measures and have uncovered not only how nodes are connected spatially, but what that spatial positioning means for the trajectories of populations within the ESU.

Defining what comprises a population remains an active research area in ecology and evolution. Indeed, relatively little work has been conducted on ascertaining what fraction of incoming recruitment affects population trajectories enough to consider them linked (Waples & Gaggiotti 2006). Hastings (1993), in a theoretical system, has shown that the 10% threshold is sufficient to consider population trajectories as linked. However, Lande, Engen & Sæther (1999) showed that under certain circumstances, i.e. weak density regulation, even very small migration rates can help to increase the spatial scale of synchrony. At two extremes, therefore, we can assume independence for populations with no edges or only outbound edges in

Fig. 3, and cannot assume independence for populations with inbound connections over 10% (Fig. 3). Even if absolute independence thresholds are not definitive, relative changes in population independence are clear from the pattern of dam addition that successively fragmented the ESU and isolated remaining populations (Fig. 6).

Graph theoretic applications are appealing from a conservation standpoint because they are relatively simple to implement and they offer critical insight at both the landscape and population level (Urban & Keitt 2001). The graphs herein show interpopulation connectivity across the ESU, population importance, and how the removal of populations over time fragmented the ESU. Because this is a riverine setting, edge removal between two populations means typically that there are no alternate edges between that pair of populations (Fagan 2002). This means that fragmentation events lower down in the trunks of a watershed (Fagan 2002) can have dramatic effects – witness the effect of two single such events (Shasta and Oroville Dams) in our ESU, which removed a total of seven populations from the ESU (Fig. 5b,d). Clearly, the Pit River (7) had a major impact on the ESU, and were it not for the considerable complexities involved with removing major dams like Shasta *and* Keswick (just downstream of Shasta and the one depicted in Fig. 2), this would be an obvious place to highlight conservation and restoration efforts. However, Shasta Dam holds much of Northern California's water and so its removal would have serious implications for both the amount of water and its flow regulation throughout Northern California.

Palmer *et al.* (2005) underscore the need for a guiding image when restoring river ecosystems, and our depiction of the historical graph (Fig. 3) provides such an image. Further, the simulation of node-removal under different scenarios provides information that could be key to managers, as it highlights which restoration methods would bring about a reduction in demographic isolation fastest. While one might assume naively that restoring large populations first would have the greatest affect, that is not the case here (Fig. 7). Clearly, a scenario centred around restoring populations with large node strength first would accomplish this by adding more connections back to the graph (Fig. 7). Somewhat counter-intuitively, ζ decreased initially under the actual removal scenario; however, this is due simply to the spatial arrangement and timing of dam removal in the Central Valley. Notably, the first populations to be removed were in the southern San Joaquin, which meant that while habitat was lost, the resulting graphs were initially more compact and less isolated. Lastly, and perhaps most importantly, our graph framework accomplished what Jansson *et al.* (2005) called for in terms of a conceptual model that shows system function, system impairment and restoration strategies that 'will move the system back to the guiding image'.

Connections are the mechanism by which recolonization can occur following disturbance, and they add stability and resilience to a system. It is intuitive that with more connections the removal of any one edge has less effect on the overall stability of the graph. Given the historical level of connections, then the graph as of 1968 (Fig. 5d) suffers from a lack of connections, and must be viewed as less resilient. This is echoed by the demographic isolation seen in Fig. 6, and adding connections back into the system would decrease demographic isolation and increase stability. There is a limit to this, however, in that a graph can have too many connections. While an increase in connectivity increases the likelihood of rescue (Brown & Kodric-Brown 1977), it also increases both the likelihood of pathogen spread (Hess 1996a) and spatial coupling. Hess (1996a,b) has shown that intermediate levels of connectivity provide a balance between extinction and persistence. With increased spatial coupling, Keeling, Bjørnstad & Grenfell (2004) have shown that synchronous populations are increasingly vulnerable to a similar extinction trajectory. Connections should therefore be viewed in light of a balance between these two opposing forces; simulation and/or analytical studies could help to uncover an optimum level of connectivity for population and ESU persistence.

The conceptual model presented herein has highlighted at least two other areas of future research. First, we might ask what other types of migration models make sense for salmon. We experimented with other models of straying, including implementing a 'wrong-turn' model where returning fish are faced with a series of choices as they migrate back to their natal stream. While this model is potentially more representative of the actual process undergone by a returning adult salmon, its results were qualitatively quite similar (see Appendix S1 in Supplementary Materials) to the more parsimonious distance-based model presented here, and it was less extensible to other systems. Secondly, we might ask how representative this model is for salmon dynamics. It was our intention that this model serve as an illustrative model of salmon connectivity, not necessarily a usable model of metapopulation dynamics. While the sensitivity results indicate that the model is fairly robust to uncertainty, they point to areas of further research. Namely, we need additional information about the percentage of fish that stray and the percentage of strays that recruit into populations.

Remarkable progress has been made in graph theory in just the last 8 years. Ecologists willing to wade into this realm will find that much awaits them in the way of different network structures, rapidly advancing algorithms and a wealth of interesting applications (Proulx, Promislow & Phillips 2005). Here graphs have enabled us to accomplish the following: (1) to enhance our understanding of the overall ESU structure; (2) to examine how ESU structure changed through time; and (3) to understand the historical importance of individual populations. In a data-limited environment,

this exercise has shed light on this system from both an ecological and conservation standpoint. Our model of directed connectivity can be extended to many other systems, riverine or otherwise, and we recommend graph theory as an attractive analytical tool for rapid assessment of critical landscapes and endangered populations.

Introduction

The Endangered Species (ESA) requires that recovery plans for listed species include “estimates of the time required and the cost to carry out those measures needed to achieve the plan’s goal and to achieve intermediate steps toward that goal” (ESA Section 4(f)(1)(B)(iiii)). The purpose of this report is to facilitate recovery planning for ESA-listed salmonid stocks in California by providing information on costs associated with habitat restoration activities relevant to their recovery.

Data from publicly available sources were used to obtain estimates of restoration cost. Ideally these estimates would be identifiable to a specific restoration activity (e.g., fish screen, culvert replacement), include life cycle project costs (e.g., planning, design, permitting, construction, monitoring, maintenance), and be relatable to the scale, scope and location of the project. However, sources vary in terms of the extent to which they provide such details. Most cost estimates originate from sources generally intended for purposes other than recovery planning (e.g., contract administration). Thus reported costs may be incomplete if, for instance, some aspects of restoration are not covered by the contract or if the work involves a match from another funding source. For projects involving multiple restoration activities, costs are more typically broken down by input (e.g., labor, materials) than by activity. Given the diverse factors that affect restoration costs (see Allen *et al.* 2004) and the lack of standardization in available project and cost data, a meta-analysis of project costs as they relate to project characteristics was not possible. However, some of the sources do provide insights into factors affecting costs; to the extent that such information is available, it is briefly summarized in the tables below.

Many of the projects discussed in this report were funded by the California Department of Fish and Game (CDFG) as part of the Fisheries Restoration Grants Program and (to a lesser extent) the Klamath River Restoration Grant Program. The report is thus approximately organized according to the restoration categories used by these two programs. Restoration activities covered by this report are as follows:

- Fish ladders (FL)
- Fish passage at stream crossings (FP) - culvert replacement/improvement
- Fish screening of diversions (SC)
- Instream barrier modification (HB) - modification of fish passage barriers in the stream channel and along the streambank (tidegates, sandbars, dams, other non-culvert barriers)
- Instream habitat restoration (HI) - enhancement of stream channel and streambank habitat (instream structures, spawning gravel supplementation, floodplain tributary reconnection, side channel reconnection, wetland/floodplain restoration, levee evaluation/repair/setback)
- Riparian restoration - restoration of area, including fencing, between the fence and middle of stream (e.g., livestock exclusion, revegetation)

- Streambank stabilization (HS) - stabilization of eroding, collapsing of otherwise de-stabilized banks
- Upland watershed restoration (HU) - largely pertains to upslope erosion control (e.g., road decommissioning/upgrade, landslide/gully stabilization, upslope planting)
- Tailwater management (TM)
- Water conservation (WC) - e.g., ditch lining, piping
- Water purchase/lease (WP)
- Habitat acquisition and conservation easement (HA)
- Monitoring status and trends (MD) - monitoring of baseline conditions and status/trends in habitat, watershed processes and/or populations.
- Monitoring watershed restoration (MO) - monitoring to determine if project treatments were constructed correctly and as planned, effectiveness monitoring to determine if restoration has produced desired habitat conditions and/or watershed processes, and validation monitoring to determine if hypothesized responses of habitat, watershed processes and/or populations to restoration were correct
- Watershed evaluation, assessment and planning (PL) - developing watershed plans with site-specific, prioritized recommendations for restoration of salmon/steelhead habitat. Includes partial assessments (e.g., road erosion surveys, stream surveys).
- Watershed organizational support and assistance (OR) - organizational support to local watershed groups and development/maintenance of databases that facilitate organizational aspects of restoration
- Cooperative fish rearing (RE)
- Water measuring devices (WD) - e.g., head gate
- Wildlife management (WM) - e.g., control of exotic species such as pike minnow
- Research (RES) - general research on productivity (e.g., life cycle monitoring/analysis), spatial structure (fish distribution surveys), genetic diversity (laboratory analysis of tissue samples), and estimation of abundance.

Restoration cost estimates were obtained by searching the published and gray literature, including the following:

- reports that provide actual or estimated costs associated with specific projects (e.g., grant proposals, contract reports),
- reports that provide average costs for multiple projects involving the same restoration activity,
- reports that describe “typical” costs associated with a particular restoration activity,
- cost guidelines associated with environmental improvement programs sponsored by entities such as the Natural Resources Conservation Service (NRCS),
- reports that use regression and other methods to relate project costs to selected project characteristics, and
- environmental impact statements that provide cost estimates for each of the restoration alternatives considered.

Only restoration cost estimates that met at least one of the following criteria are included in this report:

- Top priority for inclusion are cost estimates pertaining to restoration activities in California. However, examples from other states are also included (as available) for those activities where California examples are limited. A notable exception: Cost estimates developed by Evergreen Funding Consultants for restoration in Puget Sound (Evergreen 2003) are particularly instructive, as they cover a wide range of restoration activities, provide life cycle estimates of project costs, and demonstrate how costs vary with project characteristics. Thus all of Evergreen's cost estimates are included in this report - even when they pertain to activities where a fairly large number of California examples are also available.
- Cost estimates are generally more useful for recovery planning when related to the scale of restoration. Thus only cost estimates that are accompanied by a relevant measure of project scale (e.g., stream miles, acres of land) are included in this report.
- For most projects involving multiple types of restoration activities, data sources typically do not provide a cost breakdown by activity. Given the focus of this report on activity-specific costs, most of the cost estimates were by necessity obtained from single-activity projects. However, to ensure some representation of multi-activity projects, some projects involving several closely related activities (e.g., fencing + stockwater system, fish ladder + screen) conducted at the same site are included in this report. Also, cost summaries provided by the Pacific States Marine Fisheries Commission for projects sponsored by CalFED's Ecosystem Restoration Program (Holycross *et al.* 2007) include some estimates of cost per activity for multi-activity projects.
- To help ensure that cost estimates reflect fairly recent restoration technology, the report focuses largely on projects that have occurred since 1998. However, in cases where project data for a particular restoration activity are sparse, pre-1998 project data are also provided, as available.

All costs described in this report pertain to direct expenditures on restoration and do not include economic opportunity costs (e.g., foregone profits associated with restrictions on livestock grazing, timber harvest and other activities). It is important to note the following:

- Even the direct costs described in this report are not necessarily comparable across projects, as some cost estimates are more inclusive than others. Some data sources - e.g., Evergreen Funding Consultants (2003), Neal (2004), Steere (2004) - provide cost estimates that include pre- and post-construction requirements as well as construction itself. In other cases, cost estimates are largely limited to engineering and/or implementation aspects of the project (e.g., CDFG's Fisheries Restoration Grants

Program, NRCS Environmental Quality Improvement Program) and do not include agency involvement in planning, design, management, maintenance and monitoring. In still other cases, documentation is not adequate to determine exactly what is included and excluded from the cost estimates.

- For most projects involving capital construction (e.g., bridges, fish screens), costs are not amortized but rather provided as a lump sum. One notable exception is the Independent Economic Analysis Board's (2002) estimates of amortized capital construction costs for Columbia River hatcheries.

For each restoration activity, one or more tables are provided that include cost estimates for that activity - by location, year, project scale, cost per scale unit, and data source.

- Depending on available information, each project example is variously identified by stream/creek/river, watershed, county, recovery domain,¹ or state.
- Depending on the source of a cost estimate, year may pertain to the year of a funding proposal or contract. In cases where a document includes cost estimates for projects conducted in years prior to publication of the document, the project year is used when available; otherwise the publication year is used.
- The metric used for project scale varies, depending on the nature of the restoration activity. Thus for instance, design approach velocity (cubic feet per second, cfs) is used for fish screens; linear feet for levee work, fencing, bank stabilization; acres for revegetation, wetland restoration, land purchase/easement; and miles for road decommissioning/upgrade.
- As indicated above, this report focuses largely on 1998-2006 projects. Cost estimates for these projects are provided in current dollars (uncorrected for inflation). In situations where paucity of 1998-2006 data warranted inclusion of pre-1998 projects, costs of pre-1998 projects were corrected to 2006 dollars. In some cases, the data sources themselves provide inflation-corrected cost estimates. The base year for these estimates is documented in this report, along with the year(s) when the restoration actually occurred (e.g., Hildner/Thomson's (2007a) results are denoted "98-05" and "2003\$" to reflect the fact that their cost estimates are based on 1998-2005 project data and have been corrected to 2003 dollars).

¹ The recovery domains include: Southern Oregon/Northern California Coast (SONC), North/Central California Coast (NOCECA), Central Valley, and South Central California Coast (SCACO). There is an area of geographic overlap between the SONC and NOCECA, which is referenced in this report as NOCECA-SONC.

- The nature of the cost estimates vary somewhat, depending on the data source: (i) In cases where cost is reported for a specific project, total project cost, project scale, and average cost per scale unit are provided, as available. (ii) In cases where cost is reported as an average value across multiple projects, the sample size and range of project costs (as available) are reported along with average cost. (iii) In cases where a “typical” cost is reported, the “typical” cost and the range of “typical” costs (as available) are provided. (iv) In cases where cost is estimated from a regression equation, the equation itself is provided as well as a range of fitted values associated with the regression parameters.
- In cases where management/administrative costs are reported for a multi-activity project and the cost estimate in the table pertains to one activity, management/administrative costs (which are not solely attributable to that one activity) are provided separately and not included in the calculation of cost per scale unit.
- Data sources are identified in the tables by last name or initials of author(s) and table and/or page numbers as appropriate. In cases where the data sources were grant proposals submitted to CDFG’s Fisheries Restoration Grants Program (FRGP) or Klamath River Restoration Grant Program (KRRGP), those sources are identified in the tables by the fiscal year in which the proposal was submitted (01-02 through 06-07) and the project ID number (CDFG-xxx for the FRGP, Kxxx for the KRRGP). In cases where the data sources are projects sponsored by CALFED’s Ecosystem Restoration Program (ERP), the projects are identified by the year of the proposal and the project ID (ERP-xx-xxx). In cases where costs associated with an ERP project could be broken down by activity, that project ID appears multiple times in the tables. All data sources are fully documented in the “References” section at the end of this report.

FL - FISH LADDER.

Table FL-1 provides estimates of fish ladder costs. CDFG’s Coho Recovery Strategy (CDFG’04, p1.14) assumed \$500K/ladder on tributaries and \$900K/ladder on streams. This cost range pertains to central/northern CA coastal streams and is not necessarily applicable to projects outside that geographic range. However, most of the projects in Table FL-1 do fall within that range. Notable exceptions (exceeding \$2M/ladder) include a project in the South Central California Coast (SCACO) recovery domain (HT07a-T61, p121) and several Central Valley projects (HT07a-T61, p121, ERP-99-B03) . Note: Some of the projects pertain to ladders only, others to ladder/screen combinations.

Table FL-1. Fish Ladder (\$/project)				
Location	Year	Units	Cost Per Unit	Source
CA	2004	typical	Small waterway (tributary): \$500K/ladder Large waterway (stream): \$900K/ladder	CDFG’04, p1.14
Young’sDam	03-04	1ladder	\$494K - sloping plate, selfclean, excluding design	CDFG-057
SONC CentralVly SCACO	98-05 2003\$	1site 1site 1site	\$530.1K \$2.1M \$2.1M	HT07a-T61, p121
Gorrill Dam/Butte Creek	1997	2ladder	\$660K (\$330/ladder) +\$12.8K project mgmt + \$58.8K construction mgmt - construct ladder and screen	ERP-97-M03
Adams Dam/Butte Creek	1997	1ladder	\$298.7K (+\$6.3K project mgmt + \$3K project coordination) - construct ladder and screen	ERP-97-M04

FP - FISH PASSAGE AT STREAM CROSSINGS.

Tables FP-1 and FP-2 pertain to culvert replacement, Table FP-3 to culvert replacement with a bridge, and Table FP-4 to culvert improvement.

Table FP-1 describes Evergreen’s estimates of culvert replacement costs, while Table FP-2 provides similar estimates from other data sources. Evergreen’s estimates include not only construction but also design, permitting, monitoring, maintenance and management, and are much more inclusive than the estimates in Table FP-2. Most of the latter examples are derived from grant proposals submitted to CDFG’s Fisheries Restoration Grants Program - with costs largely limited to engineering/construction aspects of the project. The Table FP-2 estimates generally fall within the range of \$100K-\$400K/culvert, although there are some projects that cost in the \$10,000s (e.g., Dupont-T10, p66; HT07a-T60, p118; HT07a-T61, p121) and one very costly project (\$4.1M, CntySBPublicWrks) in Santa Barbara. Culvert type is reported here when available from the data source.

Evergreen’s estimates show typical culvert replacement costs for Puget Sound by road type and size of waterway. Like Evergreen, Hildner/Thomson show cost per culvert being lower for rural roads than major highways (HT07b-T42, p61) and increasing with stream order (HT07b-T44, p62). Excluding 4+ lane highways (which are not covered by Hildner/Thomson), the estimates obtained by HT from restoration contractors fall within Evergreen’s cost ranges. E.g., forest roads - Evergreen: \$15K-\$150K, HT: \$23.4K; minor 2 lane road - Evergreen: \$50K-\$280K, HT: \$227K; major 2 lane road - Evergreen: \$100K-\$450K, HT: \$420K. Small waterway - Evergreen: \$15K-\$200K, HT: \$70K; medium waterway - Evergreen: \$50K-\$350K, HT: \$175K; large waterway - Evergreen: \$80K-\$450K, HT: \$286K.

Table FP-1. Culvert Replacement - \$/project (Source: Evergreen 2003, p. 21)				
Cost estimates pertain to Puget Sound. Estimates include construction, design, permitting, basic monitoring & routine maintenance (2 yrs), reestablishing site to prior conditions, project management				
Size of Waterway	Road Type			
	Forest Road	Minor 2 Lane	Major 2 Lane	Hwy 4+ Lane
Small 0-10'	\$15K-40K	\$50K-100K	\$100K-200K	\$200K-350K
Med 10-20'	\$50K-100K	\$140K-240K	\$200K-350K	\$300K-450K
Large 20-30'	\$80K-150K	\$180K-280K	\$250K-450K	\$600K-800K

Costs of culvert replacement with bridge described in Table FP-3 generally range from \$100K to \$500K/bridge. A few projects cost <\$50K (e.g., 02-03 CDFG-065; 03-04 CDFG-201 & CDFG-311; 05-06 CDFG-077; Dupont-T9, p65). Projects that cost >\$650K all occurred in southern or south-central California (04-05 CDFG-031 & CDFG-241; 06-07 CDFG-090). Information on bridge type - which is reported here when available from the data source - suggests that prefabricated bridges fall toward the lower end of the cost spectrum. Dupont provides information on expected lifetime of various types of bridges, although his information pertains to Idaho rather than California.

Table FP-3. Culvert Replacement with Bridge (\$/project)

Most of the culvert improvement costs described in Table FP-4 range from about \$5K to \$65K. The two notable exceptions are \$463.1K (03-04 CDFG-320) and \$485K (05-06 CDFG-162) - both of which seemed to also involve substantial habitat work around the culvert. The NRCS examples pertain to culvert removal rather than improvement, but are included here in case such actions are considered for farmland in recovery planning.

SC - FISH SCREENING OF DIVERSIONS

Table SC-1 provides cost estimates for fish screens relative to the design approach velocity of the screen (cubic feet per second, cfs). Cost of screens produced by the CDFG screen shop range from \$2K to \$10K/cfs (BM, p. J-3). Most of the other cost estimates in the table fall within this range. Some notable exceptions include projects on the Klamath River (e.g., 05-06 CDFG-200) and in the Central Valley (e.g., ERP-00-B02, ERP-95-M05, ERP-96-07, ERP-97-C01, ERP-97-M07).

HB - INSTREAM BARRIER MODIFICATION FOR FISH PASSAGE

This section covers modification of non-culvert fish passage barriers in the stream channel and along the stream bank. Table HB-1 focuses on tide gates, Table HB-2 on sandbars, Table HB-3 on dam,, and Table HB-4 on other barriers.

Based on a limited number of examples, the replacement cost of a tide gate is ~\$105K; retrofit cost is \$26K.

Table HB-1. Tide Gates - \$/unit				
Location	Year	Units	Cost Per Unit	Source
HumboldtBay	03-04	3 tidegates	\$317,148 (\$105.7K/tidegate) - replace 2 tidegates & add 3rd	CDFG-143
HumboldtBay	2005	1 tidegate	Retrofit: \$26K	MA, p2

Based on a single example, cost of sandbar breaching is \$13K/breaching.

Table HB-2. Sandbar Breaching - \$/unit				
Location	Year	Units	Cost Per Unit	Source
Estero de San Antonio (MarinCnty)	1993	1breaching	\$10K/breaching (2006\$: \$13.1K) - incl equip rental	WC, p19

Based on a single example, cost of dam decommission is \$1.5M.

Table HB-3. Dam Decommission/Removal - \$/unit				
Location	Year	Units	Cost Per Unit	Source
BattleCrk/SoapCrk/RipleyCrk	1999	5 dams	\$7.53M (\$1.5M/decommission)	ERP-99-B01

Barrier modification projects identified in Table HB-4 typically involve weirs, head gates, fish screens and/or measuring structures. Most of the modifications cost \$30K-\$170K, with the exception of two \$1M+ barrier removal/fish screen projects on the Shasta River (06-07 K010 & K011). A single estimate of weir repair cost is provided: \$10.8K/weir (06-07 K034).

HI - INSTREAM HABITAT RESTORATION

This section covers restoration of instream habitat. Tables HI-1 & HI-2 pertain to instream structures such as wood/boulder structures and large woody debris, Table HI-3 to spawning gravel supplementation, Table HI-4 to floodplain tributary reconnection, Tables HI-5 and HI-6 to channel restoration, and Table HI-7 to wetland/floodplain restoration.

Evergreen (Table HI-1) estimates restoration costs for small/medium streams with small/medium transportation & material requirements on a per-mile basis, and estimates costs for large streams with medium/high transportation & material requirements on a per-structure basis. The examples in Table HI-2 also represent a mixture of per-mile and per-structure estimates; however, the units of measure in Table HI-2 were not based on any systematic criterion (as per Evergreen) but rather reflect whatever units were available from each data source. Cost-per-mile tends to be lower using Evergreen's estimates (\$10K-\$50K/mile) than the Table HI-2 estimates, which ranged from ~\$25K to \$500K/mile (with the exception of a \$1.4M/mile project (01-02 CDFG-156) where cost per mile was derived by expanding the cost of that 40' project to an entire mile). Conversely cost-per-structure tends to be higher using Evergreen's estimates (\$10K-\$80K/structure) than the Table HI-2 estimates (~\$500-\$11K/structure). These results are not surprising, given that Evergreen systematically applied cost-per-mile to lower-cost projects and cost-per-structure to higher-cost projects.

Table HI-1. Engineered Logjams and Large Woody Debris - \$/structure, \$/stream mile (Source: Evergreen 2003, p. 25)			
Cost estimates pertain to Puget Sound. Estimates include construction, design, permitting, basic monitoring & routine maintenance (2 yrs), reestablishing site to prior conditions, project management costs. All estimates assume purchased materials.			
Stream Size (cfs)	Transportation & Material Requirements		
	Low Cost	Medium Cost	High Cost
Small 1-100 cfs	\$10K-30K*	\$20K-50K*	\$20K-40K
Med 100-2000 cfs	\$20K-50K*	\$15K-45K	\$40K-70K
Lge 2000+ cfs	\$10K-20K	\$40K-60K	\$60K-80K
* Cost per stream mile, assuming 100-400 pieces per stream mile. Estimates in all other cells measured as cost per structure.

Table HI-3 pertains to spawning gravel supplementation. The WDFW example (WDFW-T3, p14), which is actually based on a British Columbia data source, estimates cost of spawning gravel supplementation at \$20-\$40/cubic yard. With the notable exception of the Stanislaus River project (ERP-97-N21) - where costs include evaluation as well as gravel treatment - the Central Valley examples indicate a range of costs (\$11-\$36/cubic yard) similar to WDFW's.

Table HI-3. Spawning Gravel Supplementation - \$/cubic yard (cy)				
Location	Year	Units	Cost Per Unit	Source
WA	2004	typical	Gravel placement: \$50-\$70/m ³ * Sorted gravel: \$20-\$40/cubic yard	WDFW-T3, p14
* Gravel placement - sorted gravel supplied, limited delivery distance, machine placed, does not include control structures.

Tuolumne River	1997	2.6 mi	\$5.054M + \$284 construction mgmt (\$1.9M/mile) - restore natural channel morphology	ERP-97-M09
Tuolumne River	1998	2.2 mi	\$5.054M (\$2.3M/mile) - restore natural channel processes & habitats	ERP-98-F06
Merced River	1998	2.2 mi	\$3.635M (\$1.7M/mile) - restore natural channel processes & habitats	ERP-98-F11

Most of the wetland restoration cost estimates in Table HI-7 pertain to San Francisco Bay/Estuary; several estimates of annual operations & maintenance (O&M) and monitoring costs are included. Steere’s information is notable in that he provides estimates by wetland type. The NRCS estimates indicate much lower wetland restoration costs for farmland (\$75-\$375/acre); these projects are likely much more modest in scale than the types of projects that occur in San Francisco Bay.

Table HI-7. Wetland Restoration - \$/acre				
Location	Year	Units	Cost per Unit	Source
Topanga Crk-LA	05-06	12acres	\$249.8K (\$20.8K/acre) - remove 26Ktons of lead contaminated fill matl	CDFG-029

HR - RIPARIAN RESTORATION

This section covers restoration of erosion-prone banks adjacent to the stream and within the riparian corridor. Riparian area is defined as the area, including any necessary fencing, between the fence and the middle of the stream. Table HR-1 pertains to fencing/livestock exclusion, Table HR-2 to fence maintenance, Tables HR-3 and HR-4 to riparian planting, Table HR-5 to irrigation, and Table HR-6 to invasive/noxious weed control.

As indicated in Table HR-1, Evergreen (Evergrn p11) estimates fence construction costs at \$1-\$12/foot, with an “overall average” of \$3-12/foot. CDFG’s Coho Recovery Strategy (CDFG’04, p1.20) uses the midpoint of this latter range (\$8/foot). Cost of all individual fencing projects (CDFG-xxx, HT07a, HT07b, NRCS CA) are expressed in \$ per foot, even for projects that also include components other than fencing (e.g., revegetation, irrigation, stock water systems). For most of these projects (even those with added components), costs generally fall within the \$1-\$12/foot range indicated by Evergreen.

Table HR-1. Fencing/Livestock Exclusion - \$/foot

----	------	---------	-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----------

Fence maintenance costs described in Table HR-2 range from \$0.09 to \$0.26/foot/year, depending on the fencing material. It should be noted that these estimates pertain to Iowa, not California.

Table HR-2. Fence Maintenance - \$/foot				
Location	Year	Units	Cost Per Unit	Source
Iowa	2005	1330'	<p><u>Fence Material:</u> Woven wire: \$0.26/ft/yr Barbed wire: \$0.21/ft/yr Hi-tensile, non-elec: \$0.15/ft/yr Hi-tensile, elec: \$0.09/ft/yr</p>	MO-T6

Table HR-3 describes Evergreen’s estimates of riparian planting cost, while Table HR-4 describes estimates from other data sources. Evergreen’s estimates are \$5K-135K/acre, and vary with the level of site preparation and material/site accessibility. The estimates used for CDFG’s Coho Recovery Strategy (CDFG-04, p1.17) are \$30K-60K/acre and were selected to fall within the range of Evergreen’s estimates. Project costs reported in HT07a and HT07b are ~ \$100K-\$120K/acre (with the notable exception of a \$434.8K/acre project). The NRCS estimates are at the low end of this range: ~\$100-\$1800/acre - depending on what is planted (trees or plants) and planting requirements (e.g., protected, shelters, wire cages, native species). An NRCS estimate of landing clearing costs is also included to address situations where clearing is a prerequisite for planting. The Bair example - \$110/acre, pertaining to riparian reforestation - was also at the lower end of Evergreen’s range .

For the examples from CDFG and Hampton, costs could be calculated on a per-mile but not a per-acre basis. Costs vary widely (\$1K to > \$200K/mile); some of this difference may be due to variations in the width of the buffer being planted (which is not clear from the data sources). Evergreen uses the following conversion from miles to acres (with acreage doubled when planting on both sides of the stream).

- 1 mile x 50 foot buffer = 6 acres (100% planted)*
- 1 mile x 50 foot buffer = 1.8 acres (30% planted)*
- 1 mile x 150 foot buffer = 18.2 acres (100% planted)*
- 1 mile x 150 foot buffer = 5.5 acres (30% planted).*

Table HR-3. Riparian Planting Projects - \$/acre (Source: Evergreen 2003, p. 16)			
Cost estimates pertain to Puget Sound. Estimates include construction, design, permitting, basic monitoring & routine maintenance (2 yrs), reestablishing site to prior conditions, project management.

CA		12 projects	\$8 (\$0.17-\$23)/ft or \$42.2K (\$898-\$121K)/mi	Hampton-T4, p125

Some of the projects in Table HR-4 above included irrigation in combination with revegetation. Table HR-5 provides estimates of irrigation costs only (NRCS CA) that range from \$800 to \$3K/acre and vary by irrigation method and habitat type. An example of capital cost (irrigation pumps, CDFG-279) is also provided.

Table HR-5. Irrigation - \$/acre, \$/project				
Location	Year	Units	Cost Per Unit	Source
CA farmland	FY07	typical	Irrig system, surf & subsurface: \$3K/acre Micro-irrig, hillside: \$1.5K/acre Micro-irrig, wildlife-upland habitat: \$800/acre Sprinkler irrig, hillside/sloping: \$2.5K/acre	NRCS CA
Eel R	04-05		\$17.3K - solar powered irrigation pumps to ensure seedling survival until natural roots grow	CDFG-279

Information on invasive weed control is limited: \$5K-\$12K/acre for projects on the Napa and Smith Rivers (04-05 CDFG-072 & CDFG-077). NRCS cost estimates for farmland are much lower (\$10-\$375/acre) and vary, depending on eradication method (e.g., mechanical/chemical, mechanical/chemical/handtool), land type (e.g., upland, wetland), and vegetation type (e.g., woody, herbaceous). A Russian River project (02-03 CDFG-325) can be costed on a per-mile basis but cost per acre is not known.

Table HR-6. Invasive/Noxious Weed Control - \$/acre, \$/mile				
Location	Year	Units	Cost Per Unit	Source
RussianR	02-03	2.5mi	\$30.2K (\$12.1K/mi,broom,native reveg)	CDFG-325

HS - BANK STABILIZATION

This section covers stabilization of eroding, collapsing or otherwise de-stabilized banks. Table HS-1 provides Evergreen’s cost estimates for streambank stabilization, Table HS-2 provides similar estimates from other data sources, and Table HS-3 focuses on levee restoration.

Evergreen’s estimates (\$30-\$1000/foot) vary by extent of excavation and waterway size. Cost estimates used in CDFG’s Coho Recovery Strategy (CDFG’04, p1.19) were \$250-\$350/foot and fall within the range of Evergreen’s estimates for small/medium waterways. Generally speaking, other project costs in Table HR-2 also fall within Evergreen’s range of estimates.

The higher cost projects appear to involve stabilization work other than just revegetation and/or work on steep terrain (e.g., 03-04 CDFG-285, 04-05 CDFG-263). For those projects that are identifiable to location, costs also appear to be higher in urban areas - e.g., southern California (05-06 CDFG-065, 069, 097) and King County, WA (Neal-T2, p159 & Neal-T3, p161). By contrast, cost in the rural Wind River watershed (\$9-\$42/ft, Bair-p107) falls toward the low end of Evergreen's range.

Table HS-1. Streambank Improvements - \$/lineal foot (Source: Evergreen 2003, p. 30)			
Cost estimates pertain to Puget Sound. Estimates include construction, design, permitting, basic monitoring & routine maintenance (2 yrs), reestablishing site to prior conditions, project management.			
Extent of Excavation	Size of Waterway		
	Small	Medium	Large
Minimal	\$30-60	\$60-150	\$150-400
Moderate	\$60-100	\$150-250	\$400-700
Substantial	\$100-200	\$250-500	\$700-1000

* Includes design, land/easements, permits, SEPA and construction. For 1995 project, replanting, irrigation and 5 year plant maintenance also included.				

Table HS-3 provides levee-related cost estimates for several Central Valley rivers, the Pajaro and San Lorenzo Rivers (in Santa Cruz/Monterey counties), and Green River (in Washington). Comparison of estimates from different time periods suggests that levee repair costs have increased significantly (beyond the rate of inflation) - perhaps reflecting major change in levee demand and/or input supply conditions in recent years.

Central Valley: A single example of levee evaluation costs was found (\$11/foot; Harder 06, p21). Levee repair costs from the 1980s and early 1990s were ~\$500-\$1000/foot (after correcting for inflation). More recent cost estimates are ~\$5K-\$6K/foot. Although per-foot cost estimates were not available for the Yuba/Feather River project (EPS '06, Tables B1&B2), levee improvement: environmental mitigation cost ratios from that project (25:1 for the Yuba, 8:1 for the Feather) are provided here, as they may also be useful for recovery planning.

Pajaro/San Lorenzo River: The 1989 cost estimates were ~\$200-\$500/foot (after correcting for inflation). The more recent estimates (developed by USACOE to evaluate various alternatives for Pajaro River flood protection) are ~\$1.5K to \$5K/foot.

Green River: Suggests the wide range of costs possible for levee repair.

HU - WATERSHED RESTORATION (UPSLOPE)

This section covers upslope restoration to reduce stream sedimentation. Table HU-1 pertains to road decommissioning, Table HU-2 to road upgrade, Table HU-3 to landslide/gully stabilization and Table HU-4 to planting in upland areas (as distinct from riparian planting described in Table HR-4).

According to Weaver/Hagans (WH-T7, p100), road decommissioning costs generally range from \$2K-\$35K/mile but may go as high as \$51K/mile for moderately difficult roads. Most of the other examples fall within Weaver/Hagans' range. CDFG's Coho Recovery Strategy (CDFG '04, p1.28) assumes \$9K/mile, which is toward the lower end of the Weaver/Hagans' range.

Table HU-1. Road Decommissioning - \$/mile

WA- ForestSvc	2000	6 sites	\$6,522 (\$1,8K-\$15K)/km, or \$4.1K (\$1.1K-\$9.3K)/mi	Coffin-T1, p53

According to Weaver/Hagans (WH-T7, p100), road upgrade costs are generally \$10K-\$35K/mile but may go higher than \$45K/mile for difficult or high-density sites. CDFG's Coho Recovery Strategy (CDFG '04, p1.27) assumes \$15.9K/mile, which is toward the lower end of the Weaver/Hagans' range (~\$23K/mile). Most of the other examples fall within Weaver/Hagans' range.

Table HU-2. Road Upgrade - \$/mile

CA	02-04	43 sites	\$169K (\$1K-\$3.5M)/mi	HT07b-T86, p123,contrctr

Limited information contained in Table HU-3 (mostly from the Eel River) shows landslide repair costs ~ \$1K-\$3.5K/site.

Table HU-3. Landslide and Gully Stabilization - \$/acre				
Location	Year	Units	Cost Per Unit	Source
EelR	04-05	34 sites	\$115.9K (\$3410/site)	CDFG-156
EelR		54 sites	\$86.5K (\$1601/site)	CDFG-160
MarinCnty		80 sites	\$279.8K (\$3497/site)	CDFG-174
EelR		30 sites	\$29.7K (\$990/site)	CDFG-213

The estimate of upland planting cost in Table HU-4 falls toward the lower end of riparian planting costs previously described in Table HR-4; however, it is difficult to generalize from a single example.

Table HU-4. Planting - \$/acre				
Location	Year	Units	Cost Per Unit	Source
TrinityCnty	02-03	100 acres	\$194,468 (\$1945/acre)	CDFG-254

TW - TAILWATER MANAGEMENT

Cost of tailwater management is represented in Table TW-1 in terms of acres of farmland irrigated by tailwater. Costs are ~\$20-\$400/acre. The NRCS example suggests that cost per acre declines as total acreage increases.

Table TW-1. Tailwater Management System - \$/acre				
Location	Year	Units	Cost Per Unit	Source
SiskiyouCnty	01-02	540 ac	\$220.2K (\$408/acre, collect, hold and return water to high end of unit for re-use)	CDFG-049
CA	1987	typical	\$125/acre (2006\$: \$198/acre)	USEPA p13
CA-rice	1990	typical	<u>System Type:</u> Static irrig system*:\$95/acre (6-10 acre basin) (2006\$: \$135/acre) Recirculating system: \$20/acre (1000 acre system) to \$150/acre (80 acre system) (2006\$: \$28-\$214/acre)	Hill 4/7 Hill 3/7
* Static irrigation consists of a ditch and flashgated pipe system that limit inflow into basin to amount required to replenish water lost to evapotranspiration and percolation. This recent innovation in rice irrigation eliminates possibility of tailwater spillage into public drains.				
CA	FY07	typical	Size of Area Covered by System: 1-50 acres: \$10K, \$400/acre(=\$10K/25ac) 51-100 acres: \$20K, \$267/acre 101-200 acres: \$30K, \$200/acre 201-300 acres: \$40K, \$160/acre 301-400 acres: \$60K, \$171/acre 401-500 acres: \$80K, \$178/acre	NRCS CA

Colorado	1998	typical	\$150-\$225/acre (earthwork, pipeline install, pump assembly)	Broner

WC - WATER CONSERVATION MEASURES

This sections cpertains to methods of providing more efficient use of water extracted from stream systems. Table WC-1 pertains to ditch lining and Table WC-2 to piping.

Canal lining costs described in Table WC-1 are ~ \$15-\$96/foot. Such projects often involve installation of related equipment such as control structures. For large projects, the cost of planning/environmental/administrative aspects can comprise a substantial portion of total project costs (e.g., 62% of total costs for the ACID project). Project life ranges from 20-50 years. In cases where proponents provided estimates of project benefits (in terms of value of conserved water), benefits were estimated using water prices of \$25-\$75/acre foot.

Table WC-1. Ditch Lining - \$/ditch length, \$/acre farmland treated				
Location	Year	Units	Cost Per Unit	Source
Anderson	01-03	2 mi	<u>Cost Breakdown:</u> Planning/environ/admin: ~\$4M Control struc, measurement flumes, SCADA systems@13 sites: \$1.494M (\$114.9K/site) Concrete anal lining: \$1M (\$96/ft) Project life=30yrs Value conserved water=\$50/af	ACID

------------	-------	------	------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	------

As indicated in Table WC-2, the only piping example found was \$16/foot.

Table WC-2. Piping - \$/pipe length				
Location	Year	Units	Cost Per Unit	Source
CA farmland	FY07	typical	\$16/ft - irrig water conveyance, aluminum pipeline	NRCS CA

WD - WATER MEASURING DEVICES

This section pertains to instream and water diversion measuring devices to track mainstem/tributary flows. Table HB-4 above provides cost estimates for instream projects that involve use of head gates with other devices. Table WD-1 pertains to head gates alone. The limited examples provided indicate head gate costs of \$2.8K-\$10K.

Table WD-1. Head Gate - \$/project				
Location	Year	Units	Cost Per Unit	Source
SiskiyouCnty	01-02	123 diversions	\$350K (\$2.8K/diversion) - lockable head gate & flow measuring device	CDFG-056
ScottR-Klamath	06-07	14 diversions	\$142K (\$10.1K/diversion) - head gate & flow measuring device	K033
CA farmland	FY07	typical	Headgate <3cfs: \$5K Headgate >3cfs: \$10K	NRCS CA

WP - WATER PURCHASE/LEASE

Table WP-1 pertains to purchase/lease/acquisition of short- or long-term water rights to improve water quality and/or quantity. The DWR sources indicate Central Valley water transfer prices of \$43 - \$246/acre foot/year. CDFG’s Coho Recovery Strategy (CDFG’04, p1.43) assumes \$100/af/yr - a value within the range of the DWR data. The water prices in Table WC-2 (previously presented in section “WC-Water Conservation Measures”) are considerably higher than the prices imputed to water conserved in estimating value of water conserved by ditch lining in Table WC-2. A major distinction between the two is that Table WC-2 pertains to conserved water valued at the existing price being paid by the water user, while the Table WP-1 prices are transfer prices.

Table WP-1. Purchase/Lease of Water Right - \$/acre foot (af)

HA - HABITAT ACQUISITIONS/LEASES/CONSERVATION EASEMENTS (\$/ACRE)

Tables HA-1 and HA-2 respectively describe Evergreen’s cost estimates for undevelopable land and parcels with medium-high development potential. Table HA-3 describes costs of easements and land purchases administered by California’s Wildlife Conservation Board (WCB). Tables HA-4 and HA-5 respectively describe land acquisition and easement costs from a variety of other sources. Evergreen’s estimates are inclusive of transaction and management costs as well as land acquisition price, while WCB’s estimates include only acquisition price. The other data sources likely also include only acquisition price.

Evergreen’s prices are \$700-\$4800/acre for undevelopable land (Table HA-1. For parcels with medium/high development potential and low to high amenity value, prices are \$5K-\$300K/acre for rural residential land, \$60K-\$600K/acre for suburban residential land, and \$300K-\$1.2M/acre for urban land; prices of parcels with very high amenity value are unpredictable (Table HA-2).

Table HA-1. Cost of Undevelopable Land - \$/acre (Source: Evergreen 2003, p. 7)		
Cost estimates pertain to Puget Sound. Estimates include appraisal, closing, commission, surveying, legal, project management costs.		
Proximity to Urban Area	Zoning	
	Forest	Agricultural
Far 41+ mi	\$700-1800	\$1800-2400
Medium 21-40 mi	\$1800-2400	\$2400-3600
Near 0-20 mi	\$2400-4800	\$3600-4800

Table HA-2. Cost of Parcels with Medium-High Development Potential - \$/acre (Source: Evergreen 2003, p. 6)				
Cost estimates pertain to Puget Sound. Estimates include appraisal, closing, commission, surveying, legal, project management costs.				
Zoning	Amenity Value			
	Low	Medium	High	Very High
Rural Residential	\$5K-35K	\$24K-60K	\$60K-300K	\$300K-1.2M
Suburban Residtl	\$60K-120K	\$120K-240K	\$300K-600K	Unpredictable
Urban	\$300K-600K	\$600K-1.2M	Unpredictable	Unpredictable

The prices in Table HA-3 were derived by dividing WCB's expenditures for purchase/easement in each county by the number of acres subject to purchase/easement. These derived prices are \$42 -\$104.7K/acre for easements, and \$267-\$45.5K/acre for acquisitions. The acquisition prices are on the low side relative to Evergreen's estimates of \$5K-\$300K/acre for rural land and \$300K-\$1.2M/acre for urban land, (Table HA-2) and likely underestimate actual costs, as WCB's wildlife habitat acquisitions are often done on a cost-share basis.

Total				

Tables HA-4 and HA-5 include information on habitat type, when available. Several projects involved expenditures on both acquisition and easement where it was not possible to determine how much was spent on each. Such projects were placed in Table HA-4 if most of the acreage involved acquisition and in Table HA-5 if most of the acreage involved easement; cost per acre was estimated by dividing total cost by total acreage (acquisition + easement).

Land acquisition values used by NMFS for the Columbia River Estuary Recovery Plan were \$5K/acre for rural land and \$100K/acre for urban land (Table HA-4, NOAA p5-46). These values are as low or lower than Evergreen's lowest prices for rural and urban land (\$5K/acre and \$300K/acre respectively, Table HA-2). For most other acquisitions described in Table HA-4, prices are ~ \$200-\$20K/acre, with the notable exception of several multi-million-dollar-per-

acre purchases in north/central California and southern California - both highly urbanized areas (Table HA-4: HT07a-T61, p121, NOCECA and SCACO). Prices of conservation easements (Table HA-5) are ~\$300-\$5.7K/acre - with the notable exception of a \$65K/acre easement in Santa Barbara (CntySBPublicWrks).

MD - MONITORING STATUS AND TRENDS (includes monitoring of baseline, status and trends in habitat, watershed processes and/or populations)

Table MD-1 includes monitoring projects funded by CDFG's Fisheries Restoration Grants Program over the past three fiscal years. Information on the nature of monitoring is provided, as available. Most of the projects focus on life history, migration, distribution, and abundance of particular species on particular streams. Costs are ~\$12K-\$300K/project. Most of the >\$200K projects (e.g., 04-05 CDFG-054, CDFG-208, CDFG-260, CDFG-261; 05-06 CDFG-158 and CDFG-159) appear to have a strong analytical as well as monitoring component.

MO - MONITORING WATERSHED RESTORATION

Table MO-1 pertains to implementation monitoring to determine if project treatments were constructed correctly and as planned, effectiveness monitoring to determine if restoration has produced desired habitat conditions and/or watershed processes, validation monitoring to determine if hypothesized responses of habitat, watershed processes and/or populations to restoration were correct.

The descriptions in Table MO-1 pertain to the type of restoration activity being monitored, with the cost estimates pertaining only to the monitoring component. The highest cost (\$221.7K, ERP-97-N13) was for a bank stabilization project involving large-scale monitoring of many variables. Costs associated with monitoring of other individual projects ranged from \$7K (for revegetation project ERP-97-N08) to \$90K (for fish screen evaluation project ERP-97-C02). Several other estimates (\$87.4K for 04-05 CDFG-036, \$142K for 05-06 CDFG-171) involved monitoring of multiple projects funded by CDFG's Fisheries Restoration Grants Program.

Table MO-1. Implementation, Effectiveness and Validation Monitoring - \$/project

Mokelumne River	2002	\$224.9K - songbird response to riparian restoration	ERP-02-P20

PL - WATERSHED EVALUATION, ASSESSMENT AND PLANNING

Table PL-1 provides examples of watershed evaluations/assessments, including partial assessments such as road erosion surveys and stream surveys. Almost all of the examples in the table come from CDFG's Fisheries Restoration Grants Program. Information on the nature of the assessment is provided, as available. Included are road inventory/sediment assessments (costed at \$/mile), stream crossing assessments (costed at \$/crossing), and watershed/estuary plans (costed at \$/acre). According to Weaver/Hagans (WH-p91), the Grants Program allows up to \$1.2K/mile for road assessments; just about all the road assessment examples in Table PL-1 meet this criterion. Stream crossing assessments cost \$650-\$1365/crossing. Most of the watershed plans cost \$8-\$13/acre and appeared to pertain mostly to erosion control. Several exceptions include a project on the Klamath River to address riparian/channel problems (\$76/acre, 05-06 CDFG-115) and two projects involving Humboldt Bay (\$853 and \$3157/acre, 02-03 CDFG-169 & 227). CDFG's Coho Recovery Strategy (CDFG'04, p1.34) uses a planning cost estimate that is not scaled to the size of the plan (\$200K/planning exercise).

Table PL-1. Watershed Evaluation, Assessment and Planning - \$/acre, \$/mile, \$/crossing

WATERSHED ORGANIZATION SUPPORT AND ASSISTANCE (OR)

Table OR-1 includes organizational support projects funded by CDFG's Fisheries Restoration Grant Program during the three most recent fiscal years. These can be roughly divided into two categories:

(1) database maintenance, costed at \$135K-\$152K/project/year. Data requiring maintenance include the California Habitat Restoration Project Database (CHRPD)(04-05 CDFG-033 & 05-06 CDFG-023), passage assessment data (04-05 CDFG-039 & 05-06 CDFG -031), and stream inventory reports (05-06 CDFG-033);

(2) watershed coordination/outreach, costed at \$24K-\$259K/project. The low end of this range (\$24K, 04-05 CDFG-219) pertains to support of a part-time watershed coordinator, while the high end (\$259.1K, 05-06 CDFG-076) pertains to organizational work by a southern California non-profit. CDFG's Coho Recovery Strategy assumes \$60K per educational/technical assistance program (CDFG'04, p.1.35).

Table OR-1. Organizational Support and Assistance - \$/project				
Location	Year	Units	Cost Per Unit	Source
CA	04-05	1 project	\$134.3K - maintenance of CHRPD	CDFG-033
CA		1 project	\$196.7K - passage assessment database	CDFG-039
SmithR		1 project	\$52.0K - watershed coordinator	CDFG-120
HumboldtCnty		1 project	\$95.9K - RCD org support to landowners	CDFG-211
LindsayCrk		1 project	\$24.1K - parttime watershed coordinator	CDFG-219
ShastaValley		1 project	\$137.3K - RCD outreach coordinator	CDFG-230

CA	05-06	1 project	\$151K - maintain CHRPD	CDFG-023
CA		1 project	\$116.9K - passage assessment database	CDFG-031

StaBarb/ Ventura		1 project	\$259.1K - organizational support by Community Environmental Council	CDFG-076
SmithR		1 project	\$103.8K - WatershedCoordinator	CDFG-098
SalmonR		1 project	\$54.2K - org support by Restoration Council	CDFG-256
AptosCrk to ORborder		1 project	\$141.3K - develop sampling frame for salmon monitoring	CDFG-268
CA	2004	typical	\$60K per education/tech assist program	CDFG'04 p1.35

PM - PROJECT MAINTENANCE FOLLOWING PROJECT IMPLEMENTATION

Weaver/Hagans suggest \$275/mile/year for culvert maintenance. Dupont estimates culvert life of 10-30 years, although his estimates pertain to Idaho (not California).

Table PM-1. Culvert maintenance - \$/culvert/year				
Location	Year	Units	Cost Per Unit	Source
CA	2004	typical	Routine culvert replacement/cleaning/fill slope excavation: \$275/mile/year	WH, p101
Idaho	2004	typical	<u>Culvert Type:</u> Iron fish ladder - \$10/yr (30 yrs) Block fish ladder - \$10/yr (10 yrs) Baffled culvert - \$20/yr (30 yrs) Drop structure - \$40/yr (30 yrs)	Dupont-T5 (p62), T6 (p63)

Maintenance of 50 screens on Scott River cost \$1.4K/screen/year. These are probably fairly small screens. Maintenance costs may be higher for larger screens.

Table PM-2. Fish Screen Maintenance - \$/screen/year				
Location	Year	Units	Cost Per Unit	Source
ScottR	01-02	50 screens	\$68,896 (\$1378/screen/year)	CDFG-034

Weaver/Hagans suggest \$25/mile/year for maintenance of forest roads. Estimates for other types of roads could not be found.

Table PM-3. Road Maintenance - \$/mile/year				
Location	Year	Units	Cost Per Unit	Source
CA	2000	typical	Maintenance inspection forest roads: \$25/mi/yr	WH, p101

The only plant thinning example found was specific to farmland. Costs were contingent on the method of thinning (mechanical, hand, chemical).

Table PM-4. Upslope/Riparian Plant Thinnings - \$/project				
Location	Year	Units	Cost Per Unit	Source
CA farmland	FY07	typical	<u>Forest Stand Improvement-Thinning</u> Mechanical: \$850/acre Hand,15-30%slope,40-60%cover: \$900/acre Hand,30-50%slope,60-90%cover: \$1200/acre Chemical: \$150/acre	NRCS CA

RE - COOPERATIVE FISH REARING

Flagg and Nash (1999) make a number of recommendations regarding operation of conservation hatcheries - e.g., select broodstock using appropriate genetic protocols, maintain broodstock on natural photoperiod and water temperatures, provide incubation and rearing environments that mimic conditions in the wild (e.g., overhead cover, instream structures/substrates), reduce rearing densities, vary water-flow velocities, provide “natural” diet composition and feeding rates, provide bottom feed delivery systems, rear fish in water from the intended return location, release hatchery smolts at sizes similar to wild smolts, provide for volitional releases that do not exceed carrying capacity, have multiple broodstock facilities to protect against local disasters (e.g., equipment failure), establish appropriate monitoring and evaluation strategies. They conclude that “Implementation of such [conservation hatchery] programs would require significant capital expenditure, with increased hatchery operating costs and reduced fish production. Some increased costs would be offset by conservation hatcheries releasing smaller numbers of highly adaptable fish.”

Construction and operational costs of a conservation hatchery depend on a variety of factors - e.g., whether the hatchery is newly constructed or a modification of an existing hatchery, which of the Flagg/Nash recommendations are implemented at the hatchery and the particular facilities and protocols needed for such implementation, scale of hatchery production, the particular species at the hatchery (since rearing time varies among species).

The Kingfisher Flat Hatchery on Big Creek operates an artificial propagation program to supplement depressed wild coho runs. The hatchery receives about \$95K/year from the CDFG Fisheries Restoration Grants Program (Table RE-1). The extent to which the \$95K reflects the cost of the hatchery’s coho conservation program is difficult to determine, given that (1) the hatchery engages in other activities as well (e.g., chinook rearing), (2) the hatchery relies heavily on volunteer labor and also receives funding from other sources, (3) the SWFSC Santa Cruz’s captive broodstock program provides gametes to the Kingfisher facility to increase coho genetic diversity (at no cost to the hatchery).

Table RE-2 describes capital and operating costs for a number of Columbia River hatcheries that are larger than Kingfisher Flat. While some of these hatcheries engage in some conservation activities, they are largely production hatcheries. Information provided in Table RE-2 is intended to give a very rough idea of hatchery costs.

Table RE-1. Hatchery Operation				
Location	Year	Cost	Production	Source
Kingfisher Flat Hatchery	04-05	\$94.3K/year	~240K chinook smolts, 45K steelhead smolts, 100s coho smolts	CDFG-281
Kingfisher Flat Hatchery	05-06	\$99K/year	~240K chinook smolts, 45K steelhead smolts, 100s coho smolts	CDFG-276

Table RE-2. Columbia River Hatcheries (Source: IEAB 2002)

Name/ Operator	Cost		Production Goal
	Annual Cost: Annualized Capital (Cap)*, O&M, M&E	\$/Released Fish

Irrigon/ ODFW	\$1.95M=\$794K (Cap) +\$1.156K (O&M)	\$1.30	1.7M summer steelhead smolts
McCall/ Idaho DFW	\$899K=\$418K (Cap) +\$481K (O&M)	\$1.09	8K adult summer chinook
* Annual capital costs, calculated as the original construction cost amortized over 50 years at 3%.			

WILDLIFE MANAGEMENT

The average cost per pikeminnow harvested in the Columbia River bounty program is \$6.05/fish. Whether this cost estimate would be similarly applicable to a California eradication program would depend on the nature and scale of the program and the extent of angler interest and success in harvesting pikeminnow.

Table WM-1. Invasive Aquatic Species (e.g., pike minnow eradication)			
Location	Year	Cost Per Unit	Source
CoIR	2005	Annual program cost (rewards+tags): \$1,546,232 Avg \$6.05/fish (= \$1,460,724 total rewards/241,357 total fish harvested)	Porter, p41

RES - RESEARCH - productivity research (life cycle monitoring/analysis), spatial structure (fish distribution surveys), genetic diversity (laboratory analysis of tissue samples), and abundance estimates

Columns 2-3 of Table RES-1 describe start-up and annual costs of monitoring activities identified by CDFG/NMFS in several recent workshops. Several caveats in interpreting the cost estimates: (1) The estimates pertain only to coastal salmonids (i.e., exclude Central Valley), (2) the estimates are incremental in that they represent what is needed over and above what is currently being spent for coastal salmonid monitoring, and (3) the estimates assume that all labor is paid (no volunteers).

Monitoring costs are provided here because monitoring data are essential to conducting research on VSP (viable salmon population) attributes. Columns 4-7 of Table RES-1 identify which types of data are relevant to evaluating which VSP attribute. Because some of the data requirements relate to multiple VSP attributes, it is impractical to devise separate costs for each attribute.

As reflected in Table RES-1, the monitoring program is intended to follow different strategies in northern and southern areas. The northern area is defined as the Oregon border to Aptos Creek (five ESUs); the southern area is defined as the Pajara River southward (two ESUs). The boundaries of the two monitoring areas do not coincide with the boundaries of the recovery domains. However, it may be possible to allocate monitoring costs among domains (e.g., on the basis of proportion of total salmonid stream miles within each domain).

The costs noted in Table RES-1 are incomplete with regard to overall coastal salmonid research needs. Other activities mentioned in Boydston and McDonald (2005) include: (1) habitat condition monitoring, (2) augmented samples for genetic monitoring, (3) other biological monitoring (e.g., otoliths, adult gender, length-weight samples), and (4) laboratory and computer analysis of data.

Table RES-1. Monitoring Activities and Costs as They Relate to Specific VSP Attributes
Source: Boydston & McDonald 2005 - pp 54-55 & Table8/p 58.

Monitoring Activity	Estimated Cost		VSP Attribute			
	Startup	Annual	Abundance	Distribution	Genetic Diversity	Productivity
Northern spawner survey (OR border-Aptos Creek)	\$566K	\$2,545K	X	X	W/additnal sampling	X
Southern steelhead monitoring (PajaroR southward)	\$65K	\$541K	X			X
Life cycle monitoring stations (2 stns per coastal recovery domain)	\$1,036K	\$1,370K				X
Juvenile salmonid surveys	\$177K	\$1,307K	Cutthroat only*	X	W/additnal sampling	Cutthroat only*
25% hatchery fish marking (additional marking needed @ Iron Gate & Rowdy Creek only)	\$0	\$69K				X
Angler creel survey SmithR-SLO Creek, except Klamath/Trinity chinook/coho (already monitored by CDFG)	\$14K	\$369K				X
Administrative/special studies	\$36K	\$789K				

* Assume monitoring from Eel River to Smith River and 30 miles inland.
