DISCLAIMER

Recovery plans delineate such reasonable actions as may be necessary, based upon the best scientific and commercial data available, for the conservation and survival of listed species. Plans are published by the National Marine Fisheries Service (NMFS), sometimes prepared with the assistance of recovery teams, contractors, State agencies and others. Recovery plans do not necessarily represent the views, official positions or approval of any individuals or agencies involved in the plan formulation, other than NMFS. They represent the official position of NMFS only after they have been signed by the Assistant Administrator. Recovery plans are guidance and planning documents only; identification of an action to be implemented by any public or private party does not create a legal obligation beyond existing legal requirements. Nothing in this plan should be construed as a commitment or requirement that any general agency obligate or pay funds in any one fiscal year in excess of appropriations made by Congress for that fiscal year in contravention of the Anti-Deficiency Act, 31 U.S.C 1341, or any other law or regulation. Approved recovery plans are subject to modification as dictated by new findings, changes in species status, and the completion of recovery actions.

LITERATURE CITATION:

ACKNOWLEDGEMENTS

The authors would like to thank and acknowledge participants in the Central Valley Technical Recovery Team, in particular Steve Lindley, whom provided much of the technical information used in the development of this Recovery Plan, and the Sacramento Area Water Forum for providing technical assistance. We also would like to acknowledge the staff of the Southwest Regional office of the National Marine Fisheries Service including Naseem Alston, Gretchen Umlauf, Howard Brown, Brian Ellrott, Nancy Fisher, Letia Gathright, Madelyn Martinez, Shawn Martin, Jeff McLain (currently with USFWS), Bruce Oppenheim, Maria Rea, Rosalie del Rosario, Erin Strange, Eric Theiss, Mike Tucker, Shirley Witalis, Rhonda Reed, Karen McCartney, Ken Cumming, Steve Hillyer, Garwin Yip, Monica Gutierrez, Chris Kwan, and Diane Windham for their contributions in preparation of this plan. This recovery plan could not have been completed without the hard work of HDR/SWRI staff including Paul Bratovich, Dianne Simodynes, Morgan Neal, John Cornell, Carol Brown, and Adrienne Moore.

The authors also would like to extend recognition to all of the many individuals who have worked over the years to conserve and protect anadromous salmonids and their habitat in the Central Valley. This recovery plan builds on the dedication of these individuals and their efforts to preserve an invaluable natural resource.

EXECUTIVE SUMMARY

Introduction: Implementation of this Recovery Plan for endangered Sacramento River winter-run Chinook salmon Evolutionarily Significant Unit (ESU), threatened Central Valley spring-run Chinook salmon (ESU), and threatened Central Valley steelhead Distinct Population Segment (DPS) is necessary to improve the viability of these species such that they can be removed from Federal protection under the Endangered Species Act. This Recovery Plan serves as a roadmap that describes the steps, strategy, and actions that must be taken to return winter-run Chinook salmon, spring-run Chinook salmon, and steelhead to viable status in the Central Valley, California thereby ensuring their long-term (time scales greater than 100 years) persistence and evolutionary potential.

Background: The rivers draining the Great Central Valley of California (“Central Valley”) and adjacent Sierra Nevada and Cascade Range once were renowned for their production of large numbers of Pacific salmon (Clark 1929; Skinner 1962 in Yoshiyama *et al.* 1998). The Central Valley system historically has been the source of most of the Pacific salmon produced in California waters (CDFG 1950, 1955; Fry and Hughes 1951; Skinner 1962; CDWR 1984 in Yoshiyama *et al.* 1998). Chinook salmon (*Oncorhynchus tshawytscha*) historically were, and remain today, the only abundant salmon species in the Central Valley system (Eigenmann 1890; Rutter 1908 in Yoshiyama *et al.* 1998), although small numbers of other salmon species also have occurred occasionally in its rivers (Collins 1892; Rutter 1904a, 1908; Hallock and Fry 1967; Moyle *et al.* 1995 in Yoshiyama *et al.* 1998). Anadromous steelhead (*O. mykiss*) apparently were common in Central Valley tributaries (USFC 1876; Clark 1973; Latta 1977; Reynolds *et al.* 1993 in Yoshiyama *et al.* 1998), but records for them are few and fragmented, partly because they did not support commercial fisheries (Yoshiyama *et al.* 1998).

Since European settlement of the Central Valley in the mid-1800s, populations of native Chinook salmon and steelhead have declined dramatically. California's salmon resources began to decline in the late 1800s, and continued to decline in the early 1900s, as reflected in the decline of Chinook salmon commercial harvest. The total commercial catch of Chinook salmon in 1880 was 11 million pounds, by 1922 it had dropped to seven million pounds, and reached a low of less than three million pounds in 1939 (Lufkin 1996).

In addition to commercial harvest of Chinook salmon, another major factor affecting anadromous salmonids during this period was hydraulic gold mining, which began in the 1850s. By 1859, an estimated 5,000 miles of mining flumes and canals diverted streams used by salmonids for spawning and nursery habitat. Habitat alteration and destruction also resulted from the use of hydraulic cannons, hydraulic and gravel mining, which leveled hillsides and sluiced an estimated 1.5 billion yd³ of debris into the streams and rivers of the Central Valley (Lufkin 1996).

Despite the prohibition of hydraulic mining in 1894, habitat degradation continued. Habitat quantity and quality have declined due to: construction of levees and barriers to migration, modification of natural hydrologic regimes by dams and water diversions, elevated water temperatures, and water pollution from agriculture and industry (Lufkin 1996).

Although the effects of habitat degradation on fish populations were evident by the 1930s, rates of decline for most anadromous fish species increased following construction of major water project facilities (USFWS 2001), which primarily occurred around the mid- 1900s. Many of these water development projects completely blocked the upstream migration of Chinook salmon and steelhead to spawning and rearing habitats, and altered flow and water temperature regimes downstream from terminal dams. As

urban and agricultural development of the Central Valley continued, numerous other stressors to anadromous salmonids emerged and continue to affect the viability of these fish today. Four of the more important stressors include: barriers to historic habitat, the continued commercial and recreational harvest of Chinook salmon, predation of Chinook salmon and steelhead from introduced species such as striped bass and black bass, and the high demand for limited water supply resulting in reduced instream flows, increased water temperatures and highly altered hydrology in the Sacramento-San Joaquin Delta.

Recovery Strategy: A broadly focused framework is necessary to serve as a strategic planning guide to integrate the actions contributing to the overarching goal of recovery of the two Chinook salmon ESUs and the steelhead DPS. Because of the complexity associated with the multi-faceted considerations for Central Valley recovery efforts, this strategic planning framework incorporates: (1) viability at both the ESU/DPS and population levels; (2) prioritizing watersheds currently occupied by at least one of the three listed species into three tiers - core 1, 2, or 3; and (3) prioritizing unoccupied watersheds for re-introductions.

Bridging the gap between the ESU/DPS and population levels are population groups or salmonid ecoregions, which are delineated based on climatological, hydrological, and geological characteristics. The Central Valley Technical Recovery Team's (TRT) identification of four population groups (hereafter referred to as diversity groups) that Chinook salmon historically inhabited in the Central Valley are as follows:

- ❑ The **basalt and porous lava diversity group** composed of the upper Sacramento River and Battle Creek watersheds;
- ❑ The **northwestern California diversity group** composed of streams that enter the mainstem Sacramento River from the northwest;
- ❑ The **northern Sierra Nevada diversity group** composed of streams tributary to the Sacramento River from the east, and including the Mokelumne River; and
- ❑ The **southern Sierra Nevada diversity group** composed of streams tributary to the San Joaquin River from the east.

Historically, the Sacramento River winter-run Chinook salmon ESU was composed of four populations within the basalt and porous lava diversity group and the Central Valley spring-run Chinook salmon ESU was represented in all four of the diversity groups, with as many as 18 or 19 total populations. In addition to the four previously mentioned diversity groups, the Central Valley steelhead DPS has two more historic diversity groups: the Suisun Bay region which consists of tributaries to or near Suisun Bay and the Central Western California region, which contains west-side San Joaquin Valley tributaries. It is hypothesized that historically 81 independent populations of steelhead were dispersed throughout the six diversity groups.

Currently, the Sacramento River winter-run Chinook salmon ESU is composed of a single population which is dependent on hatchery production and the Central Valley spring-run Chinook salmon ESU is composed of three diversity groups with fish exhibiting spring-run Chinook salmon life histories occurring in 12 watersheds. Only three of those 12 watersheds contain viable spring-run Chinook salmon populations. The current distribution of steelhead is less well understood, but the DPS is composed of at least four diversity groups and at least 26 populations.

Three priority levels have been established to help guide recovery efforts for watersheds that are currently occupied by at least one of the three listed Chinook salmon and steelhead species. Of highest priority are Core 1 populations, which have been identified based on a variety of factors, including: (1) the known ability or significant immediate potential to support independent populations; (2) the role of the population in meeting the spatial and/or redundancy viability criteria; (3) the severity of the threats facing the populations; (4) the potential ecological or genetic diversity the watershed and populations could provide to the species; and (5) the capacity of the watershed and population to respond to the critical recovery actions needed to abate those threats. Core 1 populations form the foundation of the recovery strategy and must meet the population-level biological recovery criteria for low risk of extinction set out in Table 4-1. NMFS believes that this set of Core 1 populations should be the first focus of an overall recovery effort. Core 2 population areas also form part of the recovery strategy by contributing to the highest potential to support geographically diverse populations. Core 2 populations must meet the biological recovery criteria for moderate risk of extinction set out in Table 4-1. These populations are of secondary importance in terms of recommended priority of recovery efforts. Finally, the complete attainment of ESU/DPS-level biological recovery criteria will likely also require the presence of populations listed as Core 3. Core 3 populations are present on an intermittent basis and are characterized as being dependent on other nearby populations for their existence. The presence of these populations provides increased life history diversity to the ESU/DPS and is likely to buffer against local catastrophic occurrences that could affect other nearby populations. Dispersal connectivity between populations and genetic diversity may be enhanced by working to recover smaller Core 3 populations that serve as stepping stones for dispersal.

Addressing the primary threats and risk factors for each of the ESU and DPS's will require reintroducing populations to historic, and currently unoccupied habitats. Candidate areas for reintroduction have been identified and prioritized as either primary or secondary. Efforts to reintroduce fish to these areas will be challenging, expensive, and will require unparalleled efforts to gain stakeholder support. We prioritized these areas based on watershed-specific information, which is summarized in Chapter 5 (Recovery Scenarios) and described in more detail in Appendix A (Watershed Profiles). Some areas that were historically accessible to anadromous salmonids have been excluded from consideration for reintroductions because they are so critically impaired by hydroelectric development and channel inundation that we felt efforts should be focused on areas with a higher potential for success.

Recovery will be expensive and time-consuming, and will require changes in the management and monitoring of aquatic resources and habitats. Successful implementation of this recovery plan will require the support, efforts and resources of many entities, from Federal and state agencies to individual members of the public. Because of these challenges, the Recovery Plan requires an achievable strategy to select and implement recovery actions.

This Recovery Plan establishes a strategic approach to recovery. Because recovery of the two Chinook salmon ESUs and the steelhead DPS will require implementation over an extended period of time, a stepwise strategy has been adopted, based on the threats assessment process and identification of priority threats, which first addresses more urgent near-term needs, upon which to build toward full recovery. As this Recovery Plan is implemented over time, additional information will become available to help determine whether the threats have been abated, to further develop understanding of the linkages between threats and Chinook salmon and steelhead population responses, to identify any additional threats, and to evaluate the viability of Chinook salmon and steelhead in the Central Valley.

The general near-term strategic approach to recovery includes the following elements:

- ❑ *Secure all extant populations.* Both ESUs and the DPS are far short of being viable, and extant populations, even if not presently viable, will likely be needed for recovery. The Central Valley TRT recommends that every extant population be viewed as necessary for the recovery of the ESU and DPS. Wherever possible, the status of extant populations should be improved.
- ❑ *Begin collecting distribution and abundance data for *O. mykiss* in habitats accessible to anadromous fish.* This is fundamental to designing effective recovery actions and eventual delisting. Of equal importance is assessing the relationship of resident and anadromous forms of *O. mykiss*, including the role the resident fish play in population maintenance and persistence.
- ❑ *Minimize straying from hatcheries to natural spawning areas.* Even low levels of straying from hatchery populations to wild ones works against the goal of maximizing diversity within ESUs and populations. A number of actions could reduce straying from hatcheries to natural areas, including replacing off-site releases with volitional releases from the hatchery, allowing all fish that attempt to return to the hatchery to do so, marking or tagging programs that could be used to separate wild and hatchery stocks, and reducing the amount of fish released (see CDFG and NMFS (2001), for a review of hatchery issues).
- ❑ *Conduct critical research on fish passage above rim dams, reintroductions, and climate change.* Current climate change information suggests that the Central Valley will become warmer, a challenging prospect for Chinook salmon and steelhead – both of which are coldwater fish at the southern end of their distribution. To recover Central Valley salmon ESUs and the steelhead DPS, some populations will need to be established in cooler, high elevation areas now blocked by dams or insufficient flows. Assuming that most of these dams will remain in place for the foreseeable future, it will be necessary to facilitate the movement of fish around the dams in both directions. The near-term will include assessing habitat suitability and passage logistics.
- ❑ *Listed salmonid ESUs are likely to be conservation-reliant* (Scott *et al.* 2005). It seems highly unlikely that enough habitat can be restored in the foreseeable future such that Central Valley salmonid ESUs (and DPS) could be expected to persist without continued conservation management. Rather, it may be possible to restore enough habitat such that ESUs (and DPS) can persist with appropriate management, which should focus on maintaining ecological processes at the landscape level.

The long-term approach to recovery includes the following elements:

- ❑ Ensure that every extant diversity group has a high probability of persistence.
- ❑ Until all ESU viability criteria have been achieved, no population should be allowed to deteriorate in its probability of persistence.
- ❑ High levels of recovery should be attempted in more populations than identified in the diversity group viability criteria because not all attempts will be successful.
- ❑ Individual populations within a diversity group should have persistence probabilities consistent with a high probability of diversity group persistence.

- ❑ Within a diversity group, the populations restored/maintained at viable status should be selected to:
 - Allow for normative meta-population processes, including the viability of core populations, which are defined as the most productive populations.
 - Allow for normative evolutionary processes, including the retention of the genetic diversity, as well as an increase in genetic diversity through the addition of viable populations in historic habitats.
 - Minimize susceptibility to catastrophic events.

In addition to the general near- and long-term strategies, applying the viable salmonid population guidelines and recovery criteria presented in this recovery plan results in specific recovery needs for each species. In summary, a program that ultimately results in re-establishing at least two viable populations within each diversity group will be needed to recover winter-run, spring-run, and steelhead. Some flexibility around this criteria is warranted as is explained in the Recovery Scenario chapter, which gives top-down, conceptual descriptions of what a recovered ESU/DPS would look like for each of the three species.

Recovery Goals, Objectives, and Criteria: The overarching goal of this Recovery Plan is the removal of the Sacramento River winter-run Chinook salmon ESU, Central Valley spring-run Chinook salmon ESU, and Central Valley steelhead DPS in the Central Valley Domain from the Federal List of Endangered and Threatened Wildlife (50 C.F.R. 17.11). The objectives and criteria to accomplish this goal builds upon the technical input and guidance provided by the Central Valley TRT, and much of the following discussion is taken directly from information developed by the TRT (Lindley et al. 2004; 2006; 2007).

In order for the Chinook salmon ESUs and the steelhead DPS to achieve recovery, each Diversity Group must be represented, and population redundancy within the groups must be met to achieve Diversity Group recovery. Therefore, Diversity Group criteria include:

- ❑ Three viable populations of winter-run Chinook salmon within the winter-run Chinook salmon Diversity Group at low risk of extinction;
- ❑ A minimum of two viable populations of spring-run Chinook salmon within each of the four spring-run Chinook salmon Diversity Groups, with the exception of the Northwestern California Diversity Group which historically did not contain independent spring-run Chinook salmon populations. For the Northwestern California Diversity Group, observed occupancy will suffice rather than viability, as defined; and
- ❑ A minimum of two viable populations of steelhead within each of the four extant steelhead Diversity Groups (i.e., the Basalt and Porous Lava Diversity Group, the Northwestern California Diversity Group, the Northern Sierra Nevada Diversity Group and the Southern Sierra Nevada Diversity Group)

Recovery criteria at the population level were established by the Central Valley TRT and are included in this recovery plan (and apply to all three species), as described in Lindley *et al.* (2007). The TRT incorporated the four viable salmonid population parameters (McElhany *et al.* 2000) into assessments of

population viability, and two sets of population viability criteria were developed, expressed in terms of extinction risk. The first set of criteria deal with direct estimates of extinction risk from population viability models. If data are available and such analyses exist and are deemed reasonable for individual populations, such assessments may be efficient for assessing extinction risk. In addition, the Central Valley TRT also provided simpler criteria. The simpler criteria include population size (and effective population size), population decline, catastrophic rate and effect, and hatchery influence. For a population to be considered at low risk of extinction (i.e., < 5 percent chance of extinction within 100 years), the population viability assessment must demonstrate that risk level or all of the following criteria must be met:

- ❑ The effective population size must be > 500 or the population size must be > 2,500
- ❑ The population growth rate must show that a decline is not apparent or probable
- ❑ There must be no apparent or minimal risk of a catastrophic disturbance occurring
- ❑ Hatchery influence must be low, as determined by levels corresponding to different amounts, durations and sources of hatchery strays

Additionally, qualitative threat abatement criteria must be met demonstrating that specific threats have been addressed and alleviated. These threat abatement criteria are established to address threats to, or resulting from, spawning grounds, habitat quality and quantity, overutilization, disease or predation, inadequate regulatory mechanisms, artificial propagation, climate change, water diversions, and non-indigenous aquatic nuisance species.

Recovery Scenarios: Conceptual recovery scenarios for each species (i.e., winter-run, spring-run, and steelhead) are presented in Chapter 5 of this Recovery Plan to provide initial descriptions of what a recovered ESU/DPS would look like. These ESU/DPS-level recovery scenarios have been developed based on ESU/DPS, population, and ecological considerations to identify a combination of populations and population and habitat status levels that meet biological and threat abatement recovery criteria. The scenarios represent some of the many possible combinations of populations, restoration actions, risk minimization and threat abatement.

Considerations for ESU/DPS viability depends on the number of populations within the ESU/DPS, their individual status, their spatial arrangement with respect to each other and sources of catastrophic disturbance, and diversity of the populations and their habitats. In the most general terms, ESU/DPS viability increases with the number of populations, the viability of these populations, the diversity of the populations, and the diversity of habitats that they occupy (Lindley et al 2007).

The Central Valley TRT described the historical populations of Sacramento River winter-run Chinook salmon and Central Valley spring-run Chinook salmon ESUs in the Central Valley (Lindley et al. 2004). They considered geography, migration rates, genetic attributes, life history diversity, population dynamics, and environmental characteristics in grouping the populations into independent populations and dependent populations. For the Central Valley steelhead DPS, Lindley et al. (2006) identified historical independent populations based on a model that identifies discrete habitat and interconnected habitat patches isolated from one another by downstream regions of thermally unsuitable habitat.

In addition to ESU/DPS and population viability, structure and distribution considerations, the conceptual recovery scenarios incorporate ecological or habitat objectives for each Diversity Group:

- ❑ The recovery scenario must address the entire natural ecosystem
- ❑ The recovery scenario should reflect that viable ESUs/DPSs and populations require a network of complex and interconnected habitats, which are created, altered, and maintained by natural physical process
- ❑ The spatial distribution and productive capacity of freshwater and estuarine habitats should be sufficient to maintain viable populations identified for recovery
- ❑ The diversity of habitats for recovered populations generally should resemble historic conditions given expected natural disturbance regimes (wildfire, flood, volcanic eruptions, etc.). Historic conditions represent a reasonable template for a viable population - the closer the habitat resembles the historic diversity, the greater the confidence in its ability to support viable populations
- ❑ At a large scale, habitats should be protected and restored, with a trend toward an appropriate range of attributes for salmonid viability

The conceptual recovery scenarios were developed with consideration of the biological significance and recovery feasibility of each population. Biological significance was based on current status, potential for improvement, historical significance, proximity to other selected populations with reference to catastrophic risks, and spatial distribution between independent and dependent populations. Feasibility of recovery was based on expected progress as a result of existing programs, absence of apparent impediments toward recovery, and other management considerations (e.g. fish passage potential).

As this Recovery Plan is implemented over time, additional information will become available to help determine whether the threats have been abated, to further develop understanding of the linkages between threats and Chinook salmon and steelhead population responses, identify any additional threats, and to evaluate the viability of Chinook salmon and steelhead in the Central Valley. Monitoring and adaptive management in the course of implementation of this Recovery Plan will provide more information on the feasibility of recovering the winter- and spring-run Chinook salmon ESUs and the steelhead DPS in the Central Valley Domain. Such information is expected to lead to adjustments in recovery expectations and restoration actions and, thus, recovery scenarios.

Recovery Actions: Many complex and inter-related biological, economical, social, and technological issues must be addressed in order to recover anadromous salmonids in the Central Valley. Policy changes at the Federal, State and local levels will be necessary to implement many of the recovery actions identified in this Recovery Plan. For example, without substantial strides in habitat restoration, fish passage, and changes in water use, recovery will be difficult if not impossible. In many cases, such as the Sacramento-San Joaquin Delta, an improved governance structure is needed to consolidate, streamline and focus the many, often conflicting, regulatory and land use mandates that influence water and habitat management, and species status and recovery. Most importantly, achieving a recovered species status is not likely without a focused effort to secure core populations, reintroduce fish to priority watersheds (where the majority of historic spawning habitat is located), and to restore the ecological function of the interconnected habitats upon which the species depend for their survival.

Implementation and Cost Estimates: It is a challenging undertaking to facilitate a change in practice and policy that reverses the path towards extinction of a species to one of recovery. This change can only be accomplished with effective outreach and education, strong partnerships, focused recovery strategies and solution-oriented thinking that can shift agency and societal attitudes, practices and understanding. Implementation of the recovery plan by NMFS will take many forms and is described in the NMFS Protected Resources Division Strategic Plan 2006 (NMFS 2006a). The Recovery Planning Guidance (NMFS 2006b) also outlines how NMFS shall cooperate with other agencies regarding plan implementation. These documents, in addition to the ESA, shall be used by NMFS to set the framework and environment for plan implementation. The PRD Strategic Plan asserts that species conservation (in implementing recovery plans) by NMFS will be more strategic and proactive, rather than reactive. To maximize existing resources with workload issues and limited budgets, the PRD Strategic Plan champions organizational changes and shifts in workload priorities to focus efforts towards “...those activities or areas that have biologically significant beneficial or adverse impacts on species and ecosystem recovery (NMFS 2006a).” The resultant shift will reduce NMFS engagement on those activities or projects not significant to species and ecosystem recovery.

NMFS actions to promote and implement recovery planning shall include:

- ❑ Formalizing recovery planning goals on a program-wide basis to prioritize work load allocation and decision-making (to include developing the mechanisms to make implementation (e.g., restoration) possible)
- ❑ Conducting an aggressive outreach and education program.
- ❑ Facilitating a consistent framework for research, monitoring, and adaptive management that can directly inform recovery objectives and goals.
- ❑ Establishing an implementation tracking system that is adaptive, web-based (internet), and pertinent to support the annual reporting for the Government Performance and Results Act, Biennial Recovery Reports to Congress and the 5-Year Status Reviews.

NMFS’ efforts must be as far-reaching (beyond those under the direct regulatory jurisdiction of NMFS) as the issues adversely affecting the species. Thus, to achieve recovery, NMFS will need to promote the recovery plan and provide needed technical information and assistance to other entities that implement actions that may impact the species’ recovery. For example, NMFS will work with key partners on high priorities such as facilitating passage assessment and working with Counties to ensure protective measures consistent with recovery objectives are included in their General Plans.

An implementation schedule describing time frames and costs associated with individual recovery actions has been developed and is included in this Recovery Plan. Cost estimates for near-term and longer-term recovery actions have been provided wherever possible. Cost estimates have not been identified for all actions due to uncertainties associated with new types of actions that have not been implemented before. Total cost to recovery is challenging to reliably estimate because the biological response of recovery actions is uncertain, achieving recovery will be a long-term effort likely requiring at least a few decades, and new stressors may emerge over time. However, it is estimated that the cost for implementing recovery actions will range from \$1.04 to 1.26 billion over the next 5 years, and over \$10 billion over the next 50 years.

Viable Salmonid Population

1.0 Introduction

"Salmon was now abundant in the Sacramento. Those which we obtained were generally between three and four feet in length, and appeared to be of two distinct kinds. It is said that as many as four different kinds ascend the river at different periods. The great abundance in which this fish is found gives it an important place among the resources of the country."

- Captain John C. Frémont, memoirs for 30 March-5 April 1846 in Yoshiyama et al. 1998

The rivers draining the Great Central Valley of California ("Central Valley") and adjacent Sierra Nevada and Cascade Range once were renowned for their production of large numbers of Pacific salmon (Clark 1929; Skinner 1962 in Yoshiyama et al. 1998). The Central Valley system historically has been the source of most of the Pacific salmon produced in California waters (CDFG 1950, 1955; Fry and Hughes 1951; Skinner 1962; CDWR 1984 in Yoshiyama et al. 1998).

Chinook salmon (*Oncorhynchus tshawytscha*) historically were, and remain today, the only abundant salmon species in the Central Valley system (Eigenmann 1890; Rutter 1908 in Yoshiyama et al. 1998), although small numbers of other salmon species also have occurred occasionally in its rivers (Collins 1892; Rutter 1904a, 1908; Hallock and Fry 1967; Moyle et al. 1995 in Yoshiyama et al. 1998). Anadromous steelhead (*O. mykiss*) apparently were common in Central Valley tributaries (USFC 1876; Clark 1973; Latta 1977; Reynolds et al. 1993 in Yoshiyama et al. 1998), but records for them are few and fragmented, partly because they did not support commercial fisheries (Yoshiyama et al. 1998).

Anadromous salmonids, in particular Chinook salmon, have and continue to be an important resource, both revered and harvested by humans. The Native American people depended upon these fishes for subsistence, ceremonial, and trade purposes. Prior to Euro-American settlement, Native Americans within the Central Valley drainage harvested Chinook salmon at estimated levels that reached 8.5 million pounds or more annually (Yoshiyama et al. 1998). With the advent of the California gold rush in the mid-1800s, a commercial Chinook salmon fishery developed in the San Francisco Bay and Sacramento-San Joaquin Delta ("Delta") region. Annual catches by the early in-river fisheries commonly reached 4-10 million pounds. The first west coast salmon cannery opened on a scow moored near Sacramento in 1864. Within 20 years, 19 canneries were operating in the Delta region, and processed a peak of 200,000 cases (each case comprised of 48, 1-pound cans) in 1882 (Lufkin 1996). The salmon fishery remained centered in the Delta region until the early 1900s, when ocean salmon fishing began to expand and eventually came to dominate the fishery.

1.1 The Great Central Valley of California

The northern half of the Central Valley is comprised of the Sacramento River Basin (covering approximately 24,000 square miles [mi²]), with the southern half (covering approximately 13,540 mi²) primarily composed of the San Joaquin River Basin (**Figure 1-1**). The broad expanse of the Central Valley region of California once encompassed numerous salmon-producing streams that drained the Sierra Nevada and Cascade mountains on the east and north and, to a lesser degree, the lower-elevation Coast Range on the west. The large areal extent of the Sierra Nevada and Cascades watersheds, coupled with regular, heavy snowfalls in those regions, provided year-round streamflows for a number of large rivers which supported substantial runs of Chinook salmon (Yoshiyama *et al.* 1998).

Figure 1-1. Central Valley Region of California

In the Sacramento River Basin, most Coast Range streams historically supported regular salmon

runs, although their runs were limited by the volume and seasonal availability of streamflows due to the lesser amount of snowfall west of the valley (Yoshiyama *et al.* 1998). In the San Joaquin River Basin, a number of major streams (e.g., the Merced, Tuolumne, and upper San Joaquin rivers) sustained very large salmon populations, while other streams with less regular streamflows had intermittent salmon runs in years when rainfall provided sufficient flows. All of the westside San Joaquin River Basin streams flowing from the Coast Range were highly intermittent (Elliott 1882) and none are known to have supported anadromous salmonids (Yoshiyama *et al.* 1998).

1.2 Salmon & Steelhead at Risk

Since settlement of the Central Valley in the mid-1800s, populations of native Chinook salmon and steelhead have declined dramatically. California's salmon resources began to decline in the late 1800s, and continued to decline in the early 1900s, as reflected in the decline of commercial harvest. The total commercial catch of Chinook salmon in 1880 was 11 million pounds, by 1922 it had dropped to 7 million pounds, and reached a low of less than 3 million pounds in 1939 (Lufkin 1996).

History and Current Status of Commercial Harvest

Although Chinook salmon remain an important resource, fishing for salmon has changed, most notably, in the last 20 years. 28 evolutionarily significant units (ESU'S) and distinct population segments (DPS's) of salmonids have been listed under the Endangered Species List by the National Marine Fisheries Service (NMFS) on the West Coast of the United States since 1989. This is significant because commercial ocean harvest and sport fishing for salmon, has undergone dramatic management and regulatory implementations in order to continue with the commercial fishery while at the same time finding and implementing an exploitation rate that enables sustained Chinook populations into the future. It is also now possible for the ocean fishery to be managed for specific river fisheries through genetic

sampling of the ocean harvest along the Pacific Coast. This change has altered the way ocean harvest is carried out, and further protects critical species in that life stage.

New matrixes developed by the National Oceanic and Atmospheric Administration (NOAA) Pacific Northwest Region emphasize that commercial fishing or ocean harvest is a critical parameter in the decisions used to manage sustainable fisheries or to reestablish enough returning numbers of fish to create reasonable escapement.

The National Marine Fisheries Service establishes fishery management measures in the Pacific Ocean for Chinook salmon to prevent overfishing of this species. The current management measures serve to:

- ❑ apportion ocean harvest equitably among treaty Indian, non-treaty commercial and recreational fisheries
- ❑ provide in-season adjustment flexibility so that the fishing can provide for spawning escapement that meets replacement curves
- ❑ provide in-season adjustments to manage for ESA listed species.

Sources of Habitat Decline

In addition to commercial harvest, another major factor affecting Chinook salmon and steelhead during this period was hydraulic gold mining, which began in the 1850s. By 1859, an estimated 5,000 miles of mining flumes and canals diverted streams used by salmonids for spawning and nursery habitat. Habitat alteration and destruction also resulted from the use of hydraulic cannons, which leveled hillsides and sluiced an estimated 1.5 billion yd³ of debris into the streams and rivers of the Central Valley (Lufkin 1996).

Since hydraulic mining was prohibited in 1894, habitat degradation continued. Habitat quantity and quality have declined due to construction of levees and barriers to migration, modification of natural hydrologic regimes by dams and water diversions, elevated water temperatures, and

water pollution (Lufkin 1996). Although the effects of habitat degradation on fish populations were evident by the 1930s, rates of decline for most anadromous fish species increased following completion of major water project facilities (USFWS 2001) which primarily occurred around the mid- 1900s.

Numerous water development projects blocked the upstream migration of Chinook salmon and steelhead, and altered flow and water temperature regimes downstream from terminal dams. An extensive network of reservoirs and aqueducts has been developed throughout much of California to provide water to major urban and agricultural areas. The largest system of surface reservoirs and aqueducts in California is in the Central Valley. Surface reservoirs collecting runoff in the Central Valley have a combined total capacity of about 29 million acre-feet. The two largest water projects in the Central Valley, the State Water Project (SWP) and the Federal Central Valley Project (CVP), provide a combined average total of about 10 million acre-feet of water annually for urban and agricultural uses (DWR 2006). More than 20 million Californians rely on the SWP and the CVP for at least part of their water supply, and these projects irrigate an average of nearly 3.6 million acres of farmland each year (DWR 2005a).

It has been estimated that 1,126 miles of main stream lengths presently remain of the more than 2,183 miles of Central Valley streams that were originally available to Chinook salmon – indicating an overall loss of at least 1,057 miles (48 percent) of the original total (Yoshiyama *et al.* 2001). The estimated habitat loss includes the lengths of stream used by salmon mainly as migration corridors, in addition to holding and spawning habitat. This estimated loss of habitat does not include the Delta, comprising about 700 miles of river channels and sloughs (USFWS 1995), available to various degrees as migration corridors or rearing areas for Chinook salmon and steelhead.

It is likely that the lower reaches of the Sacramento and San Joaquin rivers historically were used as rearing areas (at least during some

flow regimes) as the juveniles moved downstream, but recently they have been less suitable for rearing due to alterations in channel morphology and other degraded environmental conditions. In terms of only spawning and holding habitat, the proportionate loss of historically available habitat far exceeds 48 percent, much of which was located in upper stream reaches that have been rendered inaccessible by terminal dams (Yoshiyama *et al.* 2001). Excluding the lower stream reaches that were used as adult migration corridors (and, to a lesser degree, for juvenile rearing), it has been estimated that at least 72 percent of the original Chinook salmon spawning and holding habitat in the Central Valley drainage is no longer available (Yoshiyama *et al.* 2001).

The amount of steelhead habitat lost most likely is much higher than that for Chinook salmon, because steelhead were undoubtedly more extensively distributed. Due to their superior leaping and swimming ability, the timing of their upstream migration (which coincided with the winter rainy season), and their less restrictive preferences for spawning gravels, steelhead likely used at least hundreds of miles of smaller tributaries not accessible to even the highest migrating winter-run and spring-run Chinook salmon (Yoshiyama *et al.* 2001).

In addition to commercial exploitation, large-scale habitat degradation, blockage of historically available habitat and altered flow and water temperature regimes, other factors that may have adversely affected natural stocks of Chinook salmon and steelhead include overharvest, illegal harvest, hatchery production, entrainment, and introduction of competitors, predators and diseases. Fish populations also vary due to natural events, such as droughts and poor ocean conditions (e.g., El Niño). However, populations in healthy habitats typically recover within a few years after natural events. In the Central Valley, the decline of fish populations has continued through cycles of beneficial and adverse natural conditions, indicating the need to improve habitat (USFWS 2001).

1.3 The Recovery Planning Process

The Federal Endangered Species Act of 1973 (ESA), as amended (16 U.S.C. 1531 *et seq.*) mandates the National Oceanic and Atmospheric Administration (NOAA), National Marine Fisheries Service (NMFS) to develop and implement plans (*i.e.*, recovery plans) for the conservation and survival of NMFS listed species. Winter-run Chinook salmon are listed as endangered under the Federal ESA (as well as the California ESA [CESA]), and spring-run Chinook salmon and steelhead are listed as threatened. Implementation of the Recovery Plan for the Sacramento River winter-run Chinook salmon Evolutionarily Significant Unit (ESU), Central Valley spring-run Chinook salmon ESU, and Central Valley steelhead Distinct Population Segment¹ (DPS) is vital to the continued persistence and recovery of these populations. The Recovery Plan serves as a guideline for achieving recovery goals by describing the steps that must be taken to improve the status of the species. Although recovery plans provide guidance, they are not regulatory documents. The success of this Recovery Plan depends upon the cooperation of all stakeholders and regulatory entities to ensure appropriate implementation.

Pursuant to Section 4(f) of the ESA, a recovery plan must be developed for species listed as threatened or endangered, and this plan must be implemented unless it is found not to promote the conservation of the species. A recovery plan must include the following:

- ❑ A description of site-specific management actions necessary for recovery;
- ❑ Objective, measurable criteria, which when met, will allow delisting of the species; and

¹ On January 5, 2006, NMFS departed from their previous practice of applying the ESU policy to steelhead. NMFS concluded that within a discrete group of steelhead populations, the resident and anadromous life forms of steelhead remain “markedly separated” as a consequence of physical, ecological and behavioral factors, and may therefore warrant delineation as a separate DPS (71 FR 834 (January 5, 2006)).

- ❑ Estimates of the time and cost to carry out the recommended recovery measures.

The purpose of this Recovery Plan is to guide implementation of recovery of the species by resolving the threats to the species and ensuring self-sustaining populations in the wild, and thereby ensuring viable Chinook salmon ESUs and the steelhead DPS. This Recovery Plan may be used to inform all stakeholders including Federal, State, Tribal, and local agencies and land use actions, but it does not place regulatory requirements on such entities.

Past recovery plans generally have focused on the abundance, productivity, habitat and other life history characteristics of a species. While knowledge of these characteristics is certainly important for making sound conservation management decisions, the long-term sustainability of a species in need of recovery can only be ensured by alleviating the threats that are contributing to the status of the species as threatened or endangered. Therefore, the identification of the threats to the species is a key component of this Recovery Plan.

To be most useful for recovery planning, a threats assessment should be used to determine the relative importance of various threats to a species. A threats assessment includes: (1) identifying threats and their sources; (2) evaluating the effects of threats; and (3) ranking each threat based on relative effects. The Interim Endangered and Threatened Species Recovery Planning Guidance (NMFS 2006b) recommends “...using a threats assessment for species with multiple threats to help identify the relative importance of each threat to the species’ status, and, therefore, to prioritize recovery actions in a manner most likely to be effective for the species’ recovery.” This Recovery Plan uses this recommended approach to identify and prioritize threats to the Sacramento River winter-run Chinook salmon and Central Valley spring-run Chinook salmon ESUs, and the Central Valley steelhead DPS. The prioritized threats are then used to guide the identification of specific recovery actions.

The methodology used in the threats assessment for this Recovery Plan is generally described in the next chapter (Background) and is fully described in Appendix B.

1.3.1 A Collaborative Effort

NMFS believes it is critically important that ESA recovery plans for Pacific salmon use as their foundation the many Federal, State, regional, local, and private conservation efforts already underway throughout the region. Local support of recovery plans by those whose activities directly affect the listed species, and whose actions will be most affected by recovery requirements, is essential.

Central Valley Technical Recovery Team

As part of its recovery planning efforts, the NMFS Southwest Region designated the Central Valley as a “Recovery Domain.” The NMFS Southwest Region established the Central Valley Technical Recovery Team (TRT) to provide technical assistance to the recovery planning process for the Central Valley Domain. The NMFS’ intent in establishing the Central Valley TRT was to seek unique geographic and species expertise, and to develop a solid scientific foundation for the Recovery Plan. The Central Valley TRT identified unique habitat and biological characteristics in the Central Valley, made technical findings regarding limiting factors and stressors for each ESU and DPS and its component populations, recommended biological viability criteria at the ESU/DPS- and population-level, and provided scientific review of local and regional recovery planning efforts.

The Central Valley TRT, a collaborative body of biologists that were selected based on their expertise and local knowledge, produced three documents heavily relied upon in preparation of the Recovery Plan: (1) *Population Structure of Threatened and Endangered Chinook Salmon ESUs in California’s Central Valley Basin* (Lindley et al. 2004); (2) *Historical Population Structure of Central Valley Steelhead and its Alteration by Dams* (Lindley et al. 2006); and (3) *Framework for Assessing Viability of*

Threatened and Endangered Chinook Salmon and Steelhead in the Sacramento-San Joaquin Basin (Lindley *et al.* 2007).

Public Participation

NMFS conducted a series of Recovery Planning Workshops, designed as round-table discussions, to solicit information and promote dialogue as part of the development of the Federal Recovery Plan for winter-run Chinook salmon, spring-run Chinook salmon and steelhead in the Central Valley Domain. Public workshops were held in Sacramento, California on July 20, 2006, in Redding, California on August 15, 2006, and in Stockton, California on August 17, 2006. At these workshops, NMFS provided a general overview of: (1) the Federal recovery planning process; (2) the timeline for NMFS recovery plan development; (3) the current understanding of Chinook salmon and steelhead populations and their habitats; and (4) threats identified in original ESA listing documents.

Following the overviews, workshop participants were separated into smaller facilitated discussion groups to generate more in-depth dialogue and identify threats to specific Chinook salmon and steelhead populations and their habitats.

Information obtained at the initial series of workshops also was used in additional workshops to develop recovery actions that reduce or eliminate identified threats. These additional workshops were held in Sacramento, California on May 22, 2007 and in Redding, California on May 24, 2007.

Existing Efforts

Local water agencies and irrigation districts, municipal and county governmental agencies, watershed groups, and State and Federal agencies have undertaken major habitat restoration efforts in many parts of the Central Valley and Delta. These actions include the addition of gravel below dams, removal of small dams, riparian revegetation, bank protection, structural habitat enhancement, restoration of floodplain and tidal

wetlands, development and implementation of new flow and water temperature requirements below dams, and operational constraints in the Delta. Although local watershed efforts are vital to recovery, foremost among restoration efforts in terms of Central Valley-wide application are the programs established under the Anadromous Fish Restoration Program (AFRP) of the Central Valley Project Improvement Act (CVPIA) and the Ecosystem Restoration Program (ERP) of the California Bay/Delta Authority (CBDA, also called CALFED), and the Bay Delta Conservation Plan. Shared purposes of the AFRP and the ERP are to protect and restore diversity within and among the various naturally-producing populations of Chinook salmon and steelhead in the Central Valley, and to restore the habitats upon which the populations depend. The purpose of the Bay Delta Conservation Plan (BDCP) is to help recover endangered and sensitive species and their habitats in the Delta in a way that also will provide for a reliable water supply.

The AFRP promotes collaboration between the Department of Interior (USFWS and the Bureau of Reclamation [Reclamation]) with other agencies, organizations and the public to increase natural production of anadromous fish in the Central Valley by augmenting and assisting restoration efforts presently conducted by local watershed workgroups, the California Department of Fish and Game (CDFG), and others. Purposes of the CVPIA (Section 3402) relevant to the AFRP are: (1) to protect, restore, and enhance fish, wildlife, and associated habitats in the Central Valley; (2) to address impacts of the CVP on fish, wildlife, and associated habitats; (3) to improve the operational flexibility of the CVP; (4) to contribute to the State of California's interim and long-term efforts to protect the San Francisco Bay and Sacramento-San Joaquin Delta Estuary; and (5) to achieve a reasonable balance among competing demands for the use of CVP water, including the requirements of fish and wildlife, agricultural, municipal and industrial, and power contractors (USFWS 2001).

CALFED's objective for ecosystem restoration is to improve and increase aquatic and terrestrial habitats and improve ecological functions in the

Bay/Delta to support sustainable populations of diverse and valuable plant and animal species. All CALFED elements will contribute in varying degrees, but the ERP is the principal program element designed to restore the ecological health of the Bay/Delta ecosystem. The ERP includes actions throughout the Bay/Delta watershed and focuses on the restoration of ecological processes and important habitats. In addition, the ERP aims to reduce the effects of stressors that inhibit ecological processes, habitats and species (CALFED 1999b).

The BDCP is a multi-stakeholder effort intended to develop a long-term solution to competing demands for water in the Delta. NMFS serves in an ex-officio capacity on the Steering Committee of the BDCP, collaborating with State and Federal water agencies and contractors, non-governmental organizations, and State and other Federal fish and wildlife agencies to develop a Habitat Conservation Plan (HCP) and Incidental Take Permit (ITP) covering take of listed species resulting from certain activities over a 50 year period. The HCP aims to conserve Federal and State listed species while providing a reliable source of freshwater for agricultural and urban uses in California. Further information is available at the BDCP website: <http://resources.ca.gov/bdcp/>.

A proposed BDCP water conveyance system would include new points of diversion in the north Delta in concert with improvements to the current through-Delta water export system in the south Delta. Actions under discussion include operation of a dual conveyance system, habitat restoration, and measures to reduce other stressors to the Delta ecosystem and covered species.

The operation of a conveyance structure that diverts water directly from the Sacramento River carries additional risk for listed species that migrate, spawn, or rear in the Sacramento River or North Delta. Any new conveyance will be subject to ESA consultation, and issues of injury or mortality of juvenile fish associated with all diversion facilities, reduction of flow variability for fish life history functions, reduction of Shasta

Reservoir storage necessary for mainstem temperature control, and other potential adverse effects must be adequately addressed in any conveyance proposal.

Achieving an equitable balance between water demands and Delta ecosystem conservation will be challenging. From the salmon and steelhead recovery perspective, it is critical to ensure that the BDCP significantly improves Delta ecosystem function from its currently degraded state.

This Recovery Plan is consistent with the shared purposes of the AFRP, the ERP, and the BDCP, and recognizes the need to address populations of winter-run Chinook salmon, spring-run Chinook salmon and steelhead, and the habitats upon which they depend.

1.4 Recovery Plan Content

This introductory chapter provides an overview of many important facets of this Recovery Plan, and in particular describes the collaborative processes of the plan. The remainder of this Recovery Plan for the Sacramento River winter-run Chinook salmon ESU, the Central Valley spring-run Chinook salmon ESU and the Central Valley steelhead DPS is presented in several chapters.

The second chapter provides background including the current regulatory status, a description of the population trends and distribution of each species, and a description of the life history and habitat requirements for each species. A brief description of the reasons for listing and a current threats assessment is then presented (a detailed threats assessment is presented in Appendix B). Finally, current conservation efforts and biological constraints are discussed, including limiting factors that must be considered for the species recovery.

Next, the Recovery Strategy Chapter presents and justifies the recommended recovery program for each species. This chapter also describes the key facts, concepts and assumptions upon which the recovery program is based, the primary focus and

objectives of the recovery effort, and the overarching objectives and recovery actions of the plan and their relative priorities.

Following the Recovery Strategy Chapter is a chapter describing the recovery goals, objectives, and criteria. The ultimate goal of the Recovery Plan is delisting of the Chinook salmon ESUs and the steelhead DPS. The recovery objectives basically subdivide the goal into discrete components which collectively describe the conditions necessary for delisting. Recovery criteria are the objective and measurable standards upon which a decision to delist the ESUs and DPS are based.

The recovery actions necessary to achieve the goals and objectives of this Recovery Plan are then presented. Recovery actions are linked to the identified threats (or stressors) individually for specific populations of winter-run Chinook salmon, spring-run Chinook salmon, and steelhead within the Central Valley Domain, and are prioritized according to the priority of threats addressed.

Lastly, the Implementation Schedule and Cost Estimates Chapter is presented. This chapter is designed to satisfy the requirement under the ESA (Section 4 (f)(1)(A)(iii)) that Recovery Plans must contain “...estimates of the time required and the cost to carry out those measures needed to achieve the plan’s goal and to achieve intermediate steps toward that goal.”

2.0 Background

“The requirement for determining that a species no longer requires the protection of the ESA is that the species no longer be in danger of extinction or likely to become endangered in the foreseeable future based on evaluation of the listing factors specified in ESA Section 4(a)(1). Any new factors identified since listing must also be addressed in this analysis to ensure that the species no longer requires protection.”

- NMFS Supplement to the Lower Columbia Salmon Recovery and Fish and Wildlife Subbasin Plan 2005

The Central Valley Domain encompasses the Sacramento River winter-run Chinook salmon ESU, Central Valley spring-run Chinook salmon ESU, and Central Valley steelhead DPS. Following are descriptions of the current regulatory status, life histories, population trends and distribution, and the habitat requirements for winter- and spring-run Chinook salmon, and steelhead in the Central Valley. A brief description of the reasons for listing and a current threats assessment is then presented (a detailed threats assessment is presented in Appendix B). Finally, current conservation efforts and biological constraints are discussed, including limiting factors that must be considered for recovery of winter-run and spring-run Chinook salmon, and steelhead within the Central Valley Domain.

2.1 Winter-run Chinook Salmon

2.1.1 Brief Overview/Status of the Species

The Sacramento River winter-run Chinook salmon (*Oncorhynchus tshawytscha*) ESU, currently listed as endangered, was listed as a threatened species under emergency provisions of the ESA in August 1989 (54 FR 32085 (August 4, 1989)) and formally listed as a threatened species in November 1990 (55 FR 46515 (November 5, 1990)). In June 1992, NMFS proposed that winter-run Chinook salmon be reclassified as an “endangered”² species (57 FR 27416 (June 19, 1992)). NMFS finalized its proposed rule and re-classified winter-run Chinook salmon as an endangered species on January 4, 1994 (59 FR 440 (January 4, 1994)). NMFS concluded that winter-run Chinook salmon in the Sacramento River warranted listing as an endangered species due to several factors, including: (1) the continued decline and increased variability of run sizes since its first listing as a threatened species in 1989; (2) the expectation of weak returns in years as the result of two small year classes (1991 and 1993); and (3) continued threats to the “take” of winter-run Chinook salmon (65 FR 42421 (July 10, 2000)). On June 14, 2004, NMFS issued a proposed rule to reclassify the listing status of winter-run Chinook salmon from endangered to threatened (69 FR 33102 (June 14, 2004)). To prevent further decline of the ESU by preventing take of this species from activities that harm fish and fish habitat, NMFS proposed to apply the ESA Section 9(a) take prohibitions as the Section 4(d) limits to winter-run Chinook salmon (69 FR 33102 (June 14, 2004)).

² Under the ESA, an “endangered species” is “...any species which is in danger of extinction throughout all or a significant portion of its range...” (16 USC § 1533(20)).

Following a series of extensions to the public comment period on the proposed listing determinations, the public comment period closed during November 2004 (69 FR 61348 (October 18, 2004)). On June 28, 2005 NMFS issued a final listing determination for the Sacramento River winter-run Chinook salmon ESU, which concluded that the Sacramento River winter-run Chinook salmon ESU is “in danger of extinction” due to risks to the ESU’s diversity and spatial structure and, therefore, continues to warrant listing as an endangered species under the ESA (70 FR 37160 (June 28, 2005)). Additionally, the Sacramento River winter-run Chinook salmon ESU is listed as “endangered” under the CESA.

The Sacramento River winter-run Chinook salmon ESU includes winter-run Chinook salmon spawning naturally in the Sacramento River and its tributaries, as well as winter-run Chinook salmon that are part of the conservation hatchery program at the Livingston Stone National Fish Hatchery (LSNFH) (70 FR 37160, June 2005). The Sacramento River winter-run Chinook salmon ESU is depicted in **Figure 2-1**.

2.1.2 Species Description and Taxonomy

Chinook salmon, also largely referred to as king salmon in California, are the largest of the Pacific salmon. The following physical description of the species is provided by Moyle (Moyle 2002). Spawning adults are olive to dark maroon in color, without conspicuous streaking or blotches on the sides. Spawning males are darker than females, and have a hooked jaw and slightly humped back. There are numerous small black spots in both sexes on the back, dorsal fins, and both lobes of the tail. They can be distinguished from other spawning salmon by the color pattern, particularly the spotting on the back and tail, and by the dark, solid black gums of the lower jaw. Parr have 6 to 12 parr marks, each equal to or wider than the spaces between them and most centered on the lateral line. The adipose fin of parr is pigmented on the upper edge, but clear at its

base. The dorsal fin occasionally has one or more spots on it but the other fins are clear.

2.1.3 Life History/Habitat Requirements

Chinook salmon is the most important commercial species of anadromous fish in California. Chinook salmon have evolved a broad array of life history patterns that allow them to take advantage of diverse riverine conditions throughout the year. Four principal life history variants are recognized and are named for the timing of their upstream migration: fall-run, late fall-run, winter-run, and spring-run. The Sacramento River supports all four runs of Chinook salmon. The larger tributaries to the Sacramento River (American, Yuba, and Feather rivers) and rivers in the San Joaquin Basin also provide habitat for one or more of these runs.

Winter-run Chinook salmon are unique because they spawn during summer months when air temperatures usually approach their yearly maximum. As a result, winter-run Chinook salmon require stream reaches with cold water sources that will protect embryos and juveniles from the warm ambient conditions in summer. Winter-run Chinook salmon are primarily restricted to the mainstem Sacramento River.

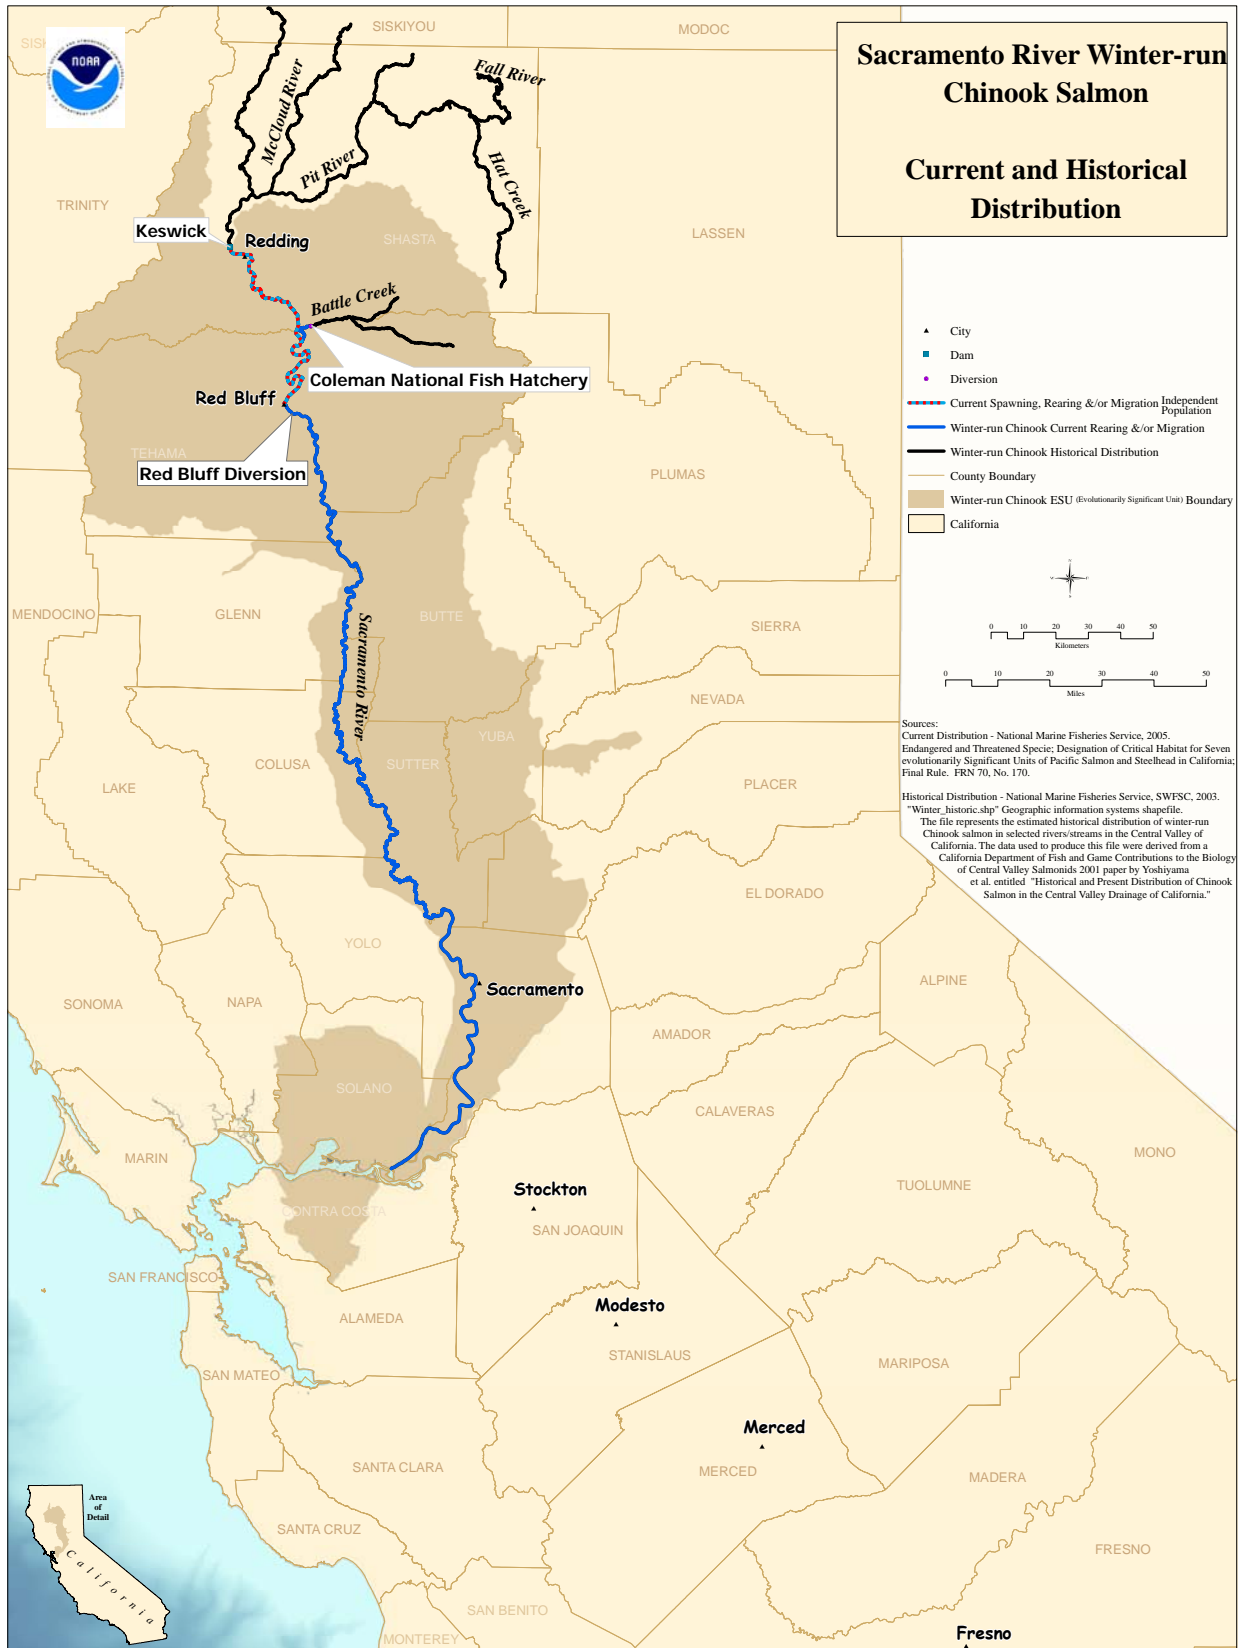

Figure 2-1. Current and Historical Sacramento River Winter-run Chinook Salmon Distribution.

Table 2-1 depicts the temporal occurrence of winter-run Chinook salmon life stages in the Sacramento River. Adult winter-run Chinook salmon immigration and holding (upstream spawning migration) through the Delta and into the lower Sacramento River occurs from December through July, with a peak during the period extending from January through April (USFWS 1995). Winter-run Chinook salmon are sexually immature when upstream migration begins, and they must hold for several months in suitable habitat prior to spawning. Winter-run Chinook salmon primarily spawn in the mainstem Sacramento River between Keswick Dam (River Mile [RM] 302) and RBDD (RM 243). Spawning occurs between late-April and mid-August, with a peak generally in June. Winter-run Chinook salmon embryo incubation in the Sacramento River can extend into October (Vogel and Marine 1991).

Winter-run Chinook salmon fry rearing in the upper Sacramento River exhibit peak abundance during September, with fry and juvenile emigration past Red Bluff Diversion Dam (RBDD) occurring from July through March (Reclamation 1992; Vogel and Marine 1991), although NMFS (1993; NMFS 1997) report juvenile rearing and outmigration extending from June through April. Emigration (downstream migration) of winter-run Chinook salmon juveniles past Knights Landing, located approximately 155.5 river miles downstream of the RBDD, reportedly occurs between November and March, peaking in December, with some emigration continuing through May in some years (Snider and Titus 2000a; Snider and Titus 2000c). The numbers of juvenile winter-run Chinook salmon caught in rotary screw traps (RST) at the Knights Landing sampling location were reportedly dependent on the magnitude of flows during the emigration period (Snider and Titus 2000a; Snider and Titus 2000c).

A description of freshwater habitat requirements for winter-run Chinook salmon is presented in the

following sections. Habitat requirements are organized by life stage.

Adult Immigration and Holding

Suitable water temperatures for adult winter-run Chinook salmon migrating upstream to spawning grounds range from 57°F to 67°F (NMFS 1997). However, winter-run Chinook salmon are immature when upstream migration begins, and need to hold in suitable habitat for several months prior to spawning. The maximum suitable water temperature reported for holding is 59°F to 60°F (NMFS 1997). Because water temperatures in the lower Sacramento River below the RBDD generally begin exceeding 60°F in April, it is likely that little, if any, suitable holding habitat exists in the lower Sacramento River. It most likely is only used by adults as a migration corridor. Following installation of the water temperature control device on Shasta Dam in 1997, it is possible that some deep water pool habitat may exist for a short distance downstream of the RBDD with suitable cold water temperatures for adult holding.

Adult Chinook salmon reportedly require water deeper than 0.8 feet and water velocities less than 8 feet per second (ft/sec) for successful upstream migration (Thompson 1972). Adult Chinook salmon are less capable of negotiating fish ladders, culverts, and waterfalls during upstream migration than steelhead, due in part to slower swimming speeds and inferior jumping ability (Bell 1986; Reiser *et al.* 2006).

Chinook salmon generally hold in pools with deep, cool, well-oxygenated water. Holding pools for adult Chinook salmon have reportedly been characterized as having moderate water velocities ranging from 0.5 to 1.3 ft/sec (DWR 2000).

Spawning

Spawning occurs from mid-April to mid-August, peaking in May and June, in the Sacramento River reach between Keswick Dam and RBDD (Vogel and Marine 1991). Chinook salmon spawn in clean, loose gravel, in swift, relatively shallow riffles, or along the margins of deeper river reaches where suitable water temperatures, depths, and velocities favor redd construction and oxygenation of incubating eggs. Winter-run Chinook salmon were adapted for spawning and rearing in the clear, spring-fed rivers of the upper Sacramento River Basin, where summer water temperatures were typically 50°F to 59°F. Water temperature conditions were created by glacial and snowmelt water percolating through porous volcanic formations that surround Mt. Shasta and Lassen Peak, which cover much of northeastern California. Chinook salmon require clean loose gravel from 0.75 to 4.0 inches in diameter for successful spawning (NMFS 1997). The construction of dams in the upper Sacramento River has eliminated the major source of suitable gravel recruitment to reaches of the river below Keswick Dam. Gravel sources from the banks of the river and floodplain have also been substantially reduced by levee and bank protection measures. Levee and bank protection measures restrict the meandering of the river, which would normally release gravel into the river through natural erosion and deposition processes. Moyle (2002) reported that water velocity preferences (i.e., suitability greater than 0.5) for Chinook salmon spawning range from 0.98 ft/sec to 2.6 ft/sec (0.3 to 0.8 meters per second (m/sec)) at a depth of a few centimeters (cm) to several meters (m), whereas USFWS (2003) reported that winter-run Chinook salmon prefer water velocities range from 1.54 ft/sec to 4.10 ft/sec (0.47 to 1.25 meters per second) at a depth of 1.4 to 10.1 feet (0.4 to 3.1 m).

Today, Shasta Dam denies access to historical winter-run Chinook salmon spawning habitats and they persist mainly because water released from Shasta Reservoir during the summer has been, for the most part, sufficiently cold.

Spawning habitat for Sacramento River winter-run Chinook salmon is restricted to the Sacramento River primarily between RBDD and Keswick Dam.

Embryo Incubation

In the Sacramento River, winter-run Chinook salmon spawning occurs from late April through mid August. Because the embryo incubation life stage begins with fertilized egg deposition and ends with fry emergence from the gravel, embryo incubation occurs from late April through mid-October. Fry emergence occurs from mid-June through mid-October (NMFS 1997). Within the appropriate water temperature range, eggs normally hatch in 40 to 60 days. Newly hatched fish (alevins) normally remain in the gravel for an additional four to six weeks until the yolk sac has been absorbed (NMFS 1997).

Physical habitat requirements for embryo incubation are the same as the requirements discussed above for spawning. However, it is also important that flow regimes remain relatively constant or at least not decrease significantly during the embryo incubation life stage.

Juvenile Rearing and Outmigration

Upon emergence from the gravel, fry swim or are displaced downstream (Healey 1991). Fry seek streamside habitats containing beneficial aspects such as riparian vegetation and associated substrates that provide aquatic and terrestrial invertebrates for food, predator avoidance cover, and slower water velocities for resting (NMFS 1996a). These shallow water habitats have been described as more productive juvenile salmon rearing habitat than the deeper main river channels. Higher juvenile salmon growth rates, partially due to greater prey consumption rates, as well as favorable environmental temperatures have been associated with shallow water habitats (Sommer *et al.* 2001b). Similar to adult salmon upstream movement, juvenile salmon downstream movement is primarily crepuscular. Once downstream movement has commenced,

salmon fry continue this movement until reaching the estuary or they might reside in the stream for a time period that varies from weeks to a year (Healey 1991). Juvenile Chinook salmon migration rates vary considerably, presumably depending on the physiological stage of the juvenile and hydrologic conditions. Kjelson *et al.* (Kjelson *et al.* 1981) found Chinook salmon fry traveled as fast as 30 kilometers (km) per day in the Sacramento River. Sommer *et al.* (2001b) found travel rates ranging from approximately 0.8 km (0.5 miles) per day, up to more than 9.7 km (6 miles) per day in the Yolo Bypass.

As juvenile Chinook salmon grow they move into deeper water with higher current velocities, but still seek shelter and velocity refugia to minimize energy expenditures (Healey 1991). Catches of juvenile salmon in the Sacramento River near West Sacramento by the USFWS (USFWS 1997) exhibited larger juvenile captures in the main channel and smaller-sized fry along the margins. Where the river channel is greater than nine to ten feet in depth, juvenile salmon tend to inhabit the surface waters (Healey 1979). Streamflow and/or turbidity increases in the upper Sacramento River basin are thought to stimulate emigration (Poytress 2007).

Emigration of juvenile Sacramento River winter-run Chinook salmon past RBDD may begin after almost one year in the river. They begin to move down river as early as mid-July, typically peaking numbers in September, and can continue through March in dry years (NMFS 1997; Vogel and Marine 1991). From 1995 to 1999, all Sacramento River winter-run Chinook salmon outmigrating as fry passed RBDD by October, and all outmigrating pre-smolts and smolts passed RBDD by March (Martin *et al.* 2001).

As Chinook salmon begin the smoltification stage, they are found rearing further downstream where ambient salinity reaches 1.5 to 2.5 parts per thousand (Healey 1979). Within the Delta, juvenile Chinook salmon forage in shallow areas with protective cover, such as tidally influenced

sandy beaches and vegetated zones (Healey 1979). Cladocerans, copepods, amphipods, and larvae of diptera, as well as small arachnids and ants are common prey items (Kjelson *et al.* 1981; MacFarlane and Norton 2002; Sommer *et al.* 2001a).

Juvenile Chinook salmon movements within the estuarine habitat are dictated by the interaction between tidally-driven salt water intrusions through the San Francisco Bay and fresh water outflow from the Sacramento and San Joaquin rivers. Juvenile Chinook salmon follow rising tides into shallow water habitats from the deeper main channels and return to the main channels when the tides recede (Healey 1991). Kjelson *et al.* (1981) reported that juvenile Chinook salmon demonstrated a diel migration pattern, orienting themselves to nearshore cover and structure during the day, but moving into more open, offshore waters at night. The fish also distributed themselves vertically in relation to ambient light. During the night, juveniles were distributed randomly in the water column, but would school up during the day into the upper three meters of the water column. Juvenile Chinook salmon were found to spend about 40 days migrating through the Delta to the mouth of San Francisco Bay, and grew little in length or weight until they reached the Gulf of the Farallon Islands (MacFarlane and Norton 2002).

Juvenile Sacramento River winter-run Chinook salmon occur in the Delta primarily from November through early May, based on data collected from trawls in the Sacramento River at West Sacramento (RM 57) (USFWS 2001). The timing of migration varies somewhat due to changes in river flows, dam operations, and water year type. Winter-run Chinook salmon juveniles remain in the Delta until they reach a fork length (FL) of approximately 118 millimeters (mm) and are from five to 10 months of age. Emigration to the ocean begins as early as November and continues through May (Fisher 1994; Myers *et al.* 1998). The importance of the Delta in the life

history of Sacramento River winter-run Chinook salmon is not well understood.

Central Valley Chinook salmon begin their ocean life in the Gulf of the Farallones, then they distribute north and south along the continental shelf primarily between Point Conception and Washington State. Upon reaching the ocean, juvenile Chinook salmon feed voraciously on larval and juvenile fishes, plankton, and terrestrial insects (Healey 1991; MacFarlane and Norton 2002). Chinook salmon grow rapidly in the ocean environment, with growth rates dependent on water temperatures and food availability (Healey 1991).

2.1.4 Abundance Trends and Distribution

One of the main threats to the Sacramento River winter-run Chinook salmon ESU is that it consists of only one population. Furthermore the one population has a small population size (Good *et al.* 2005). The population declined from an escapement of near 100,000 in the late 1960s to fewer than 200 in the early 1990s (Good *et al.* 2005). More recent population estimates of 8,218 (2004), 15,730 (2005), and 17,153 (2006) show a three-year average of 13,700 returning winter-run Chinook salmon (CDFG Website 2007). However, the run size decreased to 2,542 in 2007 and 2,850 in 2008. **Figure 2-2** depicts the estimated run sizes of Sacramento River winter-run Chinook salmon from 1970 through 2008.

The LSNFH on the upper Sacramento River has been producing and releasing winter-run Chinook salmon since 1998. This conservation program has apparently resulted in a net increase in the numbers of returning adult winter-run Chinook salmon, although hatchery fish make up a significant portion of the population (Brown and Nichols 2003).

Table 2-2 shows the annual number of winter-run Chinook salmon released from the facility from 1999 through 2006. The fish are marked with coded wire tags (CWT), adipose fin clipped and released as smolts each winter in late January or early February. The table also provides information based on data acquired during mark-recapture studies on the amount of time required by the smolts to migrate through the Delta.

Winter-run Chinook salmon originally spawned in the upper Sacramento River system (Little Sacramento, Pit, McCloud and Fall rivers) and in Battle Creek. There is no evidence that the winter-run existed in any of the other drainages prior to watershed development (Yoshiyama *et al.* 1996). The unique life history timing pattern of winter-run Chinook salmon, requiring cold summer flows, argues against this run occurring in drainages other than the upper Sacramento system and Battle Creek. Today, watershed development has eliminated all historical spawning habitat above Keswick Dam (approximately 200 river miles) and approximately 47 of the 53 miles of potential habitat in Battle Creek (Yoshiyama *et al.* 1996). **Figure 2-1** depicts the current and historical distribution of Sacramento River winter-run Chinook salmon.

Currently, winter-run Chinook salmon spawning habitat is likely limited to the reach of the Sacramento River extending from Keswick Dam downstream to the RBDD. Prior to construction of Shasta and Keswick dams, the mainstem Sacramento River primarily functioned as a rearing and migration corridor because warm water temperatures likely precluded spawning. Winter-run Chinook salmon still have access to Battle Creek above the Coleman National Fish Hatchery (CNFH) weir from a fish ladder that is opened during the peak of the winter-run Chinook migration period (Ward and Kier 1999).

Figure 2-2. Estimated Sacramento River Winter-run Chinook Salmon Run Size (1970 – 2008). Total estimate includes mainstem in-river, tributaries, hatcheries, and angler harvest. Prior to 2001, mainstem in-river estimates upstream of RBDD were based on RBDD counts. Subsequent estimates were based on carcass survey data.

Currently, if a winter-run Chinook salmon population exists in Battle Creek, its population size is unknown, likely very small, and is potentially mainly or entirely composed of strays from the mainstem Sacramento River. Additionally, a winter-run Chinook salmon migration to the upper Calaveras River may have occurred between 1972 and 1984, but this population appears to have been extirpated by drought, irrigation diversions, and blocked access by the New Hogan Dam (NMFS 1997; NMFS 1999; NMFS 2003). This somewhat ephemeral population on the Calaveras River is also thought to have been late fall-run Chinook salmon that were mistakenly identified as winter-run Chinook salmon (Yoshiyama *et al.* 2000).

The winter-run Chinook salmon population is dependant upon the provision of suitably cool water temperatures during the spawning, embryo incubation, and juvenile rearing period. Water temperatures in the upper Sacramento River are the result of interaction among: (1) ambient air temperature; (2) volume of water; (3) water temperature at release from Shasta and Trinity dams; (4) total reservoir storage; (5) location of reservoir thermocline; (6) ratio of Spring Creek Power Plant release to Shasta Dam release; (7) operation of Temperature Control Device (TCD) on Shasta Dam; and (8) tributary inflows (NMFS 1997). Water temperature varies with location and distance downstream of Keswick Dam, and depends upon the annual hydrologic conditions and annual operation of the Shasta-Trinity Division of the CVP (NMFS 1997). In general, water released from Keswick Dam warms as it moves downstream during the summer and early fall months at a critical time for the successful development and survival of juvenile winter-run Chinook salmon (NMFS 1997).

Suitable water temperatures for adult winter-run Chinook salmon migrating upstream to spawning grounds range from 57°F to 67°F (NMFS 1997). However, winter-run Chinook salmon are immature when upstream migration begins and need to hold in suitable habitat for several months

prior to spawning. The maximum suitable water temperature for holding is 59°F to 60°F (NMFS 1997). Similarly, successful spawning for Chinook salmon occurs at water temperatures below 60°F (NMFS 1997). Prior to 1997, during some years, water temperatures below Keswick Dam began exceeding 60°F in May and during July and August, water temperatures were frequently above 60°F (NMFS 1997). In 1997, a temperature control device (TCD) was installed at Shasta Dam allowing better management of water temperatures in the Sacramento River. CDFG (2004) reported that the TCD was working well and that very low egg loss occurred as a result of adverse water temperatures in 2002 and 2003.

During much of the 1980s and 1990s, the winter-run population was at a precariously low level. Since the late 1990s the population abundance has had an upward trend up to nearly 20,000 fish. This slight upward trend, after nearly two decades of dangerously low numbers, is likely a response to a number of factors, including wetter than normal winters, operation of Livingston Stone Fish Hatchery, changes in ocean harvest regulations since 1995 that have significantly reduced harvests, changes in operations at RBDD, improved water temperature management on the upper Sacramento River (including installation of a cold-water release device on Shasta Dam in 1997), improved ocean conditions, water quality improvements due to remediation of Iron Mountain Mine discharges, changes in the State and Federal water projects, and a variety of other habitat improvements.

2.1.5 Critical Habitat

Critical habitat for listed salmonids is comprised of physical and biological features essential to the conservation of the species including: space for the individual and population growth and for normal behavior; cover; sites for breeding, reproduction and rearing of offspring; and habitats protected from disturbance or are representative of the historical geographical and ecological distribution of the species. The primary constituent elements considered essential for the conservation of listed

Central Valley salmonids are: (1) freshwater spawning sites; (2) freshwater rearing sites; (3) freshwater migration corridors; (4) estuarine areas; (5) nearshore marine areas; and (6) offshore marine areas.

On August 14, 1992, NMFS published a proposed critical habitat designation for winter-run Chinook salmon (57 FR 36626 (August 13, 1992)). The habitat proposed for designation included: (1) the Sacramento River from Keswick Dam, Shasta County (RM 302) to Chipps Island (RM 0) at the westward margin of the Delta; (2) all waters from Chipps Island westward to Carquinez Bridge, including Honker Bay, Grizzly Bay, Suisun Bay, and Carquinez Strait; (3) all waters of San Pablo Bay westward of the Carquinez Bridge; and (4) all waters of San Francisco Bay to the Golden Gate Bridge (NMFS 1997).

On June 16, 1993, NMFS issued the final rule designating critical habitat for winter-run Chinook salmon (58 FR 33212 (June 16, 1993)). The habitat identified in the final designation is identical to that in the proposed ruling except that critical habitat in San Francisco Bay is limited to those waters north of the San Francisco-Oakland Bay Bridge. **Figure 2-3** depicts the designated critical habitat for Sacramento River winter-run Chinook salmon.

2.1.6 Reasons for Listing/Threats Assessment

Several factors have contributed to the decline of winter-run Chinook salmon through degradation of spawning, rearing, and migration habitats. The primary factors include blockage of historical habitat by Shasta and Keswick dams, warm water releases from Shasta Dam, juvenile and adult passage constraints at RBDD, water exports in the southern Delta, heavy metal contamination from Iron Mountain Mine, high ocean harvest rates and entrainment in a large number of unscreened or poorly screened water diversions (NMFS 1997).

Other factors include smaller water manipulation facilities and dams, loss of rearing habitat in the lower Sacramento River and Delta from levee construction, marshland reclamation, interaction with and predation by introduced species, adverse flow conditions, high summer water temperatures and vulnerability to drought (NMFS 1997).

Presumably, there were several independent populations of winter-run Chinook salmon in the Pitt, McCloud, and Little Sacramento rivers and various tributaries to these rivers, such as Hat Creek and the Fall River. These populations merged to form the present single population. If populations ever existed in Battle Creek and the Calaveras River, they have been extirpated (Good *et al.* 2005).

The spatial distribution of spawners has not expanded. The primary reason is that the naturally-spawning population is artificially maintained by cool water releases from Shasta/Keswick dams, and the spatial distribution of spawners is largely governed by water year type and the ability of the CVP to manage water temperatures in the upper Sacramento River. The fact that this ESU is comprised of a single population with very limited spawning and rearing habitat increases its risk of extinction due to local catastrophe or poor environmental conditions. There are no other natural populations in the ESU to buffer it from natural fluctuations. A single catastrophe with effects persisting for four or more years could extirpate the entire Sacramento River winter-run Chinook salmon ESU, which puts the population at a high risk of extinction over the long run (Lindley *et al.* 2007). Such potential catastrophes include volcanic eruption of Lassen Peak, prolonged drought which depletes the cold water pool in Shasta Reservoir or some related failure to manage cold water storage, a spill of toxic materials with effects that persist for four years, or a disease outbreak. The risk associated with a prolonged drought should be emphasized as Shasta Reservoir is operated to maintain only one year of

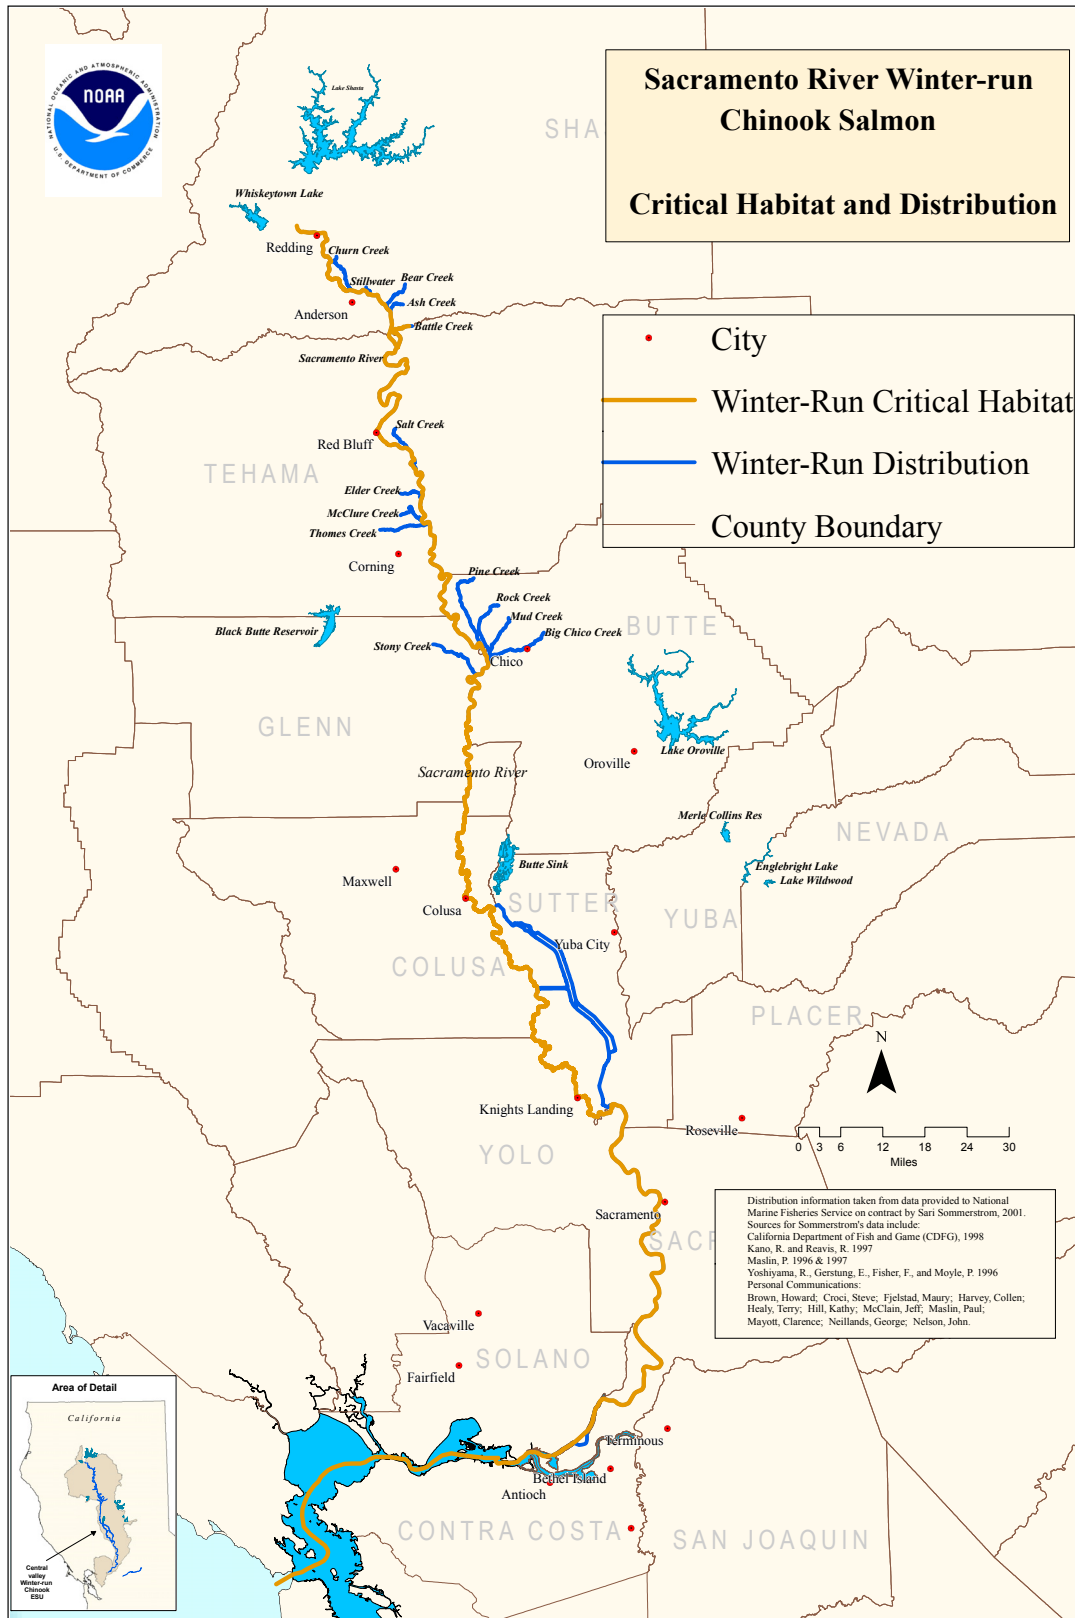

Figure 2-3. Sacramento River Winter-run Chinook Salmon Designated Critical Habitat and Distribution

carry-over storage. After two years of drought, Shasta Reservoir storage would be insufficient to provide cold water throughout the winter-run Chinook salmon spawning and embryo incubation season, resulting in complete year-class failure. A drought lasting several years would likely result in the extinction of winter-run Chinook salmon.

Another vulnerability to an ESU that is represented by a single population is the limitation in life history and genetic diversity that would otherwise increase the ability of individuals in the population to withstand environmental variation. A second naturally-spawning population is considered critical to the long-term viability of this ESU, and plans are underway to eventually establish a second population in the upper Battle Creek watershed. However, establishment of a second population of winter-run Chinook in Battle Creek has yet to be implemented because of the need to complete habitat restoration efforts in that watershed (Good *et al.* 2005).

A threats matrix has been developed and prioritized in Appendix B. Chief among the threats facing winter-run Chinook salmon is small population size—escapement fell below 200 fish in the 1990s. In 1989, the CDFG estimated that the winter-run Chinook salmon size was only 547 fish. This unexpectedly small return represented nearly a 75 percent decline from the consistent, but low, run size of 2,000 to 3,000 fish that had occurred since 1982. The final run size estimate made by the CDFG for 1991 was 191 fish. Population size declined from highs of near 100,000 fish in the late 1960s, indicating a sustained period of poor survival (Good *et al.* 2005).

The genetic integrity of winter-run Chinook salmon has been compromised due to having passed through several “bottlenecks” in the 20th century. Construction of Shasta Dam merged at least four independent winter-run Chinook populations into a single population, representing a substantial loss of genetic diversity, life history variability, and local adaptation. Episodes of

critically low abundance, particularly in the early 1990s, for the single remaining population imposed “bottlenecks” that further reduced genetic diversity (Good *et al.* 2005).

The use of a hatchery program to supplement winter-run Chinook salmon populations in the Central Valley raises concerns about the genetic integrity and fitness of the population. There is a strong perception that hatchery fish may negatively affect the genetic constitution of wild fish (Allendorf *et al.* 1997; Hindar *et al.* 1991; Waples 1991). One of the main factors contributing to this perception is the observation of a reduction in wild fish populations following the initiation of a hatchery release program (Hilborn 1992; Washington and Koziol 1993). An explanation offered for this observation is that hatchery fish are adapted to the hatchery environment; therefore, natural spawning with wild fish reduces the fitness of the natural population (Taylor 1991). Researchers from the University of California at Davis have documented that hatchery Chinook salmon were more vulnerable to predation by Sacramento pikeminnow as they pass RBDD than were wild Chinook salmon (Lufkin 1996). To minimize hatchery effects in the population, LSNFH preferentially collects wild winter-run adults for the program. A maximum of 15 percent of the estimated winter-run Chinook salmon run, but no more than 120 natural-origin winter-run Chinook salmon per broodyear may be collected for broodstock use. If necessary, up to 10 percent (a maximum of 12 fish) of the LSNFH broodstock may be composed of hatchery adult returns. To ensure that hatchery production does not overwhelm the recovering population, annual hatchery releases are kept within the 200,000 to 250,000 range and the effects of the program are well-monitored.

Recently, NMFS (NMFS 2007b) reports that the rising proportion of hatchery fish among returning adults threatens to shift the population from a low to moderate risk of extinction. Lindley *et al.* (Lindley *et al.* 2007) recommend that in order

to maintain a low risk of genetic introgression with hatchery fish, no more than five percent of the naturally-spawning population should be composed of hatchery fish. Since 2001, hatchery origin winter-run Chinook salmon have made up more than five percent of the run, and in 2005 the contribution of hatchery fish exceeded 18 percent (Lindley *et al.* 2007). Potential consequences to wild fish stocks from hatchery production include hybridization and genetic introgression, competition, predation, and increasing fishing pressure (Waples 1991).

Because LSNFH is a conservation hatchery using best management practices, a more appropriate tool to determine associated genetic risk may be the Proportionate Natural Influence (PNI). PNI is an index of gene flow rates between hatchery and natural populations that can be calculated by using the following formula:

$$PNI_{Approx} = pNOB / (pNOB + pHOS)$$

Where pNOB is defined as the Proportion of Natural Origin Brood Stock, and pHOS as the Proportion of Hatchery Origin In-River Spawners.

The Hatchery Scientific Review Group (HSRG), an independent scientific review panel for the Pacific Northwest Hatchery Reform Project, developed guidelines as minimal requirements for minimizing genetic risks of hatchery programs to naturally spawning populations. One of those guidelines is that PNI must exceed 0.5 in order for the natural environment to have a greater influence than the hatchery environment on the genetic constitution of a naturally-spawning population. A second guideline is that PNI should be greater than 0.67 for natural populations considered essential for the recovery or viability of an ESU/DPS.

The average PNI for LSNFH winter-run from 2003 through 2008 is 0.91, which satisfies the HSRG guidelines for minimizing the genetic effects of hatchery programs on natural populations (Bob Null, pers. comm. 2008).

In summary, LSNFH is one of the most important reasons that Sacramento River winter-run Chinook salmon still persist and the hatchery is beneficial to the ESU over the short term. However, if the continued existence of the ESU depends on LSNFH, it by any reasonable definition cannot be characterized as having a low risk of extinction, and therefore the ESU should not be delisted on that basis. The winter-run Chinook salmon ESU cannot be delisted until there are at least two viable populations (e.g., Battle Creek and Sacramento River above Shasta Dam). If the status of the ESU improves such that it one day has a high likelihood of persistence without LSNFH, then the LSNFH winter-run Chinook program should be phased out and eventually terminated. To obtain long-term sustainability, ESUs need to have some low-risk populations with essentially no hatchery influence in the long run; they could have additional populations with some small hatchery influence, but there needs to be a core of populations that are not dependent on hatchery production. The LSNFH winter-run program is intended to be evaluated for its benefits and risks periodically (every 5 years).

A detailed threats assessment was conducted for the Sacramento River winter-run Chinook salmon ESU (Appendix B). The threats/stressors affecting each winter-run Chinook salmon life stage are described in that appendix. A stressor matrix³, in the form of a single Microsoft Excel worksheet, was developed to structure the winter-run Chinook salmon population, life stage, and stressor information into hierarchically-related tiers so that stressors to the ESU could be prioritized. The individual tiers within the matrix, from highest to lowest, are: (1) population; (2) life stage; (3) primary stressor category; and (4) specific stressor. These individual tiers were

³ For winter-run Chinook salmon, a single stressor matrix was developed corresponding to the mainstem upper Sacramento River population, whereas for spring-run Chinook salmon and steelhead, multiple individual stressor matrices were developed corresponding to each of the extant populations for these species.

related hierarchically so that each variable within a tier had several associated variables at the next lower tier, except at the lowest (i.e. fourth) tier.

The general steps required to develop and utilize the winter-run stressor matrix are described as follows:

- ❑ Each life stage within the population was weighted so that all life stage weights in the population summed to one
- ❑ Each primary stressor category within a life stage was weighted so that all primary stressor category weights in a life stage summed to one
- ❑ Each specific stressor within a primary stressor category was weighted so that all specific stressor weights in a primary stressor category summed to one
- ❑ A composite weight for each specific stressor was obtained by multiplying the product of the population weight, the life stage weight, the primary stressor weight, and the specific stressor weight by 100
- ❑ A normalized weight for each specific stressor was obtained by multiplying the composite weight by the number of specific stressors within a particular primary stressor group
- ❑ The stressor matrix was sorted by the normalized weight of the specific stressors in descending order

Specific information explaining the individual steps taken to generate this prioritized list are provided in Appendix B.

The completed stressor matrix sorted by normalized weight is a prioritized list of the life stage-specific stressors affecting the ESU. Each life stage of winter-run Chinook salmon is affected by

stressors of “Very High” importance. These stressors include:

- ❑ The barriers of Keswick and Shasta dams, which block access to historic staging and spawning habitat
- ❑ Flow fluctuations, water pollution, water temperature impacts in the upper Sacramento River during embryo incubation
- ❑ Loss of juvenile rearing habitat in the form of lost natural river morphology and function, and lost riparian habitat and instream cover
- ❑ Predation during juvenile rearing and outmigration
- ❑ Ocean harvest
- ❑ Entrainment of juveniles at the C.W. Jones and Harvey O. Banks pumping plants

The complete prioritized list of life stage-specific stressors to the Sacramento River winter-run Chinook salmon ESU is presented in Appendix B.

2.1.7 Conservation Measures

The CVP Section 7 consultations with Reclamation likely contributed to habitat improvements benefiting the Sacramento River winter-run Chinook salmon ESU. Implementation of the 1992 reasonable and prudent alternative has provided substantial benefits to this ESU by improving habitat and fish passage conditions in the Sacramento River and the Delta. Such improvement likely has contributed to increases in abundance and productivity over the past decade through actions such as maintenance of minimum water flows during fall and winter months, establishment of temperature criteria to support spawning and rearing upstream of RBDD (coupled with water releases from Shasta Dam),

operation of the RBDD gates for improved adult and juvenile fish passage, and constraints on Delta water exports to reduce impacts on juvenile outmigrants.

In addition, two large, ongoing comprehensive conservation programs in the Central Valley provide a wide range of ecosystem and species-specific protective efforts potentially benefiting Chinook salmon – the CALFED Bay/Delta Program) and the CVPIA. CALFED is a cooperative effort of more than 20 State and Federal agencies working with local communities to improve water quality and reliability for California’s water supplies, and has made efforts to restore the Bay/Delta. Though not fully implemented, CALFED’s Ecosystem Restoration Program has funded projects involving habitat restoration, floodplain restoration and protection, instream and riparian habitat restoration and protection, fish screening and passage, research on non-native species and contaminants, research and monitoring of fishery resources, and watershed stewardship and outreach. CALFED established the Environmental Water Account (EWA) to offset losses of juvenile fish at the Delta pumps and to provide higher instream flows in the Yuba, Stanislaus, American, and Merced rivers to benefit native fish, including salmon.

The CVPIA balances the priorities of fish and wildlife protection, restoration, and mitigation with irrigation, domestic water use, fish and wildlife enhancement, and power augmentation. Reclamation and USFWS have conducted studies and implemented hundreds of actions, including modifications of CVP operations, management and acquisition of water for fish and wildlife needs, flow management for fish migration and passage, increased water flows, replenishment of spawning gravels, restoration of riparian habitats, and screening of water diversions. Actions in the Sacramento River tributaries have focused on riparian and shaded riverine aquatic habitat restoration, improved access to available upstream habitat, improved instream flows, and reduced loss of juveniles at diversions. Habitat restoration

includes water acquisition for instream flows, channel restoration and enhancement, removal of dams and blockages to migration, gravel replenishment, and construction or modifications of devices to improve instream habitat and to improve access or reduce fish mortalities during migrations (such as fish ladders and screening diversions).

Harvest protective measures benefiting winter-run Chinook salmon include seasonal constraints on sport and commercial fisheries south of Point Arena. In addition, the State has listed winter-run Chinook under the CESA, and has thus established specific in-river fishing regulations and no-retention prohibitions designed to protect this ESU (e.g., management measures for time and area closures, gear restrictions, and zero bag limits in the Sacramento River).

2.1.8 Biological Constraints and Needs

As winter-run Chinook salmon historically were dependent on access to spring-fed tributaries to the upper Sacramento River that remained cool during summer and early fall, the most obvious impact to this ESU was the construction of Shasta Dam. The dam blocked access to the ESU’s entire historic spawning habitat. With coldwater releases from Shasta creating conditions suitable for winter-run Chinook salmon 100 feet below the dam, this species was able to survive habitat alteration, but experienced significant impacts. Presumably, there were several independent populations of winter-run Chinook salmon in the Pitt, McCloud, and Little Sacramento Rivers, and in various tributaries to these rivers, such as Hat Creek and the Fall River. These populations merged to form the current single population. Any populations that may have existed in Battle Creek and the Calaveras River have since been extirpated. This ESU continues to be threatened by having only one extant population, low population size (compared to historic levels), vulnerability to drought, inadequately screened or unscreened water diversions, predation at

artificial structures and by non-native species, pollution (e.g., Iron Mountain Mine), adverse flow conditions, high summer water temperatures, unsustainable harvest rates, and passage problems at various structures.

Another potential threat to the winter-run Chinook salmon population is the possible effects of long-term climate change. California's Central Valley is located at the extreme southern limit of Chinook salmon distribution. The southern limit of Chinook salmon distribution is likely a function of climate. In California, observations reveal trends in the last 50 years toward warmer winter and spring temperatures, a smaller fraction of precipitation falling as snow, a decrease in the amount of spring snow accumulation in lower and middle elevation mountain zones and an advance in snowmelt of 5 to 30 days earlier in the spring (Knowles *et al.* 2006). Given this trend, it is likely that most species, currently at the southern extent of their range, including Chinook salmon will experience less desirable environmental conditions in the future.

If air temperatures in California rise significantly, it will become increasingly difficult to maintain appropriate water temperatures in order to manage coldwater fisheries, including winter-run Chinook salmon. A reduction in snowmelt and increased evaporation could lead to decreases in reservoir levels and, perhaps more importantly, coldwater pool reserves (California Energy Commission 2003). As a result, water temperatures in rivers supporting anadromous salmonids, including winter-run Chinook salmon, could potentially rise and no longer be able to support over-summering life stages (i.e., winter-run Chinook salmon embryo incubation, fry emergence and juvenile emigration). The California Department of Water Resources (DWR) (DWR 2006) suggests that under a warmer climate scenario, water temperature standards in the upper Sacramento River likely could not be maintained. The potential adverse effects of long-term climate change are more thoroughly discussed in Chapter 7.

2.2 Spring-run Chinook Salmon

2.2.1 Brief Overview/Status of the Species

Central Valley spring-run Chinook salmon (*O. tshawytscha*), currently listed as threatened, were proposed as endangered by NMFS on March 9, 1998. NMFS (NMFS 1998) concluded that the Central Valley spring-run Chinook salmon ESU was in danger of extinction because native spring-run Chinook salmon have been extirpated from all tributaries in the San Joaquin River Basin, which represented a large portion of the historic range and abundance of the ESU as a whole. Moreover, the only streams considered to have wild spring-run Chinook salmon at that time were Mill and Deer creeks, and possibly Butte Creek (tributaries to the Sacramento River). These populations were considered relatively small with sharply declining trends. Hence, demographic and genetic risks due to small population sizes were considered to be high. NMFS (NMFS 1998) also determined that habitat problems were the most important source of ongoing risk to this ESU.

On September 16, 1999, NMFS listed the Central Valley ESU of spring-run Chinook salmon as a "threatened" species (64 FR 50394 (September 16, 1999)). Although in the original Chinook salmon status review and proposed listing it was concluded that the Central Valley spring-run Chinook salmon ESU was in danger of extinction (Myers *et al.* 1998), in the status review update, the BRT majority shifted to the view that this ESU was not in danger of extinction, but was likely to become endangered in the foreseeable future. A major reason for this shift was data indicating that a large run of spring-run Chinook salmon on Butte Creek in 1998 was naturally produced, rather than strays from the FRFH (Good *et al.* 2005).

NMFS (64 FR 50394 (September 16, 1999)) determined that the Central Valley spring-run Chinook salmon ESU are at risk of becoming endangered in the foreseeable future throughout all or a significant portion of their range after

reviewing the best available information, including public and peer review comments, biological data on the species' status, and an assessment of protective efforts. On March 11, 2002, pursuant to a January 9, 2002 rule issued by NMFS under Section 4(d) of the ESA (15 USC § 1533(d)), the take restrictions that apply statutorily to endangered species began to apply to the Central Valley ESU of spring-run Chinook salmon (67 FR 1116 (January 9, 2002)). On June 14, 2004, following a five-year species status review, NMFS proposed that the Central Valley spring-run Chinook salmon remain a threatened species based on the BRT strong majority opinion that the Central Valley spring-run Chinook ESU is "likely to become endangered within the foreseeable future." The BRT based its conclusions on the greatly reduced distribution of Central Valley spring Chinook ESU and hatchery influences on natural population. In addition, the BRT noted moderately high risk for the abundance, spatial structure, and diversity Viable Salmonid Population (VSP) criteria, and a lower risk for the productivity criterion reflecting positive trends. On June 28, 2005, NMFS reaffirmed the threatened status of the Central Valley spring-run Chinook salmon ESU (70 FR 37160 (June 28, 2005)). **Figure 2-4** depicts the Central Valley spring-run Chinook salmon ESU.

2.2.2 Species Description and Taxonomy

The Chinook salmon, also largely referred to as king salmon in California, are the largest of the Pacific salmon. The following physical description of the species is provided by Moyle (Moyle 2002). Spawning adults are olive to dark maroon in color, without conspicuous streaking or blotches on the sides. Spawning males are darker than females, and have a hooked jaw and slightly humped back. There are numerous small black spots in both sexes on the back, dorsal fins, and both lobes of the tail. They can be distinguished from other spawning salmon by the color pattern, particularly the spotting on the back and tail, and by the dark, solid black gums of the lower jaw. Parr have 6 to 12 parr marks, each equal to or

wider than the spaces between them and most centered on the lateral line. The adipose fin of parr is pigmented on the upper edge, but clear at its base. The dorsal fin occasionally has one or more spots on it but the other fins are clear. Life History

Adult Central Valley spring-run Chinook salmon leave the ocean to begin their upstream migration in late January and early February (CDFG 1998), and enter the Sacramento River between March and September, primarily in May and June (Moyle 2002; Yoshiyama *et al.* 1998). Spring-run Chinook salmon generally enter rivers as sexually immature fish and must hold in freshwater for up to several months before spawning (Moyle 2002). While maturing, adults hold in deep pools with cold water. Spawning normally occurs between mid-August and early October, peaking in September (Moyle 2002).

The length of time required for embryo incubation and emergence from the gravel is dependant on water temperature. For maximum embryo survival, water temperatures reportedly must be between 41°F and 55.4°F and oxygen saturation levels must be close to maximum (Moyle 2002).

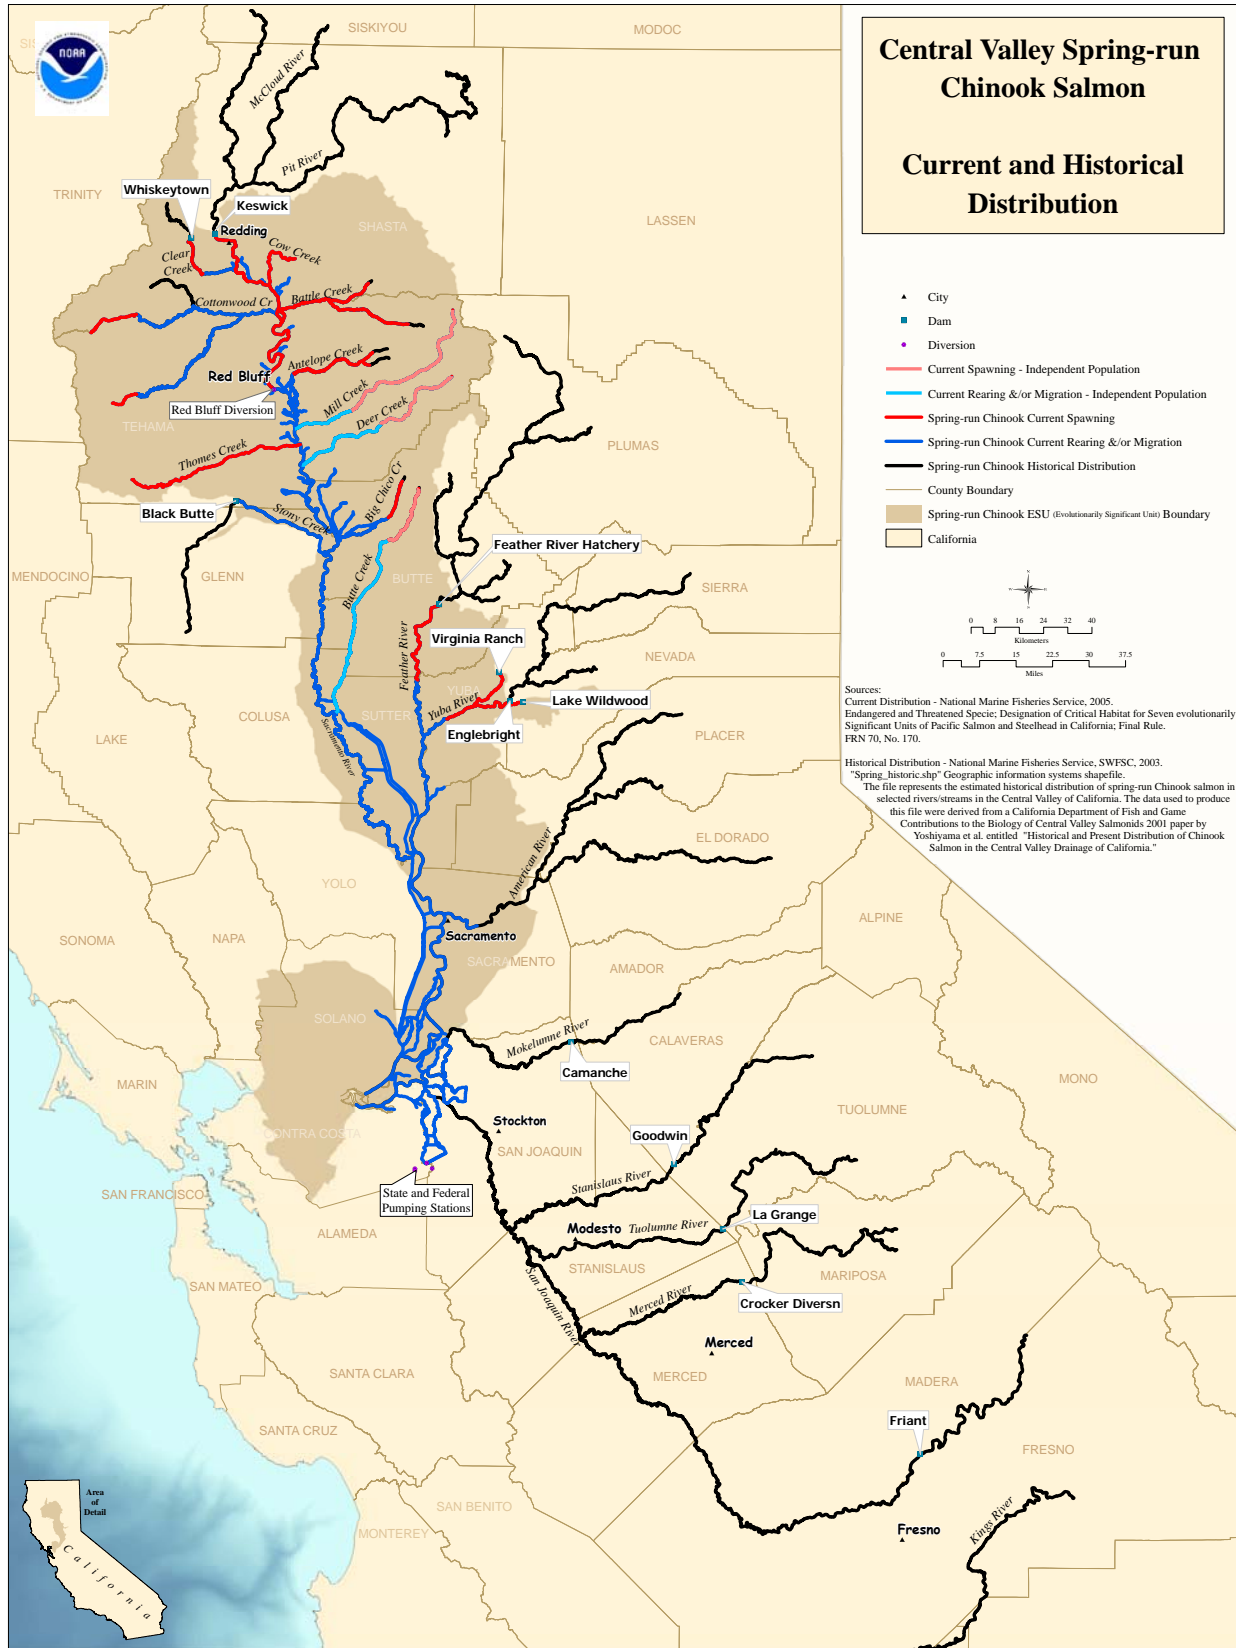

Figure 2-4. Central Valley Spring-run Chinook Salmon ESU, and Current and Historical Distribution.

Under those conditions, embryos hatch in 40 to 60 days and remain in the gravel as alevins (the life stage between hatching and egg sack absorption) for another 4 to 6 weeks before emerging as fry (Moyle 2002).

Spring-run fry emerge from the gravel from November to March (Moyle 2002). Juveniles may reside in freshwater for 12 to 16 months, but some migrate to the ocean as young-of-the-year in the winter or spring months within eight months of hatching (CALFED 2000b). The average size of fry migrants (approximately 40 mm between December and April in Mill, Butte, and Deer creeks) reflects a prolonged emergence of fry from the gravel (Lindley *et al.* 2004). By contrast, studies in Butte Creek (Ward *et al.* 2003) found the majority of spring-run migrants to be fry moving downstream primarily during December, January, and February, and that these movements appeared to be influenced by flow. Small numbers of spring-run juveniles remained in Butte Creek to rear and migrate as yearlings later in the spring. Juvenile emigration patterns in Mill and Deer creeks are very similar to patterns observed in Butte Creek, with the exception that Mill and Deer creek juveniles typically exhibit a later young-of-the-year migration and an earlier yearling migration (Lindley *et al.* 2004). By contrast, data collected on the Feather River suggests that the bulk of juvenile emigration occurs during November and December (DWR and Reclamation 1999; Painter *et al.* 1977). Seesholtz *et al.* (Seesholtz *et al.* 2003) speculate that because juvenile rearing habitat in the Low Flow Channel of the Feather River is limited, juveniles may be forced to emigrate from the area early due to competition for resources. **Table 2-3** depicts the temporal occurrence of spring-run life stages in the Sacramento River.

2.2.3 Abundance Trends and Distribution

The Central Valley drainage as a whole is estimated to have supported spring-run

Chinook salmon runs as large as 600,000 fish between the late 1880s and 1940s (CDFG 1998). More than 500,000 Central Valley spring-run Chinook salmon were caught in the Sacramento-San Joaquin commercial fishery in 1883 (Yoshiyama *et al.* 1998).

Before construction of Friant Dam, nearly 50,000 adults were counted in the San Joaquin River (Fry 1961). The San Joaquin populations essentially were extirpated by the 1940s, with only small remnants of the run persisting through the 1950s in the Merced River (Yoshiyama *et al.* 1998). Since 1970, Central Valley spring-run Chinook salmon run size estimates have fluctuated significantly from highs near 30,000 to lows near 3,000. **Figure 2-5** depicts the estimated spring-run Chinook salmon spawning run size from 1970 through 2008.

Although spring-run Chinook salmon were probably the most abundant salmonid in the Central Valley under historic conditions, large dams eliminated access to almost all historical habitat and the spring-run has suffered the most severe declines of any of the four Chinook salmon runs in the Sacramento River Basin (Fisher 1994).

Historically, spring-run Chinook salmon occurred in the headwaters of all major river systems in the Central Valley where natural barriers to migration were absent. Beginning in the 1880s, harvest, water development, construction of dams that prevented access to headwater areas and habitat degradation significantly reduced the number and range of spring-run Chinook salmon.

The only known streams that currently support viable populations of spring-run Chinook salmon in the Central Valley are Mill, Deer and Butte creeks (CDFG 1998). Each of these populations is small and isolated. **Figure 2-6** depicts the combined annual run size estimates for these populations. Additionally, these populations are genetically distinct from other

populations classified as spring-run in the Central Valley (e.g., Feather River) (DWR 2004). Banks *et al.* (Banks *et al.* 2000) suggest the spring-run phenotype in the Central Valley is actually shown by two genetically distinct subpopulations, Butte Creek, and Deer and Mill creeks. Lindley *et al.* (Lindley *et al.* 2007) report that the current distribution of viable

populations makes the Central Valley spring-run Chinook salmon ESU vulnerable to catastrophic disturbance. All three extant independent populations are in basins whose headwaters lie within the debris and pyroclastic flow radii of Lassen Peak, an active volcano that USGS views as highly dangerous.

Table 2-3. Temporal Occurrence of Adult and Juvenile Sacramento River Spring-run Chinook Salmon in the Sacramento River

Location	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

Figure 2-6. Mill, Deer, and Butte Creek Combined Spawning Run Size Estimates for Central Valley Spring-run Chinook Salmon (1970–2008). Source: (CDFG GRANDTAB 2009)

Additionally, a fire with a maximum diameter of 30 km, big enough to burn the headwaters of Mill, Deer, and Butte creeks simultaneously, has roughly a 10 percent chance of occurring somewhere in the Central Valley each year.

The FRFH was constructed in the mid 1960s by DWR to mitigate for the loss of Chinook salmon and steelhead spawning habitat by construction of Oroville Dam. The FRFH was opened in 1967 (DWR 2002) and is operated by CDFG. The FRFH is the only hatchery in the Central Valley producing spring-run Chinook salmon. The current production target for spring-run Chinook salmon at the FRFH is 2 million smolts.

Prior to 2004, FRFH hatchery staff differentiated spring-run from fall-run by opening the ladder to the hatchery on September 1. Those fish ascending the ladder from September 1 through September 15 were assumed to be spring-run Chinook salmon while those ascending the ladder after September 15 were assumed to be fall-run (Kastner 2003). This practice led to considerable hybridization between spring- and fall-run Chinook salmon (DWR 2004). Since 2007, the fish ladder remains open for 9.5 months of the year (September 15 through June 30) and those fish ascending the ladder are marked with an external tag and returned to the river. This practice allows FRFH staff to identify those previously marked fish as spring-run when they re-enter the ladder in September reducing the potential for hybridization between the spring and fall runs (DWR 2004).

The FRFH also releases a significant portion of its spring-run production into San Pablo Bay (1,000,000 juvenile smolts). This practice increases the chances that these fish will stray into other Central Valley streams when they return as adults to spawn. This straying has the potential for genetic hybridization to occur between FRFH spring-run with local spring-run and fall-run populations, increasing the risk of genetic introgression and subsequent homogeneity among Central Valley Chinook salmon runs. In addition, this straying has the potential to transfer genetic

material from hatchery fish to wild naturally-spawning fish and is generally viewed as an adverse hatchery impact. Of particular concern would be the straying of hatchery fish into Deer, Mill, or Butte creeks, affecting the genetic integrity of the only significantly distinct spring-run Chinook salmon in the Central Valley (DWR 2004). **Figure 2-7** shows the total Central Valley spring-run Chinook salmon spawning run size estimates broken down by constituent component for the years 1970 through 2008. The figure indicates that since about 1982, the proportion of the spring-run in the Central Valley comprised of FRFH fish has substantially increased. The current and historical distribution of Central Valley spring-run Chinook salmon is presented in **Figure 2-4**.

2.2.4 Habitat Requirements

The habitat requirements for spring-run Chinook salmon are the same as those described above for winter-run Chinook salmon. The primary differences in the habitat requirements between the two runs are the duration and the time of year that the different life stages of the species utilize the habitat.

2.2.5 Critical Habitat

Critical habitat for listed salmonids is comprised of physical and biological features essential to the conservation of the species including: space for the individual and population growth and for normal behavior; cover; sites for breeding, reproduction and rearing of offspring; and habitats protected from disturbance or are representative of the historical geographical and ecological distribution of the species. The primary constituent elements considered essential for the conservation of listed Central Valley salmonids are: (1) freshwater spawning sites; (2) freshwater rearing sites; (3) freshwater migration corridors; (4) estuarine areas; (5) nearshore marine areas; and (6) offshore marine areas.

NMFS proposed new critical habitat for Central Valley spring-run Chinook salmon on December 10, 2004, (FR Vol. 69, No. 237) December 10, 2004)) and published a final rule designating critical habitat for this species on September 2, 2005 (FR Vol. 70, No. 170 (Friday, September 2, 2005)). **Figure 2-8** depicts the designated critical habitat for Central Valley spring-run Chinook salmon.

Source: (CDFG GRANDTAB 2009)

Figure 2-8. Central Valley Spring-run Chinook Salmon Designated Critical Habitat and Distribution

2.2.6 Reasons for Listing / Threats Assessment

Threats to Central Valley spring-run Chinook salmon fall into three broad categories: (1) loss of historical spawning habitat; (2) degradation of remaining habitat; and (3) threats to the genetic integrity of the wild spawning populations from the FRFH spring-run Chinook salmon production program. The construction of dams in the Central Valley has eliminated virtually all historic spawning habitat of spring-run Chinook salmon in the basin. Native spring-run Chinook salmon have been extirpated from all tributaries in the San Joaquin River Basin, which represents a large portion of the historic range and abundance of the ESU. Naturally-spawning populations of Central Valley spring-run Chinook salmon currently are restricted to accessible reaches of the upper Sacramento River, Antelope Creek, Battle Creek, Beegum Creek, Big Chico Creek, Butte Creek, Clear Creek, Deer Creek, Feather River, Mill Creek, and Yuba River (CDFG 1998). Most of these populations are relatively small. The Feather River population depends on FRFH production, and is likely hybridized with fall-run Chinook salmon. Little is known about the status of the spring-run Chinook salmon population in the lower Yuba River, although the relatively recent installation of a VAKI Riverwatcher system at Daguerre Point Dam is beginning to provide more accurate estimates of population size. The upper Sacramento River may support a small spring-run Chinook salmon population, but the degree of hybridization with fall-run Chinook salmon is likely high, however, population status is poorly documented.

The construction of Shasta and Keswick dams on the Sacramento River and Oroville Dam on the Feather River and subsequent blocking of upstream migration has eliminated the spatial separation between spawning fall-run and spring-run Chinook salmon. Reportedly, spring-run Chinook salmon migrated to the upper Feather River and its tributaries from mid-March through the end of July (CDFG 1998). Fall-run Chinook salmon reportedly migrated later and spawned in

lower reaches of the Feather River than spring-run Chinook salmon (Yoshiyama *et al.* 2001). The same pattern likely also existed on the Sacramento River. Restricted access to historic spawning grounds currently causes spring-run Chinook salmon to spawn in the same lowland reaches that fall-run Chinook salmon use as spawning habitat. The overlap in spawning site locations, combined with an overlap in spawning timing (Moyle 2002) with temporally adjacent runs, may be responsible for interbreeding between spring-run and fall-run Chinook salmon in the lower Feather River (Hedgecock *et al.* 2001) and in the Sacramento River below Keswick Dam.

In the upper Sacramento River, lower Feather River, and lower Yuba River, spring-run Chinook salmon spawning may occur a few weeks earlier than fall-run spawning, but currently there is no clear distinction between the two because of the disruption of spatial segregation by Shasta and Keswick dams on the Sacramento River, Oroville Dam on the Feather River, and Englebright Dam on the Yuba River. Thus, spring-run and fall-run Chinook salmon spawning overlap temporally and spatially. This presents difficulties from a management perspective in determining the proportional contribution of total spawning escapement by the spring- and fall-runs. Because of unnaturally high densities of spawning, particularly in the in the Low Flow Channel of the Feather River, spawning habitat is likely a limiting factor. Intuitively, it could be inferred that the slightly earlier spawning Chinook salmon displaying spring-run behavior would have better access to the limited spawning habitat, although early spawning likely leads to a higher rate of redd superimposition. Redd superimposition occurs when spawning Chinook salmon dig redds on top of existing redds dug by other Chinook salmon. The rate of superimposition is a function of spawning densities and typically occurs in systems where spawning habitat is limited (Fukushima *et al.* 1998). Redd superimposition may disproportionately affect early spawners and, therefore, potentially affect Chinook salmon exhibiting spring-run life history characteristics.

In general, spring-run Chinook salmon habitat has been degraded through elevated water temperatures, agricultural and municipal diversions and returns, restricted flows, entrainment of migrating juveniles into unscreened or poorly screened diversions, predation by non-native species and the poor quality and quantity of remaining habitat. Habitat problems remain one of the most important sources of ongoing risk to the Central Valley spring-run Chinook salmon (NMFS 1998). Like most spring-run Chinook salmon, Central Valley spring-run Chinook salmon require cool freshwater while they mature over the summer. In the Central Valley, summer water temperatures are reportedly suitable for Chinook salmon only above 150 to 500-m elevations, and most such habitat is now upstream of impassable dams (NMFS 2005). Current spawning is restricted to the mainstem and a few river tributaries in the Sacramento River, where the habitat is severely degraded (NMFS 1998).

General degradation of rearing and migrating habitat includes elevated water temperatures, agricultural and municipal diversions and returns, restricted and regulated flows, entrainment of migrating fish into unscreened or poorly screened diversions, predation by nonnative species, and the poor quality and quantity of remaining habitat (NMFS 1998). Hydropower dams and water diversions in some years have greatly reduced or eliminated in-stream flows during spring-run migration periods (NMFS 1998b).

In addition, hatchery programs in the Central Valley may pose threats to spring-run Chinook salmon stock genetic integrity (NMFS 1998). Much of the Central Valley Chinook salmon production is of hatchery origin, and naturally-spawning populations may be interbreeding with both fall-run and spring-run Chinook salmon hatchery fish. This problem has been exacerbated by the continued practice of trucking juvenile Chinook salmon to the Delta for release, contributing to the straying of returning adults throughout the Central Valley, especially in light

of reports suggesting a high degree of mixing between spring- and fall- broodstock in the hatcheries. In the 1940s, trapping of adult Chinook salmon that originated from areas above Keswick and Shasta dams may have resulted in stock mixing, and further mixing with fall-run Chinook salmon apparently occurred with fish transferred to the CNFH. Deer Creek, one of the locations generally believed most likely to retain essentially native spring-run Chinook salmon, was a target of adult outplants from the 1940s trapping operation, but the success of those transplants is uncertain (NMFS 2005).

The FRFH spring-run Chinook salmon program releases half its production near the hatchery and the other half is released far downstream of the hatchery (CDFG 2001a). Given the large number of juveniles released off station, the potential contribution of straying adults to rivers throughout the Central Valley is considerable (NMFS 2005). The varying low rate of CWT marking for hatchery-derived spring-run fish and the absence of spring-run carcass surveys for most river systems prevented the accurate estimation of the contribution of naturally-spawning hatchery strays (NMFS 2005). Cramer (1996) reported that up to 20 percent of the Feather River spring-run Chinook salmon are recovered in the American River sport fishery. Furthermore, the use of a fixed date to distinguish returning spring- and fall-run fish at the FRFH may have resulted in considerable hybridization between the two runs (Campbell and Moyle 1990 *in* NMFS 2005).

Additionally, hatchery production of spring-run Chinook salmon may threaten the genetic integrity of naturally-spawning populations. Cramer and Demko (Cramer and Demko 1997) reported that half of the hatchery reared spring-run Chinook salmon returning to the Feather River did not return to the hatchery, but spawned naturally in the river. Hatchery straying is considered to be an increasing problem due to current practices of offsite releases. Given the large numbers of juveniles released offsite (1,000,000 spring-run),

the potential for straying to rivers throughout the Central Valley is high.

A detailed threats assessment was conducted for the Central Valley spring-run Chinook salmon ESU, and followed the same general procedure previously described for winter-run Chinook salmon. The threats/stressors affecting each spring-run Chinook salmon diversity group and population are described in Appendix B.

The completed stressor matrix sorted by normalized weight is a prioritized list of the life stage-specific stressors affecting the ESU. For spring-run Chinook salmon, threats were prioritized within each diversity group, as well as within each population. Specific information explaining the individual steps taken to generate these prioritized lists are provided in Appendix B.

Some major stressors to the entire Central Valley spring-run Chinook salmon ESU include passage impediments/barriers, ocean harvest, warm water temperatures for holding and rearing, limited quantity and quality of rearing habitat, predation, and entrainment. The complete prioritized list of life stage-specific stressors to this ESU is presented in Appendix B.

Some of the most important specific stressors to each diversity groups within the ESU are described below.

Northern Sierra Nevada Diversity Group

- ❑ Agricultural diversions, diversion dams, and/or weirs on Deer, Mill, Antelope, and Butte creeks impeding or blocking access to upstream spawning habitat;
- ❑ Warm water temperatures in Antelope, Butte, and Big Chico creeks during the adult immigration and holding life stage, especially in dry or extreme years;
- ❑ Englebright Dam blocking access to habitat historically used by Yuba River spring-run Chinook salmon;

- ❑ Oroville Dam blocking access to habitat historically used by Feather River spring-run Chinook salmon;
- ❑ Entrainment in Antelope Creek resulting from terminal diversions and loss of channel connectivity;
- ❑ Loss of rearing habitat in the lower and middle sections of the Sacramento River and in the Delta;
- ❑ Ocean harvest on all populations; and
- ❑ Predation on juveniles from all populations rearing and migrating through the Sacramento River and Delta.

Basalt and Porous Lava Diversity Group

- ❑ Keswick and Shasta dams blocking access to habitat historically used by spring-run Chinook salmon in the upper Sacramento River watershed;
- ❑ Passage impediments and flow fluctuations resulting from hydropower operations on the North and South Forks of Battle Creek;
- ❑ Loss of rearing habitat in the Sacramento River and Delta;
- ❑ Ocean harvest on all populations; and
- ❑ Predation on juveniles from all populations rearing and migrating through the Sacramento River and Delta.

Northwestern California Diversity Group

- ❑ Warm water temperatures in all three watersheds during the adult immigration and holding life stage;
- ❑ Limited spawning habitat availability in all three watersheds;

- ❑ Loss of rearing habitat in the lower and middle sections of the Sacramento River and in the Delta;
- ❑ Whiskeytown Dam blocking access to habitat potentially historically used by Clear River spring-run Chinook salmon;
- ❑ Ocean harvest on all populations; and
- ❑ Predation on juveniles from all populations rearing and migrating through the Sacramento River and Delta.

2.2.7 Conservation Measures

During 2004 through 2006, progress was made in addressing some of the limiting factors and threats to this ESU, largely through ESA Section 7 consultations and other ESA-related conservation efforts in the Central Valley. The CVP Section 7 consultation with Reclamation has likely contributed to habitat improvements benefiting the Central Valley spring-run Chinook salmon ESU, such as flow and temperature improvements.

In addition, CALFED and CVPIA actions in the Sacramento River tributaries have focused on riparian and shaded riverine aquatic habitat restoration, improved access to available upstream habitat, improved instream flows, and reduced loss of juveniles at diversions, particularly for spring-run Chinook salmon and steelhead. For a description of CALFED, CVPIA and other actions, refer to the previous discussion of Conservation Measures for winter-run Chinook salmon.

The Delta Pumping Plant Fish Protection Agreement was intended to mitigate for SWP and pumping plant impacts through screening of unscreened water diversions, enhanced law enforcement efforts to reduce illegal fish harvest, installation of seasonal barriers to guide fish away from undesirable spawning habitat or migration corridors, salmon habitat restoration, and removal of four dams to improve fish passage on Butte

Creek for Chinook and steelhead. Approximately one-third of the approved funding for salmon projects specifically targeted spring-run Chinook salmon and steelhead in the upper Sacramento River tributaries.

Harvest protective measures benefiting spring-run Chinook salmon include seasonal constraints on sport and commercial fisheries south of Point Arena. In addition, the State has listed spring-run Chinook under the CESA, and has thus established specific in-river fishing regulations and no-retention prohibitions designed to protect this ESU (e.g., fishing method restrictions, gear restrictions, bait limitations, seasonal closures, and zero bag limits), particularly in primary tributaries such as Deer, Big Chico, Mill, and Butte creeks, which support spring-run Chinook salmon. The CDFG has implemented enhanced enforcement efforts in spring-run tributaries and adult holding areas, which may significantly reduce illegal harvest, although there is no direct evidence that this is the case. The level of enforcement varies with funding.

2.2.8 Biological Constraints and Needs

The Central Valley spring-run Chinook salmon ESU is currently faced with three primary limiting factors and threats: (1) loss of most historic spawning habitat; (2) degradation of the remaining habitat; and (3) genetic introgression with the FRFH spring-run Chinook salmon strays. Spring-run Chinook require cool freshwater in summer, most of which is upstream of impassable dams. The ESU is currently limited to independent populations in Mill, Deer, and Butte creeks, persistent and presumably dependent populations in the Feather and Yuba rivers and in Big Chico, Antelope, and Battle creeks, and a few ephemeral or dependent populations in the Northwestern California region (e.g., Beegum, Clear, and Thomes creeks). This ESU continues to be threatened by habitat loss, degradation and modification, small hydropower dams and water diversions that reduce or eliminate instream flows

during migration, unscreened or inadequately screened water diversions, excessively high water temperatures, and predation by non-native species.

The potential effects of long-term climate change also may adversely affect spring-run Chinook salmon and their recovery. These effects are summarized above for winter-run Chinook salmon, and more thoroughly discussed in Chapter 7.

2.3 Steelhead

2.3.1 Brief Overview/Status of the Species

NMFS proposed to list the Central Valley steelhead (*Oncorhynchus mykiss*), which is currently listed as threatened, as endangered on August 9, 1996. NMFS (61 FR 41541 (August 1996)) concluded that the Central Valley steelhead ESU was in danger of extinction because of habitat degradation and destruction, blockage of freshwater habitats, water allocation problems, the pervasive opportunity for genetic introgression resulting from widespread production of hatchery steelhead and the potential ecological interaction between introduced stocks and native stocks. Moreover, NMFS (71 FR 834 (January 5, 2006)) proposed to list steelhead as endangered because steelhead had been extirpated from most of their historical range.

On March 19, 1998, NMFS listed the Central Valley steelhead as a threatened species (63 FR 13347 (March 19, 1998)). NMFS (63 FR 13347 (March 19, 1998)) concluded that the risks to Central Valley steelhead had diminished since the completion of the 1996 status review based on a review of existing and recently implemented State conservation efforts and Federal management programs (e.g., CVPIA AFRP, CALFED) that address key factors for the decline of this species. In addition, NMFS (63 FR 13347 (March 19, 1998)) asserted that additional actions benefiting Central

Valley steelhead included efforts to enhance fisheries monitoring and conservation actions to address artificial propagation.

On September 8, 2000, pursuant to a July 10, 2000, rule issued by NMFS under Section 4(d) of the ESA (16 USC § 1533(d)), the take restrictions that apply statutorily to endangered species began to apply to Central Valley steelhead (65 FR 42421 (July 10, 2000)). On January 5, 2006, NMFS reaffirmed the threatened status of the Central Valley steelhead and applied the DPS policy to the species because the resident and anadromous life forms of steelhead remain “markedly separated” as a consequence of physical, ecological and behavioral factors, and may therefore warrant delineation as a separate DPS (71 FR 834 (January 5, 2006)). NMFS (1998) based its conclusion on conservation and protective efforts that, “mitigate the immediacy of extinction risk facing the Central Valley steelhead DPS.” **Figure 2-9** depicts the Central Valley steelhead DPS.

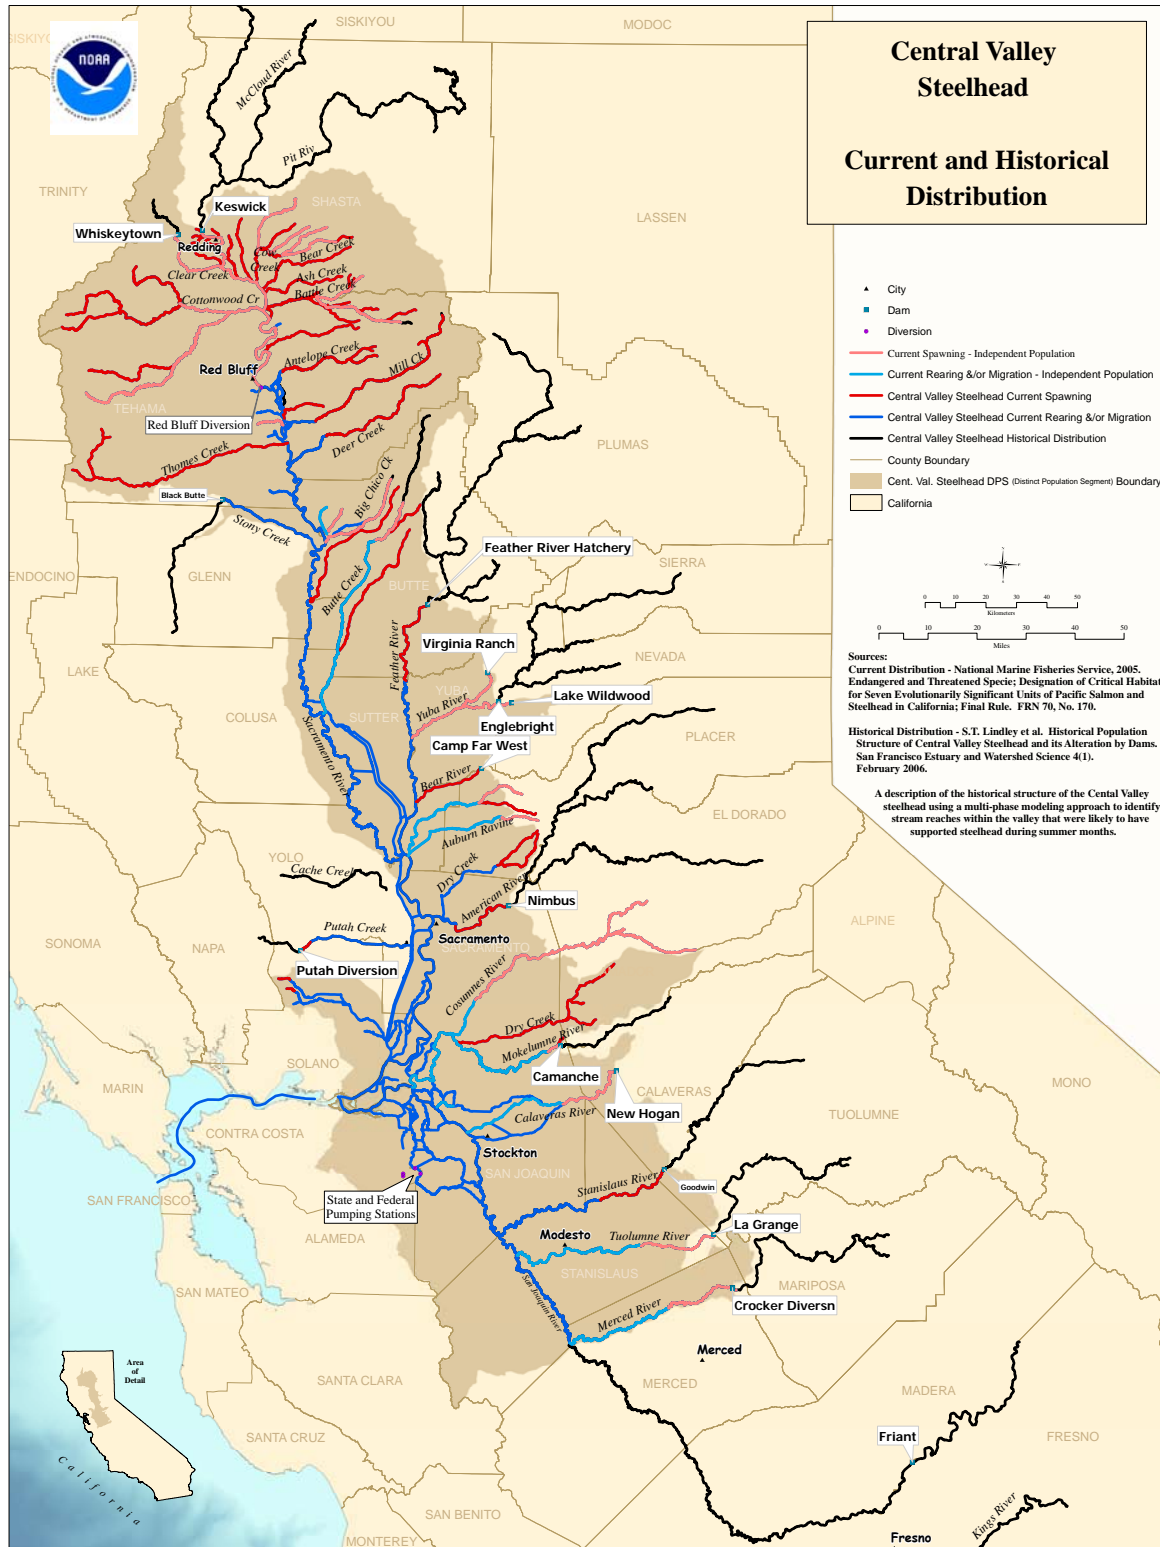

Figure 2-9. Central Valley Steelhead Distinct Population Segment, and Current and Historical Distribution. See Lindley et al. 2006 (Table 1) in Appendix D for a list of the 81 historic independent steelhead populations in the Central Valley.

2.3.2 Species Description and Taxonomy

Steelhead and rainbow trout are the same species. In general, steelhead refers to the anadromous form of the species. Normally, adult steelhead reach a larger size than resident rainbow trout. Sacramento River Basin steelhead immigrants range in size from 12 to 18 inches (30.5 to 45.7 cm) FL for adults returning after 1 year in the ocean, to 18 to 23 inches (45.7 to 58.4 cm) FL for adults returning after 2 years in the ocean (S.P. Cramer & Associates 1995).

Steelhead can be identified by the numerous black spots on the caudal fin, adipose fin, dorsal fin and back (Moyle 2002). When in freshwater, steelhead often display the pinkish to red lateral band and cheeks typical of resident rainbow trout. The back is normally an iridescent blue to brown, the sides and belly are silver, white or yellowish (Moyle 2002). The resident forms are usually darker than the sea-run. Juvenile coloration is similar to adults except that juveniles often have 8 to 13 widely spaced parr marks centered on the lateral line, 5 to 10 dark marks on the back between the head and dorsal fin, white to orange tips on the dorsal and anal fins, and few, if any, dark spots on the tail (Moyle 2002).

2.3.3 Life History

Oncorhynchus mykiss may exhibit anadromy or freshwater residency. Resident forms are usually referred to as “rainbow” trout, while anadromous life forms are termed “steelhead.” Zimmerman et al. (2008) demonstrated that resident rainbow trout can produce anadromous smolts and anadromous steelhead can produce resident rainbow trout in the Central Valley. That study indicated that the proportion of resident rainbow trout to anadromous steelhead in the Central Valley is largely in favor of the resident form with 740 of 964 *O. mykiss* examined being the progeny of resident rainbow trout (Zimmerman et al. 2008).

Steelhead typically migrate to marine waters after spending two years in fresh water. They reside in marine waters for typically two or three years prior to returning to their natal stream to spawn as four- or five-year-olds. Unlike Pacific salmon, steelhead are capable of spawning more than once before they die. However, it is rare for steelhead to spawn more than twice before dying, and most that do so are females (Moyle 2002).

Currently, Central Valley steelhead are considered “ocean-maturing” (also known as winter) steelhead, although summer steelhead may have been present prior to construction of large dams (Moyle 2002). Ocean maturing steelhead enter fresh water with well-developed gonads and spawn shortly after river entry. Central Valley steelhead enter fresh water from August through April. They hold until flows are high enough in tributaries to enter for spawning (Moyle 2002). Steelhead adults typically spawn from December through April, with peaks from January through March in small streams and tributaries where cool, well oxygenated water is available year-round (Hallock *et al.* 1961; McEwan 2001). Depending on water temperature, steelhead eggs may incubate in redds for 1.5 to 4 months before hatching as alevins. Following yolk sac absorption, alevins emerge from the gravel as young juveniles or fry and begin actively feeding (Moyle 2002).

In the Sacramento River, juvenile steelhead generally migrate to the ocean in spring and early summer at 1 to 3 years of age and 10 to 25 cm FL, with peak migration through the Delta in March and April (Reynolds *et al.* 1993). Hallock *et al.* (1961) found that juvenile steelhead in the Sacramento River Basin migrate downstream during most months of the year, but the peak emigration period occurred in the spring, with a much smaller peak in the fall.

Steelhead may remain in the ocean from one to four years, growing rapidly as they feed in the highly productive currents along the continental shelf (Barnhart 1986). Oceanic and climate conditions such as sea surface temperatures, air

temperatures, strength of upwelling, El Niño events, salinity, ocean currents, wind speed, and primary and secondary productivity affect all facets of the physical, biological and chemical processes in the marine environment. Some of the conditions associated with El Niño events include warmer water temperatures, weak upwelling, low primary productivity (which leads to decreased zooplankton biomass), decreased southward transport of subarctic water, and increased sea levels (Percy 1997). For juvenile steelhead, warmer water and weakened upwellings are possibly the most important of the ocean conditions associated with El Niño. Because of the weakened upwelling during an El Niño year, juvenile California steelhead would need to migrate more actively offshore through possibly stressful warm waters with numerous inshore predators.

Strong upwelling is probably beneficial because of the greater transport of smolts offshore, beyond major concentrations of inshore predators (Percy 1997). **Table 2-4** depicts the temporal occurrence of steelhead life stages in the Sacramento River.

2.3.4 Abundance Trends and Distribution

Prior to dam construction, water development and watershed perturbations, Central Valley steelhead were distributed throughout the Sacramento and San Joaquin rivers (Busby *et al.* 1996; NMFS 1996b, McEwan 2001). Steelhead were found from the upper Sacramento and Pit rivers (now inaccessible due to Shasta and Keswick dams) south to the Kings and possibly the Kern River systems, and in both east- and west-side Sacramento River tributaries (Yoshiyama *et al.* 1996). Lindley *et al.* (Lindley *et al.* 2006) estimated that historically there were at least 81 independent Central Valley steelhead populations distributed primarily throughout the eastern tributaries of the Sacramento and San Joaquin rivers (**see Appendix D**). Presently, impassable dams block access to 80 percent of historically available habitat, and block access to all historical spawning habitat for about 38 percent of historical populations (Lindley *et al.*

2006). Existing wild steelhead stocks in the Central Valley are mostly confined to the upper Sacramento River and its tributaries, including Antelope, Deer, and Mill creeks and the Yuba River. Populations may exist in Big Chico and Butte creeks, and a few wild steelhead are produced in the American and Feather rivers (McEwan 2001).

Recent snorkel surveys (1999 to 2002) indicate that steelhead are present in Clear Creek (J. Newton, USFWS, pers. comm. 2002, as reported in Good *et al.* 2005). Because of the large resident *O. mykiss* population in Clear Creek, steelhead spawner abundance has not been estimated.

Until recently, CV steelhead were thought to be extirpated from the San Joaquin River system. Recent monitoring has detected small self-sustaining populations of steelhead in the Stanislaus, Mokelumne, and Calaveras rivers, and other streams previously thought to be devoid of steelhead (McEwan 2001). On the Stanislaus River, steelhead smolts have been captured in rotary screw traps at Caswell State Park and Oakdale each year since 1995 (S.P. Cramer and Associates Inc. 2000, 2001).

It is possible that naturally-spawning populations exist in many other streams but are undetected due to lack of monitoring programs (IEP Steelhead Project Work Team 1999). Incidental catches and observations of steelhead juveniles also have occurred on the Tuolumne and Merced Rivers during fall-run Chinook salmon monitoring activities, indicating that steelhead are widespread, throughout accessible streams and rivers in the Central Valley (Good *et al.* 2005).

Naturally spawning populations of steelhead also occur in the Feather, Yuba, American, and Mokelumne rivers, but these populations have had substantial hatchery influence and their ancestry is not clear (Busby *et al.* 1996). Steelhead runs in the Feather and American rivers are sustained largely by the FRFH and Nimbus Hatchery (CDFG 1996). Steelhead also currently occur in the Stanislaus, Calaveras, Merced, and

Tuolumne rivers. The current and historical distribution of Central Valley steelhead is presented in Figure 2-9.

Table 2-4. The Temporal Occurrence of Adult and Juvenile Sacramento River Steelhead in the Sacramento River

Location	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

Relative Abundance:	= High				= Medium				= Low			

Note: NMFS recognizes that CDFG Steelhead Report Card Data provides a small sample size and involves some known sampling bias, but these data represent the best information available for the temporal distribution of adult steelhead in the San Joaquin River.

Historic Central Valley steelhead run sizes are difficult to estimate because of the lack of data, but may have approached one to two million adults annually (McEwan 2001). By the early 1960s the steelhead run size had declined to about 40,000 (CDFG 1996). Over the last 30 years the steelhead populations in the upper Sacramento River have declined substantially. In 1996, NMFS estimated the Central Valley total run size based on dam counts, hatchery returns, and past spawning surveys was probably fewer than 10,000 fish. Both natural and hatchery runs have declined since the 1960s. Counts at RBDD averaged 1,400 fish from 1991 to 1996, compared to counts in excess of 10,000 fish in the late 1960s (CDFG 1996). American River redd surveys and associated monitoring from 2002 through 2007 indicate that only a few hundred steelhead spawn in the river and a portion of those spawners originated from Nimbus Hatchery (Hannon and Deason 2008).

In analyzing flow-habitat relationships for anadromous salmonids in the upper Sacramento River upstream of the Battle Creek confluence and downstream of Keswick Dam, USFWS (2003) reported that it was not possible to differentiate between steelhead and resident rainbow trout. Specific information regarding steelhead spawning within the mainstem Sacramento River is limited due to lack of monitoring (NMFS 2004). Currently, the number of steelhead spawning in the Sacramento River is unknown because redds cannot be distinguished from a large resident rainbow trout population that has developed as a result of managing the upper Sacramento River for coldwater species.

2.3.5 Habitat Requirements

A description of freshwater habitat requirements for steelhead is presented in the following sections. Habitat requirements are organized by the species life stage.

Adult Immigration and Holding

Adult steelhead immigration into Central Valley streams typically begins in August and continues

into March (McEwan 2001; NMFS 2004). Steelhead immigration generally peaks during January and February (Moyle 2002). Optimal immigration and holding temperatures have been reported to range from 46°F to 52°F (CDFG 1991b).

Central Valley steelhead are known to use the Sacramento River as a migration corridor to spawning areas in upstream tributaries. Historically, steelhead likely did not utilize the mainstem Sacramento River downstream from the Shasta Dam site except as a migration corridor to and from headwater streams. The number of steelhead that spawn in the Sacramento River is unknown, but it is probably low (DWR 2003). Likewise, the Feather River below the current site of Oroville Dam was likely used only as a migration corridor to upstream reaches.

Adult Spawning

Central Valley steelhead spawn downstream of dams on every major tributary within the Sacramento and San Joaquin River systems. The female steelhead selects a site with good intergravel flow, digs a redd with her tail, usually in the coarse gravel of the tail of a pool or in a riffle, and deposits eggs while an attendant male fertilizes them. Water velocities over redds are typically 20 to 155 cm/sec, and depths are 10 to 150 cm (Moyle 2002). The preferred water temperature range for steelhead spawning is reported to be 30°F to 52°F (CDFG 2000).

Embryo Incubation

Following deposition of fertilized eggs in the redd, they are covered with loose gravel. Central Valley steelhead eggs can reportedly survive at water temperature ranges of 35.6°F to 59°F (Myrick and Cech 2001). However, steelhead eggs reportedly have the highest survival rates at water temperature ranges of 44.6°F to 50.0°F (Myrick and Cech 2001). The eggs hatch in three to four weeks at 50°F to 59°F, and fry emerge from the gravel four to six weeks later (Shapovalov and Taft 1954).

Juvenile Rearing and Outmigration

Regardless of life history strategy, for the first year or two of life rainbow trout and steelhead are found in cool, clear, fast-flowing permanent streams and rivers where riffles predominate over pools, there is ample cover from riparian vegetation or undercut banks, and invertebrate life is diverse and abundant (Moyle 2002). The smallest fish are most often found in riffles, intermediate size fish in runs, and larger fish in pools. Steelhead can be found where daytime water temperatures range from nearly 32°F to 81°F in the summer, although mortality may result at extremely low (i.e., <39°F) or extremely high (i.e., >~73°F) water temperatures if the fish have not been gradually acclimated (Moyle 2002). Juvenile steelhead in northern California rivers reportedly exhibited increased physiological stress, increased agonistic activity, and a decrease in forage activity after ambient stream temperatures exceeded 71.6°F (Nielsen et al. 1994).

When water temperatures become stressful in streams, juvenile steelhead are faced with the increased energetic costs of living at high water temperatures. Hence, juvenile steelhead will move into fast flowing riffles to feed because of the increased abundance of food, even though there are costs associated with maintaining position in fast water. At higher water temperatures, steelhead are more vulnerable to stress which can be fatal (Moyle 2002). Predators also have a strong effect on microhabitats selected by steelhead. Small steelhead select places to live based largely on proximity to cover in order to hide from predators.

Optimal water temperatures for growth of steelhead have been reported to be 59°F to 64.4°F (Moyle 2002). Many factors affect choice of water temperatures by steelhead, including the availability of food. As steelhead grow, they establish individual feeding territories. Some juvenile steelhead utilize tidal marsh areas, non-tidal freshwater marshes, and other shallow water areas in the Delta as rearing areas for short periods prior to their final emigration to the ocean.

2.3.6 Critical Habitat

Critical habitat for listed salmonids is comprised of physical and biological features essential to the conservation of the species including: space for the individual and population growth and for normal behavior; cover; sites for breeding, reproduction and rearing of offspring; and habitats protected from disturbance or are representative of the historical geographical and ecological distribution of the species. The primary constituent elements considered essential for the conservation of listed Central Valley salmonids are: (1) freshwater spawning sites; (2) freshwater rearing sites; (3) freshwater migration corridors; (4) estuarine areas; (5) nearshore marine areas; and (6) offshore marine areas.

NMFS proposed critical habitat for Central Valley steelhead on February 5, 1999 (FR Vol. 64, No. 24 (Friday, February 5, 1999)), in compliance with Section 4(a)(3)(A) of the ESA, which requires that, to the maximum extent prudent and determinable, NMFS designates critical habitat concurrently with a determination that a species is endangered or threatened (NMFS 1999). On February 16, 2000 (FR Vol. 65, No. 32 (Wednesday, February 16, 2000)), NMFS published a final rule designating critical habitat for Central Valley steelhead. Critical habitat was designated to include all river reaches accessible to listed steelhead in the Sacramento and San Joaquin rivers and their tributaries in California. Also included were river reaches and estuarine areas of the Delta, all waters from Chipps Island westward to Carquinez Bridge, including Honker Bay, Grizzly Bay, Suisun Bay, and Carquinez Strait, all waters of San Pablo Bay westward of the Carquinez Bridge, and all waters of San Francisco Bay (north of the San Francisco/Oakland Bay Bridge) from San Pablo Bay to the Golden Gate Bridge.

In response to litigation brought by the National Association of Homebuilders (NAHB) on the grounds that the agency did not adequately consider economic impacts of the critical habitat designations (NAHB v. Evans, 2002 WL 1205743 No. 00-CV-2799 (D.D.C.)), NMFS sought judicial

approval of a consent decree withdrawing critical habitat designations for 19 Pacific salmon and *O. mykiss* ESUs. The District Court in Washington DC approved the consent decree and vacated the critical habitat designations by Court order on April 30, 2002 (NAHB v. Evans, 2002 WL 1205743 (D.D.C. 2002)). NMFS proposed new critical habitat for Central Valley steelhead on December 10, 2004 (FR Vol. 69, No. 237 (Friday, December 10, 2004)) and published a final rule designating critical habitat for this species on September 2, 2005. **Figure 2-10** depicts the designated critical habitat for Central Valley steelhead.

2.3.7 Reasons for Listing / Threats Assessment

Extensive extirpation of historical populations has placed the Chinook salmon ESUs in jeopardy of extinction. The remaining populations are at low or moderate risk of extinction. The proximate problem afflicting these ESUs and the Central Valley steelhead DPS is that their historical spawning and rearing areas are largely inaccessible. For Central Valley steelhead, there are insufficient data to assess the risk of any but a few populations and, therefore, the Central Valley TRT could not assess the viability of this DPS using the quantitative approach. However, qualitative information does suggest that the Central Valley steelhead DPS is at a moderate or high risk of extinction, especially considering that most habitat is inaccessible. Threats to Central Valley steelhead are similar to those for Chinook salmon and fall into three broad categories: loss of historical spawning habitat; degradation of remaining habitat; and threats to the genetic integrity of the wild spawning populations from hatchery steelhead production programs in the Central Valley.

Historically, steelhead occurred naturally throughout the Sacramento and San Joaquin River basins; however, stocks have been extirpated from large areas in both basins. The California Advisory Committee on Salmon and Steelhead (1988) reported a reduction in Central Valley steelhead habitat from 6,000 miles historically to

300 miles at present. Reynolds *et al.* (1993) reported that 95 percent of salmonid habitat in California's Central Valley has been lost, largely due to mining and water development activities. They also noted that declines in Central Valley steelhead stocks are "*due mostly to water development, inadequate instream flows, rapid flow fluctuations, high summer water temperatures in streams immediately below reservoirs, diversion dams which block access, and entrainment of juveniles into unscreened or poorly screened diversions.*" Other problems related to land use practices (agriculture and forestry) and urbanization also have certainly contributed to stock declines.

The major threat to genetic integrity for Central Valley steelhead comes from past and present hatchery practices. Overlap of spawning hatchery and natural fish within this DPS exists resulting in genetic introgression. Also, a substantial problem with straying of hatchery fish exists within this DPS (Hallock 1989). Currently, four hatcheries in the Central Valley produce steelhead to supplement the Central Valley wild steelhead population. The hatcheries and their current production targets are listed in Table 2-5. Habitat fragmentation and population declines resulting in small, isolated populations also pose genetic risk from inbreeding, loss of rare alleles, and genetic drift.

Potential adverse effects to wild steelhead populations associated with hatchery production are similar to those described above for winter-run Chinook salmon. However, recent research has indicated that approximately 63 to 92 percent of steelhead smolt production is of hatchery origin (NMFS 2003). More importantly, these data suggest that the relative proportion of wild to hatchery smolt production is decreasing (NMFS 2003).

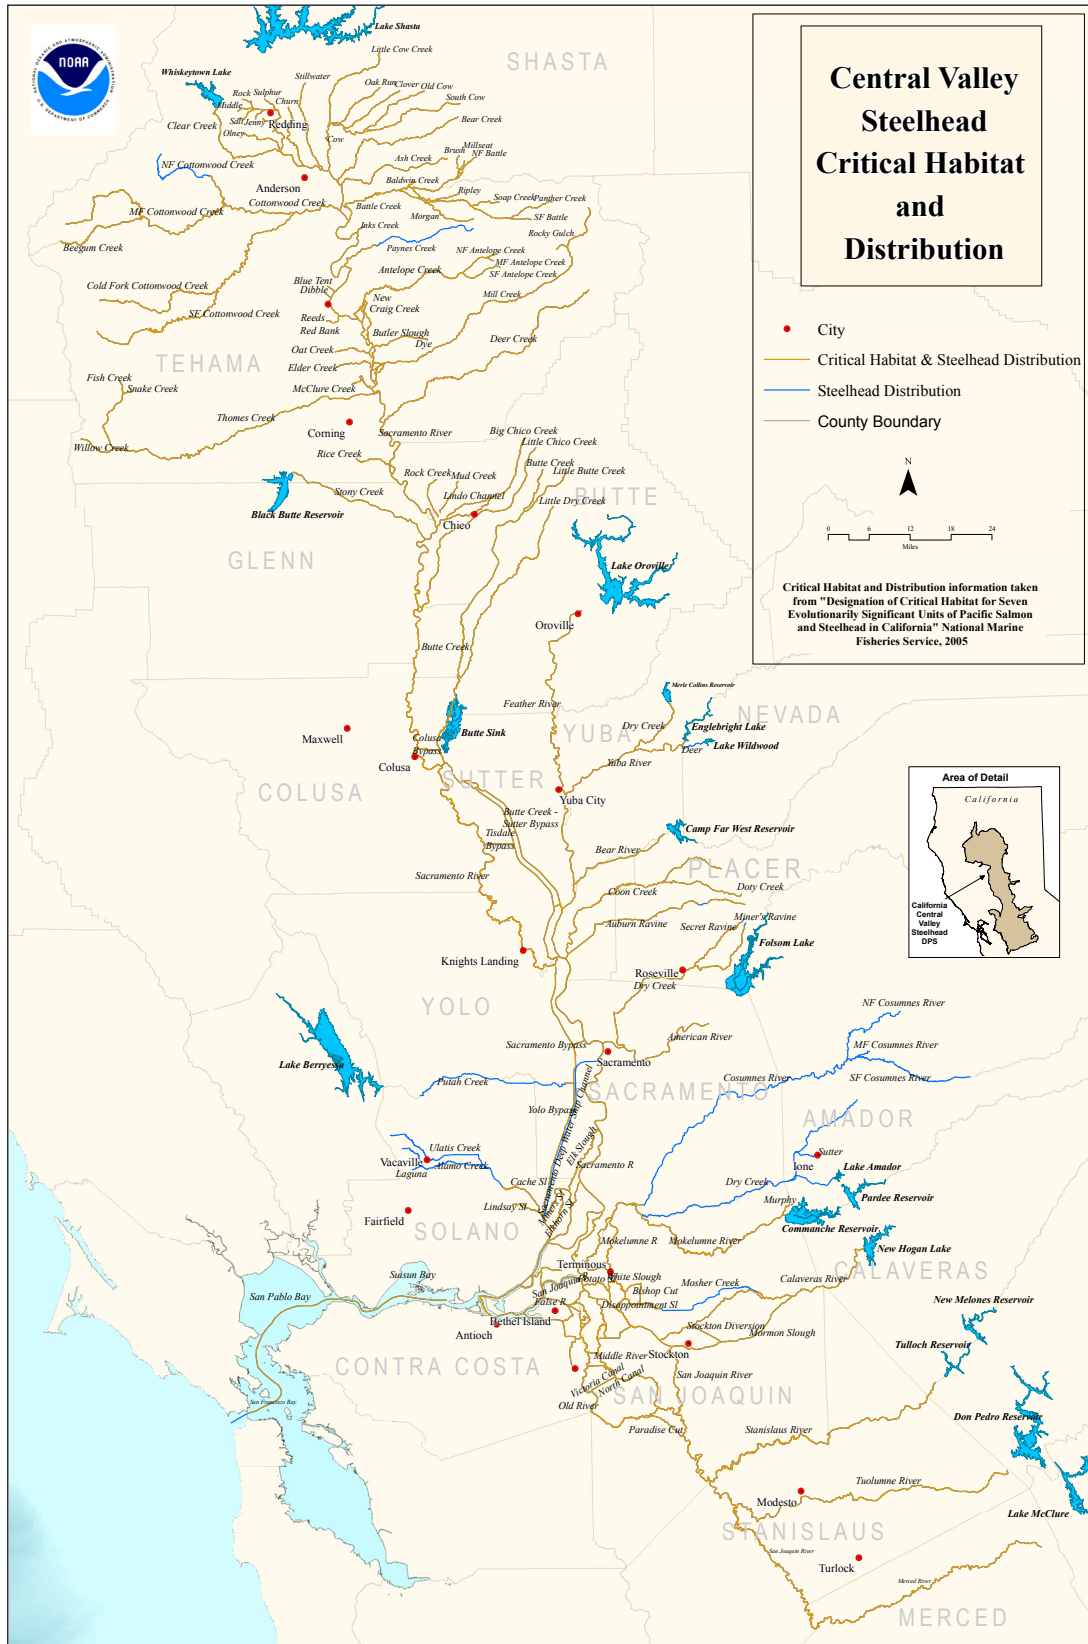

Figure 2-10. Central Valley Steelhead Designated Critical Habitat and Distribution

Potential adverse effects to wild steelhead populations associated with hatchery production are similar to those described above for winter-run Chinook salmon. However, recent research has indicated that approximately 63 to 92 percent of steelhead smolt production is of hatchery origin

(NMFS 2003), which is a higher percentage than winter-run Chinook salmon estimates. More importantly, these data suggest that the relative proportion of wild to hatchery smolt production is decreasing (NMFS 2003).

Table 2-5. Hatcheries Producing Steelhead in the Central Valley

Hatchery	Production Target
Coleman National Fish Hatchery	600,000
Feather River Fish Hatchery	500,000
Nimbus Hatchery	430,000
Mokelumne Fish Hatchery	100,000

There is still significant local genetic structure to Central Valley steelhead populations. Hatchery effects appear to be localized – for example, Feather River and the FRFH steelhead are closely related, as are American River and Nimbus Hatchery fish (DWR 2002). Leary *et al.* (1995) report that hatchery straying has increased gene flow among steelhead populations in the Central Valley, and that a smaller amount of genetic divergence is observed among Central Valley populations compared to wild British Columbia populations largely uninfluenced by hatcheries. Currently, natural annual production of steelhead smolts in the Central Valley is estimated at 181,000 and hatchery production is 1,340,000, for a ratio of 0.148 (Good *et al.* 2005).

In general, although structure was found, all naturally-spawned *O. mykiss* populations within the Central Valley basin were closely related, regardless of whether they were sampled above or below a known barrier to anadromy. This is due to some combination of preimpoundment historic shared ancestry, downstream migration and, possibly, limited, anthropogenic upstream migration. However, lower genetic diversity in above-barrier populations indicates a lack of substantial genetic input upstream and highlights lower effective population sizes for above-barrier populations. Above-barrier populations clustered with one another and below-barrier populations are most closely related to populations in far

northern California, specifically the genetic groups that include the Eel and Klamath Rivers. Since Eel River origin broodstock were used for many years at Nimbus Hatchery on the American River, it is likely that Eel River genes persist there and have also spread to other basins by migration, and that this is responsible for the clustering of the below-barrier populations with northern California ones. This suggests that the below-barrier populations in this region appear to have been widely introgressed with hatchery fish from out of basin broodstock sources. The consistent clustering of the above-barrier populations with one another, and their position in the California-wide trees, indicate that they are likely to most accurately represent the ancestral population genetic structure of steelhead in the Central Valley (Garza and Pearse 2008).

A significant transfer of genetic material has occurred among hatcheries within the Central Valley, as well as some transfer from systems outside the Central Valley. For example, an Eel River strain of steelhead was used as the founding broodstock for the Nimbus Hatchery (DWR 2002). Additionally, eyed eggs from the Nimbus Hatchery were transferred to the FRFH several times in the late 1960s and early 1970s (DWR 2002). There have also been transfers of steelhead from the FRFH to the Mokelumne Hatchery. In the late 1970s, a strain of steelhead was brought in from Washington State for the FRFH (DWR 2002).

In 1998, NMFS continued to identify long-term declines in abundance, small population sizes in the Sacramento River, and the high risk of interbreeding between hatchery and naturally spawned steelhead as major concerns for Central Valley steelhead. The significant loss of historic habitat, degradation of remaining habitat from water diversions, reduction in water quality and other factors, harvest impacts, and the lack of monitoring data on abundance also were identified as other important risk factors for this DPS. Nevertheless, NMFS concluded that the risks to Central Valley steelhead had diminished based on a review of existing and recently implemented State conservation efforts and Federal management programs that address key factors for the decline of this species. NMFS stated that Central Valley steelhead were benefiting from two major conservation initiatives, being simultaneously implemented: (1) the CVPIA, which was passed by Congress in 1992; and (2) the CALFED Program, a joint State/Federal effort implemented in 1995.

In 2005 and 2006, NMFS affirmed that risk factors for Central Valley steelhead include extirpation from most of the historical range, a consistent decline in the single available time series of abundance, declining proportion of wild fish in spawning runs, substantial opportunity for deleterious interactions with hatchery fish (including out-of-basin-origin stocks), various habitat problems, and lack of ongoing population assessments. In addition, harvest impacts have been identified. According to CDFG creel census surveys, the majority (93 percent) of steelhead catches occur on the American and Feather rivers, sites of steelhead hatcheries (CDFG 2001d). Creel census surveys conducted during 2000 indicated that 1,800 steelhead were retained, and 14,300 were caught and released. The total number of steelhead contacted might be a significant fraction of basin-wide escapement, so even low catch-and-release mortality may pose a problem for wild populations. Additionally, NMFS (2005) asserted that steelhead fisheries on some tributaries and the

mainstem Sacramento River may affect some steelhead juveniles.

A detailed threats assessment was conducted for the Central Valley steelhead DPS. The threats and stressors affecting each steelhead diversity group and population are described in Appendix B.

Some major stressors to the entire Central Valley steelhead DPS include passage impediments and barriers, warm water temperatures for rearing, hatchery effects, limited quantity and quality of rearing habitat, predation, and entrainment. The complete prioritized list of life stage-specific stressors to the DPS is presented in Appendix B.

Many of the most important stressors specific to the steelhead diversity groups correspond to the diversity group-specific stressors described for the spring-run Chinook salmon ESU on page 43. The only diversity group (i.e., area) unique to the steelhead DPS, relative to the diversity groups in the spring-run Chinook salmon ESU is the southern Sierra Nevada diversity group. Some of the most important stressors to steelhead in the southern Sierra Nevada diversity group include:

- ❑ Friant Dam blocking access to habitat historically used by San Joaquin River steelhead;
- ❑ Passage impediments on Calaveras River including Bellota Weir and flash board dams;
- ❑ Limited habitat availability in each watershed and in the mainstem San Joaquin River for spawning and juvenile rearing;
- ❑ La Grange and Don Pedro dams blocking access to habitat historically used by Tuolumne River steelhead;
- ❑ Goodwin and New Melones dams blocking access to habitat historically used by Stanislaus River steelhead;

- ❑ McSwain and Crocker Huffman dams blocking access to habitat historically used by Merced River steelhead;
- ❑ Camanche and Pardee dams blocking access to habitat historically used by Mokelumne River steelhead; and
- ❑ Entrainment at the Jones and Banks Pumping Plants and associated losses from predation
- ❑ Inadequate summer flow on the Tuolumne River

2.3.8 Conservation Measures

During 2004–2006, progress was made toward addressing some of the limiting factors and threats to this DPS, largely through ESA Section 7 consultations and other ESA-related conservation efforts in the Central Valley. The CVP Section 7 consultation with the Bureau of Reclamation likely contributed to habitat improvements benefiting the Central Valley steelhead DPS, such as flow and temperature improvements.

In addition, two large, comprehensive conservation programs in the Central Valley provide a wide range of ecosystem and species-specific protective efforts that potentially benefit steelhead—the CALFED Program and the CVPIA. For a description of CALFED, CVPIA, and other actions, refer to the previous discussion of Conservation Measures for Winter-run and Spring-run Chinook Salmon.

Other ongoing measures to protect steelhead in the State of California include 100 percent adipose fin-clipping of all hatchery steelhead, although they are not coded-wire tagged and, therefore, determination of hatchery of origin, as well as straying rates, remain problematic for stock identification. Zero bag limits for unmarked steelhead, gear restrictions, closures, and size limits designed to protect smolts are additional inland harvest measures designed to protect

steelhead. The State also works closely with NMFS to review and improve inland fishing regulations.

2.3.9 Biological Constraints and Needs

The primary limiting factor to the Central Valley steelhead DPS is the inaccessibility of more than 95 percent of its historic spawning and rearing habitat due to impassable dams. Where steelhead are still extant, natural populations are subject to habitat degradation and various impacts from water development activities and land use activities. This DPS requires cool water found at higher elevations, now largely above impassable dams. The lack of adequate status and trend monitoring and research limits our understanding of the viability of this DPS and our ability to determine how steelhead populations may have interacted before the dams were built. The geographically wide stocking of hatchery fish has had deleterious effects on native wild trout populations. It is likely many of the threats affecting Chinook salmon are also negatively impacting steelhead, such as inadequately screened water diversions, excessively high water temperatures, and predation by non-native species.

The potential effects of long-term climate change also may adversely affect steelhead and their recovery. These effects are summarized above for winter-run Chinook salmon, and are more thoroughly discussed in Chapter 7.

3.0 Recovery Strategy

"The wide-ranging migration patterns and unique life histories of anadromous salmonids take them across ecosystem and management boundaries in an increasingly fragmented world, which creates the need for analyses and strategies at similarly large scales."

- Good *et al.* 2007. Recovery Planning for Endangered Species Act-listed Pacific Salmon: Using Science to Inform Goals and Strategies

3.1 Strategic Framework

A broad strategic framework is necessary to serve as a strategic planning guide to integrate the actions contributing to the overarching goal of recovery of the two Chinook salmon ESUs and the steelhead DPS, which contain a mixture of hatchery and wild fish, and resident and anadromous fish. Because of the complexity associated with the multi-faceted considerations for these recovery efforts within the Central Valley Domain, this strategic planning framework incorporates the concepts of viability at both the population and ESU/DPS levels.

3.1.1 Population Viability

Recovery planning seeks to ensure the viability of protected species. In the short term, viability of populations (and ESU/DPS) depends on the demographic properties of the population or ESU/DPS, such as population size, growth rate, the variation in growth rate, and carrying capacity (Tuljapurkar and Orzack 1980) all of which depend largely on the quality and quantity of habitat. In the longer term, genetic diversity, and the diversity of habitats that support genetic diversity, become increasingly important (McElhany *et al.* 2000; Kendall and Fox 2002; Williams and Reeves 2003). In determining the future viability or extinction risk of a population, it is important to consider observed and predicted impacts of climate change on populations.

NMFS has developed guidelines to use in applying the four VSP parameters of abundance, productivity, spatial structure and diversity to salmonid populations for determining whether a population is viable (McElhany *et al.* 2000). These four parameters and their associated attributes are presented in **Figure 3-1**.

As presented in Good *et al.* (2005), criteria for VSP are based upon measures of population characteristics that reasonably predict extinction risk and reflect processes important to populations. Abundance is critical, because small populations are generally at greater risk of extinction than large populations. Stage-specific or lifetime productivity (i.e., population growth rate) provides information on important demographic processes. Abundance and productivity data are used to assess the status of populations of threatened and endangered ESUs (Good *et al.* 2005). Genotypic and phenotypic diversity are important in that they allow species to use a wide array of environments, respond to short-term changes in the environment, and survive long-term environmental change. Spatial structure reflects how abundance is distributed among available or potentially available habitats and how it can affect overall extinction risk and evolutionary processes that may alter a population's ability to respond to environmental change.

ABUNDANCE

A population should be large enough to have a high probability of surviving environmental variation of the patterns and magnitudes observed in the past and expected in the future.

A population should have sufficient abundance for compensatory processes to provide resilience to environmental and anthropogenic perturbation.

A population should be sufficiently large to maintain its genetic diversity over the long term.

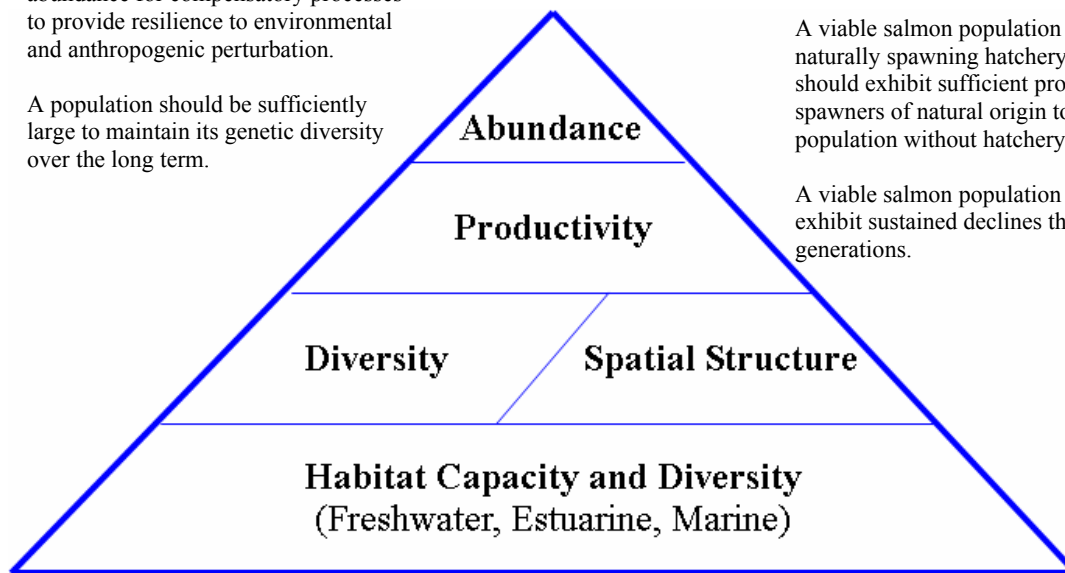

**PRODUCTIVITY
(POPULATION GROWTH RATE)**

Natural productivity should be sufficient to reproduce the population at a level of abundance that is viable.

Productivity should be sufficient throughout freshwater, estuarine, and nearshore life stages to maintain viable abundance levels, even during poor ocean conditions.

A viable salmon population that includes naturally spawning hatchery-origin fish should exhibit sufficient productivity from spawners of natural origin to maintain the population without hatchery subsidy.

A viable salmon population should not exhibit sustained declines that span multiple generations.

**DIVERSITY**

Human-caused factors such as habitat changes, harvest pressures, artificial propagation, and exotic species introduction should not substantially alter variation in traits such as run timing, age structure, size, fecundity (birth rate), morphology, behavior, and genetic characteristics.

The rate of gene flow among populations should not be altered by human caused factors.

Natural processes that cause ecological variation should be maintained.

SPATIAL STRUCTURE

Habitat patches should not be destroyed faster than they are naturally created.

Human activities should not increase or decrease natural rates of straying among salmon sub-populations.

Habitat patches should be close enough to allow the appropriate exchange of spawners and the expansion of population into underused patches.

Some habitat patches may operate as highly productive sources for population production and should be maintained.

Due to the time lag between the appearance of empty habitat and its colonization by fish, some habitat patches should be maintained that appear to be suitable, or marginally suitable, even if they currently contain no fish.

Figure 3-1. Viable salmonid population (VSP) parameters and their attributes. The quality, quantity and diversity of the habitat (habitat capacity and diversity) available to the species in each of its three main habitat types (freshwater, estuarine and marine environments) is a critical foundation to VSP. Salmon cannot persist in the wild and withstand natural environmental variations in limited or degraded habitats.

3.1.2 ESU Viability

Good *et al.* (2007) report that viability criteria for Pacific salmon ESUs rely on determining how many and which populations need to be at a particular status for the ESU as a whole to have an acceptably low extinction risk. In general, an assessment of an ESU as being viable will be more likely if it contains multiple populations (metapopulations), some of which meet viability criteria. Viability of the ESU is also more likely if: (1) populations are geographically widespread but some are close enough together to facilitate connectivity; (2) populations do not all share common catastrophic risks; and (3) populations display diverse life-histories and phenotypes (McElhany *et al.* 2000).

Considerations regarding the viability of an ESU are discussed in ISAB (2005), and are generally adopted herein for application to the two Chinook salmon ESUs and the steelhead DPS in the Central Valley Domain. To be viable, an ESU needs more than simple persistence over time; it needs to be in an ecologically and evolutionarily functional state. Evaluation of ESU viability should not only depend upon the numbers of component populations or on the abundance and productivity of those individual populations, but also should be based on the integration of population dynamics within the ecosystem as a whole. This concept of ESU viability does not accommodate the loss of populations or the anadromous or resident life history form from any given ESU, because that loss would represent a loss in diversity for the ESU that would put its long-term viability at risk. An ESU needs to contain viable populations inhabiting a variety of different habitats, interconnected as a metapopulation, if that ESU is to fulfill the entire complement of ecological and evolutionary interactions and functions (ISAB 2005).

A viable ESU consists of a group of populations existing together as a metapopulation that as an entity is self-sustaining for the foreseeable future. Populations within a viable ESU need to exhibit the abundance, productivity, diversity, and spatial

distribution of natural spawners sufficient to accomplish the following: avoid the loss of genetic and/or life history diversity during short-term losses in abundance that are expected parts of environmental cycles; fulfill key ecological functions that are attributable to the species, such as nutrient cycling and food web roles; and provide for long-term evolutionary adaptability to changing environmental conditions. However, given the high uncertainty in prediction of future environmental conditions, as well as the uncertainty in interpretation of how genetic or other diversity metrics will be expressed in future environments, this Recovery Plan endeavors to avoid loss of currently small, peripheral, or in any way seemingly less valuable populations.

In addition to the considerations alliterated by ISAB (2005), the Central Valley TRT further addressed ESU viability for the Central Valley Domain using two different approaches. The goal of both approaches is to spread risk and maximize future potential for adaptation.

In the first approach, the Central Valley TRT assessed ESU viability by examining the number and distribution of viable populations across the landscape, and their proximity to sources of catastrophic disturbance. Risk-spreading is assessed by examining how viable populations are spread among geographically-defined regions within the ESU. As stated in Lindley *et al.* (2007), the Puget Sound, Willamette/Lower Columbia and Interior Columbia TRTs have used variations of the idea of dividing ESUs into subunits (Myers *et al.* 2003; Ruckelshaus *et al.* 2002; Interior Columbia Basin Technical Recovery Team 2003), and requiring representation of all subunits and redundancy within the subunits (which the Central Valley TRT referred to as the “representation and redundancy” rule). The ESU subunits are intended to capture important components of habitat, life history or genetic diversity that contribute to the viability of salmonid ESUs (Hilborn *et al.* 2003; Bottom *et al.* 2005). If extinction risks are not strongly correlated between populations, two populations,

each with low risk of extinction, would be extremely unlikely to go extinct simultaneously (McElhany *et al.* 2003). Should one go extinct, the other could serve as a source of colonists to reestablish the extirpated population. In the second approach, the TRT attempted to account explicitly for the spatial structure of the ESU and the spatial structure of various catastrophic risks, including volcanoes, wildfires, and droughts.

Diversity Groups

As discussed in Lindley *et al.* (2004), drainages in the Central Valley Basin are characterized by a wide variety of climatological, hydrological, and geological conditions. The Central Valley TRT used the Jepson floristic ecoregions defined by Hickman (1993) as a starting point for salmon ecoregions, but modified them to account for the effect of springs, which are influential on salmonids, but less influential to upland plants. These salmonid ecoregions are referred to herein as “Diversity Groups”. The Central Valley TRT defined a “basalt and porous lava” Diversity Group that comprises the streams that historically supported winter-run Chinook salmon. All of these streams receive large inflows of cold water from springs through the summer, upon which winter-run Chinook salmon depended. This region excludes streams south of Battle Creek, but would include the part of the Upper Sacramento drainage used by winter-run, and part of the Modoc Plateau region. The southern part of the Cascades region (*i.e.*, the drainages of Mill, Deer, and Butte creeks) is added to the Sierra Nevada region, but the Sierra Nevada region is divided into northern and southern parts (split somewhat arbitrarily south of the Mokelumne River). This split reflects the greater importance of snowmelt runoff in the southern part, and distinguishes tributaries to the Sacramento and San Joaquin rivers. The Central Valley steelhead DPS has two additional salmonid ecoregions: the Suisun Bay region which consists of tributaries to or near Suisun Bay, where summer temperatures are moderated by the marine influence of nearby San Francisco Bay and the Pacific Ocean; and the

Central Western California ecoregion, which contains west-side San Joaquin Valley tributaries. A more detailed discussion of diversity group establishment and differentiation is presented in Lindley *et al.* (2004, 2007). The historic diversity group structure is presented in **Figure 3-2** for the Chinook salmon ESUs, and in **Figure 3-3** for the steelhead DPS in the Central Valley Domain.

Diversity and Population Requirements

A diversity group is a special unit of the listed entity that is geographically or otherwise identifiable and is essential to the recovery of the entire listed entity (*i.e.*, are individually necessary to conserve genetic robustness, demographic robustness, important life history stages, and other features necessary for long-term sustainability of the entire listed entity).

As such, the diversity groups contain multiple population sources in a dynamic ecosystem subject to unpredictable stochastic events, such as pyroclastic events or wild fires.

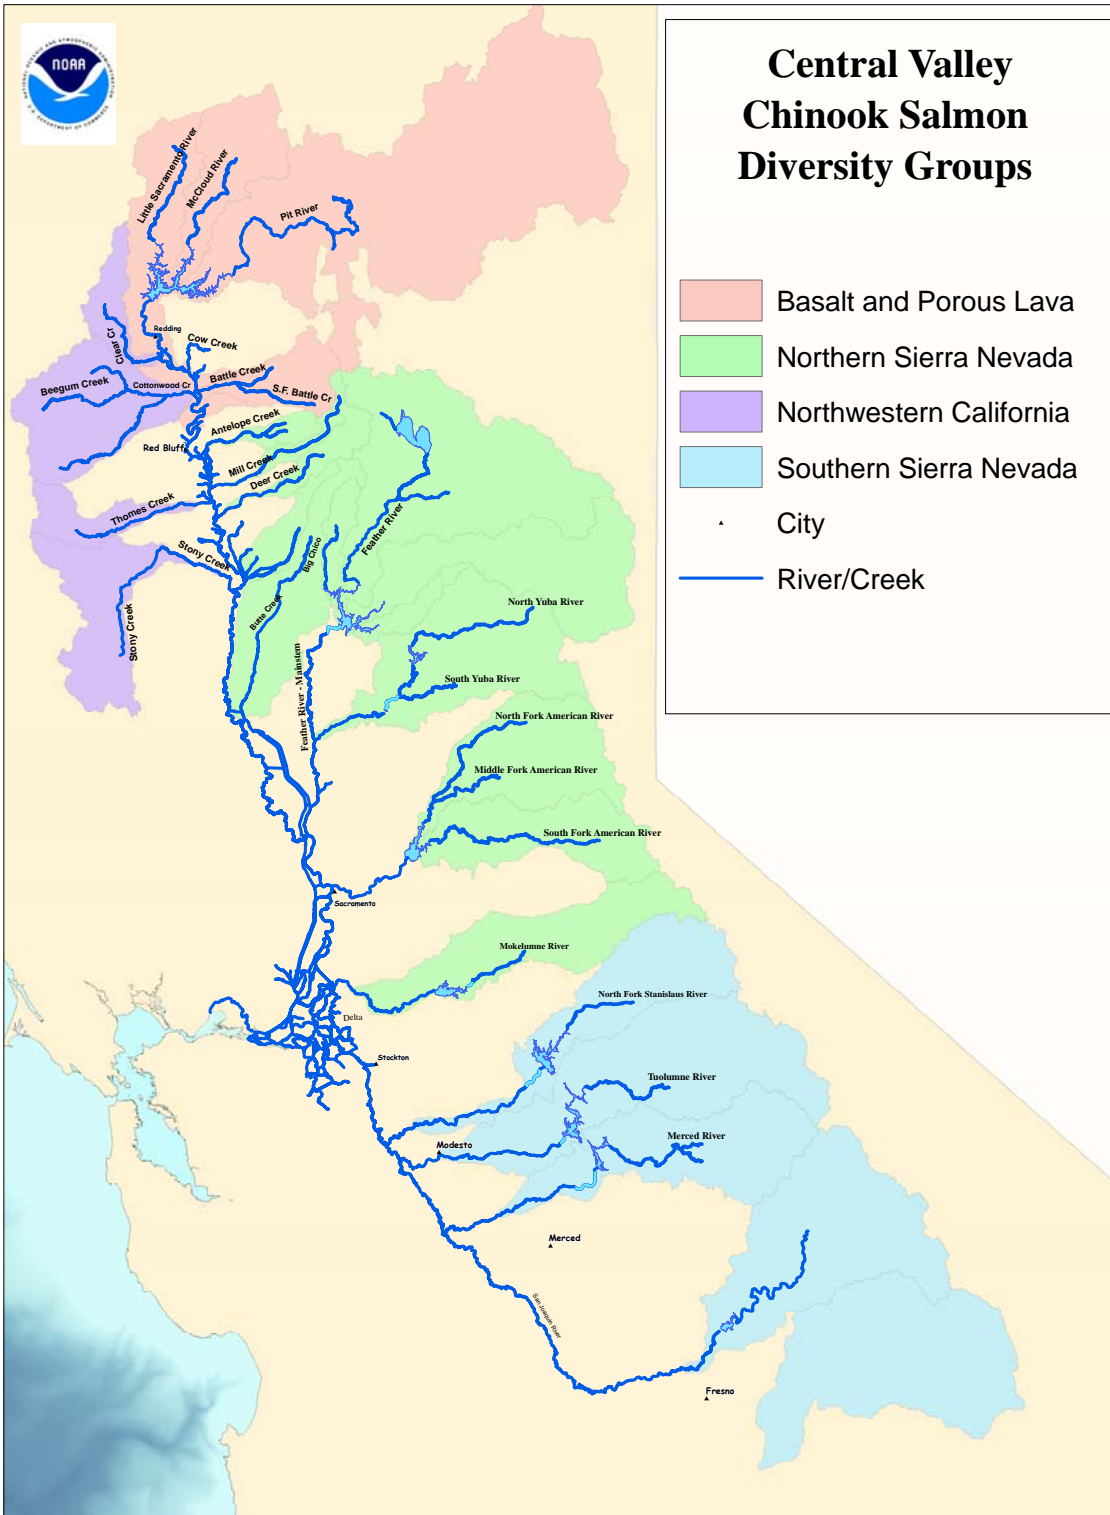

Figure 3-2. Diversity Groups for the Sacramento River Winter-run Chinook Salmon and Central Valley Spring-run Chinook Salmon ESUs in the Central Valley Domain. The Sacramento River Winter-run Chinook Salmon ESU Historically Occurred in the Basalt and Porous Lava Diversity Group, while Spring-run Chinook Salmon Occurred in all of the Diversity Groups Shown.

Figure 3-3. Diversity Groups for the Central Valley Steelhead DPS in the Central Valley Domain.

Each diversity group is necessary for the long-term health and stability of the overall listed entities and each must be recovered before the species can be delisted.

Individual populations possibly require different management than diversity groups that might be managed by different entities. Also, each population is not necessarily essential to the conservation of the species, as is the case for each diversity group.

Within the Central Valley Domain, therefore, a single diversity group encompasses multiple individual populations. Each Diversity Group must be conserved to ensure the long-term viability of the species. To achieve recovery within each Diversity group, only a subset of the populations might have to reach certain abundance estimates and threats-based criteria to be considered for de-listing.

3.1.3 Strategy for Success

This Recovery Plan establishes a strategic approach to recovery. Because recovery of the two Chinook salmon ESUs and the steelhead DPS will require implementation over an extended period of time, this Recovery Plan adopts a stepwise strategy which first addresses more urgent near-term needs, upon which to build toward full recovery. As this Recovery Plan is implemented over time, additional information will become available to help determine whether the threats have been abated, to further develop understanding of the linkages between threats and Chinook salmon and steelhead population responses, and to evaluate the viability of Chinook salmon and steelhead in the Central Valley Domain. In addition, there may also be new threats that arise. As such, periodic reviews of threats could occur to determine whether new threats and recovery action identification and prioritization processes should occur.

The Central Valley recovery strategy is based on foundational principles and the reliance on

stakeholder cooperation, local initiatives, and public support for implementation.

Foundational Principles

Foundational principles, as used in this Recovery Plan, are generally analogous to conceptual models or conceptual foundations reported elsewhere (e.g., ISG 2000; CALFED 1999), and are fundamental to the guidance of recovery actions for anadromous salmonids in the Central Valley Domain. The following foundational principles are those presented in Williams (2006) as modified critical elements of the conceptual foundation described for the Columbia River Basin (ISG 2000):

- ❑ Restoration of Central Valley anadromous salmonids must address the entire natural and cultural ecosystem, which encompasses the continuum of freshwater, estuarine, and ocean habitats where salmonid fishes complete their life histories. This consideration includes human developments, as well as natural habitats.
- ❑ Sustained salmonid productivity requires a network of complex and interconnected habitats, which are created, altered, and maintained by natural physical processes in freshwater, the estuary, and the ocean. These diverse and high-quality habitats, which have been extensively degraded by human activities, are crucial for salmonid spawning, rearing, maintenance of food webs, migration, and predator avoidance. Ocean conditions, which are variable, are important in determining the overall patterns of productivity of salmon populations.
- ❑ Life history diversity, genetic diversity, and metapopulation organization are ways that salmonids adapt to their complex and connected habitats. These factors are the basis of salmonid productivity and contribute to the ability of salmonids to cope with environmental

variation that is typical of freshwater and marine environments.

Implementation Approach

The approach of this Recovery Plan for winter-run Chinook salmon, spring-run Chinook salmon and steelhead in the Central Valley Domain includes stakeholder cooperation, local initiatives, public support, and adaptive management and monitoring components.

Stakeholder Cooperation

Individual entities alone cannot achieve recovery of winter-run Chinook salmon, spring-run Chinook salmon and steelhead in the Central Valley Domain. Partnerships and collaborations to achieve mutual goals and objectives will accelerate accomplishments, increase available resources, reduce duplication of efforts, encourage innovative solutions, improve communication, and increase public involvement and support through shared authority and ownership of habitat restoration actions (USFWS 2001). Both the Department of the Interior AFRP and the CALFED ERP plans contain processes for the building of partnerships to pursue restoration actions. Both the AFRP and the ERP continue to build partnerships and provide funds to local agencies and watershed groups, as well as other Federal and State agencies, to implement specific restoration actions throughout the Central Valley Domain. NMFS is actively engaged in both of these efforts, as well as with local agency and stakeholder efforts, and recognizes and encourages the need for the furtherance of partnerships to achieve the goals of the Recovery Plan. Achievement of these goals requires partnerships and depends upon the cooperation of all stakeholders and regulatory entities.

Local Initiatives

NMFS encourages local agencies and stakeholder groups to share or take the lead in implementing recovery and habitat restoration actions.

Influences on individual fish populations are related to specific watersheds and locally controlled water management and land use. Local development and implementation of recovery actions is essential to the success of the Recovery Plan. NMFS supports, and therefore will participate in, locally-led collaborative efforts to develop and implement recovery actions within the Central Valley Domain.

Public Support

In addition to local, State and other Federal agencies, public support is necessary for the acceptance and successful implementation of the Recovery Plan for the Central Valley Domain. As stated by USFWS (2001), public sentiment is an indicator of perceived economic and social effects of restoration actions, and public support for an action will facilitate implementation and attract partners for future actions. NMFS will continue to provide and seek additional opportunities for the public to assist in identifying, planning and implementing recovery and habitat restoration actions.

Adaptive Management and Monitoring

NMFS' implementation of the Recovery Plan includes an adaptive management and monitoring component to increase the effectiveness of, and to address the scientific uncertainty associated with, specific restoration actions. The adaptive management component allows NMFS, as well as local water agencies and irrigation districts, municipal and county governmental agencies, watershed groups, and State and other Federal agencies, to learn from past experiences through experimentation or by altering actions based on their measured effectiveness. There will be a thorough review of the recovery actions implemented and their effectiveness reflected by population and habitat condition responses at the 5-year status reviews of the Chinook salmon ESUs and the steelhead DPS.

Within the framework of the Recovery Plan, NMFS has the flexibility to work with partners to

develop and implement recovery actions to address specific problems as they arise, intensify, or as additional information becomes available regarding threats abatement, the linkages between threats and population responses, and the viability of Chinook salmon and steelhead in the Central Valley Domain. The adaptive management and monitoring component provides a framework to obtain the appropriate types and amounts of data to evaluate the effectiveness of recovery actions and the progress toward recovery. Therefore, the adaptive management and monitoring program needs to address system-wide, watershed, population and action-specific scales.

System-wide, Watershed and Population Monitoring

Several monitoring programs and studies have been developed and implemented on the system-wide, watershed and population scales by a variety of agencies and organizations. CDFG has conducted numerous monitoring programs and activities dating back to the 1940s and 1950s. These programs and activities have included spawning stock escapement (from carcass counts), creel census and inland harvest surveys, ocean harvest records, juvenile emigration (RST) surveys, snorkel surveys and redd counts, among others. The Interagency Ecological Program (IEP) continues to conduct long-term and real time monitoring programs, coordinates monitoring and manages data with particular emphasis on the Bay/Delta system. Pursuant to the CVPIA, the Comprehensive Assessment and Monitoring Program (CAMP) was prepared using a watershed-specific approach to evaluate long-term trends in anadromous fish. The AFRP has funded and implemented several watershed-specific and population-specific monitoring programs, including spawning stock escapement programs (e.g., VAKI Riverwatcher infrared and photo documentation monitoring) and instream flow evaluations, as well as site-specific habitat restoration actions. CALFED developed the Comprehensive Monitoring Assessment and Research Program (CMARP) to describe general monitoring, assessment and research needs for all

of the CALFED programs. However, CMARP has not yet been implemented, and CALFED has not yet determined a way to monitor program effectiveness.

Although each of these programs and monitoring activities provide important information to the overall status of the specific resources and their habitats of the Bay/Delta and its watersheds, they can be generally characterized as being implemented on a project-by-project basis, and the need persists for more coordinated and comprehensive system-wide watershed and population monitoring. Moreover, several streams and associated populations within the Chinook salmon ESUs and the steelhead DPS within the Central Valley Domain have no existing monitoring surveys or programs.

Existing adult Chinook salmon escapement monitoring programs in the Central Valley are currently inadequate to estimate population status and evaluate population trends in a statistically valid manner for the following management purposes: (1) providing a sound basis for assessing recovery of listed stocks; (2) monitoring the success of restoration programs; (3) evaluating the contribution of hatchery fish to Central Valley populations; and (4) managing sustainable ocean and inland harvest (Allen 2005).

The need is even greater for the development and implementation of a comprehensive monitoring plan for steelhead populations throughout the Central Valley Domain. The Central Valley Domain TRT was unable to assess the status of the Central Valley steelhead DPS because nearly all of its approximately 80 populations are classified as data deficient, with a few exceptions that are closely associated with a hatchery (Lindley *et al.* 2007).

Until recently, hatchery marking programs for Central Valley anadromous salmonids have been inadequate to evaluate hatchery contributions to Central Valley populations. CDFG and USFWS have been adipose fin-clipping all steelhead hatchery production since the late 1990's, however there has been no real effort to recover any information from this, except through the

Steelhead Report Card program. CDFG has also initiated efforts to implement a constant fractional marking and tagging program for hatchery-produced Chinook salmon within the Central Valley. The efficacy of this program depends, in part, on the tag recovery rates in the adult escapement surveys in order to determine hatchery contribution or straying rates among populations.

In addition to population status and trend evaluation, accurate estimation of adult Chinook salmon and steelhead spawner escapement is a necessary component of harvest management. Age and run-specific escapement data in the Central Valley are necessary to utilize more accurate models associated with ocean harvest management.

CALFED recently funded, as an ERP directed action, the development of a comprehensive Central Valley adult Chinook salmon escapement monitoring plan. The objective of this plan is to develop a long-term monitoring program to estimate the population status and trends in abundance of Central Valley Chinook salmon at the watershed level, in a statistically valid manner. The plan will include statistical review of current monitoring methods, recommendations for the improvement of existing programs, and will develop comprehensive databases linking escapement, hatchery production, and coded-wire tag data. The framework for the plan was developed by the Interagency Ecological Program's Central Valley Salmonid Escapement Project Work Team (CVSEPWT). Agencies involved in the development of the framework for the plan include CDFG, DWR, NMFS, USFWS, Reclamation, Pacific States Marine Fisheries Commission, Yuba County Water Agency, and East Bay Municipal Utility District. Implementation of this monitoring plan is essential to evaluate Central Valley Chinook salmon viability at the system-wide, watershed, and population levels. Although providing essential contributions to meeting the needs of this Recovery Plan, the CVSEPWT monitoring plan most likely will need to be expanded or augmented in order to address the broad expanse

of populations, watersheds and Diversity Groups associated with the Chinook salmon ESUs and the steelhead DPS throughout the Central Valley Domain. In addition, the Central Valley Steelhead Monitoring Plan is currently under development, which will provide the data necessary to evaluate threats abatement, the linkages between threats and population responses, and the viability of steelhead populations in the Central Valley Domain.

Watershed-level monitoring is necessary to evaluate the overall effects of multiple restoration actions within a single watershed. Monitoring at the watershed level should address population and/or life stage-specific attributes of target populations and of selected habitat variables. Watershed-specific monitoring evaluations will contribute to the assessment of threats abatement and population responses.

In addition to monitoring necessary to evaluate population status, trends and progress toward recovery, the long-term effects of habitat restoration actions need to be assessed throughout the Central Valley Domain. Components that require monitoring include long-term changes in the characteristics of aquatic habitat, riverine channel configuration, riparian vegetation, floodplain structure and function, and other targeted recovery/restoration components.

Action-Specific Monitoring

In addition to the multi-agency led comprehensive escapement monitoring plans, NMFS will be actively engaged with local agencies and stakeholder groups in developing and implementing watershed-specific, population-specific, and habitat restoration action-specific monitoring plans. NMFS believes that it is critically important to participate in locally-led collaborative efforts of local communities, State and Federal entities, and other stakeholder groups in order to provide input to the development and implementation of monitoring plans to help ensure that they are conducted within the adaptive management and monitoring framework of this Recovery Plan.

3.2 Applied Strategic Framework

For the Central Valley Domain, the TRT applied the strategic framework components of population and ESU viability to winter-run Chinook salmon, spring-run Chinook salmon and steelhead. The following is largely taken from the TRT report (Lindley *et al.* 2007).

3.2.1 Sacramento River Winter-run Chinook Salmon

All four historical populations of Sacramento River winter-run Chinook salmon are “extinct” in their historical spawning range. The upper Sacramento, McCloud and Pit River populations had spawning and rearing habitat far upstream of impassable Keswick and Shasta dams, although these populations were apparently in poor condition even before the construction of Shasta dam in the 1940s (Moffett 1949). Winter-run Chinook salmon no longer inhabit Battle Creek as a self-sustaining population.

The population of Sacramento River winter-run Chinook salmon that now spawns below Keswick Dam is at moderate extinction risk according to the Population Viability Analyses (PVA), and at low risk according to the other criteria. From roughly the mid-1990s until 2006, this population grew. A drop in abundance from the 2006 (17,304) run size was observed in 2007 (2,542) and 2008 (2,850). Even with the relatively low run sizes in 2007 and 2008, the population satisfies the low-risk criteria for population size, population decline, and catastrophe, but hatchery influence is a concern.

The Sacramento River winter-run Chinook salmon ESU does not currently satisfy representation and redundancy needs because it has only one population, and that population spawns outside of the ecoregion where it evolved. For the Sacramento River winter-run Chinook salmon ESU to have sufficient representation and redundancy, at least two populations would need to be re-established in the basalt-and-porous-lava region.

Obviously, an ESU represented by a single population at moderate risk of extinction is at high risk of extinction over the long run. A single catastrophe could extirpate the entire Sacramento River winter-run Chinook salmon ESU, if its effects persisted for four or more years.

3.2.2 Central Valley Spring-run Chinook Salmon

Perhaps 15 of the 18 or 19 historical populations of Central Valley spring-run Chinook salmon are extinct, with their entire historical spawning habitats behind various impassable dams (Lindley *et al.* 2007). Butte Creek and Deer Creek spring-run Chinook salmon are at low risk of extinction, satisfying both the PVA and other viability criteria. Mill Creek is at moderate extinction risk according to the PVA, but appears to satisfy the other viability criteria for low-risk status. Lindley *et al.* (2004) were uncertain whether Mill and Deer creek populations were each independent, or two parts of a single larger population. If viewed as a single population, Mill and Deer Creek spring-run Chinook salmon are at low extinction risk. Early-returning Chinook salmon persist within the FRFH population and spawn in the Feather River below Oroville Dam and the Yuba River below Englebright Dam. The current status of these fish is not assessable due to insufficient data.

With demonstrably viable populations in only one of at least three Diversity Groups that historically contained them, Central Valley spring-run Chinook salmon fail the representation and redundancy rule for ESU viability. Historically, the Central Valley spring-run Chinook salmon ESU spanned four ecoregions: the region used by winter-run Chinook salmon plus the northern and southern Sierra Nevada and the northwestern California region. There are two or three viable populations in the northern Sierra Nevada (Mill, Deer and Butte creeks). A few ephemeral or dependent populations are found in the Northwestern California region (e.g., Beegum and perhaps Clear creeks). Spring-run Chinook salmon have been almost entirely extirpated from both the basalt and porous lava region and the southern

Sierra Nevada region⁴. A small population persists on Battle Creek. The current distribution of viable populations makes the Central Valley spring-run Chinook salmon ESU vulnerable to catastrophic disturbance. All three extant independent populations are in basins whose headwaters lay within the debris and pyroclastic flow radii of Lassen Peak. The current ESU structure is vulnerable to drought and wildfires, which pose a significant threat to the ESU in its current configuration.

3.2.3 Central Valley Steelhead

There are few data with which to assess the status of any of the 81 Central Valley steelhead populations described by Lindley *et al.* (2006). With few exceptions, therefore, Central Valley steelhead populations are classified as data deficient (Lindley *et al.* 2007). The exceptions are restricted to streams with long-running hatchery programs such as Battle Creek and the Feather, American and Mokelumne rivers. In all cases, hatchery-origin fish likely comprise the majority of the natural spawning run, placing the natural populations at high risk of extinction.

Data are lacking to suggest that the Central Valley steelhead DPS is at low risk of extinction, or that there are viable populations of steelhead anywhere in the DPS. Conversely, there is evidence to suggest that the Central Valley steelhead DPS is at moderate or high risk of extinction (McEwan 2001; Good *et al.* 2005). Clearly, most of the historical habitat once available to steelhead has been lost (Yoshiyama *et al.* 1996; McEwan 2001; Lindley *et al.* 2006). Furthermore, the observation that anadromous *O. mykiss* are becoming rare in areas where they were probably once abundant McEwan (2001) indicates that an important component of life history diversity is being suppressed or lost. It should be noted, however, that habitat fragmentation, degradation, and loss are likely having a strong

negative impact on many resident as well as anadromous *O. mykiss* populations (Hopelain 2003).

3.3 Recovery Plan Strategy

The Central Valley salmon and steelhead recovery strategy is similar to, and incorporates components of the strategic approaches adopted by NMFS for the three ESUs of salmon and steelhead within the Washington Lower Columbia Management Unit (NMFS 2005a), and for six ESUs of salmon and steelhead in the Willamette and Lower Columbia river basins (NMFS 2005b). This strategy identifies actions that address threats, and establishes an adaptive management framework to adjust actions and goals as understanding of the efficacy of certain actions and ESU (and DPS) status improves over time.

Recovery of the two Chinook salmon ESUs and the steelhead DPS within the Central Valley Domain will require implementation of the plan over an extended period of time. Recovery of individual Diversity Groups or even individual populations is likely to be a challenging and slow process (Lindley *et al.* 2007). Therefore, in order to achieve the overarching goal of recovery within the Central Valley Domain, this Recovery Plan adopts a stepwise strategy which first addresses more urgent near-term needs, upon which to build toward full recovery.

3.3.1 Near-term Strategic Approach

- ❑ *Secure all extant populations.* Both ESUs and the DPS are far short of being viable, and extant populations, even if not presently viable, may be needed for recovery. The Central Valley TRT recommends that every extant population be viewed as necessary for the recovery of the ESU and DPS. Wherever possible, the status of extant populations should be improved.

⁴ Observations of small numbers of Chinook salmon returning to the Stanislaus River in the spring have been reported, but their status as spring-run Chinook salmon has not been confirmed.

- ❑ *Begin collecting distribution and abundance data for *O. mykiss* in habitats accessible to anadromous fish.* This is fundamental to designing effective recovery actions and eventual delisting. Of equal importance is assessing the relationship of resident and anadromous forms of *O. mykiss*, including the role the resident fish play in population maintenance and persistence.
- ❑ *Minimize straying from hatcheries to natural spawning areas.* Even low levels of straying from hatchery populations to wild ones works against the goal of maximizing diversity within ESU/DPSs and populations. A number of actions could reduce straying from hatcheries to natural areas, including replacing off-site releases with volitional releases from the hatchery, allowing all fish that attempt to return to the hatchery to do so, marking or tagging programs that could be used to separate wild and hatchery stocks, and reducing the amount of fish released (see CDFG and NMFS (2001), for a review of hatchery issues).
- ❑ *Conduct critical research on fish passage above rim dams, reintroductions, and climate change.* Current climate change information suggests that the Central Valley will become warmer, a challenging prospect for Chinook salmon and steelhead – both of which are coldwater fish at the southern end of their distribution. To recover Central Valley salmon ESUs and the steelhead DPS, some populations will need to be established in cooler, high elevation areas now blocked by dams or insufficient flows. Assuming that most of these dams will remain in place for the foreseeable future, it will be necessary to facilitate the movement of fish around the dams in both directions. The near-term will include assessing habitat suitability and passage logistics.
- ❑ *Listed salmonid ESUs are likely to be conservation-reliant (Scott et al. 2005).* It seems highly unlikely that enough habitat can be restored in the foreseeable future such that Central Valley salmonid ESUs and DPS could be expected to persist without continued conservation management. Rather, it may be possible to restore enough habitat such that ESUs and DPS can persist with appropriate management, which should focus on maintaining ecological processes at the landscape level.

3.3.2 Long-term Strategic Approach

Strategies for Achieving Recovery at the ESU/DPS Level

- ❑ Every Diversity Group that historically existed should have a high probability of persistence (or a low risk of extinction).
- ❑ As a strategy for achieving recovery, until all ESU viability criteria have been achieved, no population should be allowed to decrease its probability of persistence.
- ❑ As a strategy for achieving recovery, high levels of recovery should be attempted in more populations than identified in the Diversity Group viability criteria because not all attempts will be successful.

Strategies for Achieving Recovery at the Diversity Group Level

- ❑ Individual populations within a Diversity Group should have persistence probabilities which together contribute to a high probability of Diversity Group persistence.
- ❑ Within a Diversity Group, the populations restored/maintained at viable status or above should be selected to:

- Allow for normative meta-population processes, including the viability of core populations, which are defined as the most productive populations.
- Allow for normative evolutionary processes.
- Minimize susceptibility to catastrophic events.

3.4 Core Populations

The TRT (Lindley *et al.* 2007) and almost all other salmon and steelhead restoration programs and plans in the Central Valley including the USFWS' AFRP and the Calfed ERP recognize that certain specific watersheds form the foundation of restoring and recovering the Chinook salmon ESU's and steelhead DPS. These watersheds exhibit the physical and hydrological characteristics (*e.g.*, appropriate water temperatures, stream flows, pool depths and spawning habitat availability) that are most likely to support viable populations – that is, independent populations that are critical for ensuring the viability of the ESU/DPS as a whole. Dependent populations may play a role in ESU/DPS viability by increasing biocomplexity (Hilborn *et al.* 2003), spreading risk, and maximizing future potential for adaptation (Lindley *et al.* 2004, 2007). As environmental conditions change over time, populations respond, providing the opportunity for a population's status to shift from dependent to independent, further suggesting that securing all extant populations of winter-run, spring-run, and steelhead will be critical to recovering those species. The spring-run population in Butte Creek provides an example of a population whose status has shifted considerably. From the mid-1960s through the mid-1990s, the estimated annual abundance of spring-run in Butte Creek fell into the moderate to high extinction risk categories, while following that period, the estimated annual abundance surpassed the low extinction risk abundance threshold (*i.e.*, 2,500 fish) in all but one year. This population status shift was not

anticipated and the factors causing it are not well understood, suggesting that a dependent population today may be a key independent population in the future.

In **Table 3-1**, existing populations are identified as Core 1, Core 2, or Core 3. The Core 1 populations are those populations identified as having the highest priority for recovery action implementation based on the known ability or significant immediate potential to support independent populations, thereby contributing to meeting the ESU/DPS-level recovery criteria. Core 1 populations form the foundation of the recovery strategy. In the Sacramento River Basin, Core 1 populations must meet the population-level biological recovery criteria for low risk of extinction set out in Table 4-1. In the San Joaquin River Basin, Core 1 populations also include areas that have a moderate potential to support viable populations, and must meet the population-level biological recovery criteria for a moderate risk of extinction. This is largely necessitated by the need to secure San Joaquin steelhead populations that are at very low levels, and currently face a high risk of extinction. NMFS believes that this set of Core 1 populations should be the first focus of an overall recovery effort. Core 2 population areas also form part of the recovery strategy by contributing to geographically diverse populations. Core 2 populations must have the potential to reach the biological recovery criteria for moderate risk of extinction set out in Table 4-1. These populations are of secondary importance in terms of recommended priority of recovery efforts, but provide an important role in ESU/DPS viability by increasing the diversity, spatial distribution and abundance of the species. Finally, the complete attainment of ESU/DPS-level biological recovery criteria may also require the presence of populations listed as Core 3. Similar to Core 2 populations, Core 3 populations may be present on an intermittent basis and are characterized as being dependent on other nearby independent populations for their existence, but are not expected to exceed the abundance criteria for high risk of extinction. The presence of these populations provides increased life history

diversity to the ESU/DPS and is likely to buffer against local catastrophic occurrences that could affect other nearby populations. Dispersal connectivity between populations and genetic diversity may be enhanced by working to recover Core 3 populations that serve as stepping stones for dispersal.

Populations identified as being Core 1 and 2 populations would be expected to meet the population recovery criteria either as a single population or a group of interacting trans-basin populations. Further research is needed to identify these interacting groups. In the interim, the population-level recovery criteria (Table 4-1) are proposed to apply to each core population.

Public and private groups should not be dissuaded from undertaking actions that alleviate threats to the species in Core 3 watersheds. While sufficient information regarding threats and the biology and ecology of the species is available to define an overall recovery strategy, there still remain questions regarding the ecology of the species (e.g., function of certain habitats in the life history of the species, relationship between the anadromous and resident forms, rate of dispersal between watersheds). In light of this uncertainty, a prudent approach is to define a recovery strategy based on the existing information on Core 1 and 2 watersheds while recovery opportunities in Core 3 watersheds continue to be actively pursued as a precaution to reduce the risk of extinction. Therefore, while the Core 1 and 2 watersheds form the foundation for recovery of the Central Valley Recovery Domain, recovery actions to alleviate threats should be undertaken in other watersheds to complement this recovery implementation strategy.

3.5 Reintroduction Priorities

Addressing the primary threats and risk factors for each of the ESUs and DPS will require reintroducing populations to historic, and currently unoccupied habitats. These areas include watersheds that are currently inaccessible because of existing dams (e.g., Little Sacramento

River and McCloud River), and watersheds that are currently accessible, but not utilized (e.g., winter-run in Battle Creek). Candidate areas for reintroduction are identified in the Recovery Footprint maps of Chapter 5 (Recovery Scenarios). Efforts to reintroduce fish will be challenging, expensive, and will require unparalleled efforts to gain stakeholder support. Therefore we have prioritized these areas as either primary or secondary (Table 3-2). Rather than prioritize a third category, the Recovery Footprint maps have excluded from consideration the historically occupied, habitats that are so critically impaired by hydroelectric development and channel inundation that we felt addressing them was not reasonable. We prioritized areas based on information described in the Recovery Scenarios and Watershed Profiles sections of this plan. Primary priority watersheds were described in the Watershed Profile as having a high potential to support spawning populations of anadromous fish and either high quality existing conditions or a high restoration potential for anadromous fish. Secondary priorities were characterized in the Watershed Profiles as having a moderate potential to support spawning populations of anadromous fish based on existing habitat conditions and a moderate to unknown restoration potential. Secondary areas also include watersheds that historically supported large populations, but there is little existing information on habitat suitability, and further evaluation is needed to understand the reintroduction potential.

Table 3-1. Recovery Priorities for Central Valley Watersheds Currently Occupied by Winter-run, Spring-run, or Steelhead.

Diversity Group	Watershed/Population	Species	Recovery Focus
Northwestern California	Clear Creek	Spring-run Steelhead	Core 1
	Cottonwood/Beegum Creek	Steelhead	Core 2
		Spring-run	Core 2
	Thomes Creek	Steelhead	Core 2
		Spring-run	Core 3
Basalt and Porous Lava	Upper Sacramento River (Keswick to Red Bluff)	Winter-run	Core 1
		Spring-run Steelhead	Core 2
	Cow Creek	Steelhead	Core 2
	Redding Area Tributaries	Steelhead	Core 2
	Battle Creek	Spring-run Steelhead	Core 1
Northern Sierra Nevada	Antelope Creek	Steelhead	Core 1
		Spring-run	Core 2
	Mill Creek	Spring-run Steelhead	Core 1
	Deer Creek	Spring-run Steelhead	Core 1
	Big Chico Creek	Steelhead	Core 2
		Spring-run	Core 3
	Butte Creek	Spring-run	Core 1
		Steelhead	Core 2
	Lower Feather River	Spring-run Steelhead	Core 2
	Lower Yuba River	Spring-run Steelhead	Core 1
	Bear River	Spring-run Steelhead	Core 3
	Lower American River	Steelhead	Core 2
Cosumnes River	Steelhead	Core 3	
Lower Mokelumne River	Steelhead	Core 3	
Southern Sierra Nevada	Calaveras River	Steelhead	Core 1
	Lower Stanislaus River	Steelhead	Core 2
	Lower Tuolumne River	Steelhead	Core 2
	Lower Merced River	Steelhead	Core 2

Table 3-2. Reintroduction Priorities for Central Valley Watersheds.

Diversity Group	Watershed	Species	Focus for Recovery
Basalt and Porous Lava	Little Sacramento River	Winter-run Spring-run Steelhead	Primary
	McCloud River	Winter-run Spring-run Steelhead	Primary
	Battle Creek	Winter-run	Primary
Northern Sierra Nevada	NF Feather River	Spring-run Steelhead	Secondary
	Upper Yuba River	Spring-run Steelhead	Primary
	Upper American River	Spring-run	Secondary
		Steelhead	Primary
	Cosumnes River	Steelhead	Secondary
Upper Mokelumne River	Steelhead	Secondary	
Southern Sierra Nevada	Upper Stanislaus River	Steelhead	Secondary
	Upper Tuolumne River	Steelhead	Secondary
	Upper Merced River	Steelhead	Secondary
	San Joaquin River (Friant to Merced)	Spring-run	Primary

4.0 Recovery Goals, Objectives and Criteria

“Merely increasing a species’ numbers, range and abundance does not ensure its long-term health and sustainability; only by alleviating threats can lasting recovery be achieved.”

- Interim Endangered and Threatened Species Recovery Planning Guidance (NMFS 2006)

4.1 Recovery Goals

The overarching goal of this Recovery Plan is the removal of the Sacramento River winter-run Chinook salmon ESU, Central Valley spring-run Chinook salmon ESU, and Central Valley steelhead DPS from the Federal List of Endangered and Threatened Wildlife (50 C.F.R. 17.11). Recovery plans are not regulatory documents and successful implementation and recovery of listed species will require the support, efforts and resources of many entities, from Federal and state agencies to individual members of the public. Another goal will be to encourage and support effective partnerships with regional stakeholders to meet the objectives and criteria of the Recovery Plan. The objectives and criteria to accomplish this goal build upon the technical input and guidance provided by the Central Valley TRT, and other information provided during public workshops and co-manager reviews. Much of the technical recovery discussion in this section is taken directly from information developed by the TRT (Lindley *et al.* 2004; 2006; 2007).

The Endangered and Threatened Species Recovery Planning Guidance (NMFS 2006b) describes the recovery planning goal as recovery and long-term sustainability of an endangered or threatened species and, therefore, delisting of the species. Further, NMFS (2006b) states that goals usually can be subdivided into discrete component objectives which, collectively, describe the conditions (criteria) necessary for achieving the goal. Simply stated, recovery objectives are the parameters of the goal, and criteria are the values for those parameters. The objectives and related criteria, representing the components of the recovery goal, identify mechanisms for pursuing the goal (including necessary recovery actions) and allows confirmation when the goal has been reached.

According to NMFS (2006b), recovery and long-term sustainability of an endangered or threatened species require:

- ❑ Adequate reproduction for replacement of losses due to natural mortality factors (including disease and stochastic events)
- ❑ Sufficient genetic robustness to avoid inbreeding depression and allow adaptation
- ❑ Sufficient habitat (type, amount, and quality) for long-term population maintenance
- ❑ Elimination or control of threats (this may also include having adequate regulatory mechanisms in place)

4.2 Integrating TRT Products into Recovery Objectives and Criteria

The ESA requires that recovery plans, to the maximum extent practicable, incorporate objective, measurable criteria which, when met, would result in a determination in accordance with the provisions of the ESA that the species be removed from the Federal List of Endangered and Threatened Wildlife and Plants. The recovery criteria constitute the standards upon which the decision to consider reclassifying or delisting a species will be based.

Evaluating a species for potential delisting requires an explicit analysis of population or demographic parameters (the biological recovery criteria) and also of threats under the five ESA listing factors in ESA section 4(a)(1) (threats criteria). Together, these make up the “objective, measurable criteria” required under section 4(f)(1)(B).

While this plan establishes some objective, measurable criteria specific to both population demographics and to threat abatement, measurable criteria has not been provided for all demographic and threat-based factors at this time. Therefore, qualitative delisting criteria are provided in such instances.

These criteria represent the best scientific analysis incorporating the most current understanding of the ESU and DPS and their populations. As this Recovery Plan is implemented, additional information will become available that can increase certainty about whether the threats have been abated, whether improvements in populations and ESU and DPS status have occurred, and whether linkages between threats and changes in Chinook salmon and steelhead status are understood. These recovery criteria will be assessed through the adaptive management program for this Recovery Plan, and there will be a review of the criteria every five years during status reviews of the Chinook salmon ESUs and the steelhead DPS. During these reviews, the criteria may be revised, if necessary. NMFS will

apply the Recovery Plan’s criteria when it makes a decision whether to delist the ESUs and DPS.

4.2.1 Biological Recovery Criteria

In order to delist the winter-run and spring-run Chinook salmon ESUs and the steelhead DPS, the TRT stated that there must be at least two viable populations within each historic diversity group (Lindley et al. 2007). This ESU/DPS-level recovery criterion addresses the representation and redundancy rule for ESU/DPS viability. Exceptions to the ESU/DPS-level criterion include diversity groups which likely did not historically contain viable populations, such as the Northwestern California diversity group for spring-run Chinook salmon and steelhead, and the Suisun Bay and Central Western California steelhead diversity groups. For the Northwestern California diversity group, the presence of at least two populations, but not necessarily viable ones, is required to recover spring-run Chinook salmon and steelhead.

It is assumed that full recovery of Central Valley steelhead can be achieved without the presence of populations in either the Suisun Bay or Central Western California diversity groups. This assumption is based on the fact that the four Chinook salmon diversity groups, which did not include the Suisun Bay or Central Western California regions, supported abundant and diverse Chinook salmon populations for thousands of years. As such, the extent and diversity of habitats historically available in those four diversity groups would likely also support a viable steelhead DPS, if the quantity and quality of habitat currently available in those regions was sufficiently increased.

Whether or not the ESU/DPS-level criterion has been met requires application of population-level recovery criteria. The population-level criteria can be used to determine whether a population is viable or not. A viable population is one with a low extinction risk in the wild over the long-term (McElhany et al. 2000). The Central Valley TRT

assumed that a 5 percent or less risk of extinction in 100 years is an acceptably low extinction risk for populations.

The Central Valley TRT incorporated the four VSP parameters into assessments of population viability, and two sets of population viability criteria were developed, expressed in terms of extinction risk. Then, populations were classified into one of six categories, including “extinct”, “extinct in the wild”, “high”, “moderate”, and “low” extinction risk, or “data deficient” following the general approach of the IUCN (1994) as modified for Pacific salmonids by Allendorf *et al.* (1997). The first set of criteria deal with direct estimates of extinction risk from population viability models. If data are available and such analyses exist and are deemed reasonable for individual populations, such assessments may be efficient for assessing extinction risk. The Central Valley TRT used a population viability assessment based on the random-walk-with-drift model extended to account for observation error (Lindley *et al.* 2007). In addition, the Central Valley TRT also provided simpler criteria, both of which are presented in Table 4-1.

The simpler criteria include population size (and effective population size), population decline, catastrophic rate and effect, and hatchery influence. The effective population size criteria in the second row of Table 4-1 relate to loss of genetic diversity. Very small populations, for example with $N_e < 50$, suffer severe inbreeding depression (Franklin 1980; Soulé 1980 in Lindley *et al.* 2007), and normally outbred populations with such low N_e have a high risk of extinction from this inbreeding. Somewhat larger, but still small, populations can be expected to lose variation in quantitative traits through genetic drift faster than it can be replaced by mutation. With future research, it may be possible to define population size targets that conserve genetic variation and account for migration and genetic structuring within ESUs.

The population decline criteria are intended to capture demographic risks. The rationale behind the population decline criteria are fairly straightforward—severe and prolonged declines to small run sizes are strong evidence that a population is at risk of extinction.

The overall goal of the catastrophe criteria is to capture a sudden shift from a low risk state to a higher risk state. Catastrophes are defined as instantaneous declines in population size due to events that occur randomly in time, by contrast to regular environmental variation. A high risk catastrophic event is created by a 90 percent decline in population size over one generation. A moderate risk catastrophic event is one that is smaller but biologically significant, such as a year-class failure.

The spawning of hatchery fish in the wild is a potentially serious threat to the viability of natural populations. Population genetics theory predicts that fish hatcheries can negatively impact wild populations when hatchery fish spawn in the wild. In assessing the genetic impact of immigration on a population, considerations include the source of the immigrants, duration of the impact, the number of immigrants relative to the size of the recipient population, and how divergent the immigrants are from the recipient population. Definitions of the manner in which different immigration scenarios relate to extinction risk for natural populations are summarized in Figure 4-1. Application of these definitions can result in a low-risk classification even with moderate amounts of straying from best-practices hatcheries, as long as other risk measures are acceptable (Lindley *et al.* 2007).

Estimators for the various viability criteria are presented in Table 4-2 (from Lindley *et al.* 2007). The average run size is computed as the mean of up to the three most recent generations, if that much data are available. Mean population size is estimated as the product of the mean run size and the average generation time. Population growth (or decline) rate is estimated from the slope of the natural logarithm of spawners versus time for the

most recent 10 years of spawner count data. The fraction of naturally-spawning fish of hatchery origin is the mean fraction over one to four generations.

The TRT assessed the viability of winter-run Chinook salmon, spring-run Chinook salmon, and steelhead populations by applying both the PVA modeling and the simpler demographic criteria described in Table 4-1. Detailed descriptions of those assessments are provided in the Recovery Strategy chapter. In general, the only Central Valley populations with enough demographic data available for the TRT to conduct the PVA modeling were mainstem Sacramento River winter-run Chinook salmon and spring-run Chinook salmon populations in Butte, Mill, and Deer creeks. That modeling suggested that the Sacramento River winter-run Chinook salmon population and Mill Creek spring-run Chinook salmon were at a moderate risk of extinction, while spring-run Chinook salmon in Butte and Deer creeks were at a low risk. Application of the criteria in Table 4-1 placed each of those four populations into the low risk (i.e., viable) category. The TRT categorized steelhead in the Feather River, Battle Creek, American River, and Mokelumne River each into the high risk category due to high hatchery influence. All other populations of the three species being assessed were considered to be either data deficient or extinct.

The low extinction risk criteria described in Tables 4-1 and 4-2 function were used to develop interim biological delisting criteria with following exceptions: (1) diversity groups that likely did not historically contain viable populations, including the Suisun Bay and Central Western California steelhead diversity groups; (2) diversity groups that likely did not historically contain viable populations but currently have the potential to support viable, independent populations of spring-run Chinook salmon due to water projects that create suitable conditions including Clear Creek in the Northwestern California diversity group; (3) the Northern Sierra Diversity Group,

which serves as the centerpoint of the ESUs/DPS, and the biological hub in terms of interconnectivity of populations to the north and south; and (4) winter-run Chinook salmon, which are only present within one diversity group, thereby placing the ESU at a greater risk from exposure to catastrophic events or long-term events such as climate change, than other the spring-run ESU and steelhead DPS that were historically, and presently more widely distributed across several Diversity Groups.

One exception to this is that the population size recovery criterion (i.e., $N > 2,500$) could be considered an interim criteria until population-specific abundance criteria are identified.

Healthy populations should be at or near carrying capacity in most years. As such, a detailed and thorough assessment of each watershed's carrying capacity should be conducted, and the recovery criterion for abundance should be based on that estimated carrying capacity. As recovery actions are implemented and habitats are restored and expanded, the low extinction risk abundance criterion (i.e., $N > 2,500$) may be too low for large watersheds or for currently abundant populations. For example, Butte Creek has supported spring-run Chinook salmon populations well in excess of 2,500 since 1998, suggesting that the carrying capacity of that system may be greater than 2,500 adults. Similarly, in recognition that all extant populations are necessary for recovery, including relatively small ones that likely will not meet or exceed the low extinction risk abundance level (i.e., 2,500) even after habitat restoration, abundance recovery criteria that are based on carrying capacity analyses should be developed.

Table 4-1. Criteria for assessing the Level of Risk of Extinction for Populations of Pacific Salmonids, Applied to the Chinook Salmon ESUs and the Steelhead DPS in the Central Valley Domain (from Lindley et al. 2007)

Criterion	Risk of Extinction		
	High	Moderate	Low
Extinction risk from PVA	> 20% within 20 years – or any ONE of –	> 5% within 100 years – or any ONE of –	< 5% within 100 years – or ALL of –
Population size ^a	$N_e \leq 50$ –or– $N \leq 250$	$50 < N_e \leq 500$ –or– $250 < N \leq 2500$	$N_e > 500$ –or– $N > 2500$
Population decline	Precipitous decline ^b	Chronic decline or depression ^c	No decline apparent or probable
Catastrophe, rate and effect ^d	Order of magnitude decline within one generation	Smaller but significant decline ^e	not apparent
Hatchery influence ^f	High	Moderate	Low

^a Census size N can be used if direct estimates of effective size N_e are not available, assuming $N_e/N = 0.2$.

^b Decline within last two generations to annual run size ≤ 500 spawners, or run size > 500 but declining at $\geq 10\%$ per year. Historically small but stable population not included.

^c Run size has declined to ≤ 500 , but now stable.

^d Catastrophes occurring within the last 10 years.

^e Decline $< 90\%$ but biologically significant.

^f See Figure 1 for assessing hatchery impacts.

Table 4-2 Estimation Methods and Data Requirements for Population Metrics. S_t denotes the number of spawners in year t ; g is mean generation time, assumed as three years for California salmon (from Lindley et al. 2007)

Metric	Estimator	Data	Criterion
\hat{S}_t	$\sum_{i=t-g+1}^t S_i/g$	≥ 3 years spawning run estimates	Population decline
N_e	$N \times 0.2$ or other	varies	Population size
N	$\hat{S}_t \times g$	≥ 3 years spawning run estimates	Population size
Population growth rate (% per year)	slope of $\log(S_t)$ v. time $\times 100$	10 years S_t	Population decline
c	$100 \times (1 - \min(N_{t+g}/N_t))$	time series of N	Catastrophe
h	average fraction of natural spawners of hatchery origin	mean of 1-4 generations	Hatchery influence

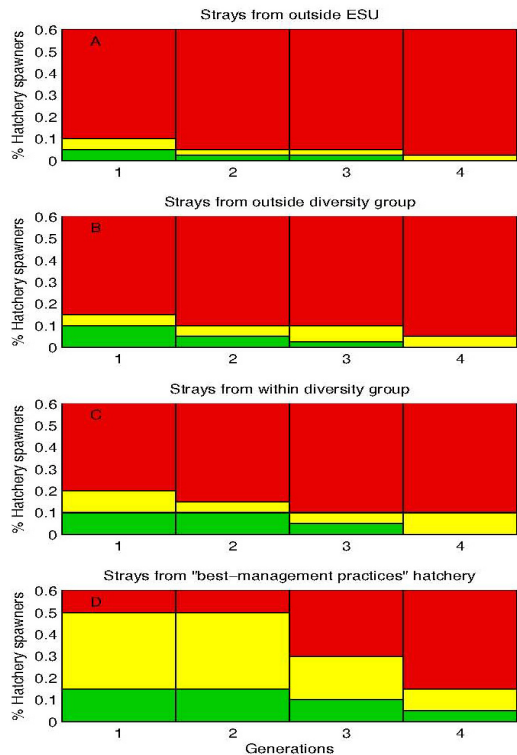

Figure 4-1. Extinction Risk Levels Corresponding to Different Amount, Duration and Source of Hatchery Strays. Green bars indicate the range of low risk, yellow bars moderate risk, and red areas indicate high risk. Which chart to use depends on the relationship between the source and recipient populations. (A) hatchery strays are from a different ESU than the wild population. (B) Hatchery strays are from the same ESU but from a different diversity group within the ESU. (C) Hatchery strays are from the same ESU and diversity group, but the hatchery does not employ "best management practices." (D) Hatchery strays are from the same ESU and diversity group, and the hatchery employs "best management practices." (from Lindley *et al.* 2007)

Such carrying capacity assessments could be accomplished by applying a consistent approach to measure habitat capacity throughout each ESU/DPS and then relating that capacity to assumed spawner density thresholds that correspond to varying levels of extinction risk (Williams *et al.* 2008). As habitats are restored and expanded, carrying capacity should increase and population-level recovery criteria for abundance will likely need to be adjusted periodically. Until such population-specific abundance recovery criteria are developed, the low and moderate extinction risk abundance criterion will serve as

benchmarks for the developing population delisting criteria; (5) the Recovery Plan includes criteria for dependent, or core 2-level populations, recognizing that smaller interconnected metapopulation viability plays an important role in the Mediterranean climate of the Central Valley, when spring-run Chinook salmon and steelhead exploit habitats when they become periodically available during consecutive wet water years.

4.3 Biological Objectives and Criteria at the ESU/DPS and Diversity Group Level and Population Level

Implementation of the Recovery Plan is designed to ultimately achieve objectives for the ESUs/DPS at the Diversity Group level, and at the population level (i.e. watershed level) for the four VSP criteria of abundance, productivity, diversity, and spatial structure. Objectives addressing these requirements include demographic parameters, reduction or elimination of threats to the species (the listing factors), and any other particular vulnerability or biological needs inherent to the species. The Central Valley TRT described these objectives in a general sense, and NMFS expects that more detailed objectives and accompanying criteria will be developed over the next several years as part of recovery plan implementation.

4.3.1 ESU/DPS and Diversity Group Objectives

ESU/DPS viability depends on the number of populations within the ESU/DPS, their individual status, their spatial arrangement with respect to each other and sources of catastrophic disturbance, and diversity of the populations and their habitats. In the most general terms, ESU/DPS viability increases with the number of populations, the viability of these populations, the diversity of the populations, and the diversity of habitats that they occupy. Each of the Diversity Groups must individually achieve recovery in order for the ESUs and DPS to be considered as

having achieved recovery. Thus, an overall objective is to achieve recovery in each of the Diversity Groups.

In addition to population objectives, in order for the Chinook salmon ESUs and the steelhead DPS to achieve recovery, each Diversity Group must meet the following habitat objectives:

- ❑ The spatial distribution and productive capacity of freshwater, estuarine, and marine habitats should be sufficient to maintain viable populations identified for recovery
- ❑ The diversity of habitats for recovered populations should resemble historic conditions and provide sufficient resilience and redundancy to withstand expected natural disturbance regimes such as wildfires, floods, volcanic eruptions, etc. Historic conditions represent a reasonable template for a viable population; the closer the habitat resembles the historic diversity, the greater the confidence in its ability to support viable populations
- ❑ At a large scale, habitats should be protected and restored, with a trend toward an appropriate range of attributes for salmonid viability. Freshwater, estuarine, and marine habitat attributes should be maintained in a non-deteriorating state

ESU Level Downlisting Criteria for Endangered Winter-run Chinook

Criteria to downlist winter-run Chinook salmon from endangered to threatened include the following two criteria:

- ❑ The existing mainstem Sacramento River spawning population must meet each of the low extinction risk criteria described in Table 4-1, with the exception of the criterion related to hatchery influence. The hatchery influence criteria does not have to be met provided that the Livingston Stone National Fish Hatchery continues to operate as a conservation hatchery using best management practices;
- ❑ In addition to the mainstem Sacramento River population, the ESU must include one other spawning population that meets the moderate extinction risk criteria described in Table 4-1.

ESU/DPS Level Delisting Criteria

In addition to population criteria, in order for the Chinook salmon ESUs and the steelhead DPS to achieve recovery, each Diversity Group must meet the following DPS criteria:

Winter-run Chinook salmon

- ❑ Three populations in the Basalt and Porous Lava Flow Diversity Group at low risk of extinction

Spring-run Chinook salmon

- ❑ One population in the Northwestern California Diversity Group at low risk of extinction
- ❑ Two populations in the Basalt and Porous Lava Flow Diversity Group at low risk of extinction
- ❑ Three populations in the Northern Sierra Diversity Group (because of their geographic proximity, Mill and Deer Creek are considered part of the same meta population at low risk of extinction

- ❑ Two populations in the Southern Sierra Diversity Group at low risk of extinction
- ❑ Maintain Core 2 populations at moderate risk of extinction

Central Valley steelhead

- ❑ Two populations in the Northwestern California Diversity Group at low risk of extinction
- ❑ Two populations in the Basalt and Porous Lava Flow Diversity Group at low risk of extinction
- ❑ Three populations in the Northern Sierra Diversity Group (because of their geographic proximity, Mill and Deer Creek are considered part of the same meta population at low risk of extinction)
- ❑ Two populations in the Southern Sierra Diversity Group at low risk of extinction
- ❑ Maintain Core 2 populations at moderate risk of extinction

4.3.2 Population Objectives

Consistent with the strategic approach to achieve recovery, this Recovery Plan establishes objectives for the viability of individual populations, similar to NMFS (2005b) and following the VSP parameters for productivity and abundance, population structure and diversity.

Productivity and Abundance Objectives

- ❑ In general, viable populations should demonstrate a combination of population growth rate and abundance that produces an acceptable probability of population persistence. Specifically, viable populations should meet the low extinction risk levels for the population decline and population size criteria described in Table 4-1.

- ❑ A population with non-negative growth rate and an average abundance approximately equivalent to estimated historic average abundance should be considered to be in the highest persistence category. The estimate of average historic abundance should be credible, the estimate of current abundance should be averaged over several generations, and the growth rate should be estimated with adequate statistical confidence

Within-Population Spatial Structure Objectives

The spatial structure of a population must support the population at the desired productivity, abundance, and diversity levels through short-term environmental perturbations, longer-term environmental oscillations, and natural patterns of disturbance regimes. The metrics and benchmarks for evaluating the adequacy of a population's spatial structure specifically address:

- ❑ Quantity: Spatial structure should be large enough to support growth and abundance, and diversity criteria
- ❑ Quality: Underlying habitat spatial structure should be within specified habitat quality limits for life-history activities such as spawning, rearing, migration, or a combination
- ❑ Connectivity: Spatial structure should have permanent or appropriate seasonal connectivity to allow adequate migration between spawning, rearing, and migration habitat
- ❑ Dynamics: The spatial structure should not deteriorate in its ability to support the population. The processes creating spatial structure are dynamic, so structure will be created and destroyed, but the rate of flux should not exceed the rate of creation over time

- ❑ Catastrophic Risk: the spatial structure should be geographically distributed in such a way as to minimize the probability of a significant portion of the structure being lost because of a single catastrophic event, either anthropogenic or natural

Because within-population spatial structure is so intricately linked to habitat quantity and quality, the threat abatement criteria described in the next section that are related to habitat act as a link between this objective and

Within-Population Diversity Objectives

Sufficient life-history diversity must exist to sustain a population through short-term environmental perturbations and to provide for long-term evolutionary processes. The metrics and benchmarks for evaluating the diversity of a population should be evaluated over multiple generations and include:

- ❑ Substantial proportion of the diversity of a life-history trait(s) that existed historically
- ❑ Gene flow and genetic diversity should be similar to historic (natural) levels and origins
- ❑ Successful utilization of habitats throughout the habitat
- ❑ Resilience and adaptation to environmental fluctuations

Population Level Delisting Criteria

Core 1 Populations (from Table 3-1) must meet low risk extinction criteria

- ❑ Census population size is >2500 adults -or- Effective population size is >500
- ❑ No productivity decline is apparent
- ❑ No catastrophic events occurring or apparent within the past 10 years

Core 2 Populations (from Table 3-1) must meet moderate risk extinction criteria

- ❑ Census population size is 250 to 2500 adults -or- Effective population size is 50 to 500 adults
- ❑ Productivity: Run size may have dropped below 500, but is stable
- ❑ No catastrophic events occurring or apparent within the past 10 years
- ❑ Hatchery influence is moderate or hatchery operates as a conservation hatchery using best management practices

4.4 Threat Abatement Criteria

It is imperative that threats to the species be controlled prior to delisting. This includes all threats identified at the time of listing, as well as any new factors identified since listing. Since listing, numerous additional threats have been identified and prioritized for the ocean, migratory corridors, and for each of the Diversity Groups and individual populations of the winter-run and spring-run Chinook salmon ESUs, and the steelhead DPS within the Central Valley Domain (Introduction, Appendix B).

NMFS proposes that, to determine that the affected ESU/DPS is recovered to the point that it no longer requires the protections of the ESA, the listing factors should be addressed according to specific criteria identified for each of them so that delisting is not likely to result in re-emergence of the threat. It is possible that current perceived threats will become insignificant in the future because of changes in the natural environment, changes in the way threats affect the entire life cycle of salmon, or the success of actions intended to ameliorate the threat. Consequently, NMFS expects that the significance of threats will change over time. It is also possible that new threats may be identified. During the status reviews, NMFS will evaluate and review the listing factor criteria under conditions at that time.

NMFS is providing the specific threat abatement criteria listed below for each of the relevant listing/delisting factors to help to ensure that underlying causes of decline have been addressed and mitigated prior to considering a species for delisting. These threat abatement criteria correspond to the listing factors identified for winter- and spring-run Chinook salmon and steelhead in this Recovery Plan, and to the stressors described in Appendix B.

Below each specific threat abatement criterion, actions and/or general goals related to eliminating or minimizing threats to winter- and spring-run Chinook salmon and steelhead are described. Unless otherwise specified, each of the individual threat abatement criteria listed below are applicable to all of the species addressed by this Recovery Plan. Although infrequent, there also are some circumstances where species-specific distinctions are required. Where these limited cases occur, a species-specific discussion is provided.

Listing Factors and Threats

[Sacramento River Winter-run Chinook Salmon](#)

Several factors have contributed to the decline of winter-run Chinook salmon through degradation of spawning, rearing, and migration habitats. The primary factors included in the listing of winter-run Chinook salmon were blockage of historical habitat by Shasta and Keswick dams, warm water releases from Shasta Dam, juvenile and adult passage constraints at RBDD, water exports in the southern Delta, heavy metal contamination from Iron Mountain Mine, high ocean harvest rates and entrainment in a large number of unscreened or poorly screened water diversions (NMFS 1997). Other factors include smaller water manipulation facilities and dams, loss of rearing habitat in the lower Sacramento River and Delta from levee construction, marshland reclamation, interaction with and predation by introduced species, adverse flow conditions, high summer water temperatures and vulnerability to drought (NMFS 1997). Since

listing, some of these threats have been addressed, although numerous additional threats have been identified and prioritized (Appendix B).

[Central Valley Spring-run Chinook Salmon](#)

Listing factors and threats to Central Valley spring-run Chinook salmon fall into three broad categories: loss of historical spawning habitat; degradation of remaining habitat; and threats to the genetic integrity of the wild spawning populations from the FRFH spring-run Chinook salmon production program and from spawning with naturally- and hatchery produced fall-run Chinook salmon. A complete prioritized list of life stage-specific stressors to this ESU is presented in Appendix B. Each of the threats criteria described below is related to one or more of the major factors limiting recovery described and listed in the NMFS 2006 Report to Congress on the PCSRF.

[Central Valley Steelhead](#)

Threats to Central Valley steelhead are similar to those for Central Valley spring-run Chinook salmon: loss of historical spawning habitat, degradation of remaining habitat, and threats to the genetic integrity of the wild spawning populations from hatchery steelhead production programs in the Central Valley. A complete prioritized list of life stage-specific stressors to the DPS is presented in Appendix B. Each of the threats criteria described below is related to one or more of the major factors limiting recovery described and listed in the NMFS 2006 Report to Congress on the PCSRF.

Factor 1: Destruction, Modification, or Curtailment of Habitat or Range

Dams in the Central Valley have: (1) blocked access to historical spawning grounds; (2) modified natural flow regimes and altered water temperatures; and (3) reduced habitat quality and complexity.

To determine that the winter- and spring-run Chinook salmon ESUs and the steelhead DPS are recovered, threats to habitat and the risks posed to the abundance, productivity, and especially to the spatial structure and diversity of the ESU/DPS should be addressed through the following criteria.

Criterion 1.1: Address Threats to Spawning Habitat

1.1.A. As appropriate or necessary to support region-wide recovery goals, passage obstructions (e.g. dams) are removed or modified to restore fish access or improve passage to historically accessible spawning habitat

- Shasta and Keswick dams are modified or circumvented to restore winter-run and spring-run Chinook salmon, and steelhead into the Little Sacramento and McCloud rivers.
- Folsom and Nimbus dams are modified or circumvented to restore steelhead.
- Englebright Dam is modified (or circumvented) to restore steelhead and spring-run Chinook salmon.
- Primary reintroduction areas for modifying or circumventing dams in the San Joaquin River Basin are identified.

1.1.B. Instream flow conditions and programs are implemented that support anadromous salmonid spawning and embryo incubation needs to meet species-specific population targets

1.1.C. Projects or programs designed to improve or supplement available spawning habitat used by anadromous salmonids are implemented

1.1.D. Segregation during spawning where spring-run and fall-run Chinook salmon habitat overlap is provided

Criterion 1.2: Address Threats to Water Quality

1.2.A. Deleterious effects of stormwater runoff are eliminated or controlled so as not to impair water quality and quantity in salmonid streams or the riparian habitats supporting them

1.2.B. Agricultural practices are implemented and programs are in place to protect and restore riparian areas, floodplains and stream channels, and to protect water quality from sediment, pesticide, herbicide and fertilizer runoff, and thermal loading. Particularly in the Delta, mainstem Sacramento and San Joaquin rivers and their major tributaries.

1.2.C. Water temperature conditions that are contributing to water quality impairment are evaluated, and management actions designed to reduce, eliminate or avoid impairment are implemented

1.2.D. Ecological functions of salmon and steelhead, including their benefits in cycling ocean-derived nutrients into freshwater areas, are considered in fishery, hatchery, and habitat management

1.2.E. Nutrient enrichment programs to determine where additional nutrient inputs can provide significant benefits to juvenile salmonid food-producing areas are evaluated

1.2.F. Urban and rural development, including land use conversion from agriculture and forest land to developed areas, is restricted so as to not impair water

quality or result in dysfunctional stream conditions

rearing, migration, and spawning habitat

1.2.G. The effects of toxic contaminants on salmonid fitness and survival in the Delta, mainstem rivers, and nearshore ocean are sufficiently limited, and programs are in place to ensure continued limitation of toxic contaminants so as not to affect recovery

- A continuous 100-mile stretch of ecologically viable riparian habitat to flood-prone lands along the Sacramento River between Colusa and Verana are restored

1.2.H. Programs and/or measures are implemented to ensure continued protection and restoration of water quality in anadromous salmonid inhabited areas so as to promote recovery

1.3.D. Floodplain and tidally-influenced habitats, including tidal swamp and marsh habitat in estuaries and the tidal freshwater portion of the lower rivers, are restored and protected as to promote recovery. Floodplain connectivity and impaired sediment delivery processes are restored in the lower portions of rivers and in estuaries.

1.2.I. Programs and/or measures are implemented to reduce instream sedimentation and turbidity in core 1 and 2 watersheds and in primary reintroduction areas.

1.3.E. Nearshore processes are protected and restored so that ecological inputs (of sediment, insects, leaves and wood) to rivers, and mudflats function properly to support anadromous salmonids and the species they prey upon

Criterion 1.3: Address Threats to Habitat Quality and Complexity

1.3.A. Instream flow conditions and programs are implemented that support anadromous salmonid migration and rearing needs (in addition to spawning needs, see Criterion 1.1B) to meet species-specific population targets

1.3.F. Activities that dredge, fill or harden streambanks and river beds are sufficiently mitigated as to support anadromous salmonids, and riparian restoration in core 1 and 2 areas and primary reintroduction areas.

1.3.B. In support of rearing, migration and spawning needs, coldwater resources are managed to reduce thermal stress to Chinook salmon and steelhead and to meet species-specific population targets

1.3.G. Forest management practices that protect and restore watershed and stream functions are implemented on Federal, State, Tribal, and private lands and programs are in place to ensure continued mitigation in core 1 and 2 areas and primary reintroduction areas.

1.3.C. Channel function, including vegetated riparian areas, instream wood, streambank stability, off-channel and side-channel habitats, natural substrate and sediment processes, and channel complexity are restored to improve

1.3.H. Stream surveys, habitat modeling, and other technical approaches are utilized to accurately assess the impacts of habitat management actions

1.3.I. Educational outreach programs are developed and conducted with

interested stakeholders or watershed groups to promote collaborative development, funding and implementation of habitat enhancement and protection projects, and to promote river stewardship among landowners

Factor 2: Overutilization for Commercial, Recreational, Scientific, or Educational Purposes

Continue the assessment of the potential overutilization of winter- and spring-run Chinook salmon populations for commercial, recreational, scientific or educational purposes. Additionally, although there are no commercial fisheries for steelhead in the ocean, inland steelhead fisheries continue to be important tribal and recreational fisheries and, thus, continue to warrant assessment.

To determine that the winter- and spring-run Chinook salmon ESUs and the steelhead DPS are recovered, any utilization for commercial, recreational, scientific, or educational purposes should be addressed through the following criteria.

Criterion 2.1: Address Threats from Overutilization

- 2.1.A. Fishery management plans that address Chinook salmon ESUs and the steelhead DPS are implemented that: (a) accurately account for total fishery mortality (i.e., both landed catch and non-landed mortalities) and constrain mortality rates for individual populations to levels that are consistent with achieving ESU/DPS viability (i.e., provide for adequate spawning escapement given intrinsic productivity for populations representative of the life history and major regional divisions in the ESU/DPS); and (b) are implemented so that any effects on the abundance, productivity, diversity, and spatial structure of populations are consistent with the recovery of the ESU/DPS

2.1.B. Modeling and other technical tools, and adaptive management are used to accurately assess the potential impacts of fishery management actions

2.1.C. Rules and regulations for fishery management actions are effectively enforced, and additional regulations are implemented as necessary, as to promote recovery

Factor 3: Disease or Predation

Both naturally spawned and artificially propagated winter- and spring-run Chinook salmon and steelhead are susceptible to threats from: (1) disease outbreaks caused by naturally occurring pathogens; and (2) predation.

To determine that the winter- and spring-run Chinook salmon ESUs and the steelhead DPS are recovered, any disease or predation that threatens its continued existence should be addressed through the following criteria.

Criterion 3.1: Address Threats from Disease Outbreaks

- 3.1.A. Hatchery operations apply measures that reduce the risk that natural populations are adversely affected by fish diseases and parasites
- 3.1.B Coldwater resources are managed to avoid water temperature-related fish disease and parasite outbreaks in anadromous salmonids

Criterion 3.2: Address Threats from Predation

- 3.2.A. Suitable methods and levels of marine mammal control are identified and implemented to mitigate negative interactions with anadromous salmonids where predation poses significant risks to recovery

- 3.2.B. Populations of introduced game fish are managed such that competition with or predation on Chinook salmon and steelhead does not impede population recovery
- 3.2.C. Predation of anadromous salmonids is minimized at diversions and other instream structures
- 3.2.D. Predation from birds and mammals is minimized in areas of low flow management (stranding)
- 3.2.E. Quantitative estimates of predation on anadromous salmonids are developed

Factor 4: Inadequacy of Existing Regulatory Mechanisms

Despite Federal and non-Federal efforts and partnerships that have been implemented to help increase the abundance and productivity of anadromous salmonids over the past 10 to 15 years, the winter-run and spring-run Chinook salmon ESUs and steelhead DPS remain at risk of extinction because the existing regulatory mechanisms do not provide sufficient certainty that efforts to reduce threats to the ESUs/DPS will be fully funded or implemented. Existing conservation efforts, research and monitoring activities also do not occur at a scale that is adequate to protect the entire Chinook salmon ESUs or steelhead DPS.

To determine that the Chinook salmon ESUs and the steelhead DPS are recovered, inadequacy of existing regulatory mechanisms that threaten their continued existence should be addressed through the following criteria.

Criterion 4.1. Address Threats Resulting from Inadequacy of Existing Regulatory Mechanisms

- 4.1.A. Regulatory mechanisms are implemented to ensure that effects on the abundance, productivity, diversity, and spatial structure of populations are

consistent with the recovery of the ESU/DPS

- 4.1.B. Technical tools (such as modeling) are used to accurately assess the potential impacts of regulatory actions
- 4.1.C. Rules and regulations related to habitat protection and restoration and water quality are effectively enforced
- 4.1.D. Fishery Management Plans are developed and implemented
- 4.1.E. Habitat conditions, watershed functions and nearshore processes are protected and restored through land-use planning that guides human population growth and development
- 4.1.F. Habitat conditions and watershed function are protected and restored through regulations that govern resource extraction such as timber harvest and gravel mining
- 4.1.G. Habitat conditions, watershed functions and nearshore processes are protected and restored through land protection agreements as appropriate, where existing policy or regulations do not provide adequate protection
- 4.1.H. Adequate resources, priorities, regulatory frameworks, and coordination mechanisms are established and/or maintained for effective enforcement of land and water use regulations that protect and restore habitats and marine and freshwater water bodies and for the effective management of fisheries
- 4.1.I. Regulatory, control, and education measures to prevent additional exotic species invasions are implemented

Factor 5: Other Natural and Manmade Factors Affecting Continued Existence

Winter-run and spring-run Chinook salmon and steelhead are susceptible to natural and man-made threats caused by the effects of: (1) artificial propagation ; (2) climate changes or El Niño ocean conditions and prolonged drought conditions; (3) unscreened water diversions; (4) migration obstructions and impediments; and (5) invasive aquatic species.

To determine that the Chinook salmon ESUs and the steelhead DPS are recovered, natural and man-made threats to their continued existence should be addressed through the following criteria.

Criterion 5.1. Address Threats Resulting from Artificial Propagation

- 5.1.A. Hatchery management plans are implemented to ensure that any effects on the abundance, productivity, diversity, and spatial structure of populations are consistent with the recovery of the ESU/DPS
- 5.1.B. Technical tools (such as modeling) are used to accurately assess the potential impacts of hatchery management actions
- 5.1.C. Rules and regulations for hatchery management and protection are developed and effectively enforced
- 5.1.D. Hatchery programs are operated in a manner that is consistent with individual watershed and region-wide recovery approaches; appropriate criteria are used for the integration of hatchery Chinook salmon and steelhead populations, and extant natural populations inhabiting watersheds where the hatchery fish return
- 5.1.E. Hatcheries operate using appropriate ecological, genetic, and demographic risk containment measures for: (1) hatchery-origin adults returning to

natural spawning areas; (2) release of hatchery juveniles; (3) handling of natural-origin adults at hatchery facilities; (4) withdrawal of water for hatchery use; (5) discharge of hatchery effluent; and (6) maintenance of fish health during their propagation in the hatchery

- 5.1.F. All Hatchery Chinook salmon and steelhead are marked or tagged so that they can be differentiated from natural Chinook salmon and steelhead in fisheries, migratory areas, and as adults returning to hatcheries and natural spawning areas (currently all listed anadromous salmonids are marked prior to hatchery release; a constant fractional marking program is in place for fall-run Chinook salmon hatchery production, although consistent, long-term funding is not secured)
- 5.1.G. Stocking practices for put-and-take fisheries do not interfere with recovery

Criterion 5.2. Address Threats Resulting from Climate Change

- 5.2.A. Research that aids in predicting the effects of climate change on salmon recovery is funded, and Federal and State commitments to respond to findings from the research are obtained

Criterion 5.3. Address Threats Resulting from Water Diversions and other Instream Structures

- 5.3.A. Entrainment and mortality of anadromous salmonids during the screening, holding and transport operations associated with the Jones and Banks pumping facilities are reduced
- 5.3.B. Alternatives to conveyance of SWP and CVP water south of the Delta that minimize/eliminate entrainment at existing facilities are evaluated and the preferred alternative is implemented

5.3.C. Entrainment at individual prioritized unscreened diversions are minimized or eliminated

5.3.D. Rates of entrainment at individual diversions are monitored

Criterion 5.4. Address Threats Resulting from Migration Obstructions and Impediments

5.4.A. Anadromous salmonid migration obstructions and impediments (e.g. due to Yolo and Tisdale bypass weirs, Sacramento Deep Water Ship Channel lock gates, diversion dams, etc.) are addressed

Criterion 5.5. Address Threats Resulting Invasive Aquatic Species

5.5.A. Mechanisms are developed and implemented to reduce the incidence of, and impacts from, introduced, invasive, or exotic species

5.5.B. The management actions for addressing aquatic invasive species described in the California Aquatic Invasive Species Management Plan are implemented.

5.0 Recovery Scenarios

“An ESU with well-distributed viable populations will avoid the situation where populations succumb to the same catastrophic risk(s), will allow for a greater potential source of diverse populations for recovery in a variety of environments (i.e., greater options for recovery), and increases the likelihood of the ESU surviving rapid environmental changes”

- Ruckelshaus et al. (2002)

5.1 Overview

The recovery scenarios presented in this section provide initial examples of how to achieve the overarching goal of this Recovery Plan - the removal of the Sacramento River winter-run Chinook salmon ESU, Central Valley spring-run Chinook salmon ESU, and Central Valley steelhead DPS in the Central Valley Domain from the Federal List of Endangered and Threatened Wildlife (50 C.F.R. 17.11). These ESU/DPS-level recovery scenarios identify a combination of populations and population status levels that meet recovery criteria for a viable ESU/DPS. The scenarios represent some of the many possible combinations of populations, restoration actions, risk minimization and threat abatement. Different scenarios may fulfill the biological requirements for recovery.

The conceptual recovery scenarios were developed with consideration of the biological significance and recovery feasibility of each population. Biological significance was based on current status, potential for improvement, historical significance, proximity to other selected populations with reference to catastrophic risks, and spatial distribution between independent and dependent populations. Feasibility of recovery was based on expected progress as a result of existing programs, absence of apparent impediments toward recovery, and other management considerations (e.g. fish passage potential).

As this Recovery Plan is implemented over time, additional information will become available to help determine whether the threats have been abated, to further develop understanding of the linkages between threats and Chinook salmon and steelhead population responses, and to evaluate the viability of Chinook salmon and steelhead in the Central Valley Domain. There will be a thorough review of the recovery actions implemented, and population and habitat condition responses, at the 5- and 10-year status reviews of the Chinook salmon ESUs and the steelhead DPS. Monitoring and adaptive management in the course of implementation of this Recovery Plan will provide more information on the feasibility of recovering the winter- and spring-run Chinook salmon ESUs and the steelhead DPS in the Central Valley Domain. Such information is expected to lead to adjustments in recovery expectations and restoration actions and, thus, recovery scenarios.

5.2 Recovery Scenario Considerations

5.2.1 ESU/DPS Level Considerations

The conceptual recovery scenarios incorporate the concepts of viability at both the population and ESU/DPS levels. ESU/DPS viability depends on the number of populations within the ESU/DPS, their individual status, their spatial arrangement with respect to each other and sources of catastrophic disturbance, and diversity of the populations and their habitats. In the most general terms, ESU/DPS viability increases with the number of populations, the viability of these populations, the diversity of the populations, and the diversity of habitats that they occupy (Lindley et al 2007).

The Central Valley TRT reviewed available data to develop ESU/DPS- and population-specific criteria that take into account the constraints that can influence viability (e.g., populations with less habitat available will need to have higher intrinsic growth rates or less variable growth, compared to populations with greater habitat availability, to achieve similar viability (Lindley et al. 2007)). Unfortunately, population-specific information is unavailable for many of the populations in the winter- and spring-run Chinook salmon ESUs, and particularly in the steelhead DPS. Thus, the Central Valley TRT developed biologically relevant criteria that are generic to *Oncorhynchus* species.

Taxonomically general criteria for identifying and prioritizing species in need of conservation have been modified for application to Pacific salmonids (Allendorf et al. 1997). The Central Valley TRT extended the criteria-based approach of Allendorf et al. (1997) to account for the effects of hatchery fish on the extinction risk of naturally-spawning populations, and explicitly define a “low” extinction risk category. This low-risk definition can serve as a default goal for recovering populations for which too little data

exist for more detailed goals to be developed (Lindley et al. 2007).

The extinction risks of populations are correlated because normal environmental influences affecting the population dynamics of salmonids are spatially correlated. The effects of catastrophes (defined as rare environmental perturbations with very strong negative effects on afflicted populations) can be quite widespread and a single catastrophic event (e.g., a toxic spill) could affect all populations even though they are widely dispersed for most of their life cycle. Because it is unlikely that all possible sources of risk can be identified and anticipated, the Central Valley TRT adopted the dual approach of managing risk and maximizing diversity within each ESU/DPS (Lindley et al. 2007).

ESU/DPS viability is assessed by examining the number and distribution of viable populations across the landscape and their proximity to sources of catastrophic disturbance. The Central Valley TRT (Lindley et al. 2007) addressed ESU/DPS viability in two ways. In the first, risk-spreading is assessed by examining how viable populations are spread among geographically-defined regions within the ESU/DPS. In the second, they attempted to account explicitly for the spatial structure of the ESU/DPS and the spatial structure of various catastrophic risks, including volcanoes, wildfires, and droughts. Therefore, for the ESUs/DPS to be considered viable, they should at a minimum be able to persist if challenged by any one of these types of catastrophes.

The Central Valley TRT defined ESU/DPS viability as requiring representation of all Diversity Groups and redundancy within the Diversity Groups (which they termed the “representation and redundancy” rule). If extinction risks are not strongly correlated between populations, two populations, each with low risk of extinction, would be extremely unlikely to go extinct simultaneously (McElhany et al. 2000). Should one go extinct, the other

could serve as a source of colonists to re-establish the extirpated population.

The conceptual recovery scenarios incorporate these considerations and approaches by the Central Valley TRT, as well as definitions of ESU (and DPS) recovery and viability based on McElhane et al. (2000), as follows.

ESUs should contain multiple populations. If an ESU (or DPS) is comprised of multiple populations, it is less likely that a single catastrophic event will cause it to become extinct. Also, ESUs (or DPS) may function as “metapopulations” over the long term and the existence of multiple populations would be necessary for the operation of sustainable population-level extinction/ re-colonization processes. In addition, multiple populations within an ESU (or DPS) increase the likelihood that a diversity of phenotypic and genotypic characteristics will be maintained, thus allowing natural evolutionary processes to operate and increase the ESU’s (or DPS’) viability in the long term.

Some populations in an ESU (or DPS) should be geographically widespread. Spatially correlated environmental catastrophes are less likely to drive a widespread ESU (or DPS) to extinction. This guideline also directly relates to the ESA mandate of protecting a species in a “significant portion of (its) range.”

Efforts to establish viable populations should be attempted in more populations than identified in the Diversity Group viability criteria (2 viable, independent populations per diversity group) because some attempts may be unsuccessful; individual population viability can be highly variable within diversity groups; catastrophic threats can often affect more than one population at a time; and climate change and extended drought conditions that are frequent in California require that we increase spatial diversity so that there is even distribution of populations throughout diversity groups, especially in the Northern Sierra Diversity

Group, which is geographically located in the middle of all other diversity groups and functions as a hub of population connectivity, and genetic flow, between populations and diversity groups that are located to the north and south.

Some populations should be geographically proximate. On long temporal scales, ESUs (or DPS) may function as “metapopulations”. Populations geographically close to one another facilitate connectivity among existing populations. Thus, a viable ESU (or DPS) requires both widespread and spatially proximate populations.

Populations should not all share common catastrophic risks. An ESU (or DPS) containing populations that do not share common catastrophic risks is less likely to be driven to extinction by correlated environmental catastrophes. Maintaining geographically widespread populations is one way to reduce risk associated with correlated catastrophes, but spatial proximity is not the only reason why two populations could experience a correlated catastrophic risk.

Populations that display diverse life-histories and phenotypes should be maintained. When an ESU’s (or DPS’) populations have a fair degree of life-history diversity (or other phenotypic diversity), the ESU (or DPS) is less likely to go extinct as a result of correlated environmental catastrophes or changes in environmental conditions that occur too rapidly for an evolutionary response. In addition, assuming phenotypic diversity is caused at least in part by genetic diversity, maintaining diversity allows natural evolutionary processes to operate within an ESU (or DPS).

Some populations should exceed VSP guidelines. Larger and more productive (“resilient”) populations may be able to recover from a catastrophic event that would cause the extinction of a smaller population. An ESU (or DPS) that contains some populations in excess of

VSP threshold criteria for abundance and population growth rate is less likely to go extinct in response to a single catastrophic event that affects all populations.

Evaluations of ESU (or DPS) status should take into account uncertainty about ESU/DPS-level processes. Our understanding of ESU/DPS-level spatial and temporal process is very limited. ESUs (or DPS) are believed to have been historically self-sustaining and the historical number and distribution of populations serves as a useful “default” goal in maintaining viable ESUs (or DPS).

In consideration of the foregoing, the conceptual recovery scenarios require that, in general, each Diversity Group must be represented, and population redundancy within the groups must be met to achieve Diversity Group recovery. Therefore, the recovery scenarios include the following Diversity Group general objectives:

A minimum of two viable populations of winter-run Chinook salmon within the winter-run Chinook salmon Diversity Group.

A minimum of two viable populations of spring-run Chinook salmon within each of the four spring-run Chinook salmon Diversity Groups, with the exception of the Northwestern California Diversity Group which historically did not contain independent spring-run Chinook salmon populations. For the Northwestern California Diversity Group, observed occupancy will suffice rather than viability, as defined.

A minimum of two viable populations of steelhead within each of the four extant steelhead Diversity Groups (i.e., the Basalt and Porous Lava Diversity Group, the Northwestern California Diversity Group, the Northern Sierra Nevada Diversity Group and the Southern Sierra Nevada Diversity Group). The historical Central Valley steelhead DPS included the two additional ecoregions of the Suisun Bay Tributaries Diversity Group and the Central Western California Diversity Group. However,

because: (1) the previously described historical Suisun Bay Tributaries Diversity Group presently is included in the Central California Coast Steelhead DPS and, therefore, is not further considered in the Central Valley Domain; and (2) steelhead have been entirely extirpated from the Central Western California Diversity Group and watersheds in this Diversity Group would require significant restoration actions, have low recovery potential, and are not considered candidate areas for reintroduction - particularly in consideration of long-term climate change. Therefore, the steelhead DPS conceptual recovery scenario does not include reestablishing viable populations of steelhead in the Central Western California Diversity Group.

5.2.2 Population Level Considerations

The Central Valley TRT described the historical populations of Sacramento River winter-run Chinook salmon and Central Valley spring-run Chinook salmon ESUs in the Central Valley (Lindley et al. 2004). They considered geography, migration rates, genetic attributes, life history diversity, population dynamics, and environmental characteristics in grouping the populations into independent populations and dependent populations. For the Central Valley steelhead DPS, Lindley et al. (2006) identified historical independent populations based on a model that identifies discrete habitat and interconnected habitat patches isolated from one another by downstream regions of thermally unsuitable habitat.

Independent populations of Chinook salmon were identified based on three criteria: (1) basin isolation; (2) basin size; and (3) substantial genetic differentiation within the basin. For the basin's isolation criterion, watersheds within a critical dispersal distance of at least 50 km in the same ecoregion were grouped together. For the basin size criterion, watersheds with an area greater than 500 km² were considered capable of supporting independent populations. For the genetic differentiation criterion, significant

environmental differences should exist among the basins inside of the distance criterion.

Populations of salmon and steelhead in the Central Valley Domain that have minimal demographic influence from adjacent populations and are viable in isolation have been classified as functionally independent populations. Dependent populations are populations that would not persist without immigration from neighboring populations. Dependent populations play a valuable role in the viability of the ESU/DPS by linking other populations, as well as containing valuable genetic traits. The presence and spatial distribution of dependent and independent populations are considered in the development of the conceptual recovery scenarios.

5.2.3 Ecological (Habitat) Restoration Considerations

In addition to ESU/DPS and population viability, structure and distribution considerations, the conceptual recovery scenarios incorporate ecological or habitat objectives for each Diversity Group:

- ❑ The recovery scenario must address the entire natural ecosystem (freshwater spawning, rearing and migration areas; estuarine habitats, and the Pacific Ocean)
- ❑ The recovery scenario should reflect that viable ESUs/DPSs and populations require a network of complex and interconnected habitats, which are created, altered, and maintained by natural physical process
- ❑ The spatial distribution and productive capacity of freshwater and estuarine habitats should be sufficient to maintain viable populations identified for recovery
- ❑ The diversity of habitats for recovered populations generally should resemble

historic conditions given expected natural disturbance regimes (wildfire, flood, volcanic eruptions, etc.). Historic conditions represent a reasonable template for a viable population - the closer the habitat resembles the historic diversity, the greater the confidence in its ability to support viable populations

- ❑ At a large scale, habitats should be protected and restored, with a trend toward an appropriate range of attributes for salmonid viability

The conceptual recovery scenarios reflect NMFS' goal to restore and conserve the habitats that support the Federally-protected anadromous fish. Critical habitat is of great importance in conserving listed salmonids. Conservation and enhancement of habitat to sustain these fish should reflect consideration of habitat areas identified in NMFS' critical habitat designation, including information from the Critical Habitat Analytical Review Team (CHART) regarding PCEs and habitat rankings:

Freshwater Spawning Sites

- have good water quality and quantity
- have substrate for spawning, incubation, and larval development

Freshwater Rearing Sites

- have good water quality and quantity and floodplain connectivity to maintain habitat conditions
- have forage for juvenile development
- have natural cover to provide refuge (such as submerged and overhanging large wood, log jams, beaver dams, aquatic vegetation, large rocks or boulders, side channels, undercut banks, etc.)

Freshwater Migration Corridors

- are unobstructed
- have good water quality and quantity

- have natural cover to provide refuge to support juvenile and adult mobility and survival
- afford safe passage conditions for migrations

Estuarine Areas

- are unobstructed
- have good water quality and quantity, with salinity conditions to support juvenile and adult physiological transitions between freshwater and saltwater
- have natural cover to provide refuge to support migrations among systems
- have forage for juvenile and adult migrating fish

Nearshore Marine Areas (not included in critical habitat designation, but important to overall species lifecycle)

- are unobstructed
- have good water quality and quantity conditions
- have forage to support growth and maturation of fish
- have natural cover to provide refuge

Offshore Marine Areas

- have good water quality conditions
- have forage to support growth and maturation

The above critical habitat attributes in the Central Valley Domain were considered in the development of the conceptual recovery scenarios, although marine areas were not explicitly considered. Habitat restoration potential of freshwater habitats (see watershed profiles) were explicitly considered in the development of the conceptual recovery scenarios.

5.2.4 Threat Abatement

As described in this Recovery Plan, it is imperative that threats to the species be controlled prior to delisting. This includes all threats identified at the time of listing, as well as any new factors identified since listing. Since listing, numerous additional threats have been identified and prioritized for each of the Diversity Groups and individual populations of the winter-run and spring-run Chinook salmon ESUs, and the steelhead DPS within the Central Valley Domain, as previously described in Appendix B.

NMFS proposes that, to determine that the affected ESU/DPS is recovered to the point that it no longer requires the protections of the ESA, the listing factors should be addressed according to specific criteria identified for each of them so that delisting is not likely to result in re-emergence of the threat. The explicit listing factor (threats) criteria previously described in this Recovery Plan correspond to the listing factors identified for winter- and spring-run Chinook salmon and steelhead, and to the stressors described in Appendix B. Accordingly, NMFS expects that if this Recovery Plan's proposed actions (Chapter 6 and Appendix C) to address the threats and limiting factors are implemented, they will make substantial progress toward meeting the listing factor (threats) criteria specified herein. These threat abatement criteria are established to address threats to, or resulting from, spawning grounds, habitat quality and quantity, overutilization, disease or predation, inadequate regulatory mechanisms, artificial propagation, climate change, water diversions, and non-indigenous aquatic nuisance species.

The conceptual recovery scenarios consider the degree to which, in both the near-term and long-term, threat abatement is anticipated for the Diversity Groups and individual populations in the Central Valley Domain.

5.3 Process for Recovery Scenario Development

Information about the population structure and the distribution of the ESU/DPS is critical to guide restoration actions in the Central Valley, and in the development of the recovery scenarios. Recovering the ESU/DPS will likely require a mix of improved access to historically available habitat and restoration of degraded habitat, as previously identified in this Recovery Plan. Understanding the current and historical structure of the ESU/DPS is important for recovery and conservation purposes, and the development of the conceptual recovery scenarios. Current distribution provides an understanding of how to efficiently safeguard the existence of the ESU/DPS. Historical distribution provides an understanding of how the species might have survived catastrophic disturbances and how an altered ESU/DPS may or may not persist in the future. Genetically diverse populations within an ESU/DPS are important for the persistence of an ESU/DPS in the event of a catastrophic or gradual change in the local environment, and recolonization by neighboring populations that are adapted to similar environmental conditions. In the case of reintroductions of salmonids to an area where they have been extirpated, knowing which populations might have members that are ecologically exchangeable would help guide reintroductions into restored habitats.

For each ESU/DPS in the Central Valley Domain, conceptual recovery footprint maps have been developed to show the historical habitat, candidate areas for reintroduction and potential examples of anticipated lifestage-specific areas within each diversity group that would be needed to support recovered populations of Sacramento River winter-run and Central Valley spring-run Chinook salmon, and Central Valley steelhead.

5.4 Conceptual Recovery Scenarios

Multi-species recovery for wide-ranging migratory species that occur across a large number of different ecosystems and landscapes can be assisted by developing a foundational approach that describes a conceptual vision of what a recovered ESU or DPS should look.

5.4.1 Spatial Distribution and Abundance

In general, the populations within each ESU/DPS should reflect historic distribution, through representation and redundancy within Diversity Groups while taking into account that not all reintroduction efforts will be successful and that population viability at any point in time is likely to vary between populations. For winter-run Chinook salmon, this means that multiple populations need to be present within the Basalt and Porous Lava Diversity Group, including the persistence of the last remaining population in the Sacramento River, below Keswick and Shasta Dams, establishing a population in Battle Creek, and reintroducing populations to the Little Sacramento and McCloud Rivers. The low extinction risk criteria in Table 4-1 of this Recovery Plan should be used as viability targets for these populations.

For Central Valley spring-run Chinook salmon, the population distribution should vary by diversity group, based on current and historic distribution patterns and habitat availability. We envision that a recovered ESU would contain populations meeting the low extinction risk criteria presented in Table 4-1 in Clear Creek, for the Northern California Diversity Group; in the Little Sacramento and McCloud Rivers and Battle Creek for the Basalt and Porous Lava Diversity Group; in Deer, Mill, and Butte creeks, and in the Feather River below Oroville Dam, and the Yuba River, including habitats above Englebright Dam for the Northern Sierra Nevada Diversity Group;

and in the San Joaquin River, below Friant Dam, and within at least one tributary of the San Joaquin River, for the Southern Sierra Diversity Group. Of course, this is a conceptual description of distribution, and other areas that are identified in the Recovery Footprint maps as candidate areas may also prove feasible as information on habitat condition and reintroduction feasibility is developed.

For Central Valley steelhead, the population distribution should also vary by diversity group, based on current and historic distribution patterns and habitat availability. We envision that a recovered DPS would include independent populations with a low risk of extinction (see Table 4-1) in Thomes, Beegum and Clear creeks, for the Northwestern California Diversity Group; in the Little Sacramento and McCloud Rivers and Battle Creek for the Basalt and Porous Lava Diversity Group; in Deer, Mill, and Butte creeks, in the Feather River below Oroville Dam, in the Yuba River, including in habitats above Englebright Dam, and in the American River above Folsom Dam, for the Northern Sierra Nevada Diversity Group; and in the within at least two tributaries of the San Joaquin River, including the Calaveras River, for the Southern Sierra Diversity Group. Similar to spring-run, this is a conceptual description of distribution, and other areas that are identified in the Recovery Footprint maps as candidate areas may also prove feasible as information on historic habitat condition and reintroduction feasibility is developed.

The reintroduction of fish to historic habitats will require numerous efforts including short-term actions to trap and haul fish to conduct pilot reintroduction tests; source population selection; habitat evaluations, and habitat suitability and carrying capacity modeling; juvenile recapture pilot testing; and long-term efforts that may include developing more volitional passage mechanisms, and implementation of long-term reintroduction and monitoring programs.

5.4.2 Network of Complex and Interconnected Habitats

The ultimate purpose of the ESA is to conserve the ecosystems upon which threatened and endangered species rely so that they no longer require the protections of the ESA to persist. Viable ESUs/DPSs and populations will require a network of complex and interconnected habitats that are created, altered, and maintained by natural physical process. Central Valley salmonid ecosystems have been extensively altered. Dams have disconnected fish from their historic habitats and altered the flow regimes downstream by storing the naturally occurring high flow events of winter and spring months and releasing these flows during summer for agricultural and municipal uses. More than 1,600 miles of levee construction in the Central Valley has constricted river channels, disconnected floodplains from active river channels, reduced riparian habitat, and reduced natural channel function, particularly in lower reaches of the Sacramento and San Joaquin Rivers and the Delta. Finally, thousands of water diversions within the Central Valley reduce instream flows, and the State and Federal pumping facilities in the south Delta reverse natural river flows, disrupt natural tidal patterns, and alter the migration patterns and survival of salmonid individuals and populations.

Restoring the ecosystem of anadromous fish in the Central Valley will be a difficult and time intensive endeavor and will require: (1) establishing reliable passage and connectivity of fish to upstream habitats; (2) restoring the geomorphic function and natural habitat processes of the lower Sacramento and San Joaquin River and the Delta; (3) providing ecological flows and alternative Delta water diversion approaches that match the life history needs of fish including habitat development and maintenance processes of river systems; and (4) significantly reducing the abundance of non-native predatory fishes that inhabit the lower river reaches and the Delta. Floodplains are a

vital component of the salmon and steelhead ecosystem and floodplain reclamation and restoration is expected to be a key habitat improvement action that will be necessary to recover these fish.

Reintroduction of anadromous to historic habitats will require a new approach to watershed management, especially in regard to the operation and licensing of hydroelectric projects. Many of the keystone passage impediments to block access to upstream habitat are regulated by the Federal Energy Regulatory Commission (FERC). In many watersheds, FERC also regulates upstream hydroelectric projects and facilities, and in most cases the licenses issued by FERC expire on different schedules, making a coordinated watershed approach to relicensing difficult. There are numerous hydroelectric licenses that are up for renewal in the next 20 years. Reintroduction of fish to historic habitats will require a concerted effort by FERC and other interested parties to align license schedules and develop watershed approaches to developing new stream flow regimes and facilitate comprehensive fish passage plans. This approach is especially necessary in the McCloud, upper Yuba, upper Merced and other watersheds where upstream hydroelectric projects may influence areas identified for reintroduction, affect downstream habitats that are essential for recovery. Reintroduction will also require improved approaches to coordinating to resource agency coordination including joint filings under FERC proceedings, aligning regulatory schedules and products, and sharing biological, technical and policy expertise on high priority projects.

For all extant populations, small passage impediments such as low-head agricultural dams, recreation dams, fish ladders and road crossings should be evaluated and reconfigured to meet NMFS fish passage criteria for all life stages that encounter a structure. In no cases should passage impediments exist that restrict the passage of fish during their migration periods. All existing impediments should be

evaluated over the next two years and upgraded within five years.

Due to the significant presence of levees in the Central Valley and their effects on river function and the creation and maintenance of anadromous salmonid habitat, achieving species recovery will require a long-term river restoration program that separates the levees from the active channels of the river systems; especially in the Sacramento River between the vicinity of Colusa and Verona California, and in the Delta. In many areas, significant urban infrastructure is present that may preclude the relocation of flood control structures. In these areas, actions that restore the habitat complexity within the river channel should be aggressively pursued. Levee designs and levee repairs should target establishing low-risk woody vegetation, instream woody material, and benches to create small engineered floodplain areas that will serve as critical refugia and growth areas for fish within urban corridors.

To assist with ecological restoration, comprehensive conservation strategies need to be developed for each of the inland biogeographic areas in this Recovery Plan (Delta, San Joaquin River, Sacramento River, and each of the Diversity Groups).

In the Delta, a strategic approach to restoring intertidal habitats along principle migration and rearing corridors should be applied. Many factions compete for the beneficial uses of the waters of the Delta ecosystem. Increasing year-round water demand, continuous drought years, and more recently, poor ocean conditions have contributed to reductions in the survival, abundance, and diversity of native Delta fish species. In order to restore the Delta ecosystem, we believe that the following actions, some of which have been recently recommended by the Governors Delta Vision Blue Ribbon Task Force are critical to undertake in the near future:

- A new system of water conveyance around the Delta to protect and restore

estuarine ecosystems and anadromous fish migration;

- An investment commitment and conservation strategy to restore and sustain a diverse Delta ecosystem;
- A monitoring and investment plan to protect and enhance unique and important characteristics of the Delta region;
- A plan to significantly improve and provide incentives for water conservation – through both wise use and reuse – in both urban and agricultural sectors throughout the state;
- A Delta levee policy with quantified objectives, based on science and peer review, that prioritizes and implements restoration projects and identifies levees that need to be maintained for priority flood control purposes, or that can be allowed to deteriorate or be decommissioned to restore intertidal and floodplain fish habitat.
- New anadromous fish flows that create positive flow conditions during essential migratory periods in order to optimize the survival of emigrants through the Delta.
- An improved, comprehensive governance system that has reliable funding, takes advantage of established and effective ecosystem restoration and science programs, and has clear authority to determine priorities and strong performance measures to ensure accountability to the new governing doctrine of the Delta.

The CDFG has recently completed the CALFED Ecosystem Restoration Program (ERP) Draft Conservation Strategy for Stage 2 Implementation in the Sacramento-San Joaquin Delta and Suisun Marsh and Bay Planning Area. This strategy proposes to address the critical environmental conditions in the Delta and Suisun Marsh/Bay during the first phase (Phase

1) of Stage 2 implementation (2009-2020). The spatial extent of the ERP includes the Sacramento and San Joaquin Valleys in addition to the Bay-Delta estuary, and the ERP implementing entities recognize how conditions in the estuary are directly influenced by the manner in which water and species are managed upstream. Conservation strategies for these upstream areas will be forthcoming as part of ongoing ERP implementation, and should incorporate this recovery plan strategy to assist with attaining recovery criteria.

5.4.3 Hatchery Management

In general, existing fish hatcheries should be managed to reduce and minimize the potential for hatchery influences on winter- and spring-run Chinook salmon and steelhead. Reviews and reform of Central Valley Hatcheries are currently being coordinated with CDFG, NMFS, and the USFWS through the development and implementation of Hatchery and Genetic Management Plans (HGMPs); which will include long-term function or purpose of each hatchery in the context of VSP criteria and recovery objectives for salmonids listed under the ESA. In addition, HGMPs will include a monitoring component. Hatcheries are expected to play a continued role in salmonid fisheries in the Central Valley, but their purposes and roles should change to assist with the conservation of listed populations. Over time, as viable, naturally produced populations increase in abundance and distribution according to the recovery criteria laid out in this plan, hatchery management should transition from meeting mitigation production goals to assisting with the recovery goals and criteria laid out in this plan. This transition should allow for consideration to sunset certain hatchery programs as viable, natural populations are re-established.

Livingston Stone National Fish Hatchery is expected to play a continuing role as a conservation hatchery for the protection, and enhancement of the existing winter-run population below Keswick and Shasta dams, but

also should play a role in re-establishing winter-run to habitats above Shasta Reservoir, and to Battle Creek. Coleman National Fish Hatchery should consider developing a spring-run Chinook salmon conservation program to assist with the reintroduction of fish to the upper Sacramento River above Keswick and Shasta Dams.

In the near term, the Feather River Fish Hatchery will continue to target mitigation production goals for spring-run Chinook salmon and steelhead, but the future management of anadromous fisheries in the Feather River will be guided by an aggressive adaptive management program that is expected to significantly affect the future of these fish. As natural and hatchery-spawned spring-run Chinook salmon are increasingly separated from fall-run, their life history and genetic diversity traits are likely to improve over time and individuals will become more fit, increasing the species natural production, abundance, diversity and resilience. Feather River spring-run Chinook salmon may be good candidates for consideration in fishery reintroduction programs throughout the Central Valley. Although the existing genetic structure of the Feather River spring-run population is largely similar to fall-run Chinook salmon, there are some significant differences, and the population continues to display spring-run phenotypic life history characteristics. The Feather River hatchery should play an increasing conservation role in the future of the Feather River natural population, but also for reintroduction purposes to areas such as the San Joaquin River. The development of HGMPs should anticipate these potential uses and develop appropriate best management practices.

Hatchery management practices in the San Joaquin River Basin will also be changed by HGMPs. Steelhead management and HGMPs should provide consideration for developing steelhead conservation hatchery practices to assist with the reintroduction of these fish both to available, and to currently inaccessible, unoccupied habitat.

5.4.4 Winter-run Chinook Salmon

Dams in the Central Valley have blocked access to the entire historical spawning grounds, altered water temperatures, and reduced habitat complexity, thus posing risks to the abundance, productivity, and especially to the spatial structure and genetic diversity of the winter-run Chinook salmon ESU. The construction and operation of Shasta Dam alone immediately reduced the winter-run Chinook salmon ESU from four independent populations to one dependent population. The remaining available habitat for natural spawners is currently maintained with cool water releases from Shasta and Keswick dams, thereby significantly limiting spatial distribution of this ESU.

The population of Sacramento River winter-run Chinook salmon that now spawns below Keswick Dam is at moderate extinction risk according to the Population Viability Analysis, and at low risk according to the other criteria (Lindley et al. 2007). At present, the population easily satisfies the low-risk criteria for population size, population decline, and catastrophe, but hatchery influence remains of concern. The continued persistence of the winter-run Chinook salmon population is dependent on hatchery production, and as such cannot be characterized as having a low risk of extinction. However, as discussed in the Background chapter, in the short-term, LSNFH does not appear to be a genetic risk to the naturally spawning population based on a high average PNI value from 2003 through 2008.

The Sacramento River winter-run Chinook salmon ESU does not currently satisfy the representation and redundancy rule because it has only one population, and that population spawns outside of the ecoregion where it evolved (Lindley et al. 2007). An ESU represented by a single population at moderate risk of extinction is at high risk of extinction over the long-term. A single catastrophe could extirpate the entire Sacramento River winter-run Chinook salmon ESU, if its effects persisted for four or more years.

The entire reach of the Sacramento River used by winter-run Chinook salmon is within the zone of influence of Mt. Lassen. Some other possible catastrophes include a prolonged drought that depletes the cold water storage of Shasta Reservoir or some related failure to manage cold water storage, a spill of toxic materials with effects that persist for four years, or a disease outbreak.

For the Sacramento River winter-run Chinook salmon ESU to satisfy the representation and redundancy rule, at least two viable, independent populations would need to be present in the Basalt and Porous Lava Diversity Group. Therefore, the conceptual recovery scenario for the winter-run Chinook salmon ESU (**Figure 5-1**) includes: (1) securing the extant population by implementing key habitat restoration actions, particularly in the near term; (2) establishment of at least one other viable independent population in the Basalt and Porous Lava Diversity Group (e.g., Battle Creek and/or in systems above Shasta Dam).

For currently occupied habitats between Keswick Dam and Red Bluff, it is unlikely that habitats can be restored to pre-dam conditions, but many of the processes and conditions that are necessary to support a population of Sacramento River winter-run Chinook can be improved and sustained with extensive long-term human intervention. In order to secure the extant population of winter-run Chinook salmon, particularly in the near term, several key habitat restoration actions have been identified, including the following:

- runoff and storage conditions, including flow fluctuation and ramping criteria (USFWS 2001)
- Use the best available data regarding winter-run Chinook salmon spawning habitat availability as a key consideration for determining Keswick Dam releases
 - Develop a long-term strategy for monitoring and regulating discharges from agricultural lands to protect waters within the Central Valley, including enforcing water quality regulations (SWRCB Website 2009)
 - Conduct periodic (e.g., every 5 years) spawning gravel assessments in the upper Sacramento River (i.e., above RBDD) and implement gravel augmentation projects, as necessary
- Achieve the daily average water temperature targets described in the Biological Opinion on the Long-Term Central Valley Project Operations Criteria and Plan (NMFS 2009)
 - Implement a river flow management plan that balances carryover storage needs with instream flow needs for winter-run Chinook salmon based on

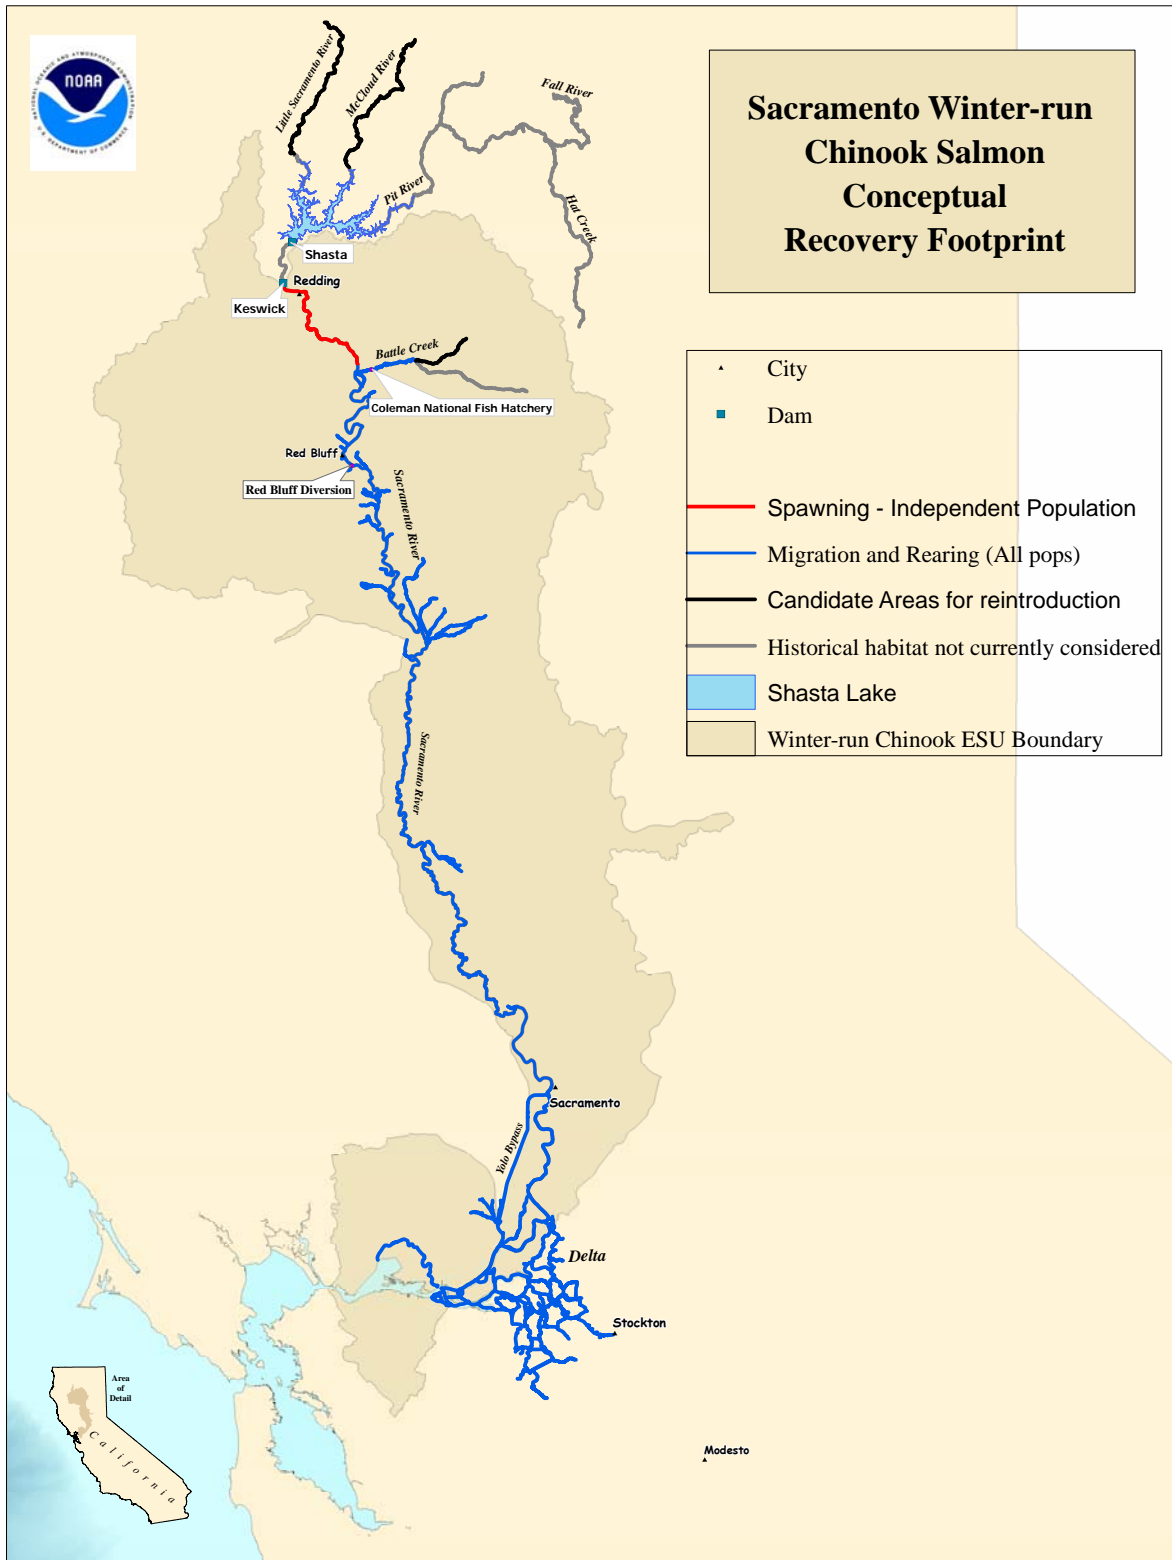

Figure 5-1. Sacramento River Winter-run Chinook Salmon ESU Conceptual Recovery Footprint. The candidate areas for reintroduction that are depicted on this map are areas where, although dams block access, the primary constituent elements that are necessary to support freshwater migration, holding, spawning, and rearing still exist or could be restored.

- ❑ Incorporate conservation measures in bank stabilization projects in the Sacramento River to provide more suitable seasonal habitat for juvenile salmon, and to reduce predation in the riprapped, leveed, or channelized sections of the Sacramento River
- ❑ Conduct feasibility studies on unscreened water diversions in the Sacramento River and at the State and Federal water project pumping plants to avoid or minimize the entrainment of juvenile salmon
- ❑ Conduct habitat evaluations and feasibility studies for reintroducing winter-run Chinook salmon to habitat above Shasta Dam, including assessing habitat suitability and passage logistics
- ❑ Design and conduct an experimental fish passage program evaluating adult distribution, survival, spawning, and production in habitats above Shasta Dam
- ❑ Develop habitat restoration / conservation and water project management operations actions in the Delta

Lindley et al. (2004) identifies four historically independent populations of Sacramento River winter-run Chinook salmon in the Central Valley, which met the two criteria for independence: basin isolation and minimum basin size. The historically independent populations were the Little Sacramento River, Pit-Fall-Hat Creek, McCloud River, and Battle Creek. The first three basins are blocked by Shasta and Keswick dams, and access to Battle Creek has been blocked by the Coleman National Fish Hatchery weir and various hydropower dams and diversions. The one independent population that presently inhabits the area of cool water between Keswick Dam

and Red Bluff was not historically used by winter-run Chinook salmon for spawning.

The Basalt and Porous Lava Diversity Group comprises the streams that historically supported winter-run Chinook salmon. All of these streams receive large inflows of cold water from springs through the summer, upon which winter-run Chinook salmon depended.

A recovery scenario that ultimately results in re-establishing viable populations in at least two of the four historic winter-run Chinook salmon populations (i.e., Little Sacramento, Pit River, McCloud River, and Battle Creek) will be needed to recover the ESU. With the exception of Battle Creek, passage past Shasta and Keswick dams will be required to achieve the representation and redundancy criterion.

For currently unoccupied historic habitats, the Little Sacramento and McCloud rivers have a high potential to support spawning adults due to the number of connected miles of suitable spawning and rearing habitat. The Pit River has a low potential due to the extensive presence of hydroelectric facilities that inundate or substantially affect historic habitat.

In order to secure long-term populations in the winter-run Chinook salmon ESU, several key actions have been identified and include:

- ❑ If the near-term experimental fish passage program demonstrates that passage above Shasta Dam can substantively contribute to the long-term viability of the ESU, then develop and implement long-term fish passage programs
- ❑ Continue to achieve the daily average water temperature targets described in the Biological Opinion on the Long-Term Central Valley Project Operations Criteria and Plan (NMFS 2009)

- ❑ Continue to implement a river flow management plan that balances carryover storage needs with instream flow needs for winter-run Chinook salmon based on runoff and storage conditions, including flow fluctuation and ramping criteria (USFWS 2001)
- ❑ Implement a long-term strategy for monitoring and regulating discharges from agricultural lands to protect waters within the Central Valley, including enforcing the regulations (SWRCB Website 2009)
- ❑ Continue to use the best available data regarding winter-run Chinook salmon spawning habitat availability as a key consideration for determining Keswick Dam releases
- ❑ Incorporate conservation measures in bank stabilization projects in the Sacramento River to provide more suitable seasonal habitat for juvenile salmon, and to reduce predation in the riprapped, leveed, or channelized sections of the Sacramento River
- ❑ Implement fish screen improvement projects for unscreened water diversions in the Sacramento River and at the State and Federal water project pumping plants to avoid or minimize the entrainment of juvenile salmon
- ❑ Implement habitat restoration/conservation and water project management operations in the Delta

Long-term climate change is an additional consideration regarding the viability of the winter-run Chinook salmon ESU and specific populations in the long-term. Global and localized climate changes, such as El Nino ocean conditions and prolonged drought conditions, may play an important role in the suitability of winter-run Chinook salmon

habitat and, hence, viability. The Sacramento River winter-run Chinook salmon ESU is highly vulnerable to drought conditions. During dry years, less cold water is available for release from Shasta Dam, which is the sole provider of cold water on which the fish are dependent. During an extended drought, the potential increased water temperatures in the Sacramento River would be expected to reduce the availability of suitable spawning and rearing conditions.

Lindley et al. (2007), in a simplified analysis, postulated three different long-term climate change scenarios potentially occurring by the year 2100. Mean summer air temperatures are expected to rise by at least 2°C, are expected to increase by around 5°C (9°F), and the less likely but still possible scenario of an 8°C (14.4°F) warming. Under the expected warming of around 5°C, substantial habitat would be lost, with remnants of habitat for winter-run Chinook salmon remaining in the upper Sacramento, McCloud, and Pit rivers, and Battle Creek. However, the net result in the long-term is uncertain, and Lindley et al. (2007) cautioned that more research is needed to evaluate the details of how warming would influence individual populations and subbasins.

Long-term climate change considerations emphasize the importance of a recovery scenario that ultimately results in re-establishing multiple viable populations among the four historic winter-run Chinook salmon populations (i.e., Little Sacramento, Pit River, McCloud River, and Battle Creek). These streams in the Basalt and Porous Lava Diversity Group that historically supported winter-run Chinook salmon receive spring-fed cold water through the summer. These watersheds offer important cold water inputs for winter-run Chinook salmon populations that could provide protection against climate change effects.

5.4.5 Spring-run Chinook Salmon

Present risks to the abundance, productivity, and especially to the spatial structure and genetic diversity of the spring-run Chinook salmon ESU result from the construction of dams in the Central Valley that have blocked access to the entire historical spawning grounds, altered water temperatures, and reduced habitat complexity. Good et al. (2005) emphasized the loss of diversity in the ESU caused by the extirpation of spring-run Chinook salmon populations from most of the Central Valley, including the San Joaquin River tributaries, as well as the close proximity of the remaining independent populations in the Central Valley spring-run Chinook salmon ESU.

Lindley et al. (2004) identify 18 historical independent populations of Central Valley spring-run Chinook salmon:

Independent Populations

- Little Sacramento River
- Pitt-Fall-Hat Rivers
- McCloud River
- Battle Creek
- Butte Creek
- Mill and Deer Creeks
- North Fork Feather River
- West Branch Feather River
- South Fork Feather River
- Yuba River
- North and Middle Forks American River
- South Fork American River
- Mokelumne River
- Stanislaus River
- Tuolumne River
- Merced River
- San Joaquin River

Each of these independent populations meets two of the three criteria for independence: basin isolation and minimum basin size. Two populations additionally met the third criterion of substantial genetic differentiation: Butte Creek, and Mill and Deer creeks. Currently,

there are only three independent populations of spring-run Chinook salmon, inhabiting Butte Creek, Mill Creek, and Deer Creek.

Lindley et al. (2004) also identified four historically dependent populations, grouped as follows:

Dependent Populations

- Kings River
- Big Chico, Antelope and Clear creeks
- Thomes and Cottonwood creeks
- Beegum and Stony creeks

The Kings River Basin is frequently inaccessible to anadromous fish. The other basins of dependent populations do not have enough habitat for spring-run Chinook salmon to persist in isolation. The following discussion regarding spring-run Chinook salmon population structure and viability is taken from Lindley et al. (2007).

Perhaps 15 of the 18 or 19 historical populations of Central Valley spring-run Chinook salmon are extinct, with their entire historical spawning habitats behind various impassable dams. Butte Creek and Deer Creek spring-run Chinook salmon are at low risk of extinction, satisfying both the PVA and other viability criteria. Mill Creek is at moderate extinction risk according to the PVA, but appear to satisfy the other viability criteria for low-risk status. Lindley et al. (2004) were uncertain whether Mill and Deer creek populations were each independent, or two parts of a single larger population. If viewed as a single population, Mill and Deer creek spring-run Chinook salmon are at low extinction risk. Early-returning Chinook salmon persist within the Feather River Hatchery population and spawn in the Feather River below Oroville Dam. Early-returning Chinook salmon also persist within the Yuba River and spawn below Englebright Dam. The current status of the Feather and Yuba river populations were not assessed by the Central Valley TRT due to insufficient data.

With demonstrably viable populations in only one of at least three diversity groups that historically contained them, Central Valley spring-run Chinook salmon fail the representation and redundancy rule for ESU viability. Historically, the Central Valley spring-run Chinook salmon ESU spanned four ecoregions: the Basalt and Porous Lava Diversity Group, the Northern Sierra Nevada Diversity Group, the Northwestern California Diversity Group and the Southern Sierra Nevada Diversity Group. There are two or three viable populations in the Northern Sierra Nevada Diversity Group (Mill, Deer and Butte creeks), although these populations were once probably relatively small compared to populations such as the Feather River. A few ephemeral or dependent populations are found in the Northwestern California Diversity Group (e.g., Beegum and Clear creeks). With the exception of a small population in Battle Creek, spring-run Chinook salmon have been entirely extirpated from the Basalt and Porous Lava Diversity Group. Spring-run Chinook salmon have been extirpated from the Southern Sierra Nevada Diversity Group – historically the most productive region for these fish.

The present distribution of viable populations of Central Valley spring-run Chinook salmon ESU renders them vulnerable to catastrophic disturbance. All three extant independent populations are in watersheds whose headwaters lie within the debris and pyroclastic flow radii of Mt. Lassen. The historical ESU was of such a large scale that neither Mt. Lassen, Mt. Shasta, or Medicine Lake could have extirpated even an entire diversity group, let alone the entire ESU. In addition, the current ESU structure is vulnerable to the catastrophic disturbances of drought and wildfires. Lindley et al. (2007) notes that the historical Central Valley spring-run Chinook salmon ESU was widespread enough to be invulnerable to all of these catastrophes, except perhaps prolonged

drought. It is possible that Central Valley spring-run Chinook salmon were less vulnerable to drought than might be expected because they once occupied diverse types of watersheds, including those with very high influence from springs.

In consideration of the foregoing, the recovery scenarios include the objectives of a minimum of two viable populations of spring-run Chinook salmon within each of the four spring-run Chinook salmon Diversity Groups, with the exception of the Northwestern California Diversity Group which historically did not contain independent spring-run Chinook salmon populations. For the Northwestern California Diversity Group, observed occupancy will suffice rather than viability, as defined.

To meet these objectives, the conceptual recovery scenario for the spring-run Chinook Salmon ESU (**Figure 5-2**) includes: (1) securing extant populations by implementing key habitat restoration actions, particularly in the near term; and (2) establishment of additional viable independent populations in the ESU. In addition to considerations of historical distribution, current population status, and recovery potential (including restoration actions) of the individual watersheds, one of the factors taken into account in the identification of candidate reintroduction watersheds is long-term climate change.

Long-term climate change is an additional consideration regarding the viability of the spring-run Chinook salmon ESU and specific populations in the long-term. Global and localized climate changes, such as El Niño ocean conditions and prolonged drought conditions, may play an important role in the suitability of spring-run Chinook salmon habitat and, hence, viability. The spring-run Chinook salmon ESU is highly vulnerable to drought conditions.

As previously described in the winter-run Chinook salmon ESU conceptual recovery scenario, Lindley et al. (2007) postulated that mean summer air temperatures are expected to rise by at least 2°C, are expected to increase by around 5°C (9°F), and the less likely but still possible scenario of an 8°C (14.4°F) warming by the year 2100. Under the expected warming of around 5°C, substantial spring-run Chinook salmon habitat would be lost, with significant amounts of habitat remaining primarily in the Feather and Yuba rivers, and remnants of habitat in the upper Sacramento and McCloud rivers, Battle and Mill creeks, and the Stanislaus River. Under the less likely but still possible scenario of an 8°C warming, spring-run Chinook salmon habitat would be found only in the upper-most reaches of the North Fork Feather River, Battle Creek and Mill Creek.

Long-term climate change considerations emphasize the importance of a recovery scenario that ultimately results in re-establishing viable populations in the spring-run Chinook salmon ESU. As depicted in Figure 5-2, candidate areas for reintroduction of spring-run Chinook salmon in the conceptual recovery scenario include:

- Little Sacramento River
- McCloud River
- North Fork Feather River
- North Fork Yuba River
- Middle Fork Yuba River
- South Fork Yuba River
- North Fork American River
- Middle Fork American River
- South Fork American River
- Mokelumne River
- Middle Fork Stanislaus River
- Tuolumne River
- Merced River
- San Joaquin River

Chinook salmon ESU in the long-term, several key actions associated with habitat restoration and reintroduction have been identified in the section titled Recovery Opportunities by Diversity Group, below. As previously described, numerous recovery actions are specific to the Sacramento River and the Delta, which serve as migratory corridors for populations of spring-run Chinook salmon spawning north of the Delta.

In order to secure the extant populations of spring-run Chinook salmon, particularly in the near term, and to recover the spring-run

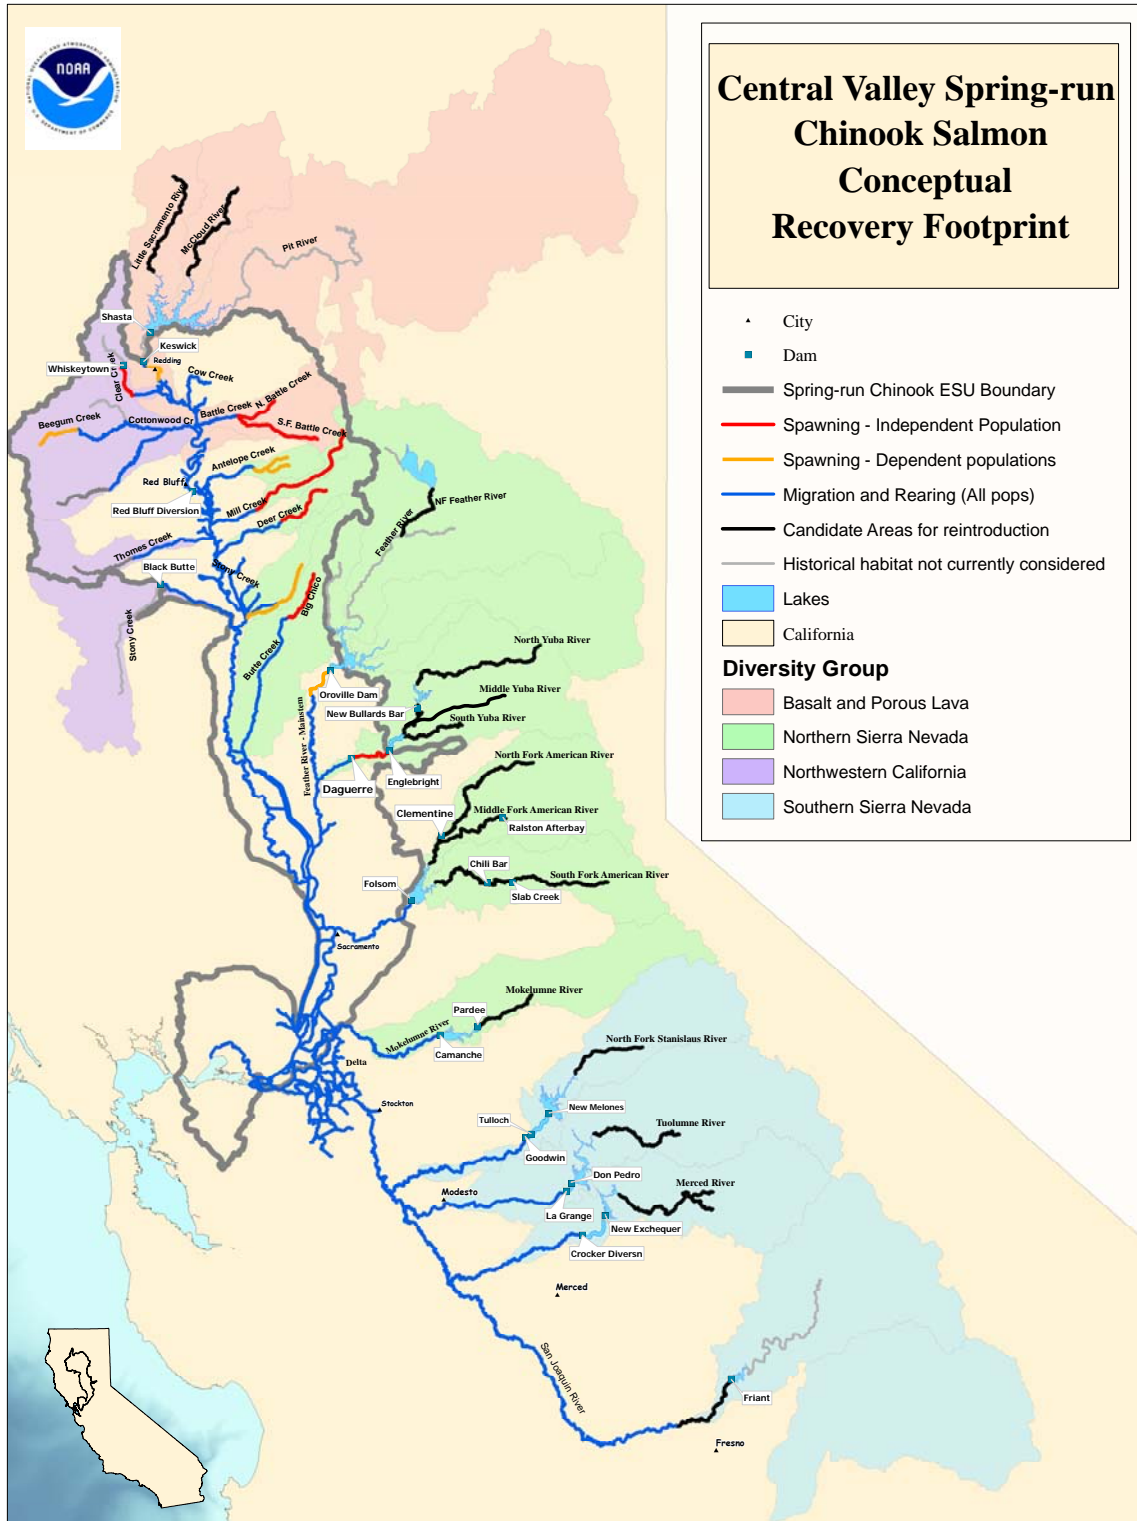

Figure 5-2 Central Valley Spring-run Chinook Salmon ESU Conceptual Recovery Footprint. The candidate areas for reintroduction that are depicted on this map are areas where, although dams block access, the primary constituent elements that are necessary to support freshwater migration, holding, spawning, and rearing still exist or could be restored.

RECOVERY OPPORTUNITIES BY DIVERSITY GROUP

BASALT AND POROUS LAVA DIVERSITY GROUP

The conceptual recovery scenario includes maintaining and enhancing persistent populations in the Basalt and Porous Lava Diversity Group. Persistent populations are primarily limited to dependent populations in the Sacramento River below Keswick Dam and in Battle Creek. The scenario also includes maintaining and enhancing the more ephemeral and dependent populations in the smaller streams tributary to the upper mainstem Sacramento River by implementing actions which are previously described in each of the individual watershed profiles.

The spring-run Chinook salmon conceptual recovery scenario for the Basalt and Porous Lava Diversity Group also includes reintroduction of spring-run Chinook salmon to the candidate areas of the Little Sacramento and McCloud rivers. Reintroductions would be dependent upon successful passage programs above Keswick and Shasta dams.

The following discussion of recovery opportunities for the Basalt and Porous Lava Diversity Group within the conceptual recovery scenario does not explicitly include those watersheds characterized by having more ephemeral and dependent populations, those that would require significant restoration actions, those that generally have relatively low recovery potential (as described in the watershed profiles (Appendix A) and other preceding sections of this Recovery Plan), and/or those that are not considered candidate areas for reintroduction of spring-run Chinook salmon. Consequently, the following conceptual recovery scenario discussion for the Basalt and Porous Lava Diversity Group focuses on Battle Creek, the Sacramento River below Keswick Dam, and the Little Sacramento and McCloud rivers.

BATTLE CREEK

Battle Creek has had persistent spawning populations of spring-run Chinook salmon in the reaches currently accessible on North Fork Battle and South Fork Battle creeks in recent years, although the populations have been relatively small. Currently, the Battle Creek Watershed has five dams blocking upstream migration of salmonids to much of the suitable and historic habitat. However, once complete, the Battle Creek Salmon and Steelhead Restoration Project (Restoration Project) (CALFED 2007) will provide access to 21 miles of currently inaccessible historical habitat, and will restore and enhance a total of nearly 50 miles of habitat.

It is anticipated that the Battle Creek Watershed, once restored, will be a conservation stronghold for spring-run Chinook salmon (Reclamation et al. 2004). Battle Creek has been identified as having high potential for successful fisheries restoration, because of its relatively high and consistent flow of cold water (Newton et al. 2008). It has the highest base flow (i.e., dry-season flow) of any tributary to the Sacramento River between the Feather River and Keswick Dam (Ward and Kier 1999, as cited in Newton et al. 2008).

Battle Creek is characterized as having a high potential to support viable independent populations of spring-run Chinook salmon. In order to secure the extant population of spring-run Chinook salmon, particularly in the near term, several key habitat restoration actions have been identified, including the following:

Install state-of-the-art fish ladders at, or remove small dams on the North Fork Battle Creek to provide fish passage

- Install state-of-the-art ladders at, or remove small dams on the South Fork Battle Creek to provide fish passage

- ❑ Increase streamflows, and flow releases from remaining diversion dams affecting anadromous fish on Battle Creek as per the Restoration Project
- ❑ Develop HGMPs and control hatchery release timing, numbers and locations in Battle Creek to minimize adverse effects to wild stock
- ❑ Conduct a feasibility study of moving and/or modifying Coleman Hatchery operations to prevent adverse impacts to wild populations of spring-run Chinook salmon in Battle Creek
- ❑ The conceptual recovery scenario for Battle Creek includes securing long-term spring-run Chinook salmon populations by continuing the implementation of the near-term actions, as well as the successful reintroduction and establishment of viable independent spawning populations in North Fork Battle Creek and South Fork Battle Creek.

Mainstem Sacramento River Below Keswick Dam

Lindley et al. (2007) did not characterize spring-run Chinook salmon populations in the upper mainstem Sacramento River, although developing information suggests that some spring-run may be present in the river. NMFS considers the spring-run Chinook salmon population in the upper mainstem Sacramento River to be data deficient, and believes that additional information needs to be collected to better understand the potential for the river to support a viable population.

For currently occupied habitats between Keswick Dam and Red Bluff, it is unlikely that habitats can be restored to pre-dam conditions, but many of the processes and conditions that are necessary to support a population spring-

run Chinook salmon can be improved and sustained with extensive long-term human intervention, including improvements to water temperature management and spawning gravel conditions. The potential to restore ecological processes capable of supporting spring-run Chinook salmon is low to moderate, primarily because the potential for reproductive isolation between spring-run Chinook salmon and fall-run Chinook salmon is complicated by overlapping migration and spawning periods.

Between Keswick Dam and Red Bluff, it is unlikely that currently occupied habitats can be restored to pre-dam conditions, but habitat can be improved and sustained. In order to secure the extant population of spring-run Chinook salmon and promote a viable population, several key near- and long-term actions have been identified, including the following:

- ❑ Achieve the daily average water temperature targets described in the Biological Opinion on the Long-Term Central Valley Project Operations Criteria and Plan (NMFS 2009)
- ❑ Implement a river flow management plan that balances carryover storage needs with instream flow needs for spring-run Chinook salmon based on runoff and storage conditions, including flow fluctuation and ramping criteria
- ❑ Use the best available data regarding spring-run Chinook salmon spawning habitat availability as a key consideration for determining Keswick Dam releases
- ❑ Develop a long-term strategy for monitoring and regulating discharges from agricultural lands to protect waters within the Central Valley, including enforcing the regulations

- ❑ Conduct periodic (e.g., every 5 years) spawning gravel assessments in the upper Sacramento River (i.e., above RBDD) and implement gravel augmentation projects, as necessary

The spring-run Chinook salmon conceptual recovery scenario also includes reintroduction of spring-run Chinook salmon to the candidate areas of the Little Sacramento and McCloud rivers. They both have a high potential to support spring-run Chinook salmon populations due to the number of connected miles of suitable spawning and rearing habitat. The Pit River has a low potential to support spring-run Chinook salmon populations due to the extensive presence of hydroelectric facilities that inundate or substantially affect historic habitat.

Northwestern California Diversity Group

As previously described, ESU recovery criteria includes a minimum of two viable populations of spring-run Chinook salmon within each of the four spring-run Chinook salmon Diversity Groups, with the exception of the Northwestern California Diversity Group. The Northwestern California Diversity Group historically did not contain independent spring-run Chinook salmon populations. For the Northwestern California Diversity Group, observed occupancy will suffice rather than viability for most of the watersheds included in this Diversity Group. However, the conceptual recovery scenario does include the establishment of an independent spawning population in Clear Creek above the current spawning distribution.

The Central Valley TRT postulated that all of the creeks in the Northwestern California Diversity Group may be dependant upon input of migrants from populations such as Deer, Mill and Butte creeks (Lindley et al. 2004). They further hypothesized that the group of streams in the Northwestern California

Diversity Group operate as a metapopulation - i.e., individual populations may not be viable on their own, but migration among members of the group maintains persistence of the whole group. The classification of these populations as dependent does not mean that they have no role to play in the persistence or recovery of the Central Valley spring-run Chinook salmon ESU. If these populations are adapted to their unusual spawning and rearing habitats, they may contain a valuable genetic resource (perhaps being more tolerant of high temperatures than other spring-run Chinook salmon). These habitats and populations may also serve to link other populations in ways that increase ESU viability over longer time scales (Lindley et al. 2004). Thus, the conceptual recovery scenario includes maintaining and enhancing the more ephemeral and dependent populations in the smaller streams in the Northwestern California Diversity Group (e.g., Thomes and Beegum creeks) by implementing actions which are previously described in each of the individual watershed profiles.

Although possibly present historically, existing conditions in Stony Creek preclude the annual production of anadromous salmonids (H.T. Harvey and Associates 2007), including spring-run Chinook salmon. Excessively low flows and warm water temperatures in Stony Creek during all life stages prevents the successful production of spring-run Chinook salmon. Stony Creek is characterized as having a low potential to support viable populations of spring-run Chinook salmon. This characterization is based on the following factors: (1) the system does not currently support populations of spring-run Chinook salmon; (2) water diversions limit instream flows; (3) the watershed is at a relatively low elevation (Lindley et al. 2004) and, thus, instream flow inputs are in the form of rainfall, not snowmelt; and (4) water temperatures under the current climate may already be beyond the thermal requirements of coldwater species such as spring-run Chinook salmon,

and climate change is expected to increase water temperatures in the Central Valley (Lindley et al. 2007).

The conceptual recovery scenario also includes maintaining and enhancing persistent populations in the Northwestern California Diversity Group. Persistent populations are primarily limited to dependent populations in Clear Creek and Cottonwood/Beegum Creek.

The following discussion of recovery opportunities for the Northwestern California Diversity Group within the conceptual recovery scenario does not explicitly include those watersheds characterized by having more ephemeral (i.e., non-persistent) and dependent populations, those that would require significant restoration actions, and those that generally have relatively low recovery potential (as described in the watershed profiles and other preceding sections of this Recovery Plan) for spring-run Chinook salmon. Consequently, the following conceptual recovery scenario discussion for the Northwestern California Diversity Group focuses on Clear and Cottonwood/Beegum creeks.

Clear Creek

Clear Creek historically was not known to support a large Central Valley spring-run population. However, since 1998, spring-run Chinook salmon have shown an increasing trend in abundance. In 2000, a small dam was removed which opened up 12 miles of prime spawning habitat for spring-run Chinook salmon. Increasing abundance is due, in part, to the reliable cool water source diverted from the Trinity River watershed, released at Whiskeytown Reservoir (Reclamation 2008). In addition, the spring-run Chinook salmon population in Clear Creek has apparently responded to extensive restoration efforts by joint agency partnerships through such programs as CVPIA and CALFED.

The Clear Creek spring-run Chinook salmon population is presently considered persistent, although dependent upon input of migrants from populations such as Deer, Mill and Butte creeks. Indications that the Clear Creek population has a high potential to become a viable independent population with a low risk of extinction include low stray rates from hatchery produced salmonids, and a recent increase in the annual number of spring-run Chinook salmon migrating into the creek. A recent review of habitat potential on Clear Creek indicated carrying capacity estimates of 3,122 spring-run Chinook salmon (M. Brown, USFWS, pers. com.).

Clear Creek is characterized as having a high potential to support a viable independent population of spring-run Chinook salmon. Restoration efforts supporting this characterization include implementation of a long-term gravel augmentation plan, managed releases of optimal flows, maintaining water temperatures below 65°F year-round and recent extensive riparian, instream channel and floodplain restoration. In order to secure the extant population of spring-run Chinook salmon, particularly in the near-term, several key habitat restoration actions have been identified, including the following:

- ❑ Develop a spawning gravel budget and implement a long-term augmentation plan in Clear Creek, and use flow management to optimize spawning weighted usable area in consideration of hydrologic limitations and lifestage requirements
- ❑ Increase stream flows in Clear Creek as needed to reduce water temperatures
- ❑ Develop a real-time water temperature model to track the coldwater pool in Whiskeytown Reservoir and budget releases to Clear Creek to meet daily water temperature of 60°F at the Igo gauge from June 1 to September 15,

and 56°F from September 15 to October 31

- ❑ Develop and implement flow ramping protocols in Clear Creek to protect all lifestages of spring-run Chinook salmon
- ❑ Develop and implement optimal pulse flow schedules and increase flow allocation for Clear Creek in years with low water availability

The conceptual recovery scenario for Clear Creek includes securing a long-term spring-run Chinook salmon viable and independent population by continuing the implementation of the near-term actions.

Cottonwood/Beegum Creek

Cottonwood/Beegum Creek historically was not known to support a large Central Valley spring-run population. Cottonwood Creek itself does not contain suitable spawning habitat to support a spring-run Chinook salmon population. However, Beegum Creek, a tributary of Cottonwood Creek, has supported a small persistent population since 1998. Lindley et al. (2004) considers the Beegum Creek population to be dependant upon input of migrants from populations such as Deer, Mill and Butte creeks.

The Cottonwood/Beegum Creek Watershed is characterized as having a low potential to support a viable independent population of spring-run Chinook salmon. Spring-run Chinook salmon in the Cottonwood/Beegum Creek Watershed have a high risk of extinction. Spring-run Chinook salmon in Beegum Creek are limited to low elevation habitat that is thermally marginal now, and will become intolerable within decades if the climate warms as expected (Williams 2006). With the implementation of successful restoration efforts in the watershed to improve habitat, the

risk of extinction of spring-run Chinook salmon may be reduced.

In order to secure the extant population of spring-run Chinook salmon, particularly in the near-term, several key habitat restoration actions have been identified, including the following:

- ❑ Develop and implement a spawning gravel augmentation plan in Beegum Creek
- ❑ Re-establish natural channel morphology in Cottonwood/Beegum Creek by: (1) applying NMFS gravel mining criteria to all gravel mining projects; (2) integrating natural morphological features and functions into bank protection and other stream side development projects; and (3) implementing non-native plant (e.g., *Arundo*) eradication plan
- ❑ Integrate riparian habitat restoration into bank protection and other stream-side development projects in Beegum Creek, and the greater Cottonwood/Beegum Creek Watershed
- ❑ Develop cooperative water use agreements (e.g., groundwater exchange agreements) with local water users to provide flows in Cottonwood Creek during the spring-run Chinook salmon adult immigration lifestage
- ❑ Enhance watershed resiliency in Beegum Creek by identifying and implementing projects that would: (1) reduce the potential for, and the magnitude of, a catastrophic wildfire; and/or (2) restore forested areas (including riparian areas) in the watershed

The conceptual recovery scenario for Cottonwood/Beegum Creek includes securing

a long-term spring-run Chinook salmon dependent population by continuing the implementation of the near-term actions.

Northern Sierra Nevada Diversity Group

The conceptual recovery scenario includes maintaining and potentially enhancing the presently viable populations (i.e., Deer, Mill, and Butte creeks) in the Northern Sierra Diversity Group. In addition, the scenario includes maintaining and enhancing persistent independent and dependent populations in this Diversity Group.

As previously discussed, the ESU recovery scenario includes the objectives of a minimum of two viable populations of spring-run Chinook salmon within each of the four spring-run Chinook salmon Diversity Groups. The Northern Sierra Nevada Diversity Group presently contains two or three viable populations of spring-run Chinook salmon. However, the present distribution of viable populations of spring-run Chinook salmon in the Northern Sierra Nevada Diversity Group renders them vulnerable to catastrophic disturbance. All viable populations are in watersheds whose headwaters lie within the debris and pyroclastic flow radii of Mt. Lassen. In addition, the viable populations in this Diversity Group are vulnerable to the catastrophic disturbances of drought and wildfires.

The spring-run Chinook salmon conceptual recovery scenario for the Northern Sierra Nevada Diversity Group also includes reintroduction of spring-run Chinook salmon to the candidate areas of the North Fork Feather River, North Fork Yuba River, Middle Fork Yuba River, South Fork Yuba River, North Fork American River, Middle Fork American River, South Fork American River and the Mokelumne River. In addition to considerations of historical distribution, current population status, and recovery potential (including restoration actions) of the

individual watersheds, one of the factors taken into account in the identification of candidate reintroduction watersheds is long-term climate change. Reintroductions also would be dependent upon successful passage programs above the dams in these watersheds. For each of these candidate areas for reintroduction, passage feasibility studies, habitat suitability assessments and other related investigations are underway in separate processes (e.g., FERC relicensings), some of which are described in Appendix A (watershed profiles), or they need to be conducted. Hence, the conceptual recovery scenario does not further discuss specific considerations regarding these candidate reintroduction areas.

The following discussion of recovery opportunities for the Northern Sierra Nevada Diversity Group within the conceptual recovery scenario does not explicitly include those watersheds characterized by having more ephemeral and dependent populations, and/or those that are not considered candidate areas for reintroduction of spring-run Chinook salmon. Consequently, the following conceptual recovery scenario discussion for the Northern Sierra Nevada Diversity Group focuses on the presently viable populations, as well as presently occupied habitats that have opportunities to support viable populations of spring-run Chinook salmon with the implementation of specific restoration actions.

Antelope Creek

Antelope Creek historically was not known to support a large spring-run Chinook salmon population. Lindley et al. (2007) did not classify the viability of spring-run Chinook salmon in Antelope Creek, but instead characterized the population as dependant upon other populations for its existence (Lindley et al. 2004). The current extinction risk for this population is high, despite low hatchery influence.

Antelope Creek is believed to support a dependent population of spring-run Chinook salmon, although CDFG (1998) states that the Antelope Creek spring-run population is not persistent. The upper reaches of Antelope Creek are still fairly undeveloped and contain good salmonid habitats. Antelope Creek reportedly has the potential to produce a sustainable population of 2,000 spring-run Chinook salmon, although inadequate flows due to two low head diversion dams prevent runs from realizing this potential (Rectenwald 1998).

Antelope Creek is characterized as having a moderate potential to support a dependent population of spring-run Chinook salmon. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed in good condition.

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of spring-run Chinook salmon in Antelope Creek. Those actions that are required are localized in nature and, when fully implemented, have a high likelihood of restoring good fish passage conditions. Antelope Creek is diverted into several channels below the Edward Diversion Dam. A single migration channel and fish passage flows need to be established to ensure that adult spring-run Chinook salmon have unimpeded access to upstream spawning habitat and juveniles have unimpaired downstream migration. Fish screens with suitable bypass flows also need to be installed at the Edward Dam. In the upper watershed Federal land management practices are guided by a long-term anadromous fish conservation strategy, although private timberland management plans lack a comprehensive anadromous habitat protection strategy.

In Antelope Creek the primary focus for spring-run Chinook salmon restoration is on

improving flow conditions and fish passage for upstream migrating adults to access important holding and spawning habitat, and for outmigration of juveniles. In order to realize Antelope Creek's moderate potential to support a dependent population of spring-run Chinook salmon, and to secure the extant population of spring-run Chinook salmon in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Restore instream flows during upstream and downstream migration periods
 - Develop water exchange agreements to provide alternative water supplies to Edwards Ranch and Los Molinos Mutual Water Company in exchange for instream fish flows
- ❑ Restore connectivity of the migration corridor during upstream and downstream migration periods
 - Implement Edwards and Penryn fish passage and entrainment improvement projects
 - Identify and define or construct a defined stream channel for upstream and downstream fish migration
- ❑ Restore the lower watershed riparian corridor

Mill Creek

Although Lindley et al. (2004) suggest that Mill Creek spring-run Chinook salmon populations were never very large historically, Mill Creek is recognized as supporting one of three remaining self-sustaining, viable spring-run Chinook salmon populations. Lindley et al. (2007) classified the Mill Creek spring-run Chinook salmon population as having a moderate risk of extinction according to the

PVA, but the population appears to satisfy the other viability criteria for low-risk status. Over the past three years, the abundance of the Mill Creek population has been in steep decline, and the extinction risk may be trending toward moderate to high. The Central Valley TRT did not conclude whether Mill and Deer creeks are independent of one another, although they did conclude that spring-run Chinook salmon in these streams are currently independent from other spring-run Chinook salmon populations and represent a significant lineage within Central Valley spring-run Chinook salmon ESU.

Habitat used for holding and spawning is located at high elevations and is considered to be high quality (CDFG 1998). The high elevation habitats in Mill Creek are isolated from fall-run Chinook salmon by low summer and fall flows. High water temperatures prevent geographic co-occurrence, and the thermal gradient maintains genetic and phenotypic diversity of the populations.

Mill Creek is considered a conservation stronghold for the ESU. With the implementation of key recovery actions, the watershed has a high potential for sustaining an independent population of spring-run Chinook salmon at a low risk of extinction because: (1) Mill Creek contains a sufficient amount of holding and spawning habitat to support a population that meets the abundance criteria for viability; (2) hatchery influence is low and expected to decrease over time; and (3) the number and magnitude of recovery actions needed within the Mill Creek watershed are limited and localized.

The aquatic habitats in Mill Creek (along with Deer, Antelope, Battle and Butte Creeks) are among the best remaining habitat above the Central Valley floor for anadromous salmonids. Although diversion structures are present in the valley section of Mill Creek, there are no major water impoundments along the Mill Creek corridor. Fish have been able to

maintain passage, and native fish communities have survived in the free-flowing sections.

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of spring-run Chinook salmon in Mill Creek. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed is in good condition. Those actions that are required are localized in nature and, when fully implemented, have a high likelihood of restoring or maintaining good fish passage conditions. A water exchange agreement already is in place between the CDFG and water users on Mill Creek. The programs are intended to develop and operate wells to offset bypass flows needed for spring-run Chinook salmon and to implement water use efficiency measures to reduce irrigation water demand. Although the agreement improves fish passage conditions for spring-run Chinook salmon, a comprehensive fish passage evaluation and monitoring plan has not been developed to assess the effectiveness of the agreement. Long-term verification of the flows, and an evaluation of existing dams for fish passage suitability are needed to ensure passage is provided at a wide range of stream flows. In the upper watershed, Federal land management practices are guided by a long-term anadromous fish conservation strategy, although private timberland management plans lack a comprehensive anadromous habitat protection strategy.

In Mill Creek the primary focus for spring-run Chinook salmon restoration is on maintaining flow conditions for upstream migrating adults so they can access important holding and spawning habitat (Mills and Ward 1996) and for outmigration of juveniles. Mill Creek is characterized as having a high potential to support a viable independent population of spring-run Chinook salmon with the implementation of key restoration actions. In

order to secure an independent viable population of spring-run Chinook salmon in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Implement a Mill Creek anadromous fish passage study (AFRP Website 2005) that will evaluate fish passage at all agricultural diversions to determine if they meet NMFS' fish passage criteria. Design and install state-of-the-art fish passage facilities at diversions that currently do not meet the passage criteria
- ❑ Conduct a study designed to determine adult fish passage flows at critical riffles and fish ladders in Mill Creek. Develop a water exchange agreement with all Mill Creek water users to allow implementation of those flows
- ❑ Enhance watershed resiliency in Mill Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce local water temperatures, or increase riparian shade and reduce sources of chronic road-related erosion of sediment (Mill Creek Conservancy Watershed Report, U.S. Forest Service Long-term Anadromous Fish Conservation Strategy)
- ❑ Eliminate sources of chronic sediment delivered to Mill Creek from roads and other near stream development by out-sloping roads, replacing under-sized culverts and applying other storm proofing guidelines
- ❑ Work with State and Federal water acquisition programs to develop

dedicated instream water; participate in the lower Mill Creek Watershed Restoration Project (AFRP Website 2005)

Deer Creek

Deer Creek is recognized as supporting one of three remaining self-sustaining, viable spring-run Chinook salmon populations, although Lindley et al. (2004) suggest that Deer Creek spring-run Chinook salmon populations were never very abundant historically, relative to spring-run Chinook salmon populations occurring in larger watersheds such as the Feather River. Lindley et al. (2007) classified the Deer Creek spring-run Chinook salmon population as having a low risk of extinction satisfying both the PVA and other viability criteria for low-risk status. The Central Valley TRT did not conclude as to whether Mill and Deer creeks are independent of one another, although they did conclude that spring-run Chinook salmon in these streams are currently independent from other spring-run Chinook salmon populations and represent a significant lineage within Central Valley spring-run Chinook salmon ESU.

The high quality holding and spawning habitat located at high elevations, and high water temperatures in the lower section prevent geographic co-occurrence with fall-run Chinook salmon, maintaining the genetic and phenotypic diversity of the populations. Deer Creek is considered a conservation stronghold for the ESU. Similar to Mill Creek, with the implementation of key recovery actions, the watershed has a high potential for sustaining a population at a low risk of extinction because: (1) Deer Creek contains a sufficient amount of holding and spawning habitat to support a population that meets the abundance criteria for viability; (2) hatchery influence is low and expected to decrease over time; and (3) the number and magnitude of recovery actions

needed within the Deer Creek watershed are limited and localized.

The aquatic habitats in Deer Creek are among the best remaining habitat above the Central Valley floor for anadromous salmonids. Although diversion structures are present in the valley section of Deer Creek, there are no major water impoundments along the Deer Creek corridor. Fish have been able to maintain passage, and native fish communities have survived in the free-flowing sections.

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of spring-run Chinook salmon in Deer Creek. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed is in good condition. Those actions that are required are localized in nature and, when fully implemented, have a high likelihood of restoring or maintaining good fish passage conditions. Water exchange programs are presently underway or in development with cooperation irrigation districts. The programs are intended to develop and operate wells to offset bypass flows needed for spring-run Chinook salmon and to implement water use efficiency measures to reduce irrigation water demand. In the upper watershed, Federal land management practices are guided by a long-term anadromous fish conservation strategy, although private timberland management plans lack a comprehensive anadromous habitat protection strategy.

In Deer Creek the primary focus for spring-run Chinook salmon restoration is on maintaining flow conditions for upstream migrating adults so they can access important holding and spawning habitat (Mills and Ward 1996) and for outmigration of juveniles. In particular, long-term fish passage improvements should be addressed by installing state-of-the-art passage facilities at the Cone-Kimball, Stanford

Vina, and Deer Creek Irrigation District dams, and existing dam structures should be replaced with inflatable bladder dams that can be installed during the irrigation season and lowered during periods of high stream flow and bedload transport.

Deer Creek is characterized as having a high potential to support a viable independent population of spring-run Chinook salmon with the implementation of key restoration actions. In order to secure the extant population and support a viable independent population of spring-run Chinook salmon, several key habitat restoration actions have been identified, including the following:

- ❑ Develop and implement a water exchange agreement with the Deer Creek Irrigation Company and the Stanford-Vina Irrigation District and dedicate fish passage flows
- ❑ Construct state-of-the-art inflatable dams and install fish ladders that meet NMFS' adult fish passage criteria at the Cone-Kimball Diversion, Stanford-Vina Dam, and the Deer Creek Irrigation District Dam
- ❑ Implement watershed restoration actions that reduce sedimentation and thermal loading in low gradient headwater habitats of Deer Creek Meadows and Gurnsey Creek
- ❑ Enhance watershed resiliency in Deer Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire
- ❑ Revise inland fishery management practices to eliminate the stocking of out-of-basin rainbow trout in Deer Creek in all waters upstream of Upper Deer Creek Falls

Big Chico Creek

Big Chico Creek historically was not known to support a large spring-run Chinook salmon population. Lindley et al. (2007) did not classify the viability of spring-run Chinook salmon in Big Chico Creek, but instead characterized the population as dependent upon migrants from other populations for its existence (Lindley et al. 2004). Spring-run Chinook salmon populations persist in Big Chico Creek, albeit at an annual population size in the tens or hundreds of fish, with no returning spawners in some years (NMFS 2009).

Because of the relatively low abundance and sporadic annual escapement of spring-run Chinook salmon, the extinction risk for this dependent population is high. Implementation of key recovery actions could improve conditions to reduce the risk of extinction.

Big Chico Creek is characterized as having a low to moderate potential to support a persistent population of spring-run Chinook salmon. Big Chico Creek is a small watershed with substantial urban impacts in the lower watershed. Big Chico Creek contains marginally suitable habitat for salmon that most likely was opportunistically used in the past by salmon and steelhead (Yoshiyama et al. 1996). However, the middle and upper watershed areas are not urbanized and much effort by local groups and land owners has been made to secure conservation easements along this portion of the river corridor. These easements protect the riparian zone from the impacts of long-term development. In addition, passage to the middle and upper watershed areas, where cooler water is found in the late summer, is provided by a ladder in Iron Canyon. There are plans to improve this fish ladder, which would be an important restoration activity to assist in securing the extant population.

With successful restoration efforts in Big Chico Creek, particularly in the lower sections of the creek and through improvements in the Iron Canyon fish ladder, the dependent population of spring-run Chinook salmon will be able to access upstream areas where cooler pools exist at Higgins Hole, an important summer holding area. In order to secure the dependent population of spring-run Chinook salmon in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Restore the lower watershed riparian corridor through native riparian planting, and improve off-channel refugia
- ❑ Improve the Iron Canyon Fish Ladder so that salmonids can pass at low summer flows

Butte Creek

Butte Creek is recognized as supporting one of three remaining self-sustaining, viable spring-run Chinook salmon populations. Lindley et al. (2007) classified the Butte Creek spring-run Chinook salmon population as having a low risk of extinction satisfying both the PVA and other viability criteria for low-risk status. Adult abundance has declined in recent years, but the population still remains strong and should still be considered to be at low risk of extinction.

Because the Butte Creek spring-run fish population is now considered persistent, independent and viable, the watershed is considered a conservation stronghold for spring-run Chinook salmon. Butte Creek is one of the most productive spring-run Chinook salmon streams in the Sacramento Valley (DWR 2005), and is one of only three streams (in addition to Mill and Deer creeks) that support a genetically distinct population of spring-run Chinook salmon (CDFG 1998).

Therefore, the viability of the Central Valley spring-run Chinook salmon ESU is reliant upon sustaining the Butte Creek spring-run Chinook salmon population.

Because of the low elevation of holding and spawning habitat in Butte Creek, historic water temperatures were likely too warm to support over-summering adult spring-run Chinook salmon and, hence, a self-sustaining population of spring-run Chinook salmon. Presently, cold water is imported from the upper West Branch Feather River, which creates habitat conditions that allow spring-run Chinook salmon to over-summer, spawn and successfully occupy Butte Creek.

The success of numerous restoration efforts that have been undertaken on Butte Creek are illustrated by the abundance of spring-run Chinook salmon that have been observed since 1998. Once impaired by numerous dams with poor fish passage facilities, no dedicated fish flows, and unscreened diversions, Butte Creek now provides state-of-the-art fish ladders and screens, and dedicated instream flows. However, elevated water temperature continues to pose a threat to holding adult spring-run Chinook salmon, particularly in consideration of long-term climate change.

Butte Creek is characterized as having a high potential to support a viable independent population of spring-run Chinook salmon with the implementation of key restoration actions. In order to secure the viable independent population of spring-run Chinook salmon in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Enhance watershed resiliency in Butte Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce

local water temperatures, or increase riparian shade (U.S. Forest Service Long-term Anadromous Fish Conservation Strategy)

- ❑ Install state-of-the-art fish ladders at DWR Weir 2 and Willow Slough Weir
- ❑ Maintain state-of-the-art fish passage facilities at diversions in Butte Creek to meet NMFS' passage criteria
- ❑ Conduct an instream flow study in Butte Creek to identify a spawning habitat-flow relationship and to identify factors (e.g., substrate size and quality, velocity, water depth) limiting spawning habitat availability

Feather River

Lindley et al. (2007) characterized the spring-run Chinook salmon population in the Feather River as data deficient, and therefore did not characterize its viability. However, the existing spring-run Chinook population in the Feather River, including fish produced by the Feather River Hatchery, may be the only remaining representatives of this important ESU component. The Feather River Hatchery spring-run Chinook salmon stock ultimately may play an important role in the recovery of spring-run Chinook in the Feather River Basin.

The lower Feather River, below Oroville Dam, is characterized as having a moderate potential to support a viable independent population of spring-run Chinook salmon, primarily based on the presence of a hatchery-supported population that is known to reproduce naturally in the Low Flow Channel between River Miles 59 and 67. CWT information from these hatchery returns indicates substantial introgression has occurred between fall-run and spring-run Chinook salmon populations within the Feather River system due to hatchery practices which have compromised

the genetic integrity of spring-run Chinook salmon.

Nonetheless, the recently signed Settlement Agreement for Licensing of the Oroville Facilities (March 2006) includes measures to improve the short- and long-term genetic management of the Feather River Hatchery, and measures to physically separate and isolate spring-run Chinook salmon from fall-run Chinook salmon.

For currently occupied habitats below Oroville Dam, it is unlikely that habitats can be restored to pre-dam conditions, but many of the processes and conditions that are necessary to support a population of spring-run Chinook salmon can be improved and sustained with extensive long-term human intervention, including improvements to water temperature management, habitat availability, spatial distribution and separation of spring- and fall-run Chinook salmon, and modified hatchery management. Implementation of the Settlement Agreement for the Oroville FERC license is expected to address these factors and considerably improve the habitat in the lower Feather River.

The spring-run Chinook salmon conceptual recovery scenario includes reintroduction of spring-run Chinook salmon to the candidate area of the North Fork Feather River. Reintroduction would be dependent upon successful passage programs above Oroville Dam. Regarding the candidate area for reintroduction above Oroville Dam, passage feasibility studies, habitat suitability assessments and other related investigations are underway in separate processes (e.g., FERC relicensing), some of which are described in Appendix A (watershed profile). Hence, the conceptual recovery scenario does not further discuss specific restoration actions associated with reintroduction.

In order to secure the extant population of spring-run Chinook salmon in the lower

Feather River, several key near-term and the long-term habitat restoration actions have been identified, including the following:

- ❑ Increase lower Feather River stream flows as needed to reduce water temperatures for juvenile rearing
- ❑ Identify stream reaches that have been most altered by anthropogenic factors and reconstruct natural channel geometry scaled to current channel forming flows in the lower Feather River
- ❑ Implement Facilities Modifications(s) to achieve lower Feather River water temperatures at least as protective as those specified in Table 2 of the Settlement Agreement For Licensing of the Oroville Facilities
- ❑ Develop a spawning gravel budget, identify gravel starved areas, and implement an augmentation plan in the lower Feather River
- ❑ Implement the use of a temporary weir in the lower Feather River to spatially segregate spring-run Chinook salmon and fall-run Chinook salmon during spawning
- ❑ Determine the feasibility of providing access to habitat above the Fish Barrier Dam
- ❑ Develop a hatchery management plan for the Feather River Fish Hatchery, including specific criteria for operating as either an integrated or segregated hatchery
- ❑ Develop a spring-run Chinook salmon conservation hatchery program at the Feather River Fish Hatchery

Yuba River

Lindley et al. (2007) characterized the spring-run Chinook salmon population in the lower Yuba River as data deficient, and therefore did not characterize its viability. There is limited information on the current population size of spring-run Chinook salmon in the lower Yuba River, although ongoing monitoring is presently providing additional information. In general, the current data indicate that adult escapement of spring-run Chinook salmon is low relative to historical levels (NMFS 2007a). According to NMFS (2007a), infrared and videographic sampling on both ladders at Daguerre Point Dam from 2003 through 2007 has provided estimates of spring-run Chinook salmon numbers migrating into the lower Yuba River ranging from several hundred to over 1,200 fish. However, these numbers should be considered to be preliminary, minimum estimates, as periodic problems with the sampling equipment have resulted in periods when fish ascending the ladders were not counted, so it is likely that the actual numbers are higher than those reported. The detection of adipose fin clips on some of these fish indicates that they were hatchery strays, most likely from the Feather River Hatchery.

The lower Yuba River supports a persistent population of spring-run Chinook salmon that spawn in the lower Yuba River below the U.S. Army Corps of Engineers' (Corps) Englebright Dam. There is no hatchery located on the lower Yuba River - thus the genetic integrity of spring-run Chinook salmon may be largely uncompromised by hatchery influence, although some straying, most likely from the Feather River Hatchery into the lower Yuba River, does occur. The estimated abundance of adult spring-run Chinook salmon indicates that the population is at a moderate risk of extinction.

The lower Yuba River, below Englebright Dam, is characterized as having a high potential to

support a viable independent population of spring-run Chinook salmon, primarily because: (1) flow and water temperature conditions are generally suitable to support all life stage requirements; (2) the river does not have a hatchery on it; (3) spawning habitat availability is believed not to be limiting; and (4) high habitat restoration potential (see the watershed profile).

For currently occupied habitats below Englebright Dam, it is unlikely that habitats can be restored to pre-dam conditions, but many of the processes and conditions that are necessary to support a viable independent population of spring-run Chinook salmon can be improved with provision of appropriate instream flow regimes, water temperatures, and habitat availability. Continued implementation of the Yuba Accord is expected to address these factors and considerably improve conditions in the lower Yuba River. Additional habitat improvements and restoration actions are anticipated to be addressed in the forthcoming Yuba County Water Agency FERC relicensing process.

The spring-run Chinook salmon conceptual recovery scenario also includes reintroduction of spring-run Chinook salmon to the candidate areas of the North Fork, Middle Fork and South Fork Yuba rivers. Reintroduction of anadromous salmonids above Englebright Dam has been the subject of recent and current investigations. Evaluation of habitat suitability for anadromous salmonids upstream of Englebright Dam was recently undertaken (DWR 2007), but those evaluations have yet to be finalized as part of the Upper Yuba River Watershed Studies Program. Currently, NMFS is evaluating the feasibility of providing passage for anadromous salmonids at Englebright Dam. Hence, the conceptual recovery scenario does not further discuss specific restoration actions associated with reintroduction.

In order to secure a viable independent population of spring-run Chinook salmon in the lower Yuba River, several key near-term and the long-term habitat restoration actions have been identified, including the following:

- ❑ Continue implementation of the Yuba Accord flow schedules to provide suitable habitat (flow and water temperature) conditions for all life stages
- ❑ Improve adult salmonid upstream passage at Daguerre Point Dam
- ❑ Improve juvenile salmonid downstream passage at Daguerre Point Dam
- ❑ Implement a spawning gravel augmentation program in the uppermost area (i.e., Englebright Dam to the Narrows) of the lower Yuba River
- ❑ Improve riparian habitats for juvenile salmonid rearing
- ❑ Create and restore side-channel habitats to increase the quantity and quality of off-channel rearing (and spawning) areas
- ❑ Implement projects to increase floodplain habitat availability to improve habitat conditions for juvenile rearing

Southern Sierra Nevada Diversity Group

Although spring-run Chinook salmon were extirpated from the Southern Sierra Nevada Diversity Group and this region is not included in the listed ESU, re-establishing wild populations in the San Joaquin River system would certainly contribute to the viability of

spring-run Chinook salmon in the Central Valley.

The spring-run Chinook salmon conceptual recovery scenario for the Southern Sierra Nevada Diversity Group includes reintroduction of spring-run Chinook salmon to the candidate areas of the North Fork Stanislaus River above New Melones Dam, the Tuolumne River above Don Pedro Dam, the Merced River above New Exchequer Dam, and the San Joaquin River into presently unoccupied areas below Friant Dam. For each of these candidate areas for reintroduction, passage feasibility studies, habitat suitability assessments and other related investigations are or will be undertaken in separate processes (e.g., FERC relicensings, San Joaquin River Restoration Program), some of which are described in Appendix A (watershed profiles).

By 1928, the California Department of Fish and Game (CDFG) issued a bulletin reporting that there were "very few" salmon remaining in the San Joaquin River above the Merced River confluence and the "historical" salmon fishery that once existed had been "severely depleted" as a result of seasonal water diversions and the operation of upstream hydropower reservoirs. Since the 1950s, the remaining Chinook salmon in the watershed consist only of fall-run Chinook salmon populations found in major tributaries to the lower San Joaquin River. Because of these developments, which caused the extinction of the San Joaquin spring-run salmon population, several legal actions were taken in the case of *NRDC et al. v. Kirk Rodgers et al.*, and resulted in a 2006 Settlement that was termed the San Joaquin River Restoration Program (SJRRP). The SJRRP Settlement Process calls for a combination of channel and structural modifications along the San Joaquin River below Friant Dam, releases of water from Friant Dam to the confluence of the Merced River, and the reintroduction of Chinook salmon.

With implementation of these actions, the San Joaquin River Watershed below Friant Dam can be characterized as having a high potential to support a spawning population of reintroduced spring-run Chinook salmon. The high potential to support a viable population of spring-run is based upon successful re-introduction through the SJRRP program. This population will be an experimental population using Sacramento River basin stock while implementing various habitat improvements throughout the restoration area between Friant Dam and the Merced River confluence. The important factor that increases the chances of a successful reintroduction of Central Valley spring-run salmon into the system is the availability of cold water releases from Friant Dam. Habitat objectives for the restoration area along the San Joaquin River were developed to address physical habitat, stream flow, water temperature and water quality impairments (SJRRP 2009).

In order to establish and maintain populations of spring-run Chinook salmon in both the near-term and the long-term, several key habitat restoration actions have been identified in the SJRRP (2009) and include the following:

- ❑ Provide flows sufficient to ensure habitat connectivity and allow for unimpeded upstream passage and outmigration
 - Modify San Joaquin River and Eastside and Mariposa bypasses to create a low-flow channel suitable to support fish passage
 - Modify channels in Reaches 2B and 4B to increase flow capacity (low-flow or migration-flow capacity)
 - Implement Settlement flow schedule
 - Implement hydrograph flexibility, buffer flows, flushing flows, and use of additional purchased water, as necessary

- Implement trap-and-haul operation to move Chinook salmon into suitable habitat areas when flows and/or habitat conditions are unsuitable
- ❑ Release flows sufficient to provide suitable Chinook salmon spawning depth and velocity
 - Implement Settlement flow schedule (see Action A3 of the 2009 Draft Fisheries Management Plan)
 - Implement hydrograph flexibility, buffer flows, flushing flows, and use of additional purchased water, as necessary (see Action A4 of the 2009 Draft Fisheries Management Plan)
 - Modify existing channel(s) to provide Chinook salmon spawning habitat
- ❑ Provide suitable flow for egg incubation and fry emergence
 - Implement Restoration Flows including hydrograph flexibility, buffer flows, flushing flows, and use of additional purchased water, as necessary (see Action A4 of the 2009 Draft Fisheries Management Plan)
- ❑ Minimize juvenile entrainment losses
 - Screen Arroyo Canal to prevent fish losses
 - Construct Mendota Pool Bypass
 - Modify the Chowchilla Bypass Bifurcation Structure to reduce juvenile Chinook salmon entrainment
 - Fill and isolate the highest priority mining pits
 - Consolidate diversion locations

- ❑ Minimize losses to nonviable pathways and prevent adult migration delays
 - Implement temporary or permanent barriers at Mud and Salt sloughs or any other location deemed necessary
 - Screen Arroyo Canal to prevent fish losses (see Action D1 of the 2009 Draft Fisheries Management Plan)
 - Fill and isolate the highest priority mining pits (see Action D3 of the 2009 Draft Fisheries Management Plan)
- ❑ Eliminate fish passage barriers and minimize migration delays
 - Modify Sand Slough Control Structure
 - Modify Reach 4B headgate
 - Retrofit Sack Dam to ensure fish passage
 - Construct Mendota Pool Bypass (see Action D2 of the 2009 Draft Fisheries Management Plan)
 - Ensure fish passage is sufficient at all other structures and potential barriers
 - Implement a trap-and-haul operation to move Chinook salmon into suitable habitat areas when flows are inadequate (see Action A5 of the 2009 Draft Fisheries Management Plan)
- ❑ Provide suitable water temperatures for upstream passage, spawning, egg incubation, rearing, smoltification, and outmigration to the extent achievable considering hydrologic, climatic, and physical channel characteristics
 - Implement Settlement flow schedule (see Action A3 of the 2009 Draft Fisheries Management Plan)
- Implement hydrograph flexibility, buffer flows, and use of additional purchased water, as necessary (see Action A4 of the 2009 Draft Fisheries Management Plan)
- Fill and isolate the highest priority mining pits (see Action D3 of the 2009 Draft Fisheries Management Plan)
- ❑ Provide suitable water temperature releases
 - Modify Friant and Madera canals to provide suitable water temperature releases from Friant Dam
- ❑ Meet or exceed the genetic fitness goals for Chinook salmon
 - Select and manage genetically fit stock sources for Chinook salmon
 - Incorporate conservation practices in artificial propagation of Chinook salmon
- ❑ Provide and/or maintain suitable water quality
 - Implement Settlement flow schedule (see Action A3 of the 2009 Draft Fisheries Management Plan)
 - Support existing public outreach and education programs incorporating education on best management practices
- ❑ Minimize in-river harvest, unlawful take, and disturbance
 - Implement public outreach program to reduce unlawful take of Chinook salmon and disturbance associated with spawning habitat
 - Restrict seasonal access in sensitive river sections (i.e., spring-run Chinook salmon holding and

- spawning habitat) and change current fishing regulation
 - Increasing law enforcement in the Restoration Area will reduce unlawful harvest of Chinook salmon
- ❑ Minimize Chinook salmon redd superimposition
 - Determine if additional spawning habitat (i.e., augment gravel at existing riffles and other suitable locations) is necessary to sustain Chinook salmon populations
 - Modify operation of Hills Ferry Barrier or construct other temporary barriers to segregate Chinook salmon runs (see Action I3 of the 2009 Draft Fisheries Management Plan)
- ❑ Minimize hybridization between spring-run and fall-run Chinook salmon
 - Modify operation of Hills Ferry Barrier or construct other temporary barriers to segregate Chinook salmon runs (see Action I3 of the 2009 Draft Fisheries Management Plan)
 - Increase the amount of Chinook salmon spawning habitat available to minimize overlap of runs and reduce hybridization
- ❑ Ensure sufficient quantity and quality of holding pool habitat to meet Restoration Goal
 - Implement Settlement flow schedule (see Action A3 of the 2009 Draft Fisheries Management Plan)
 - Implement hydrograph flexibility, buffer flows, flushing flows, and use of additional purchased water, as necessary (see Action A4 of the 2009 Draft Fisheries Management Plan)
- 2009 Draft Fisheries Management Plan)
 - Evaluate the quality and quantity of holding pool habitat
- ❑ Provide sufficient quantity and quality of spawning habitat for Chinook salmon
 - Implement Settlement flow schedule (see Action A3 of the 2009 Draft Fisheries Management Plan)
 - Implement hydrograph flexibility, buffer flows, flushing flows, and use of additional purchased water, as necessary (see Action A4 of the 2009 Draft Fisheries Management Plan)
 - Augment gravel at existing riffles and other suitable locations (see Action L1 of the 2009 Draft Fisheries Management Plan)
 - Modify channels to provide Chinook salmon spawning habitat (see Action B3 of the 2009 Draft Fisheries Management Plan)
- ❑ Minimize fine deposited and suspended sediment
 - Implement measures to clean Chinook salmon spawning gravel
 - Implement public outreach program (see Action J2 of the 2009 Draft Fisheries Management Plan)
 - Construct settling basins
- ❑ Ensure suitable quantity and quality of floodplain and riparian habitat to provide habitat and food resources for Chinook salmon and other fishes
 - Implement Settlement flow schedule (see Action A3 of the 2009 Draft Fisheries Management Plan)
 - Implement hydrograph flexibility, buffer flows, and use of additional

- purchased water, as necessary (see Action A4 of the 2009 Draft Fisheries Management Plan)
- Restore floodplain habitat
 - Create off-channel Chinook salmon rearing areas
- Ensure favorable conditions for food availability, growth, and development
- Increase invertebrate production
 - Restore floodplain habitat (see Action Q3 of the 2009 Draft Fisheries Management Plan)
- Reduce predation of Chinook salmon by nonnative fishes and other aquatic organisms
- Fill and isolate the highest priority mining pits (see Action D4 of the 2009 Draft Fisheries Management Plan)
 - Construct a low-flow channel (see Action A1 of the 2009 Draft Fisheries Management Plan)
 - Restore floodplain habitat (see Action Q3 of the 2009 Draft Fisheries Management Plan)
 - Reduce the number of nonnative predatory fishes in the Restoration Area
 - Create an increase in turbidity during juvenile downstream migration to reduce detection and therefore predation by piscivore fishes
 - Use pulse flows to displace nonnative predatory fishes in the Restoration Area

Although spring-run Chinook salmon historically were the most abundant in the San Joaquin River basin (Yoshiyama, et al 1996), spring-run were extirpated from San Joaquin Basin and below Friant Dam in the 1950's, and no clear genetic stock remains. A successfully re-introduced population in the mainstem San

Joaquin River will require flexible management objectives that allow fish that express the run timing and holding patterns of spring-run Chinook salmon to adapt to the unique and local habitat characteristics that ultimately will select which fish are most suited to inhabit this reach of the river.

The conceptual recovery scenario for the Southern Sierra Nevada Diversity Group, and for the San Joaquin Basin in particular, is likely to be conservation-reliant, particularly in the near-term (five to ten generations). It seems highly unlikely that enough habitat can be restored, particularly in the near-term, such that the spring-run Chinook salmon ESU could be expected to persist without appropriate conservation management. Although spring-run Chinook salmon historically were the most abundant in the San Joaquin River Basin (Yoshiyama, et al), spring-run were extirpated from the San Joaquin Basin and below Friant Dam in the 1950's, and no clear genetic stock remains. Reintroduction of spring-run Chinook salmon in areas of the Southern Sierra Nevada Diversity Group probably most likely will require the use of artificial propagation as a source of fish. In the short term, establishing self sustaining populations that demonstrate the phenotypic life history traits of spring-run Chinook salmon may be the most realistic objective. Unique genetic diversity will likely take many generations to achieve.

Because spring-run Chinook salmon are anadromous, populations in the Southern Sierra Nevada Diversity Group would utilize the lower San Joaquin River downstream of the confluence with the Merced River and the Delta during adult upstream migration, and juvenile rearing and outmigration. The conceptual recovery scenario recognizes that the successful reintroduction of spring-run Chinook salmon populations would, in part, be influenced by conditions in the lower San Joaquin River and the Delta.

The technical memorandum regarding the San Joaquin River Reasonable and Prudent Alternative (RPA) in the 2009 NMFS OCAP BO recognizes the importance of the lower San Joaquin River and the Delta as part of the migratory/rearing corridor for populations originating in East Side tributaries, and contains specific actions. Although many of these actions were specifically listed as pertinent to Central Valley steelhead, similar considerations would apply to habitats used by spring-run Chinook salmon. For example, *Action Suite IV.2: Flow Management* of the Delta Division RPA specifies that adequate flows should be maintained in both the Sacramento River and San Joaquin River basins to increase survival of steelhead emigrating to the estuary from the San Joaquin River, and of spring-run Chinook salmon emigrating from the Sacramento River through the Delta. As another example, *Action IV.2.1: San Joaquin River Inflow to Export Ratio* of the Delta Division RPA is designed to reduce the vulnerability of emigrating steelhead within the lower San Joaquin River to diversion into the channels of the south Delta, and thereby increasing their risk of eventual entrainment at the export pumps due to the diversion of water by the export facilities in the south Delta (NMFS 2009).

Actions in the RPA, including management of river flows on the San Joaquin River, are intended to avoid jeopardy to the Central Valley steelhead population currently residing in the San Joaquin Basin and its tributaries. The RPA identifies actions that shall be implemented in consideration of maintaining appropriate river flows in the mainstem San Joaquin River at Vernalis that are beneficial to steelhead based on the life history requirements. Management of exports as part of the implementation of the OCAP RPA will enhance the benefits derived from increasing flows on the San Joaquin River (NMFS 2009). Other issues relevant to listed anadromous fish species in the San Joaquin River Basin and the Delta that are addressed by the RPA in the

2009 NMFS OCAP BO include, but are not limited to:

- Increasing survival of emigrating smolts from the tributaries into the main stem of the San Joaquin River
- Increasing survival of emigrating smolts through the main stem of the San Joaquin River downstream into the Delta
- Increasing survival of emigrating smolts through the Delta
- The role and influence of flow and exports on survival in these migratory reaches
- Selection of routes under the influence of flows and exports
- Identifying reach-specific mortality and or loss
- The effectiveness of experimental technologies, if any, *e.g.*, non-physical barrier (“bubble curtain”)

5.4.6 Steelhead

Lindley et al. (2006) identify 81 historical independent populations of Central Valley steelhead in 48 watersheds, listed below.

Watersheds with Historical Independent Populations

American River
 Antelope Creek
 Battle Creek
 Bear River (Sacramento R. tributary)
 Bear River (Feather R. tributary)
 Big Chico Creek
 Coon Creek
 Cosumnes River

Cottonwood Creek
 Deer Creek (Kaweah R. tributary)
 Del Puerto Creek
 Elder Creek
 Feather River
 Kaweah River
 Kern River
 Kings River
 Little Cow Creek
 Lone Tree Creek
 Los Banos Creek
 Los Gatos Creek
 Marsh Creek
 McCloud River
 Merced River
 Mill Creek
 Mokelumne River
 Panoche Creek
 Paynes Creek

The posited historical existence of 81 independent populations is likely to be an underestimate because large watersheds that span a variety of hydrological and environmental conditions, such as the Pit River, probably contained multiple populations (Lindley et al. 2006). Regardless, the distribution of many discrete populations across a wide variety of environmental conditions implies that the Central Valley steelhead DPS contained biologically significant amounts of spatially structured genetic diversity (Lindley et al. 2006). However, it appears that much of the historical diversity within Central Valley *O. mykiss* has been lost or is threatened by dams, which have heavily altered the distribution and population structure of steelhead in the Central Valley (Lindley et al. 2006).

Although there were once two different runs of steelhead (summer-run and winter-run) in the Central Valley (McEwan and Jackson 1996), the summer run has been all but extirpated due to a lack of suitable holding and staging habitat, such as coldwater pools in the headwaters of Central Valley streams, presently located above impassible dams (Lindley et al. 2006).

Throughout the Central Valley (and in particular the Merced River, Tuolumne River, and upper Sacramento River) it is difficult to discriminate between adult anadromous and resident forms of *O. mykiss*, as well as their progeny (McEwan 2001), further complicating resource management agencies' understanding of steelhead distribution in the Central Valley (CDFG 2008).

Presently, steelhead populations in the Central Valley are critically depressed in most if not all rivers and streams (CDFG 2008). In many cases, particularly in the San Joaquin Basin, anadromy in *O. mykiss* populations may be nonexistent or too low to detect while resident *O. mykiss* populations in the same rivers have remained strong (CDFG 2008). Remnant steelhead populations are presently distributed through the mainstem of the Sacramento and San Joaquin rivers, as well as many of the major tributaries of these rivers. Steelhead presence in highly variable "flashy" streams and creeks in the Central Valley depend primarily on flow and water temperature, which can change drastically from year to year (McEwan and Jackson 1996). Recent spawner surveys of small Sacramento River tributaries (Mill, Deer, Antelope, Clear, and Beegum creeks; Moore 2001) and incidental captures of juvenile steelhead during Chinook salmon monitoring (Calaveras, Cosumnes, Stanislaus, Tuolumne, and Merced rivers) confirmed that steelhead are widespread, if not abundant, throughout accessible streams and rivers (Good et al. 2005).

For the Recovery Plan and this conceptual recovery scenario, 26 individual rivers/watersheds⁵ in the Sacramento and San Joaquin river systems that historically and

⁵ It is recognized that more than 26 individual rivers/watersheds exist that historically supported, and can currently support steelhead in the Central Valley. However, it is assumed that recovery of the Central Valley steelhead DPS is primarily dependent on the 26 populations included in the threats assessment (Appendix A).

currently support populations of steelhead were identified using literature describing the historical population structure of steelhead in the Central Valley (Lindley et al. 2006) and by using the best available professional knowledge of Central Valley salmonid biologists regarding the current distribution of steelhead. These 26 steelhead populations were categorized into four Diversity Groups based on the geographic structure described in Lindley et al. (2007), which are listed below.

- ❑ Basalt and Porous Lava Diversity Group
 - Battle Creek
 - Cow Creek
 - Small tributaries to the upper Sacramento River
 - Upper Sacramento River Mainstem

- ❑ Northwestern California Diversity Group
 - Cottonwood/Beegum Creek
 - Thomes Creek
 - Clear Creek
 - Stony Creek
 - Putah Creek

- ❑ Northern Sierra Nevada Diversity Group
 - Antelope Creek
 - Mill Creek
 - Deer Creek
 - Big Chico Creek
 - Butte Creek
 - Feather River
 - Bear River
 - Yuba River
 - Auburn Ravine/Coon Creek
 - Dry Creek
 - American River

- ❑ Southern Sierra Nevada Diversity Group
 - Mokelumne River

- Calaveras River
- Stanislaus River
- Tuolumne River
- Merced River
- San Joaquin River Mainstem

Without demonstrably viable populations in any of the diversity groups that historically contained them, Central Valley steelhead fail the representation and redundancy rule for DPS viability. Extant populations in the Central Valley steelhead DPS span four ecoregions, including: (1) the Basalt and Porous Lava Diversity Group; (2) the Northwestern California Diversity Group; (3) the Northern Sierra Nevada Diversity Group; and (4) the Southern Sierra Nevada Diversity Group.

The conceptual recovery scenarios require that each Diversity Group within the Central Valley steelhead DPS must be represented, and population redundancy within the groups must be met to achieve Diversity Group recovery. Therefore, the recovery scenarios include the objectives of a minimum of two viable populations of steelhead within each of the four extant steelhead Diversity Groups (i.e., the Basalt and Porous Lava Diversity Group, the Northwestern California Diversity Group, the Northern Sierra Nevada Diversity Group and the Southern Sierra Nevada Diversity Group).

To meet the aforementioned objectives, the conceptual recovery scenario for the steelhead DPS (**Figure 5-3**) includes: (1) securing extant populations by implementing key habitat restoration actions, particularly in the near-term; and (2) establishment of viable independent populations in the DPS. The recovery scenario includes the identification of candidate reintroduction watersheds. In addition to considerations of historical distribution, current population status, and recovery potential (including restoration actions) of the individual watersheds, one of

the factors taken into account in the identification of candidate reintroduction watersheds is long-term climate change.

Long-term climate change is an additional consideration regarding the viability of the steelhead DPS and specific populations in the long-term. Global and localized climate changes, such as El Nino ocean conditions and prolonged drought conditions, may play an important role in the suitability of steelhead habitat and, hence, viability. As previously described in the spring-run Chinook salmon ESU conceptual recovery scenario, Lindley et al. (2007) postulated that mean summer air temperatures are expected to rise by at least 2°C, are expected to increase by around 5°C (9°F), and the less likely but still possible scenario of an 8°C (14.4°F) warming by the year 2100. Because spring-run Chinook salmon and steelhead both exhibit juvenile over-summer rearing as part of their lifehistory strategies, long-term climate change considerations are similar for both species. Therefore, under the expected warming of around 5°C, substantial steelhead habitat would be lost, with significant amounts of habitat remaining primarily in the Feather and Yuba rivers, and remnants of habitat in the upper Sacramento and McCloud rivers, Battle and Mill creeks, and the Stanislaus River. Under the less likely but still possible scenario of an 8°C warming, steelhead habitat would be found only in the upper-most reaches of Battle Creek and Mill Creek.

Long-term climate change considerations emphasize the importance of a recovery scenario that ultimately results in re-establishing viable, independent populations in the steelhead DPS. Reestablishment of viable steelhead populations could be in watersheds currently occupied, or in candidate areas for reintroduction. As depicted in Figure5-3, candidate areas for reintroduction of steelhead in the conceptual recovery scenario include:

Little Sacramento River
 McCloud River
 North Fork Yuba River
 Middle Fork Yuba River
 South Fork Yuba River
 North Fork American River
 Middle Fork American River
 South Fork American River
 Mokelumne River
 Middle Fork Stanislaus River
 Tuolumne River
 Merced River

In order to secure the extant populations of steelhead, particularly in the near-term, and to recover the steelhead DPS in the long-term, several key actions associated with habitat restoration and reintroduction have been identified in the section titled Recovery Opportunities by Diversity Group, below. As previously described, numerous recovery actions are specific to the Sacramento River, the lower San Joaquin River and the Delta, which serve as a migratory corridor for populations of steelhead spawning in rivers and streams in the Central Valley Domain. These key actions are previously described in the spring-run recovery scenario and therefore are not repeated here, nor are they reiterated in the conceptual recovery scenario discussions of steelhead Diversity Groups or individual populations.

Figure 5-3. Central Valley Steelhead DPS Conceptual Recovery Footprint. The candidate areas for reintroduction that are depicted on this map are areas where, although dams block access, the primary constituent elements that are necessary to support freshwater migration, holding, spawning, and rearing still exist or could be restored.

Recovery Opportunities by Diversity Group

The conceptual recovery scenario requires that each Diversity Group within the Central Valley steelhead DPS must be represented, and population redundancy within the groups must be met to achieve Diversity Group recovery. Therefore, the recovery scenario includes the objective of a minimum of two viable populations of steelhead within each of the four extant steelhead Diversity Groups (i.e., the Basalt and Porous Lava Diversity Group, the Northwestern California Diversity Group, the Northern Sierra Nevada Diversity Group and the Southern Sierra Nevada Diversity Group).

Presently, no viable independent steelhead populations have been identified in any of the Diversity Groups in the steelhead DPS, and for those populations that could be classified by the Central Valley TRT (Lindley et al. 2007) all are at high risk of extinction. Therefore, the conceptual recovery scenario includes securing extant populations in the near-term, and establishing spawning populations in numerous streams and rivers within individual Diversity Groups throughout the Central Valley Domain (see Figure 3). However, the proximity of many of these rivers and streams in the individual Diversity Groups may not result in the establishment of independent populations. Rather, most of these spawning populations may be dependant upon input of migrants from other independent populations, and may operate as a metapopulation. However, if these populations are adapted to spawning and rearing habitats unique to their specific stream or river, they may contribute a valuable genetic resource to their respective Diversity Groups, and may also serve to link other populations in ways that increase DPS viability over longer time scales (Lindley et al. 2004).

The recovery potential of the Central Valley steelhead DPS overall is considered to be low to moderate due to a lack of suitable habitat (e.g.,

cool water temperatures particularly during the over-summer juvenile rearing period) and restriction to areas below presently impassable barriers, inadequate status and trends data to assess Diversity Group and individual population viability, and the widespread stocking of hatchery fish (which could negatively impact wild steelhead populations). For Central Valley steelhead, improved distribution and abundance data are needed to refine specific recovery strategies for the DPS and its Diversity Groups. It also is important to better understand the role that resident *O. mykiss* play in population maintenance and persistence, and the relationship between resident and anadromous life-history forms. Considering that approximately 80 percent of the habitat that was historically available to anadromous steelhead is now behind impassable dams (Lindley et al. 2006), restoring access to historic habitat is needed to recover the DPS.

The following discussion of recovery opportunities within each Diversity Group does not explicitly include those watersheds characterized by having more ephemeral and dependent steelhead populations, those that would require significant restoration actions, those that generally have relatively low recovery potential (as described in the watershed profiles and other preceding sections of this Recovery Plan), and/or those that are not considered candidate areas for reintroduction of steelhead. Consequently, the following conceptual recovery scenario discussion for each Diversity Group focuses on the presently anticipated potential to establish future spawning populations, including all extant 26 populations, and candidate areas for reintroduction.

In consideration of the foregoing discussions regarding steelhead population data deficiencies, the following scenario represents some of the many possible combinations of populations, restoration actions, risk minimization and threat abatement. Different scenarios may fulfill the biological requirements

for recovery. It is expected that information brought forth in the 5- and 10-year status reviews of the steelhead DPS will lead to adjustments in recovery expectations and restoration actions and, thus, the following conceptual recovery scenario for each Diversity Group.

BASALT AND POROUS LAVA DIVERSITY GROUP

Extant populations of steelhead in the Basalt and Porous Lava Diversity Group are known or believed to occur in Battle Creek, Cow Creek, small tributaries to the upper Sacramento River (e.g., Stillwater, Churn, Sulphur, Salt, Olney and Paynes creeks) and the Upper Sacramento River (mainstem).

As previously discussed, no viable independent steelhead populations have been identified in the Basalt and Porous Lava Diversity Group, and all of them are at high risk of extinction. Nonetheless, one of the recovery goals is to secure and/or improve all extant populations. Lindley et al. (2007) state with the exception of Battle Creek, which has a long-running hatchery program, all of these populations are data deficient. However, local efforts to investigate steelhead presence, habitat utilization and restoration opportunities have been conducted or are ongoing in many watersheds including Olney, Salt, Sulphur, Stillwater, Churn, Bear, and Paynes creeks. All of these watersheds are believed to have habitat conditions of limited suitability for steelhead, would require significant restoration actions, generally have relatively low recovery potential (as described in the watershed profiles) or are data deficient. Consequently, the following conceptual recovery scenario discussion for the Basalt and Porous Lava Diversity Group focuses on Battle Creek, Cow Creek and the Sacramento River below Keswick Dam, as well as candidate areas for reintroduction including the Little Sacramento and McCloud rivers.

BATTLE CREEK

Battle Creek has had persistent spawning populations of steelhead in the reaches currently accessible on North Fork Battle and South Fork Battle creeks in recent years, although the populations have been relatively small. Currently, the Battle Creek Watershed has five dams blocking upstream migration of salmonids to much of the suitable and historic habitat. However, once complete, the Battle Creek Salmon and Steelhead Restoration Project (CALFED 2007) will provide access to 21 miles of currently inaccessible historical habitat, and will restore and enhance a total of nearly 50 miles of habitat.

It is anticipated that the Battle Creek Watershed, once restored, will be a conservation stronghold for steelhead (Reclamation et al. 2004). Battle Creek has been identified as having high potential for successful fisheries restoration, because of its relatively high and consistent flow of cold water (Newton et al. 2008). Battle Creek has been identified as offering the best opportunity for wild steelhead populations in the upper Sacramento River (McEwan and Jackson 1996). It has the highest base flow (i.e., dry-season flow) of any tributary to the Sacramento River between the Feather River and Keswick Dam (Ward and Kier 1999, as cited in Newton et al. 2008).

The Battle Creek Watershed is characterized as having a high potential to support a viable independent population of steelhead. In order to secure the extant population of steelhead, particularly in the near-term, several key habitat restoration actions have been identified, and are previously described in the spring-run Chinook salmon conceptual recovery scenario.

The conceptual recovery scenario for Battle Creek includes securing long-term steelhead populations by continuing the implementation of the near-term actions and the successful establishment of spawning populations in the Battle Creek Watershed including North Fork

Battle Creek, South Fork Battle Creek, Soap Creek and Panther Creek.

COW CREEK

As reported in the Cow Creek Watershed Assessment (SHN 2001), steelhead populations have not been estimated in Cow Creek. No specific studies have been conducted on Cow Creek to estimate the size of the steelhead spawning run, although CDFG estimated that Cow Creek historically supported annual spawning runs of up to 500 steelhead (SHN 2001). Adult steelhead have been observed in North Cow, Old Cow and South Cow creeks; however, it is unknown what percentage of the steelhead run utilizes the other tributaries (SHN 2001). During February to April of 2002 snorkel surveys were conducted in South Cow Creek, but no steelhead adults, carcasses or redds were identified (Moore 2003). During February to April of 2003, snorkel surveys and one walking survey in South Cow Creek, and one snorkel survey in Old Cow Creek were conducted to identify steelhead adults, carcasses and redds. Seven adult steelhead and two possible redds were identified in South Cow Creek (Moore 2003).

The Cow Creek Watershed is considered to have a moderate potential to support a viable population of steelhead. Most steelhead spawning in South Cow Creek probably occurs above South Cow Creek diversion. The best spawning habitat occurs in the 5-mile reach of stream extending from about 1.5 miles below South Cow Creek Diversion Dam to 3.5 miles above the diversion dam (Healy 1997, as cited in SHN 2001). Additional spawning habitat occurs upstream of this reach, but it is much less abundant. Sightings of adult steelhead have been made at the South Cow Creek Campground (approximately 8.5 miles upstream of the South Cow Creek Diversion Dam) and in Atkins Creek, located just upstream from the campground (SHN 2001).

Cow Creek has been identified by CDFG and USFWS as a candidate for restoration of anadromous fisheries (SHN 2001). Cow Creek and its tributaries have been characterized as in “relatively good condition” regarding salmon and steelhead spawning habitat (SHN 2001). As previously discussed in the watershed profile, there are sections throughout the watershed that appear to have suitable water temperatures year-round (primarily in the upper reaches of Old Cow and South Cow creeks), and that overall the habitat appeared to be suitable for spawning adult and rearing juvenile steelhead, with no definite barriers to anadromy. Yet, many Cow Creek Watershed areas do not have suitable habitat, sufficient flows (with over 20 unscreened diversions in the watershed), or suitable juvenile steelhead rearing water temperatures. Restoration actions in the watershed have addressed fish passage and entrainment issues. In addition, a hydropower project has filed decommission plans, which will return flows to their natural state, and remove specific passage impediment and entrainment concerns. Nonetheless, extensive restoration is needed in the Cow Creek Watershed for a steelhead population to persist.

The conceptual recovery scenario includes maintaining a spawning population in the Cow Creek Watershed. Implementation of key recovery actions could improve the population viability of steelhead in the Cow Creek Watershed by reducing the risk of extinction to moderate. These actions include:

- ❑ Investigate measures to increase flows in Cow Creek and tributaries, such as: (1) investigating opportunities to increase irrigation efficiency; (2) managing vegetation to improve water supply and timing of supply; (3) purchasing water or water rights from willing sellers; (4) removing or laddering diversions; (5) providing alternate water sources during important periods; and (6)

implementing a conjunctive use program

- ❑ Conduct feasibility analyses and prioritize screening and laddering five agricultural diversions in Cow Creek
- ❑ Install water temperature recorders at select locations in Cow Creek; develop recommendations for minimum instream flow based on temperature needs
- ❑ Implement projects to increase floodplain habitat availability to improve juvenile rearing habitat, and restore instream and riparian habitat in Cow Creek
- ❑ Implement actions (e.g., spawning gravel augmentation) designed to increase spawning habitat availability and complement flows in Cow Creek
- ❑ Enhance watershed resiliency in Cow Creek by identifying and implementing projects that would reduce the potential for, and magnitude of, a catastrophic wildfire, and restore forested areas within the watershed including riparian areas

MAINSTEM SACRAMENTO RIVER BELOW KESWICK DAM

Lindley et al. (2007) did not characterize steelhead populations in the upper mainstem Sacramento River. Although large numbers of resident *O. mykiss* are present, little is known about potential anadromy in this population. NMFS considers the steelhead population in the upper mainstem Sacramento River to be data deficient, and believes that additional information needs to be collected to better understand the potential for the river to support a viable population.

For currently occupied habitats between Keswick Dam and Red Bluff, it is unlikely that

habitats can be restored to pre-dam conditions. The potential to restore ecological processes capable of supporting steelhead is low to moderate, primarily because water temperatures and flow regimes to support the summer spawning of winter-run Chinook salmon may discourage anadromy for steelhead.

The conceptual recovery scenario includes reintroduction of steelhead into candidate areas of the Little Sacramento and McCloud rivers. They have a high potential to support steelhead populations due to the number of connected miles of suitable spawning and rearing habitat. The Pit River has a low potential to support steelhead populations due to the extensive presence of hydroelectric facilities that inundate or substantially affect historic habitat.

In order to secure the extant population of steelhead, particularly in the near-term, several key habitat restoration actions have been identified, and the previously described actions in the spring-run Chinook salmon conceptual recovery scenario also pertain to steelhead.

NORTHWESTERN CALIFORNIA DIVERSITY GROUP

Extant populations of steelhead in the Northwestern California Diversity Group are known or believed to occur in Clear Creek, Cottonwood/Beegum Creek, Thomes Creek and Putah Creek. As previously discussed, no viable independent steelhead populations have been identified in the Northwestern California Diversity Group and all of them are at high risk of extinction, but one of the recovery goals is to secure and/or improve all extant populations.

Lindley et al. (2007) state that all of these populations are data deficient. However, local efforts to investigate steelhead presence, habitat utilization and restoration opportunities have been conducted or are ongoing in many watersheds including Clear, Cottonwood/Beegum, and Thomes creeks. Each

of these creeks supports extant populations of steelhead, and are characterized as having moderate to high potential to support steelhead recovery.

By contrast, although possibly present historically, existing conditions in Stony Creek preclude the annual production of steelhead (H.T. Harvey and Associates 2007). Excessively low flows and warm water temperatures in Stony Creek during all life stages prevents the successful production of steelhead (H.T. Harvey and Associates 2007). Stony Creek is characterized as having a low potential to support viable populations of steelhead. This characterization is based on the following factors: (1) the system does not currently support populations of steelhead; (2) water diversions limit instream flows; (3) the watershed is at a relatively low elevation (Lindley et al. 2004) and, thus, instream flow inputs are in the form of rainfall, not snowmelt; and (4) water temperatures under the current climate may already be beyond the thermal requirements of coldwater species such as steelhead, and climate change is expected to increase water temperatures in the Central Valley (Lindley et al. 2007).

Consequently, the following conceptual recovery scenario discussion for the Northwestern California Diversity Group focuses on Clear, Cottonwood/Beegum, Thomes and Putah creeks.

CLEAR CREEK

Clear Creek historically was not known to support a large Central Valley steelhead population. However, removal of the McCormick-Saeltzer Dam in 2000 has provided steelhead access to an additional 12 miles of habitat (NMFS 2009). In recent years, a multi-phase restoration project (i.e., The Lower Clear Creek Floodway Rehabilitation Project) has been implemented on lower Clear Creek. One of the actions has included spawning gravel augmentation, which has improved suitable

habitat for steelhead (NMFS 2009). Spawning distribution has recently expanded from the upper 4 miles to throughout the 18 miles of Clear Creek, although it appears to be concentrated in areas of newly added spawning gravels (NMFS 2009). Steelhead redd surveys conducted since 2001 indicate a small but increasing population resides in Clear Creek, with the highest density in the first mile below Whiskeytown Dam (USFWS 2007a, as cited in NMFS 2009).

During the summer months, flows in Clear Creek are maintained to provide adequate water temperatures for rearing steelhead. Water temperatures in Clear Creek at the USGS Igo gaging station (RM 10.85) are maintained below 65°F year-round due to releases of cool Whiskeytown Reservoir water diverted from the Trinity River (Reclamation 2008).

The Clear Creek steelhead population is presently considered persistent, although dependent upon input of migrants from populations such as Deer, Mill and Butte creeks. No hatchery steelhead (i.e., presence of adipose fin-clip) were observed during the 2003-2007 kayak and snorkel surveys, suggesting that straying of hatchery steelhead into Clear Creek is probably low (USFWS 2008a). Indications that the Clear Creek steelhead population has a high potential to become a viable independent population with a low risk of extinction include low stray rates from hatchery produced salmonids, provision of suitable water temperatures year-round, a recent increase in the annual number of steelhead migrating into the creek and spawning, and a recently implemented and ongoing habitat restoration program. A recent review of habitat potential on Clear Creek indicated a carrying capacity estimate of 7,292 steelhead (M. Brown, USFWS, pers. com., 2009).

Clear Creek is characterized as having a high potential to support a viable independent population of steelhead. Restoration efforts supporting this characterization include

implementation of a long-term gravel augmentation plan, managed releases of optimal flows, maintaining water temperatures below 65°F year-round and recent extensive riparian, instream channel and floodplain restoration. In order to secure the extant population of steelhead, particularly in the near-term, and to promote a viable independent population of steelhead in the long-term, several key habitat restoration actions have been identified, and the previously described actions in the spring-run Chinook salmon conceptual recovery scenario also pertain to steelhead.

COTTONWOOD/BEEGUM CREEK

Cottonwood Creek is one of the major tributaries to the Sacramento River system that supports steelhead spawning (CH2MHILL 2002). Because they migrate during high flows, and it is difficult to distinguish juvenile steelhead from resident rainbow trout, few steelhead population estimates have been recorded in Cottonwood Creek (CH2MHILL 2002). The USFS and CDFG have observed populations of juvenile steelhead in the upper South Fork Cottonwood Creek Yolla Bolly Middle Eel Wilderness Area in the summer of 1976 (CH2MHILL 2002). Small runs of adult steelhead have been observed to migrate in the mainstem and lower reaches of the North, Middle, and South Fork Cottonwood Creek.

The Cottonwood Creek Watershed remains relatively undeveloped and is essentially unregulated. The Beegum Creek watershed is generally forest-covered and has not been significantly modified (D. Killam, CDFG, pers. comm. 2009).

The Cottonwood Creek Watershed, including Beegum Creek has a moderate potential to support a viable population of steelhead. It is likely, however, that steelhead populations in the watershed will remain dependent upon input of migrants from populations such as Deer, Mill and Butte creeks. Although comprehensive population abundance data are

not available, there is a widespread presence of *O. mykiss* throughout the watershed, and it is currently designated as critical habitat for steelhead.

Sections of the Cottonwood Creek watershed, such as the middle fork, south fork, and Beegum Creek contain more suitable habitat than other areas within the watershed, and have the potential to support steelhead populations. However, thermal conditions in the Cottonwood/Beegum Creek Watershed may become unsuitable for steelhead within decades if the climate warms as expected. Nonetheless, with the implementation of successful restoration efforts in the watershed to improve habitat, the risk of extinction of steelhead may be reduced, particularly in the near-term.

The conceptual recovery scenario for Cottonwood/Beegum Creek includes establishing spawning populations of steelhead in the North, Middle, and South Fork Cottonwood Creek, and Beegum Creek. In order to secure the extant population and to establish spawning populations of steelhead in the Cottonwood/Beegum Creek Watershed, particularly in the near-term, several key habitat restoration actions have been identified, and the previously described actions in the spring-run Chinook salmon conceptual recovery scenario also pertain to steelhead.

THOMES CREEK

Consistent monitoring of the fish populations in Thomes Creek has not occurred and, therefore, little information is available regarding utilization of Thomes Creek by steelhead. As reported by TCRCD (2006), in 1982, 22 species of fish were recorded within various portions of Thomes Creek (Brown et. al. 1983 as cited in CALFED 2000a). Steelhead were reported to be the most abundant fish species above the "Gorge". However, these fish were likely rainbow trout, as there is an andromous fish barrier a short distance above the "Gorge" (TCRCD 2006).

The Thomes Creek watershed has limited habitat availability for fishery resources. Flows in Thomes Creek tend to rise quickly following storm events, drop equally promptly following storms, and carry very large quantities of sediment (TCRCD 2006). The snowpack in this watershed results in relatively light warm-season runoff, resulting in perennial upper stream reaches, mid-reach sections that may be dry in mid-summer, and lower reaches near the Sacramento River that may contain small amounts of water from irrigation run-off (TCRCD 2006). Thomes Creek is usually dry or intermittent below the USGS stream gage near Paskenta until the first heavy fall rains occur (DWR Website 2007).

There are no significant dams on Thomes Creek other than two seasonal diversion dams, one near Paskenta and the other near Henleyville. Several small pump diversions are seasonally operated in the stream (DWR Website 2007). Combined, seasonal diversions reduce instream flows and presumably result in undocumented levels of entrainment. Additionally, gravel mining downstream of the Tehama-Colusa Canal siphon crossing has reportedly resulted in a partial barrier to salmonids returning to Thomes Creek to spawn (Vestra Resources, Inc. 2006).

In May 2004 CDFG determined that an impassible barrier to Chinook salmon and steelhead exists at the point immediately above the confluence of the stream with Horse Trough Creek (Barron, pers. comm., 2005, as cited in TCRCD 2006). This location is approximately 9 miles upstream from Paskenta and at an elevation of approximately 1,500 feet (TCRCD 2006).

During most years, water temperatures during the summer months likely limit the suitability of juvenile steelhead over-summer rearing. In addition, the lower reach of Thomes Creek has been significantly altered by the construction of flood control levees and bank protection

measures (i.e., riprapping) (CALFED 2000b), resulting in reduced habitat availability for juvenile salmonids.

Headwaters of the streams in the Tehama West Watershed, including Thomes Creek, have relatively little, if any, drainage area with significant snowpack (TCRCD 2006). However, the upper-most elevation of Thomes Creek exceeds 5,000 feet and during some years may have significant snowpack.

Thomes Creek is characterized as having a low to moderate potential to support a steelhead population because: (1) it is uncertain whether Thomes Creek currently supports an extant population of steelhead; (2) the watershed has limited area at higher elevation and is highly dependent on rainfall, rather than having a large snowpack to provide inputs of cool snowmelt during the spring (Lindley et al. 2004); (3) an impassible barrier to steelhead exists at an elevation of approximately 1,500 feet, located approximately 9 miles upstream from Paskenta; (4) water diversions limit instream flows and also affect fish passage; and (5) with the possible exceptions of the highest elevation reach of Thomes Creek and upstream tributaries, water temperatures under current conditions may already be beyond the thermal requirements of steelhead, particularly during the over-summer rearing life stage, and climate change is expected to increase water temperatures in the Central Valley (Lindley et al. 2007).

The conceptual recovery scenario for Thomes Creek includes establishing spawning populations of steelhead in the perennial reaches of upper Thomes Creek and the upstream tributaries of Fish Creek and Willow Creek. It is likely, however, that steelhead populations in the watershed will be dependent upon input of migrants from populations such as Deer, Mill and Butte creeks.

In order to establish and support spawning populations of steelhead in the Thomes Creek Watershed, several key habitat restoration

actions have been identified, including the following.

- ❑ Conduct a feasibility study on potential channel modifications that would improve upstream migration conditions in Thomes Creek
- ❑ Enhance watershed resiliency in Thomes Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce local water temperatures, or increase riparian shade
- ❑ Develop and implement a spawning gravel augmentation plan in Thomes Creek
- ❑ Implement projects to increase floodplain habitat availability in Thomes Creek to improve juvenile rearing habitat
- ❑ Re-establish natural channel morphology in Thomes Creek by: (1) applying NMFS gravel mining criteria to all gravel mining projects; (2) integrating natural morphological features and functions into bank protection and other stream side development projects; and (3) implementing non-native plant (e.g. Arundo) eradication plan

PUTAH CREEK

Anadromous steelhead are considered to have historically spawned in the upper tributaries flowing into Putah Creek above the Berryessa Valley (now Lake Berryessa) but there have been no recently confirmed reports of anadromous steelhead in the creek. Two structures, the Putah Diversion Dam and Monticello Dam, completely block migration into historic spawning and rearing areas in the interdam reach and as far

upstream as the Berryessa Valley. Migratory rainbow trout with a steelhead-like life history continue to spawn in the upper tributaries.

Putah Creek is characterized as having a low potential to support a steelhead population. On May 23, 2000, following 10 years of litigation related to stream flows for supporting fish and other natural resources, Putah Creek Council, City of Davis, and UC Davis signed onto an historic water accord with the Solano County Water Agency, Solano Irrigation District, and other Solano water interests to establish permanent surface water flows for the 23 miles of Putah Creek below the Putah Diversion Dam. One element of the Accord is to provide permanent seasonal instream flows for anadromous steelhead.

The supplemental flow regime, although designed primarily to benefit salmon, may be adequate for rearing juvenile steelhead as well. Adult steelhead may make it up the stream under high winter flows, but it is likely that in most years flows from December to February are too low to attract steelhead, unless water is spilling from Lake Berryessa.

The conceptual recovery scenario for steelhead in the Northwestern California Diversity Group includes a spawning population of steelhead in a small reach located proximate to the Putah Diversion Dam. It is likely, however, that steelhead populations in Putah Creek will be dependent upon input of migrants from populations originating from upstream areas in the Sacramento Valley. In order to secure a spawning population of steelhead in Putah Creek, several key restoration actions have been identified, including the following.

- ❑ Develop and implement fish passage improvements at Solano and Montecello dams
- ❑ Develop and implement measures to improve flow conditions and reduce flow fluctuations

- ❑ Develop and implement spawning gravel augmentation plans
- ❑ Develop and implement habitat restoration measures to improve floodplain habitat, natural river morphology, and riparian habitat and instream cover
- ❑ Implement measures to improve water quality

NORTHERN SIERRA NEVADA DIVERSITY GROUP

Extant populations of steelhead in the Northern Sierra Diversity Group are known or believed to occur in Antelope Creek, Mill Creek, Deer Creek, Big Chico Creek, Butte Creek, Feather River, Yuba River, Bear River, Auburn Ravine/Coon Creek, Dry Creek, and the American River. As previously discussed, no viable steelhead populations have been identified in the Northern Sierra Diversity Group and all of them are either data deficient or at high risk of extinction. However, one of the recovery goals is to secure and/or improve all extant populations.

Local efforts to investigate steelhead presence, habitat utilization and restoration opportunities have been conducted or are ongoing in most of these watersheds, which are generally characterized as having moderate to high potential to support steelhead recovery. The exceptions are Big Chico Creek with a low to moderate recovery potential, and the Bear River with a low recovery potential for steelhead. Lindley et al. (2006) identified those few streams where historical habitat may still be accessible as likely candidates for conservation actions. In the Northern Sierra Nevada Diversity Group, this includes Mill, Deer, and Butte creeks.

The conceptual recovery scenario also includes establishing a spawning population of steelhead in the upper reaches of the Cosumnes River.

However, the Cosumnes River does not currently support an extant population of steelhead, and previous efforts to promote the establishment of populations in the Cosumnes River have not been successful. Therefore, the Cosumnes River should be characterized as having a low recovery potential for steelhead, is a lower priority relative to other rivers and creeks within this diversity group, and is not discussed further in the recovery scenario.

The steelhead conceptual recovery scenario for the Northern Sierra Nevada Diversity Group also includes the reintroduction of steelhead to the candidate areas of the North Fork Yuba River, Middle Fork Yuba River, South Fork Yuba River, North Fork American River, Middle Fork American River, and the South Fork American River. In addition to considerations of historical distribution, current population status, and recovery potential (including restoration actions) of the individual watersheds, one of the factors taken into account in the identification of candidate reintroduction watersheds is long-term climate change. Reintroductions also would be dependent upon successful passage programs above the dams in these watersheds. For each of these candidate areas for reintroduction, passage feasibility studies, habitat suitability assessments and other related investigations are underway in separate processes (e.g., FERC relicensings), some of which are previously described in the watershed profiles, or they need to be conducted. Hence, the conceptual recovery scenario does not further discuss specific considerations regarding these candidate reintroduction areas.

ANTELOPE CREEK

Although comprehensive population abundance data are not available, Antelope Creek is believed to support a population of steelhead. *O. mykiss* are widely distributed throughout the Antelope Creek watershed, with up to several thousand fish per mile in some reaches (M. Berry, pers. com. 2005).

Antelope Creek has a high potential to support a viable population of steelhead. The upper reaches of Antelope Creek are still fairly undeveloped. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed is in good condition. The characterization of having a high recovery potential for steelhead is based on: (1) the existing wide distribution of steelhead throughout the watershed; (2) the quality of existing spawning and rearing habitat; (3) Federal land management strategies that protect, maintain, and restore anadromous habitat within important parts of the upper watershed; (4) the small channel characteristics with up to 20 miles of suitable steelhead spawning habitat; and (5) water temperatures that support spawning and rearing.

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of steelhead in Antelope Creek. Those actions that are required are localized in nature and, when fully implemented, have a high likelihood of restoring good fish passage conditions. Antelope Creek is diverted into several channels below the Edward Diversion Dam. A single migration channel and fish passage flows need to be established to ensure that adult steelhead have unimpeded access to upstream spawning habitat and juveniles have unimpaired downstream migration. Fish screens with suitable bypass flows also need to be installed at the Edward Dam. In the upper watershed, Federal land management practices are guided by a long-term anadromous fish conservation strategy, although private timberland management plans lack a comprehensive anadromous habitat protection strategy.

The conceptual recovery scenario for Antelope Creek includes the establishment of spawning populations in the upper reaches of the creek as well as the North and South Forks of Antelope Creek. Approximately 2 and 3 miles of steelhead

habitat are available on the North and South Forks of Antelope Creek, respectively, above their confluence (Armentrout et al. 1998). Steelhead habitat is relatively unaltered in these areas, but lack of adequate migratory attraction flows into the Sacramento River to this habitat prevents optimum use by anadromous fish (DWR 2009).

In Antelope Creek the primary focus for steelhead restoration is on improving flow conditions and fish passage for upstream migrating adults to access important holding and spawning habitat, and for outmigration of juveniles. In order to realize Antelope Creek's high potential to support a viable population of steelhead, and to secure the extant population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been previously identified in the spring-run Chinook salmon recovery scenario, and also pertain to steelhead.

MILL CREEK

With the exception of some limited data on run size and timing, information regarding the status of the steelhead population in Mill Creek is generally lacking. CDFG has not systematically monitored steelhead escapement into Mill Creek since the spring of 1963, when reported escapement was 2,269 (Killam and Johnson 2008). More recently, observations using a video weir in Mill Creek from early March through mid-June 2007 indicated that peak upstream and downstream steelhead passage occurred from May 8-10, 2007 (Killam and Johnson 2008). This may represent the presence of two runs of steelhead in Mill Creek, with one run exiting the system while another run is entering the system during May (Killam and Johnson 2008). During the 2007-2008 juvenile steelhead outmigration monitoring period, 297 steelhead were captured in the Mill Creek RST from mid-October 2007 through early June 2008 (Harvey-Arrison 2008).

Mill Creek is considered a conservation stronghold for the Central Valley steelhead DPS. With the implementation of key recovery actions, the watershed has a high potential for sustaining a viable steelhead population because: (1) Mill Creek contains an extensive amount of suitable spawning and rearing habitat; (2) hatchery influence is believed to be low; and (3) the number and magnitude of recovery actions needed within the Mill Creek watershed are limited and localized. In addition, under the expected climate warming of around 5°C, substantial salmonid habitat would be lost in the Central Valley, with remnant amounts of habitat remaining in Mill Creek, among a few others. Under the less likely but still possible scenario of an 8°C warming, salmonid habitat would be found only in the upper-most reaches of the north fork Feather River, Battle Creek, and Mill Creek (Lindley et al. 2007).

The aquatic habitats in Mill Creek (along with Deer, Antelope, Battle and Butte Creeks) are among the best remaining habitat above the Central Valley floor for anadromous salmonids. Although diversion structures are present in the valley section of Mill Creek, there are no major water impoundments along the Mill Creek corridor. Fish have been able to maintain passage, and native fish communities have survived in the free-flowing sections.

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of steelhead in Mill Creek. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed is in good condition. Those actions that are required are localized in nature and, when fully implemented, have a high likelihood of restoring or maintaining good fish passage conditions. A water exchange agreement already is in place between the CDFG and water users on Mill Creek. The programs are intended to develop and operate wells to offset bypass flows needed for steelhead and to implement

water use efficiency measures to reduce irrigation water demand. Although the agreement improves fish passage conditions for steelhead, a comprehensive fish passage evaluation and monitoring plan has not been developed to assess the effectiveness of the agreement. Long-term verification of the flows, and an evaluation of existing dams for fish passage suitability are needed to ensure passage is provided at a wide range of stream flows. In the upper watershed, Federal land management practices are guided by a long-term anadromous fish conservation strategy, although private timberland management plans lack a comprehensive anadromous habitat protection strategy.

The conceptual recovery scenario for Mill Creek includes the establishment and maintenance of a steelhead spawning population in the upper reaches of Mill Creek including areas within the Lassen National Forest, starting just upstream of Rancheria Trail and extending upstream.

In order to secure the extant population and promote a viable population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been previously identified in the spring-run Chinook salmon recovery scenario, and also pertain to steelhead.

DEER CREEK

Although comprehensive population abundance data are not available, Deer Creek is believed to support a population of steelhead. With the exception of some limited data on juvenile outmigration, steelhead population monitoring data in Deer Creek is lacking.

Deer Creek is considered a conservation stronghold for the Central Valley steelhead DPS. Similar to Mill Creek, with the implementation of key recovery actions, the watershed has a high potential for sustaining a viable steelhead population because: (1) Deer Creek contains an extensive amount of suitable spawning and rearing habitat; (2) steelhead habitat in the

upper watershed is considered to be excellent with an abundance of spawning gravel (DWR 2005; USFWS 1999); (3) hatchery influence is believed to be low; (4) water temperatures throughout the Deer Creek watershed are suitable for juvenile steelhead rearing except for the summer months, although cold water refugia are likely available in the upper watershed; and (5) the number and magnitude of recovery actions needed within the Deer Creek watershed are limited and localized.

The aquatic habitats in Deer Creek are among the best remaining habitat above the Central Valley floor for anadromous salmonids. Although diversion structures are present in the valley section of Deer Creek, there are no major water impoundments along the Deer Creek corridor. Fish have been able to maintain passage, and native fish communities have survived in the free-flowing sections. Deer Creek is also considered essential to the recovery and perpetuation of the wild stocks of winter-run steelhead in the Central Valley (Reynolds et. al. 1993; McEwan and Jackson 1996) in part because of its current habitat conditions.

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of steelhead in Deer Creek. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed is in good condition. Those actions that are required are localized in nature and, when fully implemented, have a high likelihood of restoring or maintaining good fish passage conditions. In particular, long-term fish passage improvements should be addressed by installing state-of-the-art passage facilities at the Cone-Kimball, Stanford Vina, and Deer Creek Irrigation District dams, and existing dam structures should be replaced with inflatable bladder dams that can be installed during the irrigation season and lowered during periods of high stream flow and bedload transport. In

addition, water exchange programs are presently underway or in development with cooperation irrigation districts. The programs are intended to develop and operate wells to offset bypass flows needed for steelhead and to implement water use efficiency measures to reduce irrigation water demand. In the upper watershed, Federal land management practices are guided by a long-term anadromous fish conservation strategy, although private timberland management plans lack a comprehensive anadromous habitat protection strategy.

The conceptual recovery scenario for Deer Creek includes the establishment and maintenance of a steelhead spawning population in the upper reaches of Deer Creek including areas within the Lassen National Forest, starting at approximately 4 miles above Upper Dam and extending upstream. Steelhead habitat in this area is considered to be excellent with an abundance of spawning gravel.

In order to secure the extant population and promote a viable population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been previously identified in the spring-run Chinook salmon recovery scenario, and also pertain to steelhead.

BIG CHICO CREEK

Although population abundance data are not available, Big Chico Creek is believed to support a population of steelhead. Steelhead reportedly occur in Big Chico Creek along with resident trout. Steelhead are believed to use the foothill zone to spawn except in low water years, when they spawn lower in the creek.

Big Chico Creek is characterized as having a low to moderate potential to support a viable population of steelhead. Big Chico Creek is a small watershed with substantial urban impacts in the lower watershed. Big Chico Creek contains marginally suitable habitat that most likely was opportunistically used in the past by

salmon and steelhead (Yoshiyama et al. 1996). However, the middle and upper watershed areas are not urbanized and much effort by local groups and land owners has been made to secure conservation easements along this portion of the river corridor. These easements protect the riparian zone from the impacts of long-term development. In addition, passage to the middle and upper watershed areas, where cooler water is found in the late summer, is provided by a ladder in Iron Canyon. There are plans to improve this fish ladder, which would be an important restoration activity to assist in securing the extant population.

The conceptual recovery scenario for Big Chico Creek includes the establishment and maintenance of a steelhead spawning population in the upper reaches of Big Chico Creek. With successful restoration efforts in Big Chico Creek, particularly in the lower sections of the creek and through improvements in the Iron Canyon fish ladder, steelhead will be able to access upstream areas where cooler water temperatures exist.

In order to secure the extant population and promote a viable population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been previously identified in the spring-run Chinook salmon recovery scenario, and also pertain to steelhead.

BUTTE CREEK

As reported by the Butte Creek Watershed Conservancy (1999), steelhead have been reported in Butte Creek principally through reports by CDFG wardens of angler catches. However, no estimate of steelhead abundance in Butte Creek is known to be available (Butte Creek Watershed Conservancy 1999; FERC 2008). Because of the low elevation of available habitat in Butte Creek, historic water temperatures were likely too warm to support a population of steelhead. Presently, cold water is imported from the upper West Branch Feather

River, which improves habitat conditions for steelhead.

Steelhead spawning occurs in tributaries such as Dry Creek and in the mainstem of Butte Creek above Parrott-Phelan diversion during winter and spring (generally December through April). The spawning area for steelhead in Butte Creek extends from the Centerville Head Dam downstream to the vicinity of the Western Canal Siphon crossing (Butte Creek Watershed Conservancy 1999). Steelhead generally spawn upstream of the Parrott-Phelan diversion. Spawning gravel in the reach of the creek from the Centerville Head Dam downstream to the vicinity of Helltown is extremely limited, with the major gravel beds existing below the Centerville Powerhouse (Butte Creek Watershed Conservancy 1999). The Sutter Bypass is reportedly used by juvenile steelhead as rearing habitat (Butte Creek Watershed Conservancy 1999).

Butte Creek is characterized as having a moderate potential to support a viable population of steelhead. Numerous restoration efforts have been undertaken on Butte Creek. Once impaired by numerous dams with poor fish passage facilities, no dedicated fish flows, and unscreened diversions, Butte Creek now provides state-of-the-art fish ladders and screens, and dedicated instream flows. However, elevated water temperature continues to pose a threat to steelhead, particularly in consideration of long-term climate change.

The conceptual recovery scenario for Butte Creek includes the maintenance of a steelhead spawning population in reaches of Butte Creek extending from Centerville Diversion Dam upstream approximately equidistant in the West Branch Butte Creek and Butte Creek, and in the upper reaches of Little Dry Creek.

In order to secure the extant population and promote a viable population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been previously

identified in the spring-run Chinook salmon recovery scenario, and also pertain to steelhead.

FEATHER RIVER

Lindley et al. (2007) characterized the spring-run Chinook salmon population in the Feather River as data deficient, and therefore did not characterize its viability. However, Lindley et al. (2007) characterized the existing steelhead population in the Feather River, including fish produced by the Feather River Hatchery, at a high level of extinction risk. NMFS (2007b) is concerned that the proportion of naturally produced fish is declining. The artificial propagation program for steelhead in the Feather River Hatchery may decrease risk to the DPS to some degree by contributing increased abundance to the DPS. However, hatchery-origin fish likely comprise the majority of the natural spawning run, placing the natural populations at high risk of extinction.

The lower Feather River, below Oroville Dam, is characterized as having a moderate potential to support a viable population of steelhead, primarily based on the presence of a hatchery-supported population that is known to reproduce naturally in the Low Flow Channel between River Miles 59 and 67. Nonetheless, the recently signed Settlement Agreement for Licensing of the Oroville Facilities (March 2006) includes the Lower Feather River Habitat Improvement Plan, which requires the development and implementation of numerous programs and projects that will improve the ecological condition of the Lower Feather River, in a manner that is expected to improve the quality and quantity of steelhead habitat for the next 50 years. The Settlement Agreement includes measures to improve the short- and long-term genetic management of the Feather River Hatchery, and measures that will increase the spatial availability of spawning habitat for steelhead.

The conceptual recovery scenario for the Feather River includes the maintenance of a steelhead

spawning population in the reach extending from approximately the confluence with Honcut Creek upstream through the Low Flow Channel. In order to secure the extant population and promote a viable population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been previously identified in the spring-run Chinook salmon recovery scenario, and also pertain to steelhead. One additional habitat restoration action specifically for steelhead in the Feather River includes increasing stream flows as needed to reduce water temperatures for steelhead juvenile rearing.

YUBA RIVER

As with spring-run Chinook salmon, there has been little information published on population trends and abundance of steelhead in the Yuba River (NMFS 2007a). Lindley et al. (2007) characterized the steelhead population in the lower Yuba River as data deficient, and therefore did not characterize its viability. The available information on the current population size of steelhead in the lower Yuba River indicates that adult escapement of steelhead is relatively low compared to historical levels (NMFS 2007a). Prior to construction of Englebright Dam, CDFG fisheries biologists stated that they observed large numbers of steelhead spawning in the uppermost reaches of the Yuba River and its tributaries (CDFG 1998; Yoshiyama et al. 1996).

Infrared and videographic sampling on both ladders at Daguerre Point Dam since 2003 has provided estimates of steelhead numbers migrating up the Yuba River, annually ranging from about 150 to over 750 adults (CDFG unpublished data, as cited in NMFS 2007a). However, these estimates should be considered preliminary, minimum numbers, as periodic problems with the sampling equipment have caused periods when fish ascending the ladders were not counted. Additionally, because steelhead can be similar in size to many other species of fish in the Yuba River, only those

infrared images that were backed up by photographic images clearly showing that the fish was a steelhead were included in the counts. Therefore, it is likely that the actual numbers of steelhead passing Daguerre Point Dam are higher than those reported, and does not take into account steelhead that may have remained in the lower Yuba River below Daguerre Point Dam.

Clearly, the lower Yuba River supports a persistent population of steelhead. There is no hatchery located on the lower Yuba River - thus the genetic integrity of steelhead may be largely uncompromised by hatchery influence. CDFG stopped stocking steelhead from the Coleman National Fish Hatchery into the lower Yuba River in 1979, and currently manages the river to protect natural steelhead through strict "catch-and release" fishing regulations (NMFS 2007a).

The lower Yuba River, below Englebright Dam, is characterized as having a high potential to support a viable population of steelhead, primarily because: (1) the river supports a persistent population of steelhead and historically supported the largest, naturally-reproducing population of steelhead in the Central Valley (McEwan and Jackson 1996); (2) flow and water temperature conditions are generally suitable to support all life stage requirements; (3) the river does not have a hatchery on it; (4) spawning habitat availability does not appear to be limited; and (5) high habitat restoration potential (see the watershed profile).

The conceptual recovery scenario for the lower Yuba River includes the maintenance of a steelhead spawning population in the reach extending from Englebright Dam downstream to the confluence with the Feather River. For currently occupied habitats between below Englebright Dam, it is unlikely that habitats can be restored to pre-dam conditions, but many of the processes and conditions that are necessary to support a population of steelhead can be improved with improvements to instream flow

regimes, water temperatures, and habitat availability. Continued implementation of the Yuba Accord is expected to address these factors and considerably improve conditions in the lower Yuba River. Additional habitat improvements and restoration actions are anticipated to be addressed in the forthcoming Yuba County Water Agency FERC relicensing process.

The steelhead conceptual recovery scenario includes reintroduction of steelhead to the candidate areas of the North Fork, Middle Fork and South Fork Yuba rivers. Reintroduction of anadromous salmonids above Englebright Dam has been the subject of recent and current investigations. Evaluation of habitat suitability for anadromous salmonids upstream of Englebright Dam was recently undertaken (DWR 2007), but those evaluations have yet to be finalized as part of the Upper Yuba River Watershed Studies Program. Currently, NMFS is evaluating the feasibility of providing passage for anadromous salmonids at Englebright Dam. Hence, the conceptual recovery scenario does not further discuss specific restoration actions associated with reintroduction of steelhead above Englebright Dam.

In order to secure the extant population and promote a viable population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been previously identified in the spring-run Chinook salmon recovery scenario, and also pertain to steelhead.

BEAR RIVER

The Bear River is considered to support an extant population of steelhead, although utilization of the river most likely is opportunistic under certain hydrologic conditions. Although present historically, existing conditions in the Bear River preclude the establishment of a self-sustaining population of steelhead. Minimum releases below Rollins Lake (10 cfs) and Lake Combie (5 cfs) from approximately June to November result in warm

water temperatures that are suitable only for bass and other warm water species (Bear River Watershed Group Website 2009). However, during periods of high flows, steelhead are known to utilize the river for limited spawning (JSA 2004). Because environmental conditions do not support a self-sustaining population of steelhead in the Bear River, those steelhead that do spawn during high flow years have likely originated from the Feather River Fish Hatchery. The present system of diversions results in abnormal flow fluctuations, in contrast to historical natural seasonal flow variations (Bear River Watershed Group Website 2009).

The Bear River is characterized as having a low potential to support viable populations of steelhead. This characterization is based on the following factors: (1) the system does not currently support populations of steelhead, particularly due to inadequate instream flows; (2) the lower reach has become narrow and incised; (3) downstream gravel recruitment has been limited for many years and would have to be actively supplemented to provide suitable habitat conditions for steelhead (Bear River Watershed Group Website 2009); and (4) New Camp Far West Reservoir is both shallow and warm and may not be able to provide releases or through-flows during late summer and early fall at water temperatures that are suitable to juvenile salmonids downstream (Bear River Watershed Group Website 2009).

The conceptual recovery scenario includes the goal of securing extant populations, albeit opportunistic and dependent in the Bear River. Habitat improvements and restoration actions to accomplish this goal are anticipated to be addressed in the ongoing FERC relicensing process. Presently, key restoration actions include the following.

- ❑ Develop and implement measures to improve flow conditions (i.e., low flows and flow fluctuations)

- ❑ Develop and implement measures to improve water temperature conditions
- ❑ Develop and implement spawning gravel augmentation programs
- ❑ Implement measures to improve water quality
- ❑ Develop and implement habitat restoration actions to improve natural river morphology, riparian habitat, floodplain habitat and instream cover

AUBURN RAVINE/COON CREEK

Information regarding steelhead presence and habitat utilization in Auburn Ravine is generally lacking. However, CDFG (2005a, unpublished data) electrofishing survey results indicate that Auburn Ravine may constitute a probable steelhead spawning area given the presence of very small juveniles during spring. Auburn Ravine, both upstream and downstream of the Auburn Tunnel Outlet, may represent a year-round rearing area for juvenile steelhead, given the presence of both YOY and larger juveniles during November, December, and April (County of Placer 2009).

Compared to the historical flow regime, current management practices produce higher flows year-round and more consistent flows during the spring and summer months in Auburn Ravine. Most of the instream flow in Auburn Ravine is water imported from the Yuba River, Bear River, and American River watersheds to meet domestic and agricultural needs in western Placer County and southeastern Sutter County (Sierra Business Council 2003). Current water management practices in Auburn Ravine likely provide cold water habitat for salmonids during time periods which historically lacked cold water habitat (Sierra Business Council 2003).

The Auburn Ravine/Coon Creek Watershed is characterized as having a moderate to high potential to support viable populations of

steelhead, primarily based on the present abundance of *O. mykiss*, generally suitable habitat conditions particularly in upstream areas, and habitat restoration potential. Auburn Ravine, Coon Creek, and Doty Ravine all support steelhead and have the potential to support higher levels of production after an ecosystem restoration program is implemented (County of Placer 2002).

Auburn Ravine provides a diversity of aquatic habitats, including shallow, fast-water riffles, glides, runs and pools. Similar to the lower reach of Auburn Ravine, the middle reaches of Coon Creek and portions of Doty Ravine also contain sandy substrate (County of Placer 2002). Summer water temperatures are adequate to support salmonids throughout the summer in about half of the channel lengths in Auburn Ravine, Coon Creek and Doty Ravine (County of Placer 2002). In Auburn Ravine, the lack of riparian buffers along the downstream reaches likely contributes to elevated water temperatures.

Installation of seasonal dams during the spring and removal during the fall reportedly can affect the upstream migration of steelhead (JSA 1999). As reported by SARSAS (2009), Placer Legacy and NID are currently in the process of retrofitting the Lincoln Gaging Station and Hemphill Dam for fish passage. These dams will reportedly be retrofitted in 2009. Fish will then be able to reach the base of NID's Gold Hill Diversion Dam. NID has identified retrofitting Gold Hill Dam to facilitate fish passage as a focus for NID after fish are able to reach the Gold Hill Dam (SARSAS 2009).

The conceptual recovery scenario for the Auburn Ravine/Coon Creek watershed includes the maintenance steelhead spawning populations in the upper reaches of Auburn Ravine and Coon Creek, and in Doty Ravine. In order to secure the extant populations and promote viable populations of steelhead in both the near-term and the long-term, several key

habitat restoration actions have been identified, including the following:

- ❑ Conduct an anadromous fish passage assessment in the Auburn Ravine/Coon Creek Watershed to develop recommendations for improving passage conditions
- ❑ Conduct a hydrologic analysis of the Auburn Ravine/Coon Creek watershed that explores conjunctive use opportunities to reduce water allocations that are dependent on surface water
- ❑ Increase habitat complexity and enhance riparian vegetation to improve juvenile rearing and emigration conditions
- ❑ Enhance watershed resiliency by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce local water temperatures, or increase riparian shade
- ❑ Assess feasibility of providing enhanced steelhead habitat
- ❑ Consolidate diversions
- ❑ Reduce flow fluctuations
- ❑ Reduce non-point application of pesticides (timing, amount and dilution)

DRY CREEK

General information on the historical presence of anadromous salmonids, including steelhead, in Dry Creek is available through many small-scale inventory surveys and anecdotal information, and suggests that the watershed supports a persistent population of steelhead. CDFG conducted a reconnaissance-level assessment of steelhead distribution and

abundance, relative to stream habitat conditions, in 1998 and 1999. At that time, steelhead escapement to the upper Dry Creek watershed was estimated at a few hundred fish. Monitoring of juvenile salmonid emigration also was conducted by CDFG during 1999 and 2000. During both years, juvenile steelhead were collected in rotary screw traps located immediately downstream of the confluence of Secret and Miners ravines (ECORP Consulting 2003). During the fall/winter of 2004 and the spring of 2005, CDFG conducted two-pass electrofishing surveys on a total of seven reaches in Dry Creek, as well as in several reaches in Miners and Secret ravines. No steelhead/rainbow trout were captured in Dry Creek or Miners Ravine. However, 41 steelhead/rainbow trout were captured in Secret Ravine in 2004, and 95 were captured during 2005 (CDFG 2005b, unpublished data).

These surveys, as well as previous studies and anecdotal information suggest that Dry Creek is utilized as a migratory corridor for anadromous salmonid passage upstream to spawning and rearing habitat in the upstream tributaries (Secret Ravine and Miners Ravine). The Dry Creek Watershed Coordinated Resource Management Plan (ECORP Consulting 2003) states that the mainstem of Dry Creek is not suitable anadromous salmonid habitat and is considered only as a migratory corridor to upstream areas containing suitable spawning and rearing habitat.

The Dry Creek Watershed is characterized as having a moderate potential to support viable populations of steelhead, primarily based on the present abundance of *O. mykiss*, generally suitable habitat conditions particularly in upstream areas, and habitat restoration potential. Miners Ravine still supports salmonids, although many reaches are heavily degraded. Secret Ravine also still supports salmonids and has the highest quality fisheries habitat in the Dry Creek watershed (ECORP Consulting 2003).

Land use impacts have affected the form and function of stream channels throughout the Dry Creek Watershed, which in turn have impacted riparian and aquatic communities. Throughout the watershed, reaches have been straightened, floodplain area reduced, reaches dredged, and riparian vegetation removed, resulting in eroding banks, sediment deposition, lack of cover, lack of pools and riffles, lack of riparian vegetation, and barriers to fish passage. However, Dry Creek does support a relatively healthy riparian corridor upstream of Folsom Road to the confluence with Miners and Secret ravines (ECORP Consulting 2003), and water temperatures in the upstream portions of the watershed may remain somewhat suitable for over-summer juvenile steelhead rearing.

Several studies and projects have been implemented to improve fish passage and restore aquatic habitat in Miners Ravine, Secret Ravine, and small tributaries. For example, riparian trees have been planted along Dry Creek by the City of Roseville in association with the Dry Creek Reforestation Project.

The conceptual recovery scenario for the Dry Creek Watershed includes the maintenance of steelhead spawning populations in Miner's Ravine and Secret Ravine. In order to secure the extant population and promote viable populations of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Improve passage conditions in the Dry Creek watershed
- ❑ Improve flow conditions (i.e., low flows) associated with attraction and migratory cues affecting adult immigration, as well as juvenile rearing and outmigration
- ❑ Develop a spawning gravel augmentation plan

- ❑ Develop a program to restore natural morphology, riparian habitat and instream cover

AMERICAN RIVER

The American River provides habitat for a persistent, dependent population of steelhead. The Central Valley steelhead DPS includes naturally-spawned steelhead in the American River (and other Central Valley stocks) and excludes steelhead spawned and reared at Nimbus Fish Hatchery. The abundance of naturally-spawning steelhead in the lower American River has been low for several years. From 2002 through 2007, annual population abundance estimates for American River steelhead spawning in the river have ranged from about 160 to about 240 individuals (Hannon and Deason 2008).

Lindley et al. (2007) classify the listed (i.e., naturally-spawning) population of American River steelhead at a high risk of extinction because this population is reportedly mostly composed of steelhead originating from Nimbus Fish Hatchery. The relatively small population size, complete loss of historic spawning habitat, and reduced genetic diversity further support this classification (NMFS 2009).

The American River watershed can be characterized as having a moderate potential to support a viable population of steelhead. There is a general consensus in the available literature suggesting that habitat for steelhead in the American River is impaired (Reclamation 2008; Water Forum 2005a; SWRI 2001; CDFG 2001). Of particular concern are warm water temperatures from spring through early fall, especially during the summer (NMFS 2009).

In addition to elevated water temperatures during the steelhead embryo incubation, juvenile rearing, and juvenile migration periods, past habitat alterations primarily associated with bank protection have reduced natural river function and morphology and, consequently,

have degraded steelhead habitat suitability. Flow fluctuations are another major stressor, and have been documented to result in steelhead redd dewatering (Hannon et al. 2003; Water Forum 2005b; Hannon and Deason 2008), and juvenile stranding and isolation in the lower American River (NMFS 2009).

However, the reasonable and prudent alternative (RPA) for the lower American River in the 2009 NMFS OCAP BO (NMFS 2009) includes implementing a new Flow Management Standard and water temperature management plan, minimization of flows exceeding 4,000 cfs to reduce potential flow fluctuation effects, technological modifications to improve water temperature management of Folsom Reservoir's coldwater pool and resultant downstream water temperatures, and development of a Genetics Management Plan for the Nimbus Hatchery. These actions are anticipated to improve near-term habitat conditions and accomplish the previously stated goal of securing the extant population and increasing the viability of the American River steelhead population.

The conceptual recovery scenario includes the reintroduction of steelhead above Folsom Dam into the North Fork American River, Middle Fork American River and South Fork American River. Indeed, reintroduction of steelhead into the American River Watershed above Folsom Dam is included in the 2009 OCAP NMFS BO (NMFS 2009). The BO states that by January 2011, Reclamation, with assistance from a Steering Committee, shall complete a 3-year plan for a Fish Passage Pilot program, including the American River Basin.

- ❑ The conceptual recovery scenario for the American River includes the maintenance of a steelhead spawning population in the reach extending from approximately the Nimbus Fish Hatchery Weir downstream to approximately Watt Avenue. In order to secure the extant population and

promote a viable population of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Conduct a passage feasibility study, including an assessment of potential salmonid habitat above Nimbus and Folsom dams
- ❑ Implement physical and structural modifications to the American River Division of the CVP in order to improve water temperature management
- ❑ Evaluate the potential to replace the Nimbus Fish Hatchery broodstock with genetically more appropriate sources (e.g., the O.mykiss in the watershed above Folsom Dam which retain ancestral American River steelhead genetics)
- ❑ Develop a Nimbus Fish Hatchery Genetic Management Plan for steelhead
- ❑ Evaluate Nimbus Fish Hatchery steelhead production and stocking practices to identify and implement measures that would promote restoration of wild steelhead in the lower American River
- ❑ Develop State and national levee vegetation policies to maintain and restore riparian corridors in the American River (Corps vegetation management policy and FloodSAFE)
- ❑ Utilize bio-technical techniques that integrate riparian restoration for river bank stabilization instead of conventional rip rap in the American River
- ❑ Inventory locations for creating shallow inundated floodplain habitat in the

American River for multi-species benefits and implement where suitable opportunities are available

- ❑ Continue to implement spawning habitat improvement and gravel augmentation measures
- ❑ Develop and implement side channel habitat improvement and creation, and riparian habitat restoration measures
- ❑ Develop and implement a woody debris maintenance program

SOUTHERN SIERRA NEVADA DIVERSITY GROUP

Extant populations of steelhead in the Southern Sierra Diversity Group are known or believed to occur in the Calaveras, Stanislaus, Tuolumne, and Merced rivers (NMFS 2009). In addition, a hatchery-dependent steelhead population is present on the Mokelumne River (Marsh 2007). As previously discussed, no viable independent steelhead populations have been identified in the Southern Sierra Diversity Group, and all of them are either data deficient or at high risk of extinction. However, one of the recovery goals is to secure and/or improve all extant populations. Specifically, the Southern Sierra Diversity Group is critical to preserving the spatial structure of the Central Valley steelhead DPS (NMFS 2009).

Local efforts to investigate steelhead presence, habitat utilization and restoration opportunities targeting steelhead have been minimal in most of these watersheds. Watersheds in this diversity group are generally characterized as having low to moderate potential to support steelhead recovery. However, the steelhead conceptual recovery scenario for the Southern Sierra Diversity Group includes the maintenance and/or establishment of spawning steelhead populations in the Mokelumne River, Dry Creek, and the Calaveras, Stanislaus, Tuolumne and Merced rivers.

The steelhead conceptual recovery scenario for the Southern Sierra Nevada Diversity Group also includes the reintroduction of steelhead to the candidate areas of the North Fork Mokelumne River, the Middle Fork Stanislaus River, the upper Tuolumne River, the upper Merced River and the South Fork Merced River. In addition to considerations of historical distribution, current population status, and recovery potential (including restoration actions) of the individual watersheds, one of the factors taken into account in the identification of candidate reintroduction watersheds is long-term climate change. Reintroductions also would be dependent upon successful passage programs above the dams in these watersheds.

It is clear that the long-term viability of this diversity group will depend not only on implementation of actions related to flow, water temperature, and habitat specified in the RPA of the 2009 NMFS OCAP BO, but also additional actions, particularly increasing flows in the Tuolumne and Merced rivers (NMFS 2009). The State Water Resources Control Board has made establishing additional flows in these rivers a priority and intends to take action within the near-term. A CVP/SWP operations consultation with NMFS that will be triggered by implementation of San Joaquin Restoration Program flows also will provide further opportunities to update and refine actions critical to this diversity group (NMFS 2009).

MOKELUMNE RIVER

Steelhead historically were abundant in the Mokelumne River. Recent monitoring has detected small, self-sustaining populations of steelhead (although influenced by the Mokelumne River Hatchery steelhead program) in the Mokelumne River (NMFS 2009). The Central Valley steelhead DPS includes naturally-spawned steelhead in the Mokelumne River (and other Central Valley stocks) and excludes steelhead spawned and reared at Mokelumne River Hatchery.

Since implementation of the Joint Settlement Agreement, East Bay Municipal Utilities District has conducted recent monitoring of *O. mykiss* populations in the lower Mokelumne River using video monitoring as the Woodbridge Irrigation District Dam (WIDD) fish ladder, rotary screw traps in the lower Mokelumne River downstream of the WIDD, and conducted seasonal fish surveys from Camanche Dam downstream to WIDD (EBMUD et al. 2008). Steelhead redd surveys in the lower Mokelumne River are conducted between Camanche Dam and the Elliott Road Bridge (EBMUD et al. 2008). Monitoring results regarding steelhead populations in the lower Mokelumne River are presently becoming available.

The Mokelumne River Watershed can be characterized as having a low potential to support a viable population of steelhead. Mokelumne River natural-origin steelhead are reportedly extinct (USFWS 1998), and the steelhead population is believed to be maintained by hatchery supplementation (Marsh 2007). Elevated water temperatures, low flow conditions, flow fluctuations, and limited supplies of instream gravel diminish the potential for a viable population of steelhead in the Mokelumne River.

The conceptual recovery scenario for the Mokelumne River Watershed includes the maintenance of steelhead spawning populations in the upper reach of the Mokelumne River below Camanche Reservoir, and in the upper reaches of Dry Creek. Over the past few years, Mokelumne River studies have used an extensive acoustic receiver array system deployed in the river to track the movement, survival, and habitat use of hatchery origin steelhead smolts, hatchery steelhead kelts and multiple life stages (>160mm) of the wild river population of *O. mykiss* (Workman et al. 2008). EBMUD, CDFG and USFWS continue to collaboratively work to improve conditions for the lower Mokelumne River. Restoration objectives have focused on providing additional salmonid spawning gravel, improving

intergravel water quality, and increasing floodplain connectivity in the first 1 mile below Camanche Dam (EBMUD 2009). Side channel and riparian habitat restoration projects also have been conducted. Woodbridge Irrigation District has completed the rebuilding of the dam at Woodbridge with improved fish passage facilities and improved screening at the diversion (USFWS 2008b).

The conceptual recovery scenario also includes the reintroduction of steelhead above Pardee Reservoir into the North Fork Mokelumne River. Habitat conditions in the North Fork Mokelumne River are likely suitable for steelhead spawning and juvenile rearing.

In order to secure the extant populations and promote viable populations of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Evaluate and, if feasible, develop and implement a fish passage program for Camanche and Pardee dams
- ❑ Evaluate pulse flow benefits for steelhead attraction and passage in the Mokelumne River; if pulse flows are determined to be effective for attracting steelhead, implement the most beneficial pulse flow regime
- ❑ Develop and implement a spawning gravel augmentation plan for the Mokelumne River
- ❑ Develop a Mokelumne River Steelhead Hatchery Genetic Management Plan to minimize adverse effects to the wild stock
- ❑ Manage cold water pools in Camanche and Pardee Reservoirs to provide suitable water temperatures for all steelhead life stages

- ❑ Develop and implement an instream flow management plan that fully considers all steelhead life history stages

CALAVERAS RIVER

A small, apparently self-sustaining population of steelhead reportedly exists in the Calaveras River (NMFS 2008). Current annual escapements of steelhead in the Calaveras River are limited due to the long-term scarcity of steelhead in the basin (Reclamation 2001). Data regarding hatchery influence on the Calaveras River steelhead population is lacking (USFWS 2003).

The Calaveras River is characterized as having a moderate potential to support a viable population of steelhead. Historically, steelhead production in the Calaveras River was limited by low, intermittent flows during summer and fall. Mormon Slough, the primary salmonid migration channel, still experiences dry periods during summer and early fall as it did under the pre-1964 unregulated hydrologic regime (Marsh 2006). Instream flow is reported to be a principal factor currently limiting salmonids in the Calaveras River (CALFED 2000b, as cited in Marsh 2006). Below the Bellota Weir, the spawning gravels are limited and have poor permeability. Several steelhead redds were present in this area in 2002, but water temperatures reached lethal levels for steelhead eggs during the spring (USFWS 2003).

However, the Calaveras River does have the potential to support anadromous fish based on habitat qualities such as geomorphology (i.e., 22 feet per mile gradient, numerous riffles and pools), adequate spawning gravels, and a dense riparian canopy (USFWS 1993, CALFED 2000b, as cited in Marsh 2006), particularly upstream of the Bellota Weir. Along the 18 miles between the Bellota Weir and New Hogan Dam there is a dense riparian corridor bordering the river (USFWS 1998, as cited in Marsh 2006). Spawning gravels in the first mile below New Hogan Dam do exhibit low permeability, but are reportedly

adequate to support several hundred pairs of salmon (USFWS 2003).

The conceptual recovery scenario for the Calaveras River includes the maintenance of a steelhead spawning population in the upper reach of the Calaveras River extending from the Bellota Weir upstream to New Hogan Dam. Restoration actions in the Calaveras River have focused on passage and instream flow improvements. Opportunities to improve fish passage and aquatic habitat for anadromous salmonids have been identified at several locations, including the Mormon Slough flood control channel, the Old Calaveras River channel, and at the SEWD and the CCWD facilities (Fishbio 2008). SEWD and CCWD are working cooperatively with NMFS to improve conditions for salmonids in the Calaveras River by including appropriate conservation measures and an adaptive management plan as part of this Calaveras River Habitat Conservation Plan. SEWD also is continuing to implement interim fish passage improvements until long-term fish passage and screening solutions are identified and implemented (Fishbio 2008).

In order to secure the extant populations and promote viable populations of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Develop and implement spawning gravel augmentation programs
- ❑ Improve fish passage conditions in Mormon Slough, the Old Calaveras River channel, at Bellota Weir, and other locations
- ❑ Improve flow conditions (i.e., low flows) and reduce flow fluctuations
- ❑ Improve water quality conditions (i.e., urban and agricultural runoff)
- ❑ Develop and implement restoration actions to reduce water temperatures

STANISLAUS RIVER

Steelhead were previously thought to be extirpated from the Stanislaus River, however, monitoring has detected a small self-sustaining (i.e., non-hatchery origin) population of steelhead in the Stanislaus River (McEwan 2001, as cited in NMFS 2009). A fish counting weir operated in the river near the town of Riverbank has documented the passage of large *O. mykiss* moving upstream. Although the abundance of steelhead in the Stanislaus River is unknown, the catch of adult steelhead using hook-and-line began to increase in 1997 and again in 1999 (SRFG et al. 2003).

The Stanislaus River Watershed below Goodwin Dam can be characterized as having a low to moderate potential to support a viable population of steelhead. A series of dams in the Stanislaus River has blocked access to spawning habitat in the upper watershed, and has blocked the transport of gravel to downstream reaches (KDH Environmental Services 2008). Gravel recruitment was reduced by 92 percent following construction of Goodwin Dam in 1912 (KDH Environmental Services 2008). Kondolf et al. (2001) and references therein identify a reduction of more than 60 percent of the spawning area in the Stanislaus River since 1966. Along most of the lower Stanislaus River, agricultural and urban encroachment has separated the river from its floodplain. As a result, the channel is incised, which prevents the river from developing and maintaining shallow spawning and rearing habitats necessary for salmonids. The lack of suitable spawning and rearing habitat may reduce the likelihood of establishing a viable steelhead population in the Stanislaus River.

However, the reasonable and prudent alternative (RPA) for the Stanislaus River in the 2009 NMFS OCAP BO (NMFS 2009) includes implementation of a year-round flow regime to

support juvenile steelhead rearing habitat formation and inundation, and to create pulse flows to cue juvenile steelhead outmigration, in addition to implementation of water temperature requirements downstream of Goodwin Dam (NMFS 2009). The RPA also includes spawning gravel augmentation of 50,000 tons of gravel by 2014 (NMFS 2009).

The conceptual recovery scenario for the Stanislaus River includes the maintenance of a steelhead spawning population in the upper reach of the Stanislaus River extending from approximately Orange Blossom Bridge (RM 47) upstream to Goodwin Dam. Although steelhead redd surveys have not been conducted, it is presumed that a majority of the spawning occurs between Goodwin Dam and the Orange Blossom Bridge (SRFG et al. 2003). Moreover, steelhead rearing in the Stanislaus River occurs upstream of Orange Blossom Bridge, where gradients are highest (NMFS 2009).

Despite the future implementation of actions to improve water temperature management in the Stanislaus River, NMFS (2009) concluded that steelhead will continue to be vulnerable to adverse effects of elevated water temperatures during dry and critically dry years. Water temperatures are expected to increase with climate change and increased water demands. Therefore, the conceptual recovery scenario also includes the reintroduction of steelhead above New Melones Reservoir into the Middle Fork Stanislaus River. Moreover, an evaluation of reintroducing steelhead into the Stanislaus River Watershed above New Melones Reservoir is included in the 2009 NMFS OCAP BO (NMFS 2009). The BO states that by March 31, 2011, Reclamation shall develop a plan to obtain information needed to evaluate options for fish passage on the Stanislaus River above Goodwin, Tulloch and New Melones Dams. By December 31, 2018, Reclamation shall develop recommendations regarding fish passage into the upper Stanislaus River (NMFS 2009).

Restoration actions conducted to date in the Stanislaus River have been limited to spawning gravel augmentation and providing additional water to supplement flows in accordance with Section 3406(b)(2) and 3406(b)(3) provisions of the Central Valley Project Improvement Act (CVPIA)⁶. Additional restoration work is needed to replace gravel lost to mining and dams, and to provide additional floodplain habitat (USFWS 2008c). In order to secure the extant populations and promote viable populations of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Manage releases from New Melones Reservoir in consideration of all steelhead life stages
- ❑ Implement the Spawning Gravel Augmentation Program (Reclamation); augment spawning gravel in suitable locations upstream of Oakdale
- ❑ Conduct feasibility studies for allowing steelhead access to habitat above New Melones Dam, including assessing habitat suitability and passage logistics. If the feasibility studies suggest that fish passage can be successful, then design and conduct an experimental fish passage program evaluating adult distribution, survival, spawning, and production in habitats above New Melones Dam
- ❑ Evaluate pulse flow benefits for steelhead attraction and passage in the Stanislaus River; if pulse flows are determined to be effective for attracting

⁶ Section 3406(b)(2) of the CVPIA directs the Secretary of the Interior to dedicate and manage annually eight hundred thousand acre-feet of Central Valley Project yield for the primary purpose of implementing the fish, wildlife, and habitat restoration purposes and measures authorized by the CVPIA. The 800,000 acre-feet of water dedicated by the CVPIA is referred to as "(b)(2) water."

steelhead, implement the most beneficial pulse flow regime

- ❑ Work with State and Federal water acquisition programs to dedicate instream water in the Stanislaus River
- ❑ Develop and implement floodplain habitat restoration measures

TUOLUMNE RIVER

Steelhead historically occurred throughout the Tuolumne River Watershed. Recent fisheries monitoring for the Don Pedro Project (FERC Project No. 2299) by the Turlock Irrigation District (TID) and the Modesto Irrigation District (MID) has documented the presence of *O. mykiss* in the lower Tuolumne River (TID/MID 2005). During 2008, a total of 135 YOY/juvenile (< 150 mm FL) and 45 adult (> 150 mm FL) *O. mykiss* were observed from RM 51.8 to RM 41.1 within the study reach extending down to RM 39.6 (TID/MID 2009). Approximately 3,096 *O. mykiss* were estimated within the survey reach, with 95% confidence bounds of 1,905–3,047 and 325–914 for the YOY/juvenile and adult size classes, respectively (TID/MID 2009).

The lower Tuolumne River is characterized as having a low to moderate potential to support a viable population of steelhead. Extensive habitat restoration has already occurred in the lower watershed through AFRP programs and other agreements. However, steelhead production in the lower Tuolumne River is limited by low flows. It is reported that the remaining accessible prime spawning reach of the lower Tuolumne River lacks native riparian vegetation and floodplain habitat, and has a high fine sediment load (Tuolumne River Preservation Trust 2002). In addition, despite previous restoration actions, the lower Tuolumne River lacks channel complexity and off-channel juvenile rearing habitats.

However, over the past several years, the AFRP has been working with the Tuolumne River Technical Advisory Committee (TRTAC) and the FERC Settlement Agreement framework to develop restoration and monitoring strategies in the Tuolumne River (USFWS 2008d). Initial priorities include: (1) continue to develop and fund the remaining two segments within the 6-mile Mining Reach; (2) complete restoration of two large in-channel pits; (3) develop a sediment management plan that will protect and restore critical spawning and rearing areas in the upper Tuolumne River; (4) work with agriculture and municipal interests in the lower river to establish and restore a riparian corridor; and (5) continue to work with local interests and the Corps on a flood protection strategy (USFWS 2008d). The AFRP also is working with the TRTAC to finalize river-wide and project-specific monitoring strategies that will guide adaptive management and allow the TRTAC to evaluate efficacy of FERC Settlement Agreement actions (USFWS 2008d).

The conceptual recovery scenario for the Tuolumne River includes the maintenance of a steelhead spawning population in the upper reach of the Tuolumne River extending from approximately RM 46.6 to RM 52.1 (i.e. the critical spawning reach).

The conceptual recovery scenario also includes the reintroduction of steelhead above Don Pedro Reservoir. Aquatic habitat above the Don Pedro and La Grange reservoir system historically was likely suitable for steelhead spawning and juvenile rearing. In addition, the upper Tuolumne River downstream of Yosemite National Park is designated a National Wild and Scenic River.

In order to secure the extant populations and promote viable populations of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following:

- ❑ Continue with research to determine the distribution of steelhead and assess the

relationship between resident and anadromous forms of *O. mykiss*

- ❑ Improve production of native steelhead by improving adequate water temperature and flow regimes, particularly for juvenile rearing
- ❑ Improve project operations, outlet modifications, and establishment of minimum pools for reservoirs so that cool water temperatures could be provided in late-summer and fall
- ❑ Install fishways on presently impassable dams to allow access to tail water habitat

MERCED RIVER

Steelhead historically occurred throughout the upper Merced River drainage, occupying habitat as far upstream as Yosemite Valley on the mainstem, and potentially upstream of Wawona on the South Fork, in addition to most of its lower elevation tributaries. Incidental catches and observations of steelhead juveniles have occurred on the Merced River recently (Good et al. 2005), but population abundance data is lacking. During juvenile outmigration surveys in 2007, no *O. mykiss* were captured (USFWS 2007b).

The lower Merced River is characterized as having a low to moderate potential to support a viable population of steelhead. As reported in the Geomorphic and Riparian Vegetation Investigations Report for the Merced River Corridor Restoration Plan (Stillwater Sciences 2001), the major constraints to restoring geomorphic and riparian processes in the Merced River include: (1) drastic reduction in the flood magnitude, frequency, and duration and the resulting reduction in bedload transport; (2) elimination of floods exceeding 6,000 cfs; (3) the presence of vulnerable structures and land uses in the floodplain; (4) lack of coarse sediment supply; (5) limits to

channel migration caused by reduced flows, bank revetment, and development in the floodplain; (6) the extent of bedload impedance reaches throughout the Gravel Mining 1 and Gravel Mining 2 reaches; and (7) chronic fragmentation and clearing of riparian vegetation for floodplain development. To date, numerous projects to restore and protect floodplain function, as well as channel and riparian habitat have been initiated or completed on the Merced River as a result of the CVPIA and the Merced River Corridor Restoration Plan; however, consistent monitoring of juvenile Chinook salmon and steelhead emigration has been lacking (Stillwater Sciences 2001; USFWS 2007b).

The conceptual recovery scenario for the Merced River includes the maintenance of a steelhead spawning population in the upper reach of the lower Merced River extending from approximately the Highway 59 bridge (RM 42) upstream to the Crocker Huffman Dam (RM 52). Suitable *O. mykiss* spawning and juvenile rearing habitat is restricted to this reach.

The conceptual recovery scenario also includes the reintroduction of steelhead above New Exchequer Reservoir on the mainstem Merced River and on the South Fork Merced River. Aquatic habitat above the New Exchequer and Crocker Huffman dams historically was likely suitable for steelhead spawning and juvenile rearing. In addition, the upper Merced River and South Fork Merced River are designated as National Wild and Scenic Rivers (National Park Service 2005).

In order to secure the extant populations and promote viable populations of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following.

- ❑ Improve production of steelhead by improving adequate water temperature and flow regimes, particularly for juvenile rearing

- ❑ Improve project operations, outlet modifications, and establishment of minimum pools for reservoirs so that cool water temperatures could be provided in late-summer and fall
- ❑ Install fishways on presently impassable dams to allow access to tail water habitat
- ❑ Maintain, recover, and restore stream flow regimes sufficient to sustain desired conditions for populations of steelhead

MAINSTEM SAN JOAQUIN RIVER

There is reportedly an existing population of resident *O. mykiss* below Friant Dam on the San Joaquin River, although this population is substantially supplemented from hatchery releases (SJRRP 2009). Flows released from Friant Dam are reportedly insufficient to provide year-round fisheries habitat except during high flow events (USACE and Reclamation Board 1999).

The San Joaquin River is characterized as having a low potential to support a viable population of steelhead. As a result of litigation over the past two decades related to instream flows on the San Joaquin River, a settlement was reached between the Natural Resources Defense Council, Friant Water Users Authority and the U.S. Departments of the Interior and Commerce in 2006. The area of the San Joaquin River to be addressed by the Settlement extends from Friant Dam downstream to the confluence with the Merced River (SJRRP 2009). The Settlement provides a framework for accomplishing restoration and water management goals, including establishment of the San Joaquin River Restoration Program (SJRRP). The SJRRP calls for a combination of channel and structural modifications along the San Joaquin River below Friant Dam, releases of water from Friant Dam to the confluence of the Merced River, and the

reintroduction of Chinook salmon. The SJRRP also identifies population abundance targets for Chinook salmon. However, the SJRRP did not determine numeric objectives for steelhead for two reasons: (1) difficulties associated with a viability assessment; and (2) steelhead were not specifically identified as a target species in the Settlement (SJRRP 2009). Subsequent to restoration efforts on the San Joaquin River reach above the Merced River confluence, steelhead may potentially utilize the habitat, although the lack of side channel and small tributary habitat will diminish the potential for establishing a viable steelhead population in this reach. In the event that steelhead reestablish in the San Joaquin River above the Merced River confluence as a result of the SJRRP, NMFS may develop additional steelhead recovery goals.

The conceptual recovery scenario for the San Joaquin River does not include the maintenance of a steelhead spawning population, although the San Joaquin River does serve as a critical migration corridor for Stanislaus, Tuolumne and Merced river steelhead populations below the Merced River confluence. Therefore, in order to secure these extant populations and promote viable populations of steelhead in both the near-term and the long-term, several key habitat restoration actions have been identified, including the following.

- ❑ Improve flow conditions (i.e., low flows) associated with adult steelhead attraction and migratory cues, and juvenile outmigration
- ❑ Develop and implement measures to improve water temperature and water quality conditions (i.e., urban and agricultural runoff, dissolved oxygen)
- ❑ Develop and implement measures to restore floodplain habitat, riparian habitat and instream cover

6.0 Recovery Actions

“Once there is a firm commitment and a strategy alternative has been decided upon, the third and final pillar of an effective salmon recovery effort is that a number of specific actions will be required to achieve effective implementation.”

- Jeffrey J. Dose. Commitment, Strategy, Action: The Three Pillars of Wild Salmon Recovery in Salmon 2100: the future of wild Pacific salmon

This Recovery Plan establishes a strategic approach to recovery, which identifies critical recovery actions for the Central Valley, as well as watershed- and site-specific recovery actions. Watershed-specific recovery actions address threats occurring in each of the rivers or creeks that currently support spawning populations included in the Sacramento River winter-run Chinook salmon ESU, the Central Valley spring-run Chinook salmon ESU, or the Central Valley steelhead DPS. Site-specific recovery actions address threats to these species occurring within a migration corridor (e.g., San Francisco Bay or the Delta).

This Recovery Plan maintains a consistent strategic framework for the establishment of recovery goals and criteria, the identification and prioritization of threats, and the identification of recovery actions. As described in the Recovery Strategy chapter, the framework for ESU or DPS recovery includes goals and criteria directed at the diversity group and population levels. Similarly, the threats assessment framework for each ESU or DPS also was organized by diversity groups and populations. For winter-run Chinook salmon, threats were prioritized within the Sacramento River population, whereas for spring-run Chinook salmon and steelhead, threats were prioritized within each diversity group as well as within each population.

Three steps were used to prioritize recovery actions as they are presented in this plan. First, results from the threats assessment and prioritization process (described in Appendix B) were used to guide the identification of watershed- and site-specific recovery actions for each diversity group and population. This step prioritized recovery actions separately for each species. The second step to prioritize recovery actions was undertaken through consideration of specific actions that benefit multiple species and populations. Results from the second step included tables of recovery actions listed in descending order of priority by geographic region (e.g., Delta, mainstem Sacramento River, Diversity Group) based on multiple species benefits (see Appendix C). These first two steps were the only steps taken to prioritize recovery actions that were presented in the Co-Manager Review Draft Recovery Plan. Based on feedback from co-managers, it was apparent that the priority with which recovery actions should be undertaken was not clear. To address this, we implemented a third step and prioritized each of the region-specific recovery actions according to two categories. Priority 1 actions are those critical actions that must be taken to prevent extinction or to prevent the species from declining irreversibly. Priority 2 actions must be taken to prevent a significant decline in species population/habitat quality or in some other significant negative impact short of extinction. Priority 1 actions are presented in narrative form in this chapter and an implementation schedule for these actions is described in Chapter 8. Priority 2 actions are presented in Appendix C. All priority 1 actions have been assigned a specific number beginning with the number 1 (e.g., 1.1, 1.2, etc.), while all priority 2 actions are identified by a numbering system starting with 2.

A number of ecosystem and/or anadromous fish enhancement plans for the Central Valley, as well as input received from two recovery planning public workshops, held May 22nd and 24th, 2007 in Sacramento and Redding, respectively, have been used to identify recovery actions. These documents include:

- ❑ Final Restoration Plan for the Anadromous Fish Restoration Program (USFWS 2001)
- ❑ AFRP Planning Documents (AFRP Website 2005; AFRP Website 2006a; AFRP Website 2006b)
- ❑ Ecosystem Restoration Plan Planning Documents (CALFED 2006; CALFED 2007)
- ❑ Summary of Threats and Recovery Actions for Spring-run Chinook salmon and Winter-run Chinook Salmon Recovery Actions. Sacramento Salmon and Steelhead Recovery Workshop (NMFS 2007c)
- ❑ Summary of Threats and Recovery Actions for Steelhead. Sacramento Salmon and Steelhead Recovery Workshop (NMFS 2007a)
- ❑ Steelhead Restoration and Management Plan for California (CDFG 1996)
- ❑ Lower Yuba River Revised Implementation Plan and Appendices (CALFED and YCWA 2005)
- ❑ Ecosystem Restoration Program Plan (ERPP) (CALFED 1999a)
- ❑ Restoring Central Valley Streams: A Plan for Action (CDFG 1993)
- ❑ Lower Yuba River Fisheries Management Plan (CDFG 1991a)
- ❑ Initial Fisheries and In-Stream Habitat Management and Restoration Plan for the Lower American River (Water Forum 2001)
- ❑ CALFED Bay/Delta Program Multi-Species Conservation Strategy. Final Programmatic EIS/EIR Technical Appendix (CALFED 2000a)
- ❑ Potential for Re-establishing a Spring-Run Chinook Salmon Population in the Lower Feather River (MWD 2005)
- ❑ Central Valley Salmon – A perspective on Chinook and Steelhead in the Central Valley of California (Williams 2006)
- ❑ What caused the Sacramento River fall Chinook stock collapse? (Lindley et al. 2009)

6.1 Priority 1 Recovery Actions for the Central Valley

The recovery actions in this recovery strategy target core 1 populations in the Sacramento River Basin, Core 1 and Core 2 populations in the San Joaquin River Basin, and highly ranked threats in the mainstem Sacramento and San Joaquin Rivers, the Bay-Delta region and the Pacific Ocean, and primary reintroduction areas. These actions represent the critical elements for alleviating major threats to populations in core watersheds. Actions are also specified to address limited knowledge regarding the biology and ecology of the species, as well as its changing status within individual core watersheds.

Priority 1 recovery actions have the highest priority across the ESU/DPS and within core watersheds to achieve recovery objectives and criteria. Opportunistically, priority 2 recovery actions or other actions benefiting winter-run, spring-run, and/or steelhead may be implemented prior to these actions, but NMFS considers priority

1 actions to be the keystones for population recovery or measurement of recovery; such actions are also widely recognized in the scientific literature as addressing threats which have caused the wide-spread decline of these species throughout their natural range.

6.1.1 Recovery Action Narrative

Recovery actions have been categorized into eleven geographic scales or regions:

- 1.1 Throughout California
- 1.2 Throughout the Central Valley
- 1.3 Pacific Ocean
- 1.4 San Francisco Bay
- 1.5 Delta
- 1.6 Mainstem Sacramento River
- 1.7 Northwestern California Diversity Group
- 1.8 Basalt and Porous Lava Diversity Group
- 1.9 Northern Sierra Nevada Diversity Group
- 1.10 Mainstem San Joaquin River
- 1.11 Southern Sierra Nevada Diversity Group

The actions for each scale or region are described below.

1.1 THROUGHOUT CALIFORNIA

1.1.1 Implement Federal, State, and local initiatives and programs to improve water conservation in order to reduce state-wide water use by 20 percent per capita by 2020.

This effort should take into account regional differences and find ways to improve agricultural efficiency as well as urban water use efficiency.

1.2 THROUGHOUT THE CENTRAL VALLEY

1.2.1 Promote Central Valley resource managers to cooperatively develop and implement an ecosystem based management approach that integrates harvest, hatchery, habitat, and water management, in consideration of ocean conditions and climate change. An ecosystem-based management and ecological risk assessment framework could improve management of Central Valley Chinook stocks by placing harvest

management in the broader context of the Central Valley salmon ecosystem, which is strongly influenced by hatchery operations and management of different ecosystem components, including water, habitat and other species (Lindley et al. 2009).

1.2.2 Support programs to provide educational outreach and local involvement in restoration, including programs like Salmonids in the Classroom, Aquatic Wild, Adopt a Watershed, school district environmental camps, and other programs teaching the effects of human land use on anadromous fish survival.

1.2.3 Develop a monitoring program to determine the level of entrainment at individual diversions. Prioritize diversions based on this monitoring and screen those that are determined to have the greatest impacts on juvenile survival.

1.2.4 Provide additional funding for increased law enforcement to reduce illegal take of anadromous fish, stream alteration, and water pollution and to ensure adequate protection for juvenile fish at pumps and diversions.

1.2.5 Control or relocate the discharge of irrigation return flows and sewage effluent, and restore riparian forests to help provide suitable water temperatures for anadromous salmonids.

1.2.6 Implement and evaluate actions to minimize and/or eliminate the effects of exotic (non-native invasive) species (plants and animals) on production of anadromous fish.

1.2.7 Restore tributaries by evaluating the feasibility of screening or relocating diversions, switching to alternative sources of water for upstream diversions, restoring and maintaining a protected riparian strip, limiting excessive erosion, enforcing dumping ordinances, removing toxic materials or controlling their source, replacing bridge and ford combinations with bridges or larger culverts and installing siphons to prevent truncation of small streams at irrigation canals, and implement actions to address harmful effects.

1.2.8 Conduct Central Valley-wide assessment of keystone dams and passage opportunities and implement programs to restore access to properly functioning habitat that was historically available.

1.2.9 Evaluate passage at small dams or other anthropogenic obstructions and implement fish passage per NMFS criteria.

1.2.10 Increase integration of the State and Federal water projects through shared storage and conveyance agreements.

1.2.11 Secure agreements with or purchase water rights from landowners and Federal and State agencies to provide additional instream flows.

1.2.12 Form a hatchery science review panel to review Central Valley hatchery practices. The panel should address the issues contained within actions 1.2.13 – 1.2.18.

1.2.13 Evaluate impacts of outplanting and broodstock transfers among hatcheries on straying and population structure and evaluate alternative release strategies.

1.2.14 Evaluate whether production levels are appropriate and if they could be adjusted according to expected ocean conditions.

1.2.15 Evaluate the potential to modify hatchery procedures to benefit native stocks of salmonids and implement beneficial modifications.

1.2.16 Evaluate and avoid potential competitive displacement of naturally produced juvenile salmonids with hatchery-produced juveniles by implementing release strategies for hatchery-produced fish designed to minimize detrimental interactions.

1.2.17 Evaluate and implement specific hatchery spawning protocols and genetic evaluation programs to maintain genetic diversity in hatchery and natural stocks.

1.2.18 Evaluate a program to tag and fin-clip all or a significant portion of hatchery-produced fish as a means of collecting better information regarding harvest rates on hatchery and naturally produced fish and effects of hatchery-produced fish on naturally produced fish.

1.2.19 Implementation of a comprehensive life history monitoring plan for Central Valley steelhead that will result in basin-wide (Sacramento and San Joaquin) estimates of hatchery and wild steelhead population abundance, production, diversity and distribution.

1.3 OCEAN

1.3.1 Work with the PFMC and NMFS to re-evaluate and modify management measures, annual conservation objectives, harvest forecasting techniques, NMFS consultation standards for ESA listed salmon stocks, and consider implementing an ecosystem-based salmon fishery management plan that considers multi-trophic interactions, ocean currents, upwelling patterns, ocean temperatures, and other relevant factors. Development of the fishery management plan will include the following actions:

- Consult with PFMC to identify sources of, and solutions to reduce bycatch.
- Use of genetic stock identification to determine to what extent listed salmonids are being intercepted in ocean fisheries.

1.3.2 Work with the PFMC and NMFS to implement restrictions that limit harvest of listed anadromous salmonids in commercial and recreational fisheries considering mechanisms such as:

- Genetic Stock Identificaiton (GSI) – Develop a research, testing and monitoring plan to test this technology and establish optimal bycatch levels based on GSI data.
- Review, assess and modify seasonal and area harvest restrictions and closures

- NMFS, CDFG and USFWS coordinate with the Southwest Fisheries Science Center to convene a science panel to review potential measures such as mass marking and mark selective fisheries and make recommendations to improve the identification of listed stocks in the Ocean.
- Consider using hot spot closures in commercial and recreational fisheries when large numbers of listed fish become congregated in certain areas.

1.4 SAN FRANCISCO BAY

1.4.1 Implement projects that improve wastewater and stormwater treatment throughout the Bay and surrounding residential and commercial areas.

1.4.2 Increase monitoring and enforcement to ensure that the water quality criteria established in the Central Valley Water Quality Control Plan (Basin Plan) are met for all potential pollutants.

1.4.3 Cities, counties, districts, joint powers authority or other political subdivisions of the State involved with water management should implement agricultural drainage management projects to treat, store, convey, and/or dispose of agricultural drainage.

1.5 DELTA

1.5.1 Develop alternative water operations and conveyance systems that ensure multiple and suitable salmonid rearing and migratory habitats for all Central Valley salmonids and that restore the ecological flow characteristics of the Delta ecosystem.

1.5.2 Large-Scale Habitat Restoration – Identify funding and direct restoration of 80,000 acres of tidal marsh, 130,000 acres of terrestrial grasslands, and 60,000 acres of floodplain habitat. Floodplain habitats should be restored to appropriate elevations using Frequently Activated Floodplain principles and modeling. The habitats should be along primary migration and rearing corridors,

and connected in ecologically beneficial ways. This will require separating levee systems from active river and estuary channels, restoring dendritic channel systems in areas where this habitat feature existed historically, and allowing for natural developmental processes to maintain habitats.

1.5.3 Integrate the Ecosystem Restoration Program and the Calfed Science program into an effort to restore the Delta ecosystem.

1.5.4 Implement programs and measures designed to control non-native predatory fish (e.g., striped bass, largemouth bass, and smallmouth bass), including harvest management techniques, non-native vegetation management, and minimizing structural barriers in the Delta, which attract non-native predators and/or that delay or inhibit migration.

1.5.5 Enhance the Yolo Bypass by re-configuring Fremont and Sacramento weirs to: (1) all for fish passage through Fremont Weir for multiple species; (2) enhance lower Putah Creek floodplain habitat; (3) improve fish passage along the toe drain/Lisbon weir; (4) enhance floodplain habitat along the toe drain; and (5) eliminate stranding events; and (6) create annual spring inundation of at least 8,000 cfs to fully activate the Yolo Bypass floodplain.

1.5.6 Implement Actions IV.1 through IV.6 of the Reasonable and Prudent Alternative described in the NMFS biological opinion on the long-term operations of the CVP/SWP (NMFS 2009):

- Action IV.1: Modify DCC gate operations and evaluate methods to control access to Georgiana Slough and the Interior Delta to reduce diversion of listed fish from the Sacramento River into the southern or central Delta.
- Action IV.2: Control the net negative flows toward the export pumps in Old and Middle rivers to reduce the

likelihood that fish will be diverted from the San Joaquin or Sacramento River into the southern or central Delta.

- ❑ Action IV.3: Curtail exports when protected fish are observed near the export facilities to reduce mortality from entrainment and salvage.
- ❑ Action IV.4: Improve fish screening and salvage operations to reduce mortality from entrainment and salvage.
- ❑ Action IV.5: Establish a technical group to assist in determining real-time operational measures, evaluating the effectiveness of the actions, and modifying them if necessary.
- ❑ Action IV.6: Do not implement the South Delta Barriers Improvement Program.

1.5.7 Develop a comprehensive governance system that has reliable funding, takes advantage of established and effective ecosystem restoration and science programs, and has clear authority to determine priorities and strong performance measures to ensure accountability to the new governing doctrine of the Delta: operation for coequal goals of Delta ecosystem restoration and protection and reliable water supply.

1.5.8 Following the first autumn flows exceeding 15,000 cfs at Wilkins Slough, maintain suitable rearing and migratory habitats for emigrating winter-run salmon throughout the Sacramento River and distributaries in the Delta through the end of April.

1.5.9 Provide pulse flows of at least 20,000 cfs measured at Freeport periodically during the winter-run emigration season to facilitate outmigration past Chipps Island (i.e., December-April).

1.6 MAINSTEM SACRAMENTO RIVER

1.6.1 Restore and maintain a continuous meanderbelt along the Sacramento River from Keswick downstream to Colusa.

- Pursue these opportunities, consistent with efforts conducted pursuant to Senate Bill 1086 (SB 1086), to create a meander belt from Keswick Dam to Colusa to recruit gravel and large woody debris, to moderate temperatures and to enhance nutrient input. Also pursue actions under the Sacramento River Flood Control Project and the Central Valley Plan for Flood Control.

1.6.2 Restore and maintain a continuous 60-mile stretch of riparian habitat and functioning floodplains of an appropriate, science-based width to maintain ecologically viable flood-prone lands along both banks of the Sacramento River between Colusa and Verona.

- Separate levee systems from active river channels, restore dendritic channel systems in areas where this habitat feature existed historically, and allow for the natural development of floodplain habitats. Pursue actions under the Sacramento River Flood Control Project and the Central Valley Plan for Flood Control.

1.6.3 Restore and maintain a continuous 70-mile stretch of riparian habitat and maintain existing floodplain terraces along both banks of the Sacramento River between Verona and Collinsville. Restore floodplain areas as necessary to achieve the restoration targets described in action 1.5.2

- Seek opportunities through the Army Corps of Engineers Sacramento River Bank Protection Project, the Central Valley

Plan for Flood Control, and other flood management programs and agencies, such as the Sacramento Area Flood Control Agency, to protect existing riparian habitat, restore riparian, protect remaining floodplain terraces, and integrate flood plain bench designs into levee repair projects.

1.6.4 Relocate the M&T Ranch fish screen and water diversion from its current location to a downstream, geomorphically stable, river reach and relocate the 300,000 cubic yards of dredged gravel to upstream reaches of the Sacramento River for spawning habitat enhancement.

1.6.5 Develop an ecological flow tool for the Sacramento River below Keswick and Shasta Dams and use in conjunction with Frequently Activated Floodplain (FAF) tools and hydrodynamic river models to create and implement a floodplain inundation program that allows for existing functional floodplains to be activated in two out of three years for at least seven days between mid-March to mid-May.

1.6.6 Implement a river flow management plan that balances carryover storage needs with instream flow and water temperature needs for winter-run, spring-run, and steelhead based on runoff and storage conditions, including flow fluctuation and ramping criteria.

1.6.7 Implement Action I.3.1 and I.3.2 (Long-term and interim operations of RBDD) of the Reasonable and Prudent Alternative described in the NMFS biological opinion on the long-term operations of the CVP/SWP (NMFS 2009) and install NMFS-approved, state-of-the-art fish screens at the Tehama Colusa Canal diversion point.

1.6.8 Develop a long-term gravel augmentation plan to enhance spawning habitat downstream of Keswick and Shasta Dams.

1.7 NORTHWESTERN CALIFORNIA DIVERSITY GROUP

1.7.1 CLEAR CREEK

1.7.1.1 Operate the Clear Creek weir to separate spring-run and fall-run Chinook salmon.

1.7.1.2 Develop a spawning gravel budget and implement a long-term augmentation plan in Clear Creek.

1.7.1.3 Develop and implement optimal flow schedules to mimic the natural hydrograph (including spring pulse flows and winter spillway releases to restore a proper functioning system) and use instream flow study results to guide flow schedule development.

1.7.1.4 Develop a real time water temperature model to track the coldwater pool in Whiskeytown Reservoir and budget releases to Clear Creek to meet daily water temperature of 60°F at the Igo gauge from June 1 to September 15 and 56°F from September 15 to October 31.

1.8 BASALT AND POROUS LAVA DIVERSITY GROUP

1.8.1 LITTLE SACRAMENTO RIVER

1.8.1.1 Develop and implement a phased approach to salmon reintroduction planning to recolonize historic habitats above Keswick and Shasta Dams in the Little Sacramento River.

- Conduct feasibility studies
- Conduct habitat evaluations
- Conduct 3-5 year pilot testing program
- Implement long-term fish passage program

1.8.2 McCLOUD RIVER

1.8.2.1 Develop and implement a phased approach to salmon reintroduction planning to re-

colonize historic habitats above Keswick and Shasta Dams in the McCloud River.

- Conduct feasibility studies
- Conduct habitat evaluations
- Conduct 3-5 year pilot testing program
- Implement long-term fish passage program

1.8.3 BATTLE CREEK

1.8.3.1 Develop and implement a salmon reintroduction plan to re-colonize historic habitats after implementation of the Battle Creek Restoration Project.

1.8.3.2 Fully fund and implement the Battle Creek Restoration Project through Phase 2.

1.9 NORTHERN SIERRA NEVADA DIVERSITY GROUP

1.9.1 ANTELOPE CREEK

1.9.1.1 Restore instream flows during upstream and downstream migration periods through water exchange agreements and provide alternative water supplies to Edwards Ranch and Los Molinos Mutual Water Company in exchange for instream fish flows.

1.9.1.2 Restore connectivity of the migration corridor during upstream and downstream migration periods by implementing Edwards and Penryn fish passage and entrainment improvement projects and identify and construct a defined stream channel for upstream and downstream fish migration

1.9.2 MILL CREEK

1.9.2.1 Implement a Mill Creek anadromous fish passage study (AFRP Website 2005) that will evaluate fish passage at all agricultural diversions to determine if they meet NMFS' fish passage criteria. Design and install state-of-the-art fish

passage facilities at diversions that currently do not meet the passage criteria.

1.9.2.2 Conduct a study designed to determine adult fish passage flows at critical riffles and fish ladders in Mill Creek. Develop a water exchange agreement with all Mill Creek water users to allow implementation of those flows.

1.9.2.3 Eliminate sources of chronic sediment delivered to Mill Creek from roads and other near stream development by out-sloping roads, constructing diversion prevention dips, replacing under-sized culverts and applying other storm proofing guidelines.

1.9.3 DEER CREEK

1.9.3.1 Develop and implement a water exchange agreement with the Deer Creek Irrigation Company and the Stanford-Vina Irrigation District and dedicate fish passage flows.

1.9.3.2 Construct state-of-the-art inflatable dams and install fish ladders that meet NMFS' adult fish passage criteria at the Cone-Kimball Diversion, Stanford-Vina Dam, and the Deer Creek Irrigation District Dam.

1.9.3.3 Implement the Deer Creek Flood Improvement Project.

1.9.3.4 Implement watershed restoration actions that reduce sedimentation and thermal loading in low gradient headwater habitats of Deer Creek Meadows, and Gurnsey Creek.

1.9.4 BUTTE CREEK

1.9.4.1 Develop, implement and evaluate a Butte Creek flow test for the PG&E DeSabra-Centerville Hydroelectric Project to determine the flow conditions that optimize coldwater holding habitat and spawning distribution.

1.9.4.2 Install state-of-the-art fish ladders at DWR weir 2 and Willow Slough weir.

1.9.4.3 Maintain state-of-the-art fish passage facilities at diversions in Butte Creek to meet NMFS' passage criteria.

1.9.5 FEATHER RIVER

1.9.5.1 Implement the use of a weir in the Feather River to spatially segregate spring-run Chinook salmon and fall-run Chinook salmon during their spawning migrations.

1.9.5.2 Develop a hatchery genetic management plan for the Feather River Fish Hatchery, including specific criteria for operating as either an integrated or segregated hatchery.

1.9.5.3 Develop and implement a spring-run pulse flow schedule that is coordinated with Yuba River operations for dry and critically dry years.

1.9.5.4 Develop a spawning gravel budget, identify gravel depleted areas, and implement an augmentation plan in the Feather River.

1.9.5.5 Construct steelhead side channel habitats using carrying capacity models sufficient to support a viable naturally spawning population of steelhead in the lower Feather River.

1.9.5.6 Implement facilities modifications(s) to achieve Feather River water temperatures at least as protective as those specified in Table 2 of the Settlement Agreement For Licensing of the Oroville Facilities (March 2006)

1.9.6 YUBA RIVER

1.9.6.1 Develop and implement a phased approach to salmon reintroduction planning to re-colonize historic habitats above Englebright Dam. Implement actions to: (1) enhance habitat conditions including providing flows and suitable water temperatures for successful upstream and downstream passage, holding, spawning and rearing; and (2) improve access within the area above Englebright Dam, including increasing minimum flows, providing passage at Our House, New Bullards Bar, and Log Cabin dams, and

assessing feasibility of passage improvement at natural barriers. The phased approach should include:

- Conduct feasibility studies
- Conduct habitat evaluations
- Conduct 3-5 year pilot testing program
- Implement long-term fish passage program

1.9.6.2 Improve spawning habitat in the lower river by gravel restoration program below Englebright Dam and improve rearing habitat by increasing floodplain habitat availability.

1.9.7 AMERICAN RIVER

1.9.7.1 Develop and implement a phased approach to steelhead reintroduction planning to re-colonize historic habitats above Folsom Dam.

- Conduct feasibility studies
- Conduct habitat evaluations
- Conduct 3-5 year pilot testing program
- Implement long-term fish passage program

1.9.7.2 Implement physical and structural modifications to the American River Division of the CVP in order to improve water temperature management

1.9.8 MOKELUMNE RIVER

1.9.8.1 Evaluate and, if feasible, develop and implement a fish passage program for Camanche and Pardee dams. Any actions should be phased and consider the following elements:

- Conduct feasibility studies
- Conduct habitat evaluations
- Conduct 3-5 year pilot testing program

- Implement long-term fish passage program

1.9.8.2 Manage cold water pools in Camanche and Pardee Reservoirs to provide suitable water temperatures for all downstream life stages.

1.10 MAINSTEM SAN JOAQUIN RIVER

1.10.1 Develop and implement a suite of actions to improve salmon and steelhead outmigration survival through the lower San Joaquin River by:

- Restoring floodplain habitat, and implementing ecological flow schedules to create frequently activated floodplain;
- Reducing contaminants;
- Implementing remedies for the biological oxygen demand and low dissolved oxygen levels in the Stockton Deep Water Ship channel that delay or impede fish migration.

1.10.2 Implement Action IV.2.1 (San Joaquin River Inflow to Export Ratio) of the Reasonable and Prudent Alternative described in the NMFS biological opinion on the long-term operations of the CVP/SWP (NMFS 2009) to improve juvenile outmigration for steelhead and future spring-run Chinook salmon.

1.11 SOUTHERN SIERRA NEVADA DIVERSITY GROUP

1.11.1 STANISLAUS RIVER

1.11.1.1 Evaluate and, if feasible, develop and implement a fish passage program for Goodwin, New Melones and Tulloch dams as generally described in Appendix C.

1.11.1.2 Manage cold water pools behind Goodwin, New Melones and Tulloch dams to provide suitable water temperatures for all downstream life stages.

1.11.2 CALAVERAS RIVER

1.11.2.1 Develop long-term instream flow schedules and requirements based on physical habitat modeling and critical riffle analysis.

1.11.2.2 Establish a minimum carryover storage level at New Hogan Reservoir that meets the instream flow and water temperature requirements in the lower Calaveras River.

1.11.2.3 Remove or modify all fish passage impediments in the lower Calaveras River to meet NMFS fish passage criteria.

1.11.3 TUOLUMNE RIVER

1.11.3.1 Evaluate and, if feasible, develop and implement a fish passage program for La Grange and Don Pedro dams. Any reintroduction actions should be a phased approach and consider the following elements:

- Conduct feasibility studies
- Conduct habitat evaluations
- Conduct 3-5 year pilot testing program
- Implement long-term fish passage program

1.11.3.2 Manage cold water pools behind La Grange and Don Pedro dams to provide suitable water temperatures for all downstream life stages.

1.11.4 SAN JOAQUIN RIVER (Friant Dam to Merced River confluence)

1.11.4.1 Implement the San Joaquin River Restoration Program (SJRRP). The SJRRP is a comprehensive long-term effort to restore flows to the San Joaquin River from Friant Dam to the confluence of Merced River and re-establish spring-run Chinook salmon in the river while reducing or avoiding adverse water supply impacts from restoration flows. SJRRP actions include:

- Implement interim and long-term settlement flows

- ❑ Develop and implement a spring-run Chinook salmon reintroduction strategy
- ❑ Construct channel modifications to increase the channel capacity from 475 cfs to 4,500 cfs.
- ❑ Minimize entrainment and fish losses to non-viable migration pathways
 - Screen Arroyo Canal
 - Retrofit Sack Dam to ensure unimpeded fish passage
 - Construct Mendota Pool Bypass
 - Fill and isolate high priority gravel pits
 - Implement temporary barriers at Mud and Salt Sloughs

7.0 Climate Change and Recovery of Salmon and Steelhead

"Climate variability plays a large role in driving fluctuations in salmon abundance by influencing their physical environment, the availability of food, the competitors for that food, and the predators that prey on small salmon. The complexity of influences on salmon, both climate and otherwise, combined with the scarcity of observations of factors important to salmon in estuaries and the ocean, make it challenging to identify the links between salmon and climate."

- Climate Impacts Group (2004)

7.1 Overview

The scientific basis for understanding the processes and sources of climate variability has grown significantly in recent years, and our ability to forecast human and natural contributions to climate change has improved dramatically. With consensus on the reality of climate change now established (Oreskes 2004; IPCC 2007), the scientific, political, and public priorities are evolving toward determining its ecosystem impacts, and developing strategies for adapting to those impacts. Climate forces directly influence regional temperature, wind, precipitation, snowpack and streamflow patterns, which may impact the habitat suitability for marine and anadromous species directly or indirectly (Schwing 2009).

Salmon populations throughout the West Coast are at historically low levels due to stresses imposed by a variety of human activities including dam construction, logging, pollution, and over-fishing. Climate change affects salmon throughout their life cycle and poses an additional stress. As more winter precipitation falls as rain rather than snow, higher winter flows scour streambeds, damaging spawning redds and washing away eggs incubating in the streambed. Earlier peak flows flush young salmon from rivers to estuaries before they are physically mature enough for the transition, increasing a variety of stresses including the risk of being eaten by predators. Earlier snowmelt leaves rivers and streams warmer and shallower during the summer and fall (Thomas et al. 2009).

Increasing air temperatures, particularly during the summer, lead to rising water temperatures, which increase stress on coldwater fish such as salmon and steelhead. Projected temperatures for the 2020s and 2040s under a higher emissions scenario suggest that the habitat for these fish is likely to decrease dramatically (Mote et al. 2008; Salathé et al. 2005; Keleher et al. 1996; McCullough et al. 2001). Reduced summer flows and warmer water temperatures will create less favorable instream habitat conditions for salmon and other coldwater fish species. Warmer water causes eggs to hatch earlier in the year, resulting in young that are smaller and more vulnerable to predators. Warmer conditions also increase the fish's

metabolism, taking energy away from growth and forcing the fish to find more food, but earlier hatching of eggs could put them out of sync with the insects they consume (Thomas et al. 2009). In addition, diseases and parasites that infect salmon tend to flourish in warmer water. Climate change also impacts the ocean environment, where salmon spend years of their lives. Historically, warm periods in the coastal ocean have coincided with relatively low abundances of salmon, while cooler ocean periods have coincided with relatively high salmon numbers (Janetos et al. 2008; Crozier et al. 2008).

Studies suggest that up to 40 percent of Pacific Northwest salmon populations may be lost by 2050 (Battin et al. 2007). In California and the Pacific Northwest, most wild salmon populations are extinct or imperiled in 56 percent of their historical range (Francis and Mantua 2003). Studies also suggest that about one-third of the current habitat for salmon and other coldwater fish will no longer be suitable for them by the end of this century as key temperature thresholds are exceeded (Thomas et al. 2009). Because climate change impacts on salmon and steelhead habitat is projected to be negative, climate change is expected to hinder efforts to recover depleted populations of Chinook salmon and steelhead (Thomas et al. 2009).

7.2 Climate Change and Environmental Variability

For ecosystem concerns (e.g., warming, wildfire, sea level rise, anthropogenic influences, El Niño) related to long-term climate changes, all regions under the management jurisdiction of NMFS are expected to experience environmental conditions that have not been experienced before (NMFS 2007). Warming over this century is projected to be considerably greater than over the last century (Thomas et al. 2009). Since 1900, the global average temperature has risen by about 1.5°F. By about 2100, it is projected to rise between 2°F and 10.5°F (**Figure 7-1**), but could increase up to 11.5°F (Thomas et al. 2009; California Climate Change

Center 2006). In the United States, the average temperature has risen by a comparable amount and is very likely to rise more than the global average over this century, with some variation according to location. Several factors will determine future temperature increases. Increases at the lower end of this range are more likely if global heat-trapping gas emissions are substantially reduced.

If emissions continue to rise at or near current rates, temperature increases are more likely to be near the upper end of the range. Volcanic eruptions or other natural variations could temporarily counteract some of the human-induced warming, slowing the rise in global temperature, but these effects would only last a few years (Thomas et al. 2009).

Climate-related fire dynamics also will be affected by changes in the distribution of ecosystems across the landscape. Torn et al. (1998) project that there will be a doubling of catastrophic wildfires in some regions due to faster and more intense burning associated with warming, drying vegetation, and elevated wind speed. Increasing temperatures and shifting precipitation patterns also will drive declines in high elevation ecosystems such as alpine forests. As an example, under higher emissions scenarios (Figure 7-1), high-elevation forests in California are projected to decline by 60 to 90 percent before the end of the century. At the same time, grasslands are projected to expand, another factor likely to increase fire risk. Climate changes also could create subtle shifts in fire behavior, allowing more “runaway fires” – fires that are thought to have been brought under control, but then rekindle (Thomas et al. 2009).

Current climate trends predict a future of warmer oceans and melting glaciers and icecaps, all of which are expected to raise mean sea levels, leading to the inundation and displacement of many estuaries. A rise in sea level will most dramatically affect those estuaries that are confined by surrounding development, which

prohibits their boundaries from naturally shifting in response to inundation. Projections for sea level rise by 2100 vary from 0.18 to 0.58 meters (m), to 0.5 to 1.4 m (Edgerton 1991 in NMFS 2009; IPCC 2007a; Rahmstorf 2007; Raper and Braithwaite 2006). Paleoclimatic data suggest that the rate of future melting of Greenland and Antarctic ice sheets and related sea-level rise could be faster than currently projected (NMFS 2009). A projected 1 m rise in sea level could potentially inundate 65 percent of the coastal marshlands and estuaries in the United States. In addition, there could be shifts in the quality of the habitats in

affected coastal regions. Prior to being inundated, coastal watersheds would become saline due to saltwater intrusion into the surface and groundwater. Regarding California's water supply, the largest effect of sea level rise would likely be in the Delta (DWR 2005). Increased intrusion of salt water from the ocean into the Delta could lead to increased releases of water from upstream reservoirs or reduced pumping from the Delta to maintain compliance with Delta water quality standards (Anderson et al. 2008).

Figure 7-1. Summary of Projected Global Warming Impacts (2070 to 2099 compared to 1961 to 1990).

(Source: California Climate Change Center 2006)

Anthropogenic influences on salmon and steelhead habitat play a primary role in climate influences on extinctions (Francis and Mantua 2003). Over the past 150 years, human activities have degraded, and in some cases completely eliminated, much of the historic stream and estuarine habitats for anadromous salmonids. In many ways, human actions have forced semi-permanent changes to the salmonid landscape that parallel those typically associated with climate change (Karr 1994). For example, stream temperatures, flow regimes, sediment transports, and pool-to-riffle ratios are all subject to anthropogenic and climate changes. Karr (1994) indicates that one major difference between perturbations due to natural climate events versus one caused by human activities is the time scale of the resulting impacts. A warm phase of the El Niño-Southern Oscillation generally impacts precipitation and flow over a single year, while hydropower dam construction alters flow for decades to centuries (Francis and Mantua 2003).

Because it affects the distribution of heat in the atmosphere and the oceans, climate change will affect winds and currents that move along the nation's coasts, such as the California Current that bathes the West Coast from British Columbia to Baja California (Thomas et al. 2009). Wind-driven upwelling of deeper ocean water along the coast in this area is vital to moderation of temperatures and the high productivity of Pacific Coast ecosystems (Figure 7-2). Warmer temperatures are likely to increase ocean stratification, yet possible increases in winds may counter that in ways that mitigate or even increase the wind-driven upwelling of nutrients that fuel a productive food web (CIG 2004).

Figure 7-2. Schematic of Coastal Upwelling Near the California Coast. Winds from the northwest during spring and summer drive surface water offshore, and it is replaced by cool water high in nutrients that is “upwelled” onto the continental shelf. (Source: NMFS 2009 - image from NOAA Cordell Bank National Marine Sanctuary).

Coastal currents are subject to periodic variations caused by the El Niño-Southern Oscillation and the Pacific Decadal Oscillation, which have substantial effects on the success of salmon and other fishery resources. Climate change is expected to affect such coastal currents, and possibly the larger scale natural oscillations as well, although these effects are not yet well understood (Thomas et al. 2009).

In addition to carbon dioxide’s heat-trapping effect, the increase in its concentration in the atmosphere is gradually acidifying the ocean (Thomas et al. 2009). About one-third of the carbon dioxide emitted by human activities has been absorbed by the ocean, resulting in a decrease in the ocean’s pH. Since the beginning of the industrial era, ocean pH has declined demonstrably and is projected to decline much more by 2100 if current emissions trends continue (Thomas et al. 2009). Because less dissolved carbon is available as carbonate ions at a lower pH (Feely et al. 2008; Janetos et al. 2008), further declines in pH are very likely to continue to affect the ability of living organisms to create and maintain shells or skeletons of calcium carbonate. Ocean acidification also is anticipated to affect important plankton species in the open ocean,

mollusks and other shellfish, and corals (Feely et al. 2008; Janetos et al. 2008; Royal Society 2005; Orr et al. 2005). Reductions in pH also affect photosynthesis, growth, and reproduction. The upwelling of deeper ocean water, deficient in carbonate and thus potentially detrimental to the food chains supporting juvenile salmon, has recently been observed along the West Coast (Feely et al. 2008).

It is unclear how coastal ocean conditions will respond to long-term climate change and, in turn, affect Chinook salmon and steelhead populations during their marine lifestages. Results of studies by Percy (1992) and Francis and Hare (1994) indicate that many climate-related biophysical linkages to salmonid populations occur very early in the salmon's marine life history - likely just months after juvenile fish enter the ocean. Climate-related investigations conducted by Francis and Mantua (2003) address the superposition of natural climate variability on anthropogenically stressed salmon ecosystems, believed to be an issue of serious concern for the future sustainability of salmon populations. Those authors focused on two particular elements: (1) linear relationships between climate and salmon meta-population variability along the Pacific Coast, from Alaska to California, which yielded a robust large-scale pattern of salmon meta-population responses to climate variability; and (2) selection of case studies to illustrate complex, nonlinear relationships between climate influences and salmon population variability. Of particular interest regarding climatic influences on salmon survival, interdecadal environmental fluctuations associated with the Pacific Decadal Oscillation appear to have significantly reduced ecosystem carrying capacity for West Coast coho salmon since a regime shift occurred during 1977 (Francis and Mantua 2003). While Francis and Mantua's (2003) studies focused on West Coast coho salmon, their results agree with those of previous studies that identify the first few months of the salmon's ocean life as the period of critical climatic influences on survival which, in turn, suggests that coastal and estuarine environments

are key areas of biophysical interaction. It seems likely that the polarity of the Pacific Decadal Oscillation climate pattern will continue to change at interdecadal time scales as it has over (at least) the past century.

7.3 Climate Change Effects on Ocean Conditions

Most climate factors affect the entire West Coast complex of salmonids. This is particularly true in their marine phase, because the California populations are believed to range fairly broadly along the coast and intermingle, and climate impacts in the ocean occur over large spatial scales (Schwing 2009). Because ocean warming will be widespread, populations at the southern extreme of their ranges will be most susceptible to future warming. Salmon and steelhead residing in coastal areas where upwelling is the dominant process are more sensitive to climate-driven changes in the strength and timing of upwelling. Coastal sea level is generally not a major issue along the West Coast, but future sea level rise will be important to juvenile fish in the San Francisco Bay and Delta, as well as in lagoons and estuaries where the annual cycle of bar development and breaching are important to salmonid life history strategies. Perhaps the greatest uncertainty is how ocean acidification will affect salmonids and their marine ecosystem (Schwing 2009). The following is a general discussion of anticipated future changes in ocean conditions, as they may affect off-shore areas used by winter- and spring-run Chinook salmon, and steelhead during their marine life stages.

7.3.1 California Current Ecosystem

The California Current Ecosystem (CCE) is designated by NMFS as one of eight large marine ecosystems within the United States Exclusive Economic Zone. The California Current begins at the northern tip of Vancouver Island, Canada and ends somewhere between Punta Eugenia and the tip of Baja California Mexico (NMFS 2009). The

northern end of the current is dominated by strong seasonal variability in winds, temperature, upwelling, plankton production and the spawning times of many fishes, whereas the southern end of the current has much less seasonal variability. For some groups of organisms, the northern end of the CCE is dominated by sub-arctic boreal fauna whereas the southern end is dominated by tropical and sub-tropical species. Faunal boundaries (i.e., regions where rapid changes in species composition are observed) are known for the waters between Cape Blanco Oregon/Cape Mendocino California, and in the vicinity of Point Conception California (**Figure 7-3**). Higher trophic level organisms often take advantage of the strong seasonal cycles of production in the north by migrating to the region during the summer to feed. Climate signals in this region are quite strong. During the past 10 years, the North Pacific has seen two El Niño events (1997/98, 2002/03), one La Niña event (1999), a four-year climate regime shift to a cold phase from 1999

until late 2002, followed by a four-year shift to warm phase from 2002 until 2006. The response of ocean conditions, plankton and fish to these events is well documented in the scientific literature. The biological responses are often so strong that the animals give early warning of events before such shifts are noticed in the physical oceanographic records (Osgood 2008). Numerous climate stressors (e.g., warming, sea level rise, freshwater flow) impact productivity and structure throughout the CCE. It is difficult to isolate the effect of individual stressors on most individual species, and most of these stressors impact many species at multiple trophic levels. Five climate-related issues are of greatest concern in the CCE (Osgood 2008). The following provides a summary of these issues, based upon the analysis developed as part of NMFS' framework for a long-term plan to address climate impacts on living marine resources (Osgood 2008).

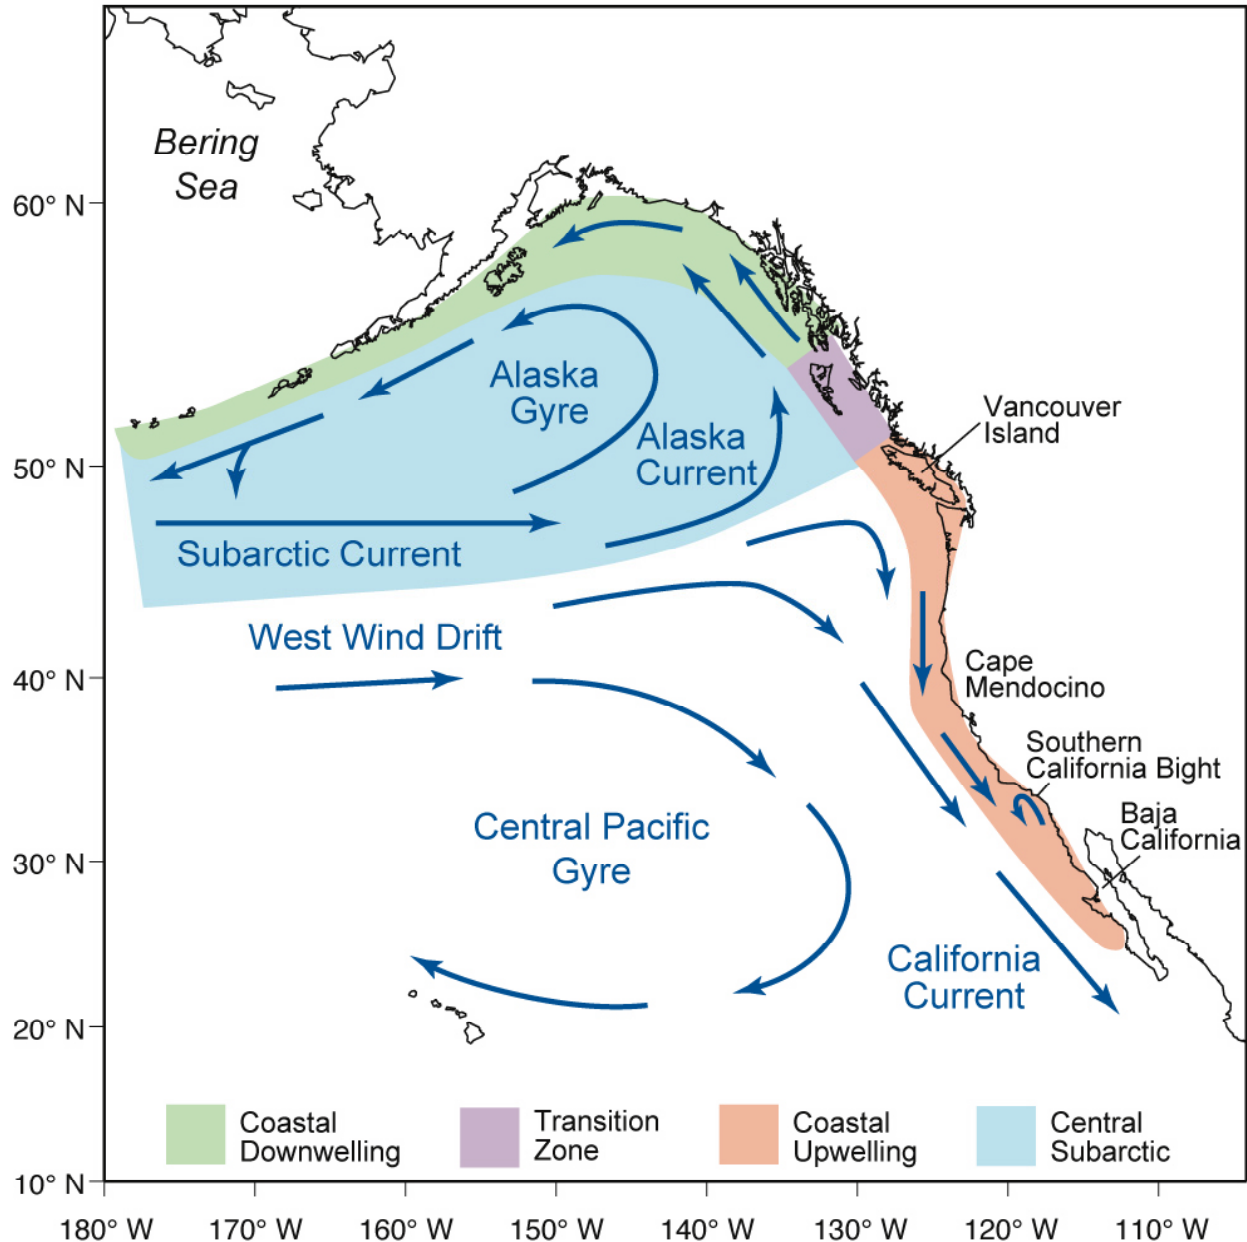

Figure 7- 3. The Principal Ocean Currents Affecting the Coastal Waters off of California. Eastward flow (West Wind Drift) bifurcates as it nears the west coast. The southward arm (the California Current) transports, cool, low salinity, nutrient-rich water along the U.S. west coast. (Source: Image from J.A. Barth, Oregon State University)

Increased Future Climate Variability

One of the likely consequences of global climate change will be a more volatile climate with greater extreme events on the intra-seasonal to inter-annual scales. For the CCE, more frequent and severe winter storms are expected to occur,

with greater wind mixing, higher waves and coastal erosion, and more extreme precipitation events and years, which would impact coastal circulation and stratification. Some global climate models predict a higher frequency of El Niño events; others predict that the intensity of these events will be stronger. If true, primary and secondary production will be greatly

reduced in the CCE, with negative effects transmitted up the food chain.

The Pacific Decadal Oscillation is a pattern of Pacific climate variability that shifts phases approximately every 20 to 30 years. During a “warm”, or “positive” phase, the west Pacific becomes cool and part of the eastern ocean warms; during a “cool” or “negative” phase, the opposite pattern occurs. Most models project roughly the same timing and frequency of decadal variability in the North Pacific under the impacts of global warming. However, combined with the global warming trend, the CCE is expected to experience a greater frequency of years consistent with historical periods of lower productivity (e.g., positive Pacific Decadal Oscillation values). Based on ongoing observations, a positive Pacific Decadal Oscillation and a warmer ocean result in dominance of small warm-water zooplankton (which are lipid-depleted), which may result in food chains with lower bioenergetic content. By about 2030, it is expected that the minima in decadal regimes will be above the historical mean of the 20th Century (i.e., the greenhouse gas warming trend will be as large as natural variability).

The Extent and Timing of Freshwater Input

While variability in ocean conditions has substantial impacts on salmon survival and growth, future changes in freshwater and river conditions also will have a great effect on production of anadromous fish. Warmer air temperatures will result in more precipitation earlier in the year, and less snowpack. Changes in the seasonal and inter-annual timing and intensity of rainfall and snowpack, for example, are expected to increase winter and spring runoff and decrease summer runoff. These hydrologic changes may alter the way that water supplies from the Sacramento River are managed for hydropower generation and water storage, which may affect the manner in which Chinook

salmon, steelhead and other estuarine-dependent species are managed.

Climate models project the 21st Century will feature greater annual precipitation in the Pacific Northwest, extreme winter precipitation events in California, and a more rapid spring snowmelt leading to a shorter, more intense spring period of river flow and freshwater discharge (Thomas et al. 2009). These changes are projected to considerably alter coastal stratification and mixing, riverine plume formation and evolution, and the timing of transport of anadromous fish populations to and from the ocean. A warmer and drier future also means that extra care will be needed in planning the allocation of water for the coming decades (Thomas et al. 2009). The current allocation of water resources between salmon and human requirements in the western United States has been a critical factor in the success of many salmon populations, and will be more so if future water availability is altered (Osgood 2008).

Changes in the Timing and Strength of the Spring Transition, and Their Resultant Effects on Marine Populations

The primary issue for the CCE is the onset and length of the upwelling season - when upwelling begins and ends (i.e., the “spring” and “fall” transitions). The biological transition date provides an estimate of when seasonal cycles of significant plankton and euphausiid production are initiated. At present, there is some evidence that coastal upwelling has become stronger over the past several decades due to greater contrasts between warming of the land (resulting in lower atmospheric pressure over the continent), relative to ocean warming. The greater cross-shelf pressure gradient will result in higher along-shore wind speeds and the potential for more upwelling (Bakun 1990). Regional climate models project that not only will upwelling-favorable winds will be stronger in summer, but that the peak in seasonal

upwelling will occur later in the summer (Snyder et al. 2003).

Even though southward winds that cause coastal upwelling are likely to increase in magnitude, these winds may be less effective in driving vertical transport of nutrient-rich water because it is not known if these winds will be able to over-ride increased water column stratification (Osgood 2008; NMFS 2009). That is, the winds may not be able to mix this light buoyant water or transport it offshore resulting in the inability of the cold nutrient-rich water to be brought to the ocean surface. Thus, phytoplankton blooms may not be as intense, which may impact organisms up the food chain (Roemmich and McGowan 1995).

Given that the future climate will be warmer, the upper ocean at the watershed scale will almost certainly be, on average, more stratified (Osgood 2008). This will make it more difficult for winds and upwelling to mix the upper layers of the coastal ocean, and will make offshore Ekman pumping less effective at bringing nutrients into the photic zone. The result will be lower primary productivity throughout the salmon marine habitat (with the possible exception of the nearshore coastal upwelling zones) (Osgood 2008).

Should global warming result in shorter winters in the Pacific Northwest, areas where production is light limited (e.g., the northern California Current) may see higher productivity (Osgood 2008). During most years since 2002, phytoplankton blooms are initiated as early as February off northern California in years when storm intensity is low. These early blooms result in bursts in egg production by both copepods and euphausiids, initiating a cohort of animals that reach adulthood one to two months earlier than a cohort that is initiated with the onset of upwelling during March or April. The result would be a longer plankton production season. Alternatively, regional climate projections are for a later shift in the start time, peak times and end of the upwelling season, which could counter the idea of a longer upwelling season (Osgood 2008).

Ocean Warming and Increased Stratification, and Their Resultant Effects on Pelagic Habitat

This issue focuses on the central and southern California Current, and on the organisms that utilize the upper ocean habitat in this region. Generally warmer ocean conditions will cause a northward shift in the distribution of most species, and possibly the creation of reproductive populations in new regions. Existing faunal boundaries are likely to remain as strong boundaries, but their resiliency to shifts in ocean conditions due to global climate change is not known (Osgood 2008). Warmer water temperatures also will affect freshwater salmon and steelhead habitats by reducing habitat opportunity on both spatial and seasonal time scales. In coastal and oceanic regions, the southern boundaries of pelagic habitats used by many populations are expected to shift northward.

Warmer air temperatures may lead to increased stratification of the coastal CCE. The warmer temperatures will increase the heat flux into the ocean. Mixing and diffusion are not likely to redistribute this heat rapidly enough to prevent an increase in thermal stability and stratification of the upper ocean (Osgood 2008). The vertical gradient in ocean water temperature off of the California coast has intensified over the past several decades (Palacios et al. 2004). Areas with enhanced riverine input into the coastal ocean will also see greater vertical stratification. Moreover, increased melting of glaciers in the Gulf of Alaska coupled with warmer sea surface temperatures will result in increased stratification. Because some of the source waters that supply the northern California Current originate in the Gulf of Alaska, more stratified source waters will contribute to increased stratification of coastal waters of the northern California Current (Osgood 2008).

Changes to Ocean Circulation and Their Resultant Effects on Species Distribution and Community Structure

NMFS (2008) states that this is a climate-induced ecosystem concern primarily for the northern California Current, although changes in transport are known to have subtle effects on the entire Current. A particular biological concern is related to the variability in the transport of organisms, which impacts zooplankton species composition and regional recruitment patterns for demersal fish stocks.

As previously discussed, the California Current extends from the northern tip of Vancouver Island, Canada to southern Baja California, Mexico. As the current flows from north to south, the waters warm and mix with offshore waters such that both temperature and salinity increase gradually in a southward direction (Osgood 2008). Observations of the biota of the California Current show that there are pronounced latitudinal differences in the species composition of plankton, fish, and benthic communities, ranging from cold water boreal sub-arctic species in the north to warm water subtropical species in the south. Changes in abundance and species composition can be gradual in some cases, but it is widely accepted that faunal boundaries (zones of rapid change in species composition) are present in the waters in the vicinity of Capes Blanco and Mendocino, and at Point Conception.

The strongest contrasts are observed during summer (Osgood 2008).

The strong contrast in species composition between shelf and offshore waters during summer is due to the upwelling process. A combination of upwelling itself, along with the sub-arctic water which feeds the inshore arm of the northern end of the CCE, create conditions favorable for development of a huge biomass of sub-arctic zooplankton. This pattern is slightly modified as a function of the phase of the Pacific Decadal Oscillation. During a cool phase, all of the northern CCE becomes more sub-Arctic in character (both shelf-slope-oceanic regions); during a warm phase of the Pacific Decadal Oscillation, the water masses and associated copepod community become far more similar to a sub-tropical community. Copepod biodiversity increases in coastal waters, due to shoreward movement of offshore waters onto the continental shelf, due to either weakening of southward wind stress in summer or strengthening of northward wind stress in winter. Thus, when Pacific Decadal Oscillation is in a positive phase, a greater proportion of the water entering the northern end of the current is sub-tropical in character rather than sub-Arctic.

Regardless of the season, the source waters that feed into the California Current from the north and from offshore can exert some control over the phytoplankton and zooplankton species that dominate the current (**Figure 7-4**).

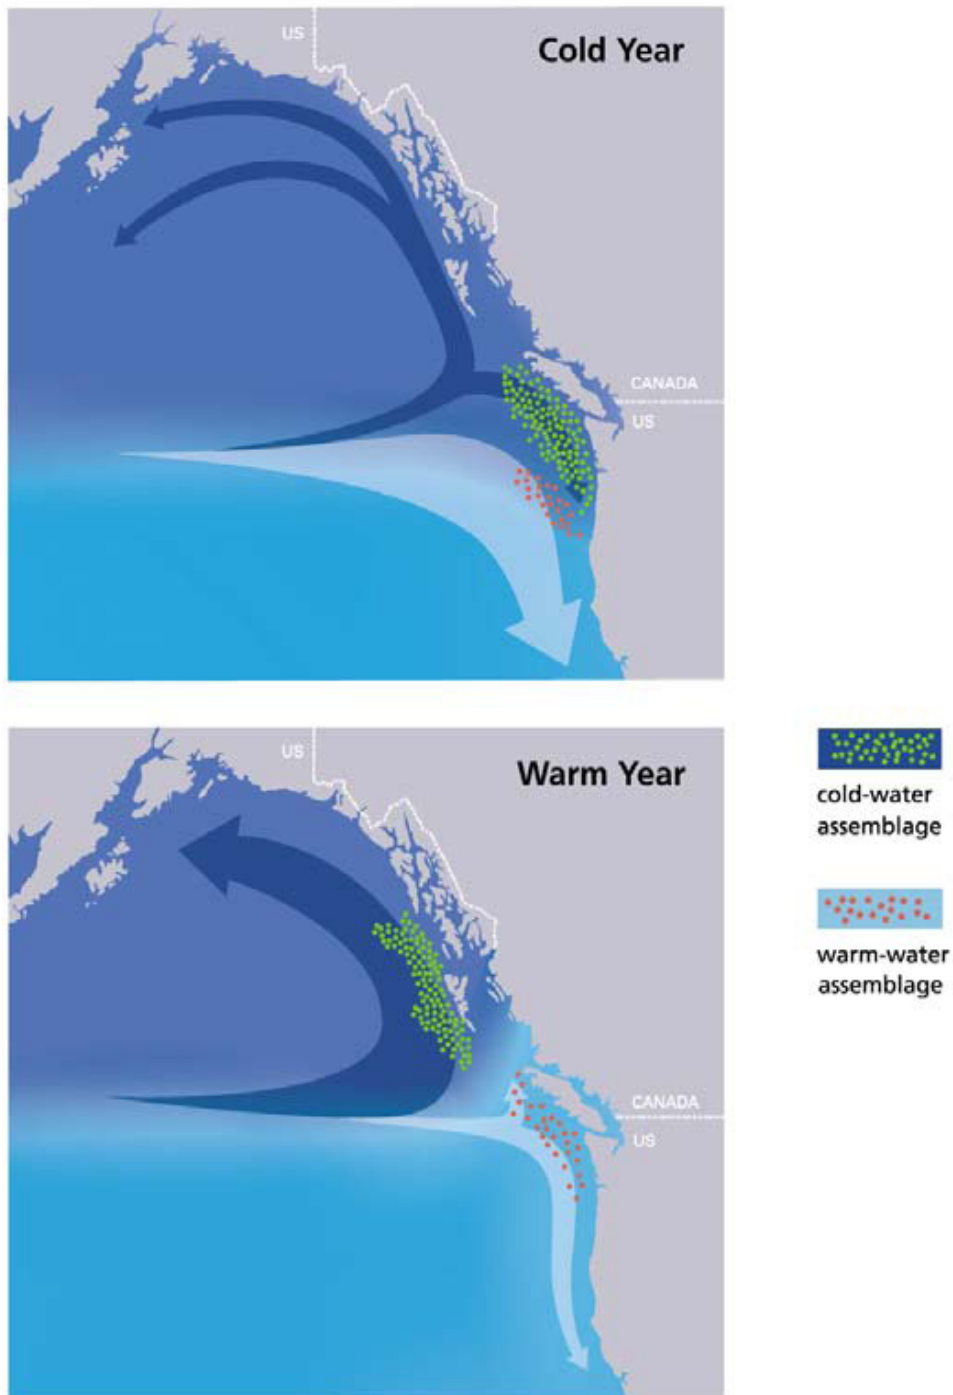

Figure 7-4. Schematic of the Flow of the North Pacific Current South into the California Current and North into the Gulf of Alaska. Cool years (such as La Niña and negative PDO years) are associated with greater flow into the California Current, which favors a southward displacement of coldwater and warmwater species. (Source: Osgood 2008)

Hooff and Peterson (2006) suggest that knowledge of source waters is critical to understanding ecosystem dynamics in the shelf waters of the Northern CCE because waters from the Gulf of Alaska carry large, lipid-rich copepods to the shelf waters, whereas waters coming from an offshore source carry small, oceanic lipid-poor copepods to the shelf waters. Thus, changes reflected by Pacific Decadal Oscillation shifts may result in local food chains that have considerably different bioenergetic content. Given, for example, that: (a) salmon returns are low when the Pacific Decadal Oscillation is in a positive, warm water phase, but high when the Pacific Decadal Oscillation is in a negative, cold-water phase; and (b) salmon returns to Pacific Northwest rivers are highly correlated with copepod community structure (Peterson and Schwing 2003), variations in the bioenergetic content of the food web may represent a mechanistic link between Pacific Decadal Oscillation sign change and salmon survival (Osgood 2008).

Northward shifts in distribution also are possible. Generally warmer conditions could result in a northward shift in the distribution of some species, and possibly the creation of reproductive populations in new regions. Alternatively, if upwelling strengthens due to global climate change, regardless of the sign of the Pacific Decadal Oscillation, cold-water species should still be favored in the coastal upwelling zones (Osgood 2008). However, the onshore-offshore gradients in temperature and species abundance should strengthen if offshore waters become warmer and upwelling becomes stronger, creating stronger upwelling fronts, and perhaps a greater level of mesoscale activity. It is unclear how faunal boundaries might be affected (Osgood 2008).

7.4 Recommended Strategies for Considering Climate Effects and Application to Recovery Planning

While climate change clearly cannot be easily slowed or reversed, its impacts can be identified

and mitigated at local scales (Schwing 2009). Based on the information presented above, it is possible to determine a relatively small set of regional physical factors of future climate change, which can be useful in targeting recovery of Chinook salmon and steelhead (Schwing 2009). In consideration of the differences in particular climate impacts to a domain, and the sensitivity of their salmon and steelhead stocks to climate change and other stressors, we can begin to recommend planning actions for each domain.

Compared to marine conditions, differences in the freshwater impacts of climate change are believed to be greater between domains, due largely to regional variability in precipitation and runoff, combined with a wide variety of watershed types and features and a range of other human pressures on those systems (Schwing 2009). As with their ocean phase, salmonid stocks will be more thermally stressed by stream warming at the southern ends of their ranges. Warming also is stressful in systems that are shallow and have lower flows in summer, and where access to cooler reaches is restricted by existing human barriers. Increased sedimentation will occur in concert with shifting forest and vegetation patterns, but will be less of a concern in shorter and stronger flowing streams and greater in systems where the other consequences of climate change will be formidable to salmonids. All domains are threatened by future alterations in flow regimes, and more so when there are other demands for water resources. Domains dependent on runoff from Sierra snowmelt are at greatest risk of seasonal change (Schwing 2009).

From this broad and initial assessment, and other information presented in this Recovery Plan in the Watershed Profiles (Appendix A), the Threats Assessment (Appendix B) and the Recovery Scenarios (Chapter 5), it appears that the combination of climate change impacts to freshwater and marine habitats utilized by Chinook salmon and steelhead, as well as the long history of a variety of human stresses, pose some of the greatest threats to the Central Valley

ESUs/DPS. The steelhead DPS and the Chinook salmon ESUs possess an elastic life history strategy, and those populations residing in unaltered watersheds are more likely to withstand the pressures of future climate change (Schwing 2009). In addition, Francis and Mantua (2003) offer several recommendations regarding salmonid vulnerabilities to climate fluctuations, and discuss possible strategies to preserve and enhance salmon meta-population resilience in the face of climate fluctuations. These considerations also are useful when planning for recovery, and have been incorporated into the conceptual recovery scenarios developed for winter- and spring-run Chinook salmon and steelhead.

- ❑ Climate alone is not likely to tip the balance. However, climate variability clearly has the capacity to amplify the risk and likelihood of extinction when superimposed upon salmonid ecosystems under extreme stress from humans
- ❑ Because climate-related effects on salmon appear to be much more significant at interdecadal than annual time scales, and because interdecadal time-scale climate change can only be recognized in hindsight, the effects of climate change need to be incorporated into fishery management policy (e.g., different management strategies and algorithms may be required for different climatic regimes)
- ❑ Climate-related negative impacts on salmon production at the regional scale likely have much more severe implications for individual breeding populations than for meta-populations as a whole. Clearly, this has been the case for thousands of years. However, combining the effects of human activities with climate fluctuations likely amplifies a number of these negative influences.

According to Francis and Mantua (2003), it is believed that salmon populations in regions with healthy habitat will probably survive, as long as the time scale of environmental change does not exceed their rate of adaptation. Enhancement of connectivity also will be a vitally important form of restoration in any strategic response to climate change (Bakke 2009). Those populations that are presently stressed by occupying healthy, marginal or fragmented habitat, will most likely face more acute threats of extinction with the additional burden of significant anthropogenic climate changes (Francis and Mantua 2003).

In addition to other restoration and threat abatement actions, recovery efforts should address how human behavior may be used or altered to mitigate and adapt to climate change. It is possible that these anthropogenic changes will be accentuated as the global climate continues to warm, and may lead to impacts to California's water resources and water project operations (Anderson et al. 2008). Examples include changes in water allocation patterns, population shifts and watershed development, and energy production that may further damage habitat (e.g., power generating dams) or provide alternative mechanisms (e.g., tidal and wave energy systems) that will not affect salmon habitat or add to atmospheric greenhouse gas concentrations. Schwing (2009) states that recovery efforts need to include actions that prepare infrastructure for future long-term adaptation and potential mitigation to address future climate change. This includes approaches to habitat restoration, fishing effort and catch limits, and hatchery production. Schwing (2009) also suggests that managers may wish to consider climate impacts in activities such as:

- ❑ Ecosystem restoration, including in-river habitat
- ❑ Enhancing connectivity between higher quality streams or river segments
- ❑ Enhancing restoration recovery programs,

for wild populations and selected habitats (e.g., Delta and river floodplains)

- Hatchery reforms
- Trucking and release of juvenile Chinook salmon populations
- Changes in production of selected threatened and non-threatened runs

As part of recovery planning efforts, future management actions must enhance system and population resilience, and identify the populations that are both most resilient and most vulnerable to environmental factors affected by climate change (Schwing 2009). It will be necessary to commit considerable resources to protect and reduce the threats of climate and other human actions to the least resilient salmonid populations, while it may eventually be determined that the most resilient populations must be protected and sustained in a limited resource environment.

7.5 Climate Change in Relation to Central Valley Domain Recovery

In California, there have been observed changes in air temperatures, annual precipitation, runoff, and sea levels over the past century (Anderson et al. 2008). Regional-scale climate models for California are in broad agreement that temperatures in the future will warm significantly, total precipitation may decline, and snowfall will decline significantly (Lindley et al. 2007). Literature suggests that by 2100, mean summer temperatures in the Central Valley may increase by 2 to 8°C, precipitation will likely shift to more rain and less snow, with significant declines in total precipitation possible, and hydrographs will likely change, especially in the southern Sierra Nevada mountains. Thus, climate change poses an additional risk to the survival of salmonids in the Central Valley. As with their ocean phase, Chinook salmon and steelhead will be more thermally stressed by stream warming at the

southern ends of their ranges (e.g., Central Valley Domain). For example, warming at the lower end of the predicted range (about 2°C) may allow spring-run Chinook salmon to persist in some streams, while making some currently utilized habitat inhospitable (Lindley et al. 2007). At the upper end of the range of predicted warming, very little spring-run Chinook salmon habitat is expected to remain suitable (Lindley et al. 2007).

The complex life history of salmonids as well as the complexity of their multiple aquatic habitats makes it difficult to isolate what environmental factors, or drivers, are responsible for variability in these populations (Schwing 2009). Overall, the climate-species linkages for salmon are extremely complex. In a recent report to the Pacific Fishery Management Council, CDFG identified 46 possible reasons for the collapse of the 2004 and 2005 broods of Central Valley fall-run Chinook salmon. It is difficult to isolate the immediate effect of an individual stressor on a species, and most stressors impact many species at multiple trophic levels. Further, it is not likely that there is one single stressor, but a combination of several factors that drive ecosystem variability and change (Schwing 2009). Nevertheless, it is possible to focus on a relatively small number of factors that are sufficiently sensitive to climate change and impact the populations and freshwater and marine ecosystems of California anadromous salmonids.

This Recovery Plan addresses the Central Valley steelhead DPS, and two Chinook salmon ESUs - Sacramento River winter-run Chinook salmon, and Central Valley spring-run Chinook salmon. Because of their extended use of the Sacramento and San Joaquin River systems, they are very dependent on runoff from the Sierra snowpack and the variability of precipitation affecting it (Osgood 2008), as previously discussed. The future climate of the freshwater habitats of the Central Valley Domain is expected to include:

- More frequent intense winter storms, high stream flow events, and floods

- ❑ Earlier snowmelt, with higher peak flows in winter, less spring runoff, and much lower summer flows
- ❑ Considerably warmer stream, river and ocean water temperatures during the summer
- ❑ Greater inter-annual precipitation variability, more frequent wet and drought years, and extended droughts
- ❑ Years with weaker fall storms, and delays in the onset of high stream flows
- ❑ More frequent wildfires and infestations, and increased erosion and sedimentation
- ❑ Delays in the onset of coastal upwelling, and associated delayed biological production
- ❑ Declining ocean conditions
- ❑ Sea level rise and more saline estuarine and Delta conditions

An important distinction in the winter-run and spring-run Chinook salmon ESUs is the timing of their life history events, which has implications for different climate change impacts. Winter-run Chinook salmon adults return and migrate upstream in winter through early spring, where they hold for several months before spawning in late spring and summer (Williams 2006). This provides an advantage over the spring- and late fall-runs of longer stream rearing times without juvenile fish having to over-summer (Yoshiyama et al. 1998). However, incubation, the most temperature-sensitive life stage, coincides with the time when river temperatures can exceed the lethal range for embryo incubation. Thus, winter-run Chinook salmon occur currently only in the Sacramento River, where summer water temperatures are cool enough to enable successful embryo incubation, but warm enough in winter to

support juvenile rearing (Stillwater 2006 in Schwing 2009). They also spawn in deeper water than other populations (Moyle 2002). Juvenile winter-run Chinook salmon have historically exploited the floodplain habitat created by winter flooding in the Sacramento River Basin, which results in higher juvenile growth rates and presumably higher ocean survival (Sommer et al. 2001 in Schwing 2009).

The life history of spring-run Chinook salmon is to migrate upstream in spring, hold through the summer in deep pools, and then spawn in early fall, with juveniles emigrating after either a few months or a year in freshwater. However, they have considerable flexibility in their life history strategies. Age at spawning for spring-run Chinook salmon varies from two to four years.

Central Valley watersheds are fed predominantly by runoff from Sierra snowmelt, which has been historically highest during the late spring and early summer. The resulting high flow allows Chinook salmon to reach their summer holding areas, while the lower flow extending from the summer into early fall is cool enough for spawning. In the San Joaquin River drainage, snowmelt at high elevations produced a long runoff period that benefited Chinook salmon, making them the dominant run in the region. However, the recent trend toward an earlier seasonal runoff and lower flow in spring and summer has reduced the potential for survival in these watersheds, and will make the transit of adults returning to their spawning streams more difficult (see watershed profile information for individual rivers located in the Southern Sierra Nevada Diversity Group).

Because eggs and juveniles are less tolerant of warm water temperatures, spawning occurs during the fall, after streams cool. On their migration to the ocean, juvenile fish access temporary habitats with warmer water temperatures and abundant food in floodplain, tidal marsh, and estuarine habitats. These habitats are very important in smolt growth and survival -

smolt size at ocean entry strongly affects survival during the first year at sea (Williams 2006). After reaching the ocean in the late spring and summer, smolts forage near the coast on crustaceans, euphausiids, and prey fishes (MacFarlane and Norton 2002) that is associated with upwelling. Smolt survival over their first winter is dependent on a threshold of prey and the resultant smolt condition after the first summer at sea (Williams 2006).

Because of their close proximity, a relatively small wildfire could simultaneously burn the headwaters of all three remaining spring-run Chinook populations. Such a fire has a 10 percent chance of occurring in any given year in California (Lindley et al. 2007), but this probability will increase due to climate change. Prolonged drought due to lower precipitation shifts in snowmelt runoff, and greater climate extremes could also easily render most existing spring-run Chinook salmon habitat unusable, either through temperature increases or lack of adequate flows.

Increased water temperature, low flow, drought and other climate-related events will compound the threats to Chinook salmon due to human manipulation of their freshwater habitats. Because of these watersheds' great dependence on Sierra snowpack melt, the projected shift toward earlier runoff (Dettinger and Cayan 1995; Cayan et al. 2001) will exacerbate sensitivity to low flow and warm stream conditions at critical lifestages. Winter-run Chinook salmon are especially vulnerable to climate warming, prolonged drought, and other catastrophic climate events, because they have only one remaining population that spawns in the hottest time of the year (also see the conceptual recovery scenario for winter-run Chinook salmon). Additionally, future ocean productivity will decline due to altered upwelling cycles, thus reducing prey availability and salmon ocean survival (NMFS 1997 in Schwing 2009).

Central Valley steelhead also exhibit a flexible life history, allowing them to compensate for the variable conditions and extremes of their habitat

(McEwan 2001). Most juveniles remain in their streams for one or two years before becoming smolts and emigrating out to the Delta and ocean (Hallock 1961 in Schwing 2009). Others may remain in the rivers their entire lives. Temperature and water quality are critical factors for fry and juvenile survival (Moyle 2002). Fry move into cooler, deeper, faster-flowing channels in the late summer and fall (Hartman 1965, Everest and Chapman 1972, and Fontaine 1988 in Schwing 2009). Juvenile steelhead prefer deep pools with heavy cover, as well as higher-velocity rapids (Bisson et al. 1982, 1988 and Dambacher 1991 in Schwing 2009).

The distribution of steelhead today is greatly reduced from the historical distribution. Dams and water diversions limit steelhead access to less than 20 percent of their historical spawning and rearing areas in the Central Valley (Yoshiyama et al. 2001; Lindley et al. 2006). Climate warming will further restrict access to cool water streams. Most of the same climate factors that affect other California steelhead populations are critical to Chinook salmon. The diversity and variability of their life history complicates their management. Yet this same attribute reduces their vulnerability to climate change.

Additionally, the Central Valley TRT (Lindley et al. 2007) reports that low flows during juvenile rearing and outmigration are associated with poor survival (Kjelson and Brandes 1989; Baker and Morhardt 2001; and Newman and Rice 2002) and poor returns in subsequent years (Speed 1993). Climate change also may impact Central Valley salmonids through community effects. For example, warming may increase the activity and metabolic demand of predators, reducing the survival of juvenile salmonids (Vigg and Burley 1991).

7.6 Additional Considerations Applied to the Conceptual Recovery Scenarios

Currently, there is little information in the literature on the geomorphic effects of climate change (Bakke 2009). Most of the existing research has focused on the impacts to climate itself and to gross-scale hydrological change. Tools for predicting geomorphic impacts at specific locations are possible, but poorly developed. However, the general principles discussed below can be used to suggest ways to screen the landscape for habitat that is potentially resilient or sensitive to climate change. Development of such screening tools may ultimately provide a systematic and consistent way to address recovery, restoration, and conservation in the context of climate change (Bakke 2009).

Taking into consideration species- and watershed-specific information (see watershed profiles in Appendix A for more detail), each of the concepts described below were either directly or indirectly incorporated in the conceptual recovery scenarios for winter-run Chinook Salmon, spring-run Chinook salmon and steelhead within the Central Valley Domain.

7.6.1 Resiliency

In ecology, resiliency carries the additional meaning of how much disturbance a system can "absorb" without crossing a threshold and entering an entirely different state of equilibrium (e.g., distinctly different physical habitat structure or conditions) (Bakke 2009). In regard to recovery, habitat restoration, and conservation of at-risk aquatic species, resiliency also requires that certain key habitat characteristics or processes will change little, or not at all, in response to climate change. When it comes to stream aquatic habitat, the most important elements to remain steady are temperature and disturbance regime (Bakke 2009). Resiliency is temporally dependent and given

enough time, large disturbances are virtually certain to occur on the landscape and to the climate. Resiliency can only function on a landscape scale; there must be enough individual rivers available with the appropriate habitat and connectivity so that a disturbance to one portion of the system has a minimal impact on at-risk aquatic species because other parts of the system are able to support sensitive populations through the recovery and recolonization period (Bakke 2009).

In the long-term, there is no substitute for a landscape that offers redundancy of habitat opportunities. Many of the features that make up high-quality salmonid habitat, such as buried organic matter, large gravel deposits, side channels, and logjams, for example, are relics of the legacy of past disturbances. The issue is not to shun stream reaches that are more prone to disturbance, but to identify and work with stream reaches that are likely to have a consistent disturbance regime as opposed to ones that will drastically change as the climate continues to change. This will assure that the habitat identified retains its physical morphology and patterns of cyclic evolution rather than shifting to some different, and presumably less stable, habitat type. In essence, the strategy suggested is to provide multiple interconnected refugia which undergo severe disturbances at differing periods of time (Bakke 2009).

7.6.2 Refugia

Refugia are places in the landscape where organisms can go to escape extreme conditions (Bakke 2009). Typically, this refers to short-term conditions such as floods or high water temperatures. But in the context of climate change, refugia can also be places where a population may persist through decades and centuries of unfavorable climate conditions and instability. For coldwater obligate fish species, refugia will continue to be areas where groundwater emergence influences water temperature and volume. These refugia will exist on several scales: (1) local areas of cool water emergence within a

reach otherwise insufficiently cool; and (2) entire stream systems where groundwater hydrology is dominant or snowmelt hydrology is preserved due to high elevations. Thus, the same set of circumstances producing cool water conditions in the current landscape may, to varying degrees, produce thermal refugia against global warming. Maintaining connectivity amongst these refugia will be difficult. It will be important to protect these areas and in some cases to enhance them or improve their connectivity (Bakke 2009).

7.6.3 Restoration

Enhancement of connectivity will be a vitally important form of restoration in any strategic response to climate change. Restoration has traditionally been driven by a combination of political and biological considerations. If scarce restoration funds are to be targeted for species recovery in the face of climate change, it is highly important that a site-selection hierarchy based on resource values, and a hierarchy of priority actions based on long-term sustainability be followed. Sustainable restoration includes activities which reestablish the structure and function of the stream ecosystem in a manner that the ecosystem will become self-maintaining. Site selection should prioritize areas of high resource value, tempered by considerations of resiliency to climate change. Areas of high resource value would include strongholds and refugia. Highest priority actions in these areas would be protection of good habitat, improving connectivity and access to existing habitat not currently occupied, and only then followed by process-based restoration of lower quality habitat. All actions should be analyzed in relation to sustainability, resiliency, and threats from climate change.

When river restoration is performed, or when “fish friendly” river engineering is contemplated, the dynamic nature of climate change effects makes redundancy of actions desirable. Redundancy can be applied in both horizontal and vertical dimensions. Building engineered log jam structures higher and bulkier than current design practice to accommodate larger peak flows in the future would be one simple example of vertical redundancy. Horizontal redundancy would include the placement of structures in currently inactive side channels to assure function in the event of channel avulsions or accelerated channel migration.

In addition, restoration site selection will need to consider geomorphic instability. Some of the most productive spawning areas for many fish are in sensitive response reaches, which are likely to undergo an episode of geomorphic instability because of climate change. If active restoration, such as enhancement of instream habitat with large wood, is to be performed in potentially unstable settings, it will be important to design these projects with the appropriate level of redundancy to accommodate greater rates of channel migration and flood magnitudes. This potential needs to be incorporated into discussions of the definition of success, long-term sustainability, and cost of the project. Passive restoration techniques, such as establishment of wider riparian buffers, may be a more sustainable alternative in light of increased geomorphic instability caused by global warming.

8.0 Implementation and Cost Estimates

“Although recovery actions can, and should, start immediately upon listing a species as endangered or threatened under the ESA, prompt development and implementation of a recovery plan will ensure that recovery efforts target limited resources effectively and efficiently into the future.”

NMFS 2006. Interim Endangered and Threatened Species Guidance

8.1 Time and Cost

Section 4(f) of the ESA requires that recovery plans include “estimates of the time required and the cost to carry out those measures needed to achieve the Plan’s goal and to achieve intermediate steps toward that goal” (16 U.S.C. 1531-1544, as amended). NMFS estimates that recovery for listed Central Valley salmon and steelhead, like for most of the ESA-listed Pacific Northwest salmon and steelhead, could take 50 to 100 years. While there is an extensive list of actions that need to be undertaken to recover the listed Central Valley salmonids, there are many uncertainties involved in predicting the course of recovery and in estimating total costs. Such uncertainties include biological and ecosystem responses to recovery actions as well as long term and future funding.

Obtaining and evaluating cost estimates for recovery actions can be challenging, and projecting costs into the future becomes increasingly imprecise. NMFS believes it is impracticable to estimate all projected actions and costs over 50 to 100 years, given the large number of economic, biological, and social variables involved, and that it is more appropriate to initially focus on the first five or 10 years of implementation.

The Southwest Fisheries Science Center (SWFSC) produced a draft report providing information on costs associated with restoration activities (**Appendix E**). Data from publicly available sources were used to obtain estimates of restoration costs for a variety of restoration activities. All costs described in the report pertain to direct expenditures on restoration and do not include economic opportunity costs (*e.g.*, foregone profits associated with restrictions on livestock grazing, timber harvest and other activities). Many cost estimates for restoration activities in the Central Valley are specifically based on CALFED Ecosystem Restoration Program (ERP) implementation and/or contracted costs (most notably fish screening projects, gravel supplementation, channel restoration, bank stabilization, land acquisition, conservation easements, proposed watershed effectiveness monitoring, and a 5-dam decommissioning and removal project), so are specific to the Central Valley and are referenced as such in the draft report. Also, levee-related and water purchase/lease activity cost estimates for the Central Valley were included in the report, based on information from DWR, county water agencies, and ERP. Irrigation ditch activity costs, including water control structures, were developed from information from county water agencies in the Central Valley. The rest of the draft report contains extensive data from the northernmost part of California, Oregon, Washington, and Idaho, where costs (labor, materials, equipment, *etc.*) may be lower than in the Central Valley of California.

The report offers ranges of costs applicable at the ESU scale. Actual costs may vary widely from one watershed to another and across the extent of the Central Valley Domain due to potential differences in regional labor costs, property values, availability of expert contractors and materials, and permitting issues, etc.

Many of these costs would likely be born through necessary changes in California's water system as a result of current increased demands or from other ongoing or planned conservation programs or regulatory mechanisms. Many of the recovery actions seek to remedy effects of projects authorized before the country and States cornerstone environmental laws such as the Clean Water Act, the Clean Air Act, the National Environmental Policy Act, the California Environmental Quality Act, and the State and Federal Endangered Species Act.

Recovery of listed Central Valley salmon and steelhead will have significant costs, but will also provide economic benefits. Recovery actions taken on behalf of Sacramento River winter-run and spring run Chinook salmon and Central Valley steelhead are likely to benefit other listed species in the Central Valley Domain, including fall and late-fall-run Chinook salmon, thus increasing the cost effectiveness of the actions. Habitats restored to highly functioning conditions offer tangible benefits such as improved water quality, and less tangible benefits such as reduced expenditures on bank stabilization or flood control. Restoration activities will generate positive socioeconomic benefits. Because of their direct and indirect economic value as a resource for fishing, recreation and tourism related activities, each dollar spent on salmon recovery may generate thousands of dollars for local, state, Federal, and tribal economies. In other words, salmon recovery is best viewed not as a cost, but as an investment and opportunity to derive, diversify, and strengthen the economy. The dollars required to recover salmon should be made available without delay such that the benefits can begin to accrue as soon as possible.

Importantly, the general model for viewing cost versus benefits must be viewed in terms of long-term benefits derived from short term costs.

Without factoring the economic benefits associated with recovery, and simply focusing on the cost to implement recovery actions, the cost is estimated to range from \$1,040,695,000 to \$1,260,695 over the next five years. Extending the 5 year implementation costs over 50 years may cost nearly \$10,406,950,000.

8.2 Implementation Table

Information related to the implementation of Priority 1 recovery actions is presented in Table 8-2. Priority 1 actions are those critical actions that must be taken to prevent extinction or to prevent the species from declining irreversibly. Priority 2 actions must be taken to prevent a significant decline in species population/habitat quality or in some other significant negative impact short of extinction. Priority 2 actions are presented in Appendix C. All priority 1 actions have been assigned a specific number beginning with the number 1 (e.g., 1.1, 1.2, etc.), while all priority 2 actions are identified by a numbering system starting with 2.

Priority 1 recovery actions have been categorized into eleven geographic scales or regions:

- 1.1 Throughout California
- 1.2 Throughout the Central Valley
- 1.3 Pacific Ocean
- 1.4 San Francisco Bay
- 1.5 Delta
- 1.6 Mainstem Sacramento River
- 1.7 Northwestern California Diversity Group
- 1.8 Basalt and Porous Lava Diversity Group
- 1.9 Northern Sierra Nevada Diversity Group
- 1.10 Mainstem San Joaquin River
- 1.11 Southern Sierra Nevada Diversity Group

Table 8-2. Implementation table for priority 1 recovery actions.

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
Throughout California	Winter-run Spring-run Steelhead	Water management	1.1.1 Implement Federal, State, and local initiatives and programs to improve water conservation in order to reduce state-wide water use by 20 percent per capita by 2020. This effort should take into account regional differences and find ways to improve agricultural efficiency as well as urban water use efficiency.	Year 1 through year 10	Agriculture industry, city and county planners, DWR, Reclamation, SWRCB	\$5 million
Throughout Central Valley	Winter-run Spring-run Steelhead	Harvest, hatchery effects, habitat loss and degradation, and water management	1.2.1 Promote Central Valley resource managers to cooperatively develop and implement an ecosystem based management approach that integrates harvest, hatchery, habitat, and water management, in consideration of ocean conditions and climate change.	Year 5 through year 10	CDFG, DWR, NMFS, PFMC, Reclamation, SWRCB, USFWS	\$2 million
Throughout Central Valley	Winter-run Spring-run Steelhead	Habitat loss and degradation	1.2.2 Support programs to provide educational outreach and local involvement in restoration, including programs like Salmonids in the Classroom, Aquatic Wild, Adopt a Watershed, school district environmental camps, and other programs teaching the effects of human land use on anadromous fish survival.	Year 1 through year 20	CDFG, DWR, NMFS, PFMC, Reclamation, SWRCB, USFWS	\$500,000
Throughout Central Valley	Winter-run Spring-run Steelhead	Habitat degradation	1.2.3 Develop a monitoring program to determine the level of entrainment at individual diversions. Prioritize diversions based on this monitoring and screen those that are determined to have the greatest impacts on juvenile survival.	Year 5 through year 10	CDFG, DWR, NMFS, USFWS	\$1 million
Throughout Central Valley	Winter-run Spring-run	Habitat degradation	1.2.4 Provide additional funding for increased law enforcement to reduce illegal take of anadromous fish, stream alteration, and water pollution and to ensure adequate protection for juvenile fish at	Year 1 through year 20	CDFG, NMFS	6.25 million

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
	Steelhead		pumps and diversions.			
Throughout Central Valley	Winter-run Spring-run	Habitat degradation	1.2.5 Control or relocate the discharge of irrigation return flows and sewage effluent, and restore riparian forests to help provide suitable water temperatures for anadromous salmonids.	Year 2 through year 10	ACOE, City and County planners, NMFS, SWRCB, USFWS	\$50 million
	Steelhead					
Throughout Central Valley	Winter-run Spring-run	Habitat degradation	1.2.6 Implement and evaluate actions to minimize and/or eliminate the effects of exotic (non-native invasive) species (plants and animals) on production of anadromous fish.	Year 1 through year 10	Department of Boating and Waterways	\$2 million
	Steelhead					
Throughout Central Valley	Winter-run Spring-run	Habitat degradation	1.2.7 Restore tributaries by evaluating the feasibility of screening or relocating diversions, switching to alternative sources of water for upstream diversions, restoring and maintaining a protected riparian strip, limiting excessive erosion, enforcing dumping ordinances, removing toxic materials or controlling their source, replacing bridge and ford combinations with bridges or larger culverts and installing siphons to prevent truncation of small streams at irrigation canals, and implement actions to address harmful effects.	Year 1 through year 20	Caltrans, USFS, SWRCB	Details provided for specific watersheds below
	Steelhead					
Throughout Central Valley	Winter-run Spring-run	Habitat loss	1.2.8 Conduct Central Valley-wide assessment of keystone dams and passage opportunities and implement programs to restore access to properly functioning habitat that was historically available.	Long-term with evaluations beginning in year 1. Long term implementation may begin by year 20	CDFG, DWR, NMFS, Reclamation, USFWS, USFS	Details provided for specific watersheds below
	Steelhead					

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
Throughout Central Valley	Winter-run	Habitat loss	1.2.9 Evaluate passage at small dams or other anthropogenic obstructions and implement fish passage per NMFS criteria.	Year 1 through year 10	CDFG, DWR, NMFS, Reclamation, USFWS, USFS	Details provided for specific watersheds below
	Spring-run					
	Steelhead					
Throughout Central Valley	Winter-run	Water management	1.2.10 Increase integration of the State and Federal water projects through shared storage and conveyance agreements.	Year 5 through year 20	DWR, Reclamation	No cost agreements
	Spring-run					
	Steelhead					
Throughout Central Valley	Winter-run	Water management	1.2.11 Secure agreements with or purchase water rights from landowners and Federal and State agencies to provide additional instream flows.	Year 1 through year 10	DWR, Reclamation, county water agencies	No cost agreements
	Spring-run					
	Steelhead					
Throughout Central Valley	Winter-run	Hatchery effects	1.2.12 Form a hatchery science review panel to review Central Valley hatchery practices. The panel should address the issues contained within the following six hatchery-related actions.	Year 1 through year 5	CDFG, DWR, NMFS, Reclamation, USFWS	\$1 million
	Spring-run					
	Steelhead					
Throughout Central Valley	Winter-run	Hatchery effects	1.2.13 Evaluate impacts of outplanting and broodstock transfers among hatcheries on straying and population structure and evaluate alternative release strategies.	Year 3 through year 20	CDFG, DWR, NMFS, Reclamation, USFWS	See previous
	Spring-run					
	Steelhead					
Throughout Central Valley	Winter-run	Hatchery effects	1.2.14 Evaluate whether production levels are appropriate and if they could be adjusted according to expected ocean conditions.	Year 1 through year 10	CDFG, DWR, NMFS, Reclamation, USFWS	See previous
	Spring-run					

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
	Steelhead					
Throughout Central Valley	Winter-run Spring-run	Hatchery effects	1.2.15 Evaluate the potential to modify hatchery procedures to benefit native stocks of salmonids and implement beneficial modifications.	Year 1 though year 5	CDFG, DWR, NMFS, Reclamation, USFWS	See previous
	Steelhead					
Throughout Central Valley	Winter-run Spring-run	Hatchery effects	1.2.16 Evaluate and avoid potential competitive displacement of naturally produced juvenile salmonids with hatchery-produced juveniles by implementing release strategies for hatchery-produced fish designed to minimize detrimental interactions.	Long-term, beginning in year 1	CDFG, DWR, NMFS, Reclamation, USFWS	See previous
	Steelhead					
Throughout Central Valley	Winter-run Spring-run	Hatchery effects	1.2.17 Evaluate and implement specific hatchery spawning protocols and genetic evaluation programs to maintain genetic diversity in hatchery and natural stocks.	Long-term, beginning in year 1	CDFG, DWR, NMFS, Reclamation, USFWS	See previous
	Steelhead					
Throughout Central Valley	Winter-run Spring-run	Hatchery effects	1.2.18 Evaluate a program to tag and fin-clip all or a significant portion of hatchery-produced fish as a means of collecting better information regarding harvest rates on hatchery and naturally produced fish and effects of hatchery-produced fish on naturally produced fish.	Long-term, beginning in year 1	CDFG, DWR, NMFS, Reclamation, USFWS	See previous
	Steelhead					
Throughout Central Valley	Steelhead	Lack of data	1.2.19 Implementation of a comprehensive life history monitoring plan for Central Valley steelhead that will result in basin-wide (Sacramento and San Joaquin) estimates of hatchery and wild steelhead population abundance, production, diversity and distribution.	Long-term beginning in year 1	CDFG, NMFS, USFWS	\$10 million

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
Ocean	Winter-run Spring-run	Harvest	1.3.1 Work with the PFMC and NMFS to re-evaluate and modify management measures, annual conservation objectives, harvest forecasting techniques, NMFS consultation standards for ESA listed salmon stocks, and consider implementing an ecosystem-based salmon fishery management plan that considers multi-trophic interactions, ocean currents, upwelling patterns, ocean temperatures, and other relevant factors.	Long-term, beginning in year 1	PFMC, NMFS, CDFG	\$2 million
Ocean and inland	Winter-run Spring-run	Harvest	1.3.2 Work with PFMC and NMFS to implement restrictions that limit harvest of listed anadromous salmonids in commercial and recreational fisheries considering mechanisms such as: <ul style="list-style-type: none"> Genetic Stock Identification (GSI) – Develop a research, testing and monitoring plan to test this technology and establish optimal bycatch levels based on GSI data Review, assess and modify seasonal and area harvest restrictions and closures NMFS, CDFG and USFWS coordinate with the Southwest Fisheries Science Center to convene a science panel to review potential measures such as mass marking and mark selective fisheries and make recommendations to improve the identification of listed stocks in the Ocean. Consider using hot spot closures in commercial and recreational fisheries when large numbers of listed fish 	Long-term, beginning in year 1	PFMC, NMFS, CDFG	See previous

become congregated in certain areas.						
San Francisco Bay	Winter-run Spring-run Steelhead	Water quality	1.4.1 Implement projects that improve wastewater and stormwater treatment throughout the Bay and surrounding residential and commercial areas.	Long-term, beginning in year 1	SWRCB	\$50 million
San Francisco Bay	Winter-run Spring-run Steelhead	Water quality	1.4.2 Increase monitoring and enforcement to ensure that the water quality criteria established in the Central Valley Water Quality Control Plan (Basin Plan) are met for all potential pollutants.	Long-term, beginning in year 1	CVRWQCB	\$1 million
San Francisco Bay	Winter-run Spring-run Steelhead	Water quality	1.4.3 Cities, counties, districts, joint powers authority or other political subdivisions of the State involved with water management should implement agricultural drainage management projects to treat, store, convey, and/or dispose of agricultural drainage.	Long-term, beginning in year 1	CVRWQCB, Agriculture industry	\$1 million
Delta	Winter-run Spring-run Steelhead	Water management	1.5.1 Develop alternative water operations and conveyance systems that ensure multiple and suitable salmonid rearing and migratory habitats for all Central Valley salmonids and that restore the ecological flow characteristics of the Delta ecosystem.	Long-term, beginning in year 5	BDCP agencies and stakeholders	Alternatives under review. No cost currently available
Delta	Winter-run Spring-run Steelhead	Habitat loss and degradation	1.5.2 Large-Scale Habitat Restoration – Identify funding and direct restoration of 80,000 acres of tidal marsh, 130,000 acres of terrestrial grasslands, and 60,000 acres of floodplain habitat. Floodplain habitats should be restored to appropriate elevations using Frequently Activated Floodplain principles and modeling. The habitats should be	50 years, beginning in year 1	ACOE, DWR, Reclamation	\$135 to 270 million

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
			along primary migration and rearing corridors, and connected in ecologically beneficial ways. This will require separating levee systems from active river and estuary channels, restoring dendritic channel systems in areas where this habitat feature existed historically, and allowing for natural developmental processes to maintain habitats.			
Delta	Winter-run Spring-run Steelhead	Habitat loss and degradation	1.5.3 Integrate the Ecosystem Restoration Program and the Calfed Science program into an effort to restore the Delta ecosystem.	Beginning in year 1	USFWS, Calfed	No cost
Delta	Winter-run Spring-run Steelhead	Predation	1.5.4 Implement programs and measures designed to control non-native predatory fish (e.g., striped bass, largemouth bass, and smallmouth bass), including harvest management techniques, non-native vegetation management, and minimizing structural barriers in the Delta, which attract non-native predators and/or that delay or inhibit migration.	Long-term, beginning in year 1	CDFG, Sport fishing community	\$5 million
Delta	Winter-run Spring-run Steelhead	Habitat loss and degradation	1.5.5 Enhance the Yolo Bypass by re-configuring Fremont and Sacramento weirs to (1) allow for fish passage through Fremont Weir for multiple species; (2) enhance lower Putah Creek floodplain habitat; (3) improve fish passage along the toe drain/Lisbon weir; (4) enhance floodplain habitat along the toe drain; (5) eliminate stranding events; and (6) create annual spring inundation of at least 8,000 cfs to fully activate the Yolo Bypass floodplain.	Year 5 through 10	Reclamation, DWR	\$10 million
Delta	Winter-run	Water management	1.5.6 Implement Actions IV.1 through IV.6 of the	Year 1 through 25	Reclamation, DWR	Costs are currently

			woody debris, to moderate temperatures and to enhance nutrient input. Also pursue actions under the Sacramento River Flood Control Project and the Central Valley Plan for Flood Control.			
Lower and middle Sacramento River	Winter-run Spring-run Steelhead	Habitat degradation and loss	<p>1.6.2 Restore and maintain a continuous 60-mile stretch of riparian habitat and functioning floodplains of an appropriate, science-based width to maintain ecologically viable flood-prone lands along both banks of the Sacramento River between Colusa and Verona.</p> <ul style="list-style-type: none"> Separate levee systems from active river channels, restore dendritic channel systems in areas where this habitat feature existed historically, and allow for the natural development of floodplain habitats. Pursue actions under the Sacramento River Flood Control Project and the Central Valley Plan for Flood Control. 	Long-term, beginning in year 2	Army Corps, DWR, SAFCA, CDFG, TNC, USFWS	\$100 million
Lower and middle Sacramento River	Winter-run Spring-run Steelhead	Habitat degradation and loss	<p>1.6.3 Restore and maintain a continuous 70-mile stretch of riparian habitat and maintain existing floodplain terraces along both banks of the Sacramento River between Verona and Collinsville. Restore floodplain areas as necessary to achieve the restoration targets described in action 1.5.2</p> <ul style="list-style-type: none"> Seek opportunities through the Army Corps of Engineers Sacramento River Bank Protection Project, the Central 	Long-term, beginning in year 2	Army Corps, DWR, SAFCA, CDFG, CDPR, DWR, USFWS, local agencies, NGOs	\$50 million

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
			Valley Plan for Flood Control, and other flood management programs and agencies, such as the Sacramento Area Flood Control Agency, to protect existing riparian habitat, restore riparian, protect remaining floodplain terraces, and integrate flood plain bench designs into levee repair projects.			
Middle Sacramento River	Winter-run Spring-run Steelhead	Habitat degradation and loss	1.6.4 Relocate the M&T Ranch fish screen and water diversion from its current location to a downstream, geomorphically stable, river reach and relocate the 300,000 cubic yards of dredged gravel to upstream reaches of the Sacramento River for spawning habitat enhancement.	Within 5 years		\$20 million
Lower, middle, and upper Sacramento River	Winter-run Spring-run Steelhead	Habitat degradation and loss	1.6.5 Develop and implement an ecological flow tool for the Sacramento River below Keswick and Shasta Dams and use in conjunction with Frequently Activated Floodplain (FAF) tools and hydrodynamic river models to create and implement a floodplain inundation program that allows for existing functional floodplains to be activated in two out of three years for at least seven days between mid-March to mid-May.	Long-term, Long-term, beginning in year 2 through year 5		\$ 2 million development costs
Lower, middle, and upper Sacramento River	Winter-run Spring-run Steelhead	Water management	1.6.6 Implement a river flow management plan that balances carryover storage needs with instream flow <u>and water temperature</u> needs for winter-run, spring-run, and steelhead based on runoff and storage conditions, including flow fluctuation and ramping criteria.	Long-term, beginning in year 1		Costs are in development

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
Middle Sacramento River, Red Bluff Diversion Dam	Winter-run Spring-run Steelhead	Water management	1.6.7 Implement Action I.3.1 and I.3.2 (Long-term and interim operations of RBDD) of the Reasonable and Prudent Alternative described in the NMFS biological opinion on the long-term operations of the CVP/SWP (NMFS 2009) and install NMFS-approved, state-of-the-art fish screens at the Tehama Colusa Canal diversion point.	Beginning in year 1	DWR, Reclamation, TCCA	\$120 million
Upper Sacramento River	Winter-run Spring-run Steelhead	Habitat degradation and loss	1.6.8 Develop and implement a long-term gravel augmentation plan to enhance spawning habitat downstream of Keswick and Shasta Dams.	Long-term, Long-term, beginning in year 1	CDFG, NMFS, Reclamation, USFWS	\$2 million
Northwestern California diversity group – Clear Creek	Spring-run	Habitat degradation and loss	1.7.1.1 Operate the Clear Creek weir to separate spring-run and fall-run Chinook salmon	Long-term, beginning in year 1	USFWS	\$100 thousand
Northwestern California diversity group – Clear Creek	Spring-run Steelhead	Habitat degradation and loss	1.7.1.2 Develop and implement a spawning gravel budget and implement a long-term augmentation plan in Clear Creek.	Long-term, beginning in year 1	Reclamation, USFWS	\$2 million
Northwestern California diversity group – Clear Creek	Spring-run Steelhead	Habitat degradation and loss	1.7.1.3 Develop and implement optimal Clear Creek flow schedules to mimic the natural hydrograph (including spring pulse flows and winter spillway releases to restore a proper functioning system) and use instream flow study results to guide flow schedule development.	Long-term, beginning in year 1	Reclamation, USFWS	\$ 1 million
Northwestern	Spring-run	Water temperature	1.7.1.4 Develop a real time water temperature	Long-term,	Reclamation,	\$ 250 thousand

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
California diversity group – Clear Creek	Steelhead		model to track the coldwater pool in Whiskeytown Reservoir and budget releases to Clear Creek to meet daily water temperature of 60°F at the Igo gauge from June 1 to September 15 and 56°F from September 15 to October 31.	beginning in year 2 through year 5	USFWS	
Basalt and porous lava diversity group – Little Sacramento River	Winter-run Spring-run Steelhead	Habitat loss	1.8.1.1 Develop and implement a salmon reintroduction plan to re-colonize historic habitats above Keswick and Shasta Dams, into the Little Sacramento River. <ul style="list-style-type: none"> • Conduct feasibility study • Conduct habitat evaluations • Conduct 3-5 year pilot testing program • Implement long-term fish passage program 	Long-term: Evaluations beginning in year 1 Pilot testing in year 2 through year 5 Long-term passage program beginning in year 10	CDFG, NMFS, Reclamation, USFWS	\$50,000,000 50 year costs are not known at this time.
Basalt and porous lava diversity group – McCloud River	Winter-run Spring-run Steelhead	Habitat loss	1.8.2.1 Develop and implement a salmon reintroduction plan to re-colonize historic habitats above Keswick and Shasta Dams, into the McCloud River. <ul style="list-style-type: none"> • Conduct feasibility study • Conduct habitat evaluations • Conduct 3-5 year pilot testing program • Implement long-term fish passage program 	Long-term: Evaluations beginning in year 1 Pilot testing in year 2 through year 5 Long-term passage program beginning in year 10	CDFG, NMFS, Reclamation, USFWS	\$50 million for feasibility study, habitat evaluations, development of reintroduction plans, and implementation of pilot reintroductions 50 year costs are not known at this time,.
Basalt and porous lava diversity group – Battle Creek	Winter-run Spring-run Steelhead	Habitat degradation and loss	1.8.3.1 Develop and implement a salmon reintroduction plan to re-colonize historic habitats after implementation of the Battle Creek Restoration Project.	Long-term, Beginning in year 1	CDFG, NGOs, NMFS, PG&E, Reclamation, USFWS	\$5 million

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
Basalt and porous lava diversity group – Battle Creek	Winter-run Spring-run Steelhead	Habitat degradation and loss	1.8.3.2 Fully fund and implement the Battle Creek Restoration Project through Phase 2	Long-term, beginning in year 1	Reclamation, CDFG, NMFS, PG&E, USFWS	\$47 million
Northern Sierra Nevada DG – Antelope Creek	Spring-run Steelhead	Water management	1.9.1.1 Restore instream flows during upstream and downstream migration periods through water exchange agreements and provide alternative water supplies to Edwards Ranch and Los Molinos Mutual Water Company in exchange for instream fish flows.	Long-term	CDFG, Edwards Ranch, Los Molinos Water Company	\$2 million
NSN – Antelope Creek	Spring-run Steelhead	Water management	1.9.1.2 Restore connectivity of the migration corridor during upstream and downstream migration periods by implementing Edwards and Penryn fish passage and entrainment improvement projects and identify and construct a defined stream channel for upstream and downstream fish migration	Long-term	CDFG, Edwards Ranch	Costs are in development
NSN – Mill Creek	Spring-run Steelhead	Habitat degradation and loss	1.9.2.1 Implement a Mill Creek anadromous fish passage study (AFRP Website 2005) that will evaluate fish passage at all agricultural diversions to determine if they meet NMFS' fish passage criteria. Design and install state-of-the-art fish passage facilities at diversions that currently do not meet the passage criteria.	Long-term	CDFG, USFWS	\$500 thousand
NSN – Mill Creek	Spring-run Steelhead	Habitat degradation and loss	1.9.2.2 Conduct a study designed to determine adult fish passage flows at critical riffles and fish ladders in Mill Creek. Develop a water exchange agreement with all Mill Creek water users to allow implementation of those flows.	Long-term	CDFG, Mill Creek water users	\$200 thousand

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
NSN – Mill Creek	Spring-run Steelhead	Habitat degradation	1.9.2.3 Eliminate sources of chronic sediment delivered to Mill Creek from roads and other near stream development by out-sloping roads, constructing diversion prevention dips, replacing under-sized culverts and applying other storm proofing guidelines.	Long-term	CDFG, USFS	\$5 million
NSN – Deer Creek	Spring-run Steelhead	Habitat degradation	1.9.3.1 Develop and implement a water exchange agreement with the Deer Creek Irrigation Company and the Stanford-Vina Irrigation District and dedicate fish passage flows. The agreement should identify water infrastructure facilities required meet fish passage needs.	Long-term	CDFG, Deer Creek Irrigation Company, Stanford-Vina Irrigation District, USFWS	\$500 thousand Infrastructure costs may exceed \$5 million
NSN – Deer Creek	Spring-run Steelhead	Habitat degradation	1.9.3.2 Construct state-of-the-art inflatable dams and install fish ladders that meet NMFS' adult fish passage criteria at the Cone-Kimball Diversion, Stanford-Vina Dam, and the Deer Creek Irrigation District Dam.	Long-term	CDFG, Deer Creek Irrigation Company, Stanford-Vina Irrigation District, USFWS	\$3 million
NSN – Deer Creek	Spring-run Steelhead	Habitat degradation	1.9.3.3 Implement the Deer Creek Flood Improvement Project.	Long-term		\$10 million
NSN – Deer Creek	Spring-run Steelhead	Habitat degradation	1.9.3.4 Implement watershed restoration actions that reduce sedimentation and thermal loading in low gradient headwater habitats of Deer Creek Meadows, and Gurnsey Creek.	Long-term	CDFG, USFS, Deer Creek landowners	\$500 thousand

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
NSN – Butte Creek	Spring-run Steelhead	Water management	1.9.4.1 Develop, implement and evaluate a Butte Creek flow test for the PG&E DeSabra-Centerville Hydroelectric Project to determine the flow conditions that optimize coldwater holding habitat and spawning distribution.	Long-term	CDFG, PG&E	Costs integrated into ongoing project relicensing
NSN – Butte Creek	Spring-run Steelhead	Habitat degradation and loss	1.9.4.2 Install state-of-the-art fish ladders at DWR weir 2 and Willow Slough weir.	Long-term	DWR	\$10 million (already obligated)
NSN – Butte Creek	Spring-run Steelhead	Habitat degradation and loss	1.9.4.3 Maintain state-of-the-art fish passage facilities at diversions in Butte Creek to meet NMFS' passage criteria.	Long-term		\$20 thousand
NSN – Feather River	Spring-run	Habitat loss	1.9.5.1 Implement the use of a weir in the Feather River to spatially segregate spring-run Chinook salmon and fall-run Chinook salmon during their spawning migrations.	Long-term	DWR	\$1 million
NSN – Feather River	Spring-run Steelhead	Hatchery effects	1.9.5.2 Develop a hatchery genetic management plan for the Feather River Fish Hatchery, including specific criteria for operating as either an integrated or segregated hatchery.	Long-term	CDFG, DWR	\$100 thousand
NSN – Feather River	Spring-run Steelhead	Water management	1.9.5.3 Develop and implement a spring-run pulse flow schedule that is coordinated with Yuba River operations for dry and critically dry years	Long-term	DWR, YCWA	Costs under development

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
NSN – Feather River	Spring-run Steelhead	Habitat degradation and loss	1.9.5.4 Develop a spawning gravel budget, identify gravel depleted areas, and implement an augmentation plan in the Feather River.	Long-term	DWR	\$1 million
NSN – Feather River	Steelhead	Habitat degradation and loss	1.9.5.5 Construct steelhead side channel habitats using carrying capacity models sufficient to support a viable naturally spawning population of steelhead in the lower Feather River.	Long-term	DWR	\$5 million
NSN – Feather River	Spring-run Steelhead	Water temperature	1.9.5.6 Implement facilities modifications(s) to achieve Feather River water temperatures at least as protective as those specified in Table 2 of the Settlement Agreement For Licensing of the Oroville Facilities (March 2006)	Long-term	DWR, FERC, SWRCB	Feasibility study to begin in near futures. Costs under development
NSN – Yuba River	Spring-run Steelhead	Habitat degradation and loss	1.9.6.1 Develop and implement a salmon reintroduction plan to re-colonize historic habitats above Englebright Dam. Implement actions to: (1) enhance habitat conditions including providing flows and suitable water temperatures for successful upstream and downstream passage, holding, spawning and rearing; and (2) improve access within the area above Englebright Dam, including increasing minimum flows, providing passage at Our House, New Bullards Bar, and Log Cabin dams, and assessing feasibility of passage improvement at natural barriers. <ul style="list-style-type: none"> • Conduct feasibility study • Conduct habitat evaluations • Conduct 3-5 year pilot testing program • Implement long-term fish passage program 	Long-term: Evaluations beginning in year 1 Pilot testing in year 2 through year 5 Long-term passage program beginning in year 10	CDFG, NMFS, PG&E, USFWS, YCWA	\$50 million for feasibility study, habitat evaluations, development of reintroduction plans, and implementation of pilot reintroductions 50 year costs are not known at this time.

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
NSN – Yuba River	Spring-run Steelhead	Habitat degradation	1.9.6.2 Improve spawning habitat in the lower river by gravel restoration program below Englebright Dam and improve rearing habitat by increasing floodplain habitat availability.	Long-term	CDFG, NMFS, PG&E, USFWS, YCWA	\$2 million
NSN – American River	Steelhead	Habitat degradation and loss	1.9.7.1 Develop and implement a steelhead reintroduction plan to re-colonize historic habitats above Nimbus and Folsom dams. <ul style="list-style-type: none"> • Conduct feasibility study • Conduct habitat evaluations • Conduct 3-5 year pilot testing program • Implement long-term fish passage program 	Long-term: Evaluations beginning in year 1 Pilot testing in year 2 through year 5 Long-term passage program beginning in year 10	CDFG, NMFS, Reclamation, USFWS	\$50 million for feasibility study, habitat evaluations, development of reintroduction plans, and implementation of pilot reintroductions 50 year costs are not known at this time.
NSN – American River	Steelhead	Water temperature	1.9.7.2 Implement physical and structural modifications to the American River Division of the CVP in order to improve water temperature management	Long-term	ACOE, CDFG, NMFS, Reclamation, USFWS	
NSN – Mokelumne River	Spring-run Steelhead	Habitat degradation and loss	1.9.8.1 Evaluate and, if feasible, develop and implement a fish passage program for Camanche and Pardee dams <ul style="list-style-type: none"> • Conduct feasibility study • Conduct habitat evaluations • Conduct 3-5 year pilot testing program • Implement long-term fish passage program 	Long-term	CDFG, NMFS, Reclamation, USFWS	\$2 million for feasibility study and habitat evaluations 50 year costs are not known at this time.

<u>LOCATION</u>	<u>SPECIES</u>	<u>THREAT CATEGORY</u>	<u>PRIORITY 1 RECOVERY ACTIONS</u>	<u>DURATION</u>	<u>INVOLVED PARTIES</u>	<u>5 YEAR COST ESTIMATES</u>
NSN – Mokelumne River	Spring-run Steelhead	Water temperature	1.9.8.2 Manage cold water pools in Camanche and Pardee Reservoirs to provide suitable water temperatures for all downstream life stages	Long-term	CDFG, EBMUD, NMFS, Reclamation, USFWS	
Mainstem San Joaquin River downstream from the Merced River	Spring-run Steelhead	Habitat degradation and loss; water quality	1.10.1 Develop and implement a suite of actions to improve salmon and steelhead outmigration survival through the lower San Joaquin River by: <ul style="list-style-type: none"> <input type="checkbox"/> Restoring floodplain habitat, and implementing ecological flow schedules to create frequently activated floodplain; <input type="checkbox"/> Reducing contaminants; <input type="checkbox"/> Implementing remedies for the biological oxygen demand and low dissolved oxygen levels in the Stockton Deep Water Ship channel that delay of impede fish migration 	Long-term	CDFG, DWR, NMFS, Reclamation, SWRCB, USFWS, water districts	\$10 million
Mainstem San Joaquin River downstream from the Merced River	Spring-run Steelhead	Water management	1.10.2 Implement Action IV.2.1 (San Joaquin River Inflow to Export Ratio) of the Reasonable and Prudent Alternative described in the NMFS biological opinion on the long-term operations of the CVP/SWP (NMFS 2009) to improve juvenile outmigration for steelhead and future spring-run Chinook salmon. - Implement temporary barriers at Mud and Salt Sloughs

8.3 Integrating Recovery into NMFS Actions

It is a challenging undertaking to facilitate a change in practice and policy that reverses the path towards extinction of a species to one of recovery. This change can only be accomplished with effective outreach and education, strong partnerships, focused recovery strategies and solution-oriented thinking that can shift agency and societal attitudes, practices and understanding.

Implementation of the recovery plan by NMFS will take many forms and is generally and specifically described in the NMFS Protected Resources Division Strategic Plan 2006 (NMFS 2006a). The Recovery Planning Guidance (NMFS 2006b) also outlines how NMFS shall cooperate with other agencies regarding plan implementation. These documents, in addition to the ESA, shall be used by NMFS to set the framework and environment for plan implementation. The PRD Strategic Plan asserts that species conservation (in implementing recovery plans) by NMFS will be more strategic and proactive, rather than reactive. To maximize existing resources with workload issues and limited budgets, the PRD Strategic Plan champions organizational changes and shifts in workload priorities to focus efforts towards *“...those activities or areas that have biologically significant beneficial or adverse impacts on species and ecosystem recovery”* (NMFS 2006a). The resultant shift will reduce NMFS engagement on those activities or projects not significant to species and ecosystem recovery.

NMFS actions to promote and implement recovery planning shall include:

- ❑ Formalizing recovery planning goals on a program-wide basis to prioritize work load allocation and decision-making (to include developing the mechanisms to make implementation (e.g., restoration) possible).
- ❑ Conduct an aggressive outreach and education program.
- ❑ Facilitate a consistent framework for research, monitoring, and adaptive management that can directly inform recovery objectives and goals.
- ❑ Establish an implementation tracking system that is adaptive and pertinent to support the annual reporting for the Government Performance and Results Act, Bi-Annual Recovery Reports to Congress and the 5-Year Status Reviews.

NMFS' efforts must be as far-reaching (beyond those under the direct regulatory jurisdiction of NMFS) as the issues adversely affecting the species. Thus, to achieve recovery, NMFS will need to promote the recovery plan and provide needed technical information and assistance to other entities that implement actions that may impact the species' recovery. For example, NMFS will work with key partners on high priorities such as facilitating passage assessment and working with Counties to ensure protective measures consistent with recovery objectives are included in their General Plans.

While recovery plans are guidance documents not regulatory documents, the intent is that they are used to prioritize and target necessary actions for the survival and recovery of the species. The Recovery Planning Guidance (NMFS 2006b) specifically outlines NMFS' obligations:

“...the ESA clearly envisions recovery plans as the central organizing tool for guiding each species' recovery process. They should also guide Federal agencies in fulfilling their obligations under section 7(a)(1) of the ESA... and provide context and a framework for implementing other provisions of the ESA such as section 7(a)(2), development of Habitat Conservation Plans or Safe Harbor agreements under section 10, special rules for threatened species under section 4(d)”.

Furthermore, recovery plans should guide enhancement provisions of sections 4 and 5, take prohibitions through sections 4(d) and 9, cooperation with state(s) under section 6, needed research under section 10, fishery management actions taken and Essential Fish Habitat (EFH) consultations conducted under the provisions of the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA).

The approaches NMFS intends to use when implementing various sections of the ESA and MSFCMA are discussed in detail and are summarized in **Table 8-3**. These approaches are intended to formalize the recovery plans in the daily efforts and decision-making at NMFS in the Southwest Region. Of necessity, some of these methods address the urgent issues of staffing and workload that NMFS faces. As a result, our commitment to implementing recovery plans extends to the ways in which we prioritize the many requests for consultations and permits we receive. The discussion below outlines the specific action recommendations found the highest priorities in the recovery planning process for the Domain.

8.3.1 Working with Constituents and Stakeholders

NMFS commits to using recovery plans as the guiding mechanism for its daily endeavors. Successful implementation of this recovery plan will require the support, efforts and resources of many entities, from Federal and state agencies to individual members of the public. NMFS' efforts must be as far-reaching as the issues adversely affecting the species, extending beyond the direct regulatory jurisdiction of NMFS. NMFS commits to working cooperatively with other individuals and agencies to implement recovery actions and to encourage other Federal agencies to implement actions where they have responsibility or authority.

8.3.2 ESA Section 4

Section 4 provides the mechanisms to list new species as threatened or endangered, designate critical habitat, develop protective regulations for threatened species, and develop recovery plans. Critical habitat designations may be revised as needed to reflect recovery strategies.

Critical habitat is designated in specific geographical areas where physical or biological features essential to the species are found and where special management considerations or protections may be needed to preserve and protect them. Sacramento River winter-run Chinook salmon critical habitat was designated on June 16, 1993, and includes the Sacramento River from Keswick Dam (RM 302) to Chipps Island (RM 0) at the westward margin of the Delta; all waters from Chipps Island westward to Carquinez Bridge, including Honker Bay, Grizzly Bay, Suisun Bay, and Carquinez Strait; all waters of San Pablo Bay westward of the Carquinez Bridge; and all waters of San Francisco Estuary to the Golden Gate Bridge north of the San Francisco/Oakland Bay Bridge (58 FR 33212). CV spring-run Chinook salmon and CV steelhead critical habitat was designated on September 2, 2005, and includes and includes stream reaches such as those of the Feather and Yuba Rivers, Big Chico, Butte, Deer, Mill, Battle, Antelope, and Clear Creeks, the Sacramento River, as well as portions of the northern Delta. (70 FR 52488).

NMFS will reevaluate the designation in light of the data and criteria developed for this plan, and may designate additional habitat (including marine habitat), or currently unoccupied habitat deemed essential for the conservation of the species. The key recovery areas, special management considerations and recovery priorities identified in this recovery plan are the benchmark for making future critical habitat designations. Certain unoccupied historic habitats may be essential for recovery, and that are recommended for future critical habitat consideration include:

Sacramento River winter-run Chinook salmon

- Little Sacramento River
- McCloud River
- Battle Creek
- Non-natal rearing tributaries to the middle Sacramento River

These areas provide several primary constituent elements (PCE) that are necessary for the survival and recovery of the species. In the Little Sacramento and McCloud Rivers and Battle Creek, PCE's include freshwater rearing, migration and spawning habitats. Although these habitats are currently blocked by dams, the many miles of relatively unimpaired cold water habitats, and the potential to establish up to two viable spawning populations in the Basalt Lava Diversity Group (assuming that the little Sacramento and McCloud Rivers would be considered a single population) the makes these areas highly valuable to the recovery of the species. In the non-natal rearing tributaries to the Sacramento River, the PCEs include freshwater rearing habitat. Some non-natal rearing areas have a high value because they provide critical and improved growing conditions during high winter flow events on the Sacramento River.

CV spring-run Chinook salmon and CV steelhead

- Little Sacramento River
- McCloud River
- North Fork Feather River
- North, Middle and South Yuba River
- Upper American River
- Mokelumne River
- North Fork Stanislaus River
- Tuolumne River
- Merced River
- San Joaquin River (CV spring-run Chinook salmon only)

This list represents the unoccupied historic habitat identified in the Recovery Footprint maps. These areas provide several primary constituent elements (PCE) that are necessary for the survival

and recovery of the species. It is important to note that these areas are candidate areas for reintroduction and it may not be necessary to reintroduce fish to all of these systems to meet the recovery criteria for CV spring-run Chinook salmon or CV steelhead. It may not be necessary to re-establish populations to all of these rivers. The highest priority areas are the Little Sacramento River, the McCloud River, the North Fork American River, and the San Joaquin River. In the Little Sacramento, McCloud, Yuba Rivers, and Battle Creek, PCE's include freshwater rearing, migration and spawning habitats. Although these habitats are currently blocked by dams, the many miles of relatively unimpaired cold water habitats, and the potential to establish additional viable spawning populations in the Basalt Lava, and Northern Sierra Diversity Groups makes these areas highly valuable to the recovery of the species.

The existing PCEs in the American and San Joaquin Rivers are not in the same high quality condition as the previously described rivers, but the cold waters, deep pools and abundant spawning sized gravels of the upper American River could provide extensive high quality summer holding and spawning habitat and contribute significantly to the production and abundance of the species, while buffering against the effects of climate change. The San Joaquin is currently heavily degraded and does not support PCEs for CV spring-run Chinook salmon. However, the San Joaquin River Restoration Program is currently undertaking an ambitious effort to create a population of CV spring-run Chinook salmon below Friant Dam by 2020. We expect that implementation of this project will re-establish historic PCEs in the river including freshwater rearing and migration, freshwater holding and freshwater spawning.

Under ESA section 4(d), tailored section 9 take prohibitions and regulatory limits that are deemed advisable to contribute to the recovery of the

species, may be developed for species that are listed as threatened. Such rules currently are in place for Central Valley spring-run Chinook salmon and CV steelhead. These rules do not apply to endangered species; therefore winter-run Chinook salmon do not qualify unless they are reclassified as a threatened species. To authorize take of Sacramento River winter-run Chinook salmon, section 7(a)(2) or 10 (a)(1)(B) processes are the legal mechanism available under the ESA.

Based on our review of the special management considerations necessary to implement recovery actions, the following additional 4(d) prohibitions and limits are recommended for consideration:

4(d) limits for CV spring-run Chinook salmon and CV steelhead

- ❑ Fish screen construction and operation that is consistent with NMFS fish screen design criteria
- ❑ Fish passage facilities that are consistent with NMFS fish passage criteria
- ❑ Watershed or fishery restoration actions that are identified in comprehensive watershed or fishery plans
- ❑ Levee construction or maintenance activities that meet the following requirements:
 - Part of a comprehensive flood management program that has been approved by NMFS and includes a detailed conservation strategy for implementing recovery actions for floodplain and riparian habitat restoration

- Levee relocations that reclaim or create frequently activated floodplain areas, and minimize the potential for the stranding of juvenile fish
- Slurry wall construction within urban river corridors
- In-river repair and maintenance actions within urban flood corridor that meet NMFS design and maintenance criteria for urban levees
- ❑ Spawning gravel augmentation projects below dams
- ❑ Adult and juvenile fish collection and relocation actions that are part of NMFS-approved fishery reintroduction program

8.3.3 ESA Section 5

Section 5 is a program that applies to land acquisition with respect to the National Forest System. Multiple National Forests lands are present within the Central Valley domain.

8.3.4 ESA Section 6

Section 6 describes protocols for consultation and agreements between NMFS and the states for the purpose of conserving threatened or endangered species.

Congress established the Pacific Coast Salmon Recovery Fund (PCSRF) to contribute to the restoration and conservation of Pacific salmon and steelhead populations and their habitats. The states of Washington, Oregon,

Table 8-3. Summary of approaches NMFS intends to use when implementing various sections of the ESA and MSFCMA.

<u>Authority</u>	<u>Description</u>	<u>Implementation Actions</u>
<u>ESA</u> <u>Section 7</u>	<u>Section 7(a)(1)</u> <u>Interagency</u> <u>Cooperation</u> (Use of authorities)	<u>Use threats assessments and recovery actions to guide Federal partners to further the conservation of listed Central Valley salmon and steelhead.</u>
<u>ESA</u> <u>Section 7</u>	<u>Section 7(a)(2)</u> <u>Interagency</u> <u>Cooperation</u> <u>(Consultation</u> <u>)</u>	<u>Use recovery criteria and objectives as a reference point to determine effects of proposed actions on the likelihood of species' recovery.</u>
	<u>Note: Permits issued under section 10(a)(1) of the ESA also undergo section 7 consultation prior to issuance.</u>	<u>Use threats assessments and recovery strategy as a guide to prioritizing consultations when making workload decisions.</u>
		<u>Place high priority on consultations for actions that implement recovery strategy or specific actions.</u>
		<u>Streamline consultations for those actions with little or no effect on recovery areas or priorities.</u>
<u>ESA</u> <u>Section 9</u>	<u>Section 9 Enforcement</u>	<u>Prioritize those actions and areas deemed of greatest threat or importance for focused efforts to halt illegal take of listed species.</u>
<u>ESA</u> <u>Section 10</u>	<u>Section 10(a)(1)(B)</u> <u>Incidental</u> <u>Take Permits</u>	<u>Prioritize permit applications that address identified research and monitoring needs in the recovery plan.</u>
		<u>Prioritize cooperation and assistance to landowners proposing activities or programs designed to achieve recovery objectives.</u>
		<u>Standardize monitoring methods in HCPs to the TRT research needs and the recovery plan template.</u>
<u>Magnuson-</u> <u>Steve</u> <u>ns</u> <u>Fishe</u> <u>ry</u> <u>Mana</u> <u>geme</u> <u>nt</u>	<u>Fishery Management</u>	<u>Implement fishery regulations to maintain salmon harvest levels at or below those necessary to allow for the recovery of listed salmon and steelhead.</u>
		<u>Implement fishery regulations to reduce bycatch of salmon in federally-managed fisheries.</u>

California, Idaho, and Alaska, and the Pacific Coastal and Columbia River tribes receive Congressional PCSRF appropriations from NMFS each year. The fund supplements existing state, tribal, and local programs to foster development of federal-state-tribal-local partnerships in salmon and steelhead recovery and conservation. NOAA Fisheries Service has established memoranda of understanding (MOU) with the states of Washington, Oregon, California, Idaho, and Alaska, and with three tribal commissions on behalf of 28 Indian tribes. The MOUs establish criteria and processes for funding priority PCSRF projects.

8.3.5 ESA Section 7

Section 7(a)(1) provides that all Federal agencies shall "...in consultation with and with the assistance of the Secretary, utilize their authorities in furtherance of the purposes of this Act by carrying out programs for the conservation of endangered species and threatened species...." "Conservation" is defined in the ESA as those measures necessary delist a species. In other words, the theme is *recovery*. To date, other Federal agencies have not complied with the section 7(a)(1) requirement to develop conservation programs for listed Central Valley salmon and steelhead. To prompt Federal agencies to develop conservation programs, NMFS shall:

1. Encourage development of a SWR Sacramento Office or Regional Memorandum of Understanding (MOU) similar to a 1994 MOU [Daily Env't Rep. (BNA) No. 188, at E-1] between Agencies (which expired in 1999), establishing a framework for cooperation and participation to further the purposes of the ESA that specifically outlines a process for coordinating and implementing appropriate recovery actions identified in recovery plans.
2. Prepare, and send after recovery plan approval, a letter to all other appropriate Federal agencies outlining section 7(a)(1) obligations and meet with these agencies to discuss listed salmonid conservation and recovery priorities.
3. Encourage development of Conservation Bank Agreements for creating an array of individual conservation bank sites that will provide credits as compensation for actions that may affect anadromous salmonids within the Central Valley recovery domain. Focus conservation bank sites in key listed Central Valley salmon and steelhead watersheds.
4. Encourage meaningful and focused mitigation, in alignment with recovery goals for restoration and threat abatement, for all actions that incidentally take listed Central Valley salmon and steelhead or affect their habitat.
5. Encourage Federal partners to include recovery actions in project proposals.
6. Conduct outreach to Federal partners, and provide an outline of 7(a)(1) obligations.
7. The purpose of section 7(a)(2) is to "insure that any action authorized, funded, or carried out by [a Federal agency] is not likely to jeopardize the continued existence of any [listed species] or result in the destruction or adverse modification of [a listed species' critical habitat]." The theme is not one of recovery but of "no jeopardy" or "adverse modification." Federal agencies request interagency consultation with NMFS (and/or FWS) when they determine an action may affect a listed species or its critical habitat. NMFS then conducts an analysis of potential effects of the action. In the process of consultation, NMFS currently expends considerable effort to assist agencies in avoiding and

minimizing the potential effects of proposed actions, and to ensure agency actions do not jeopardize a species or destroy or degrade habitat. Consultations have helped prevent and minimize direct take but have not led to recovery.

To improve the section 7(a)(2) consultation process, NMFS will utilize its authorities to:

- Use recovery criteria and objectives as a reference point to determine effects of proposed actions on the likelihood of species' recovery.
- Place high priority on consultations for actions that implement recovery strategy or specific actions.
- Develop and maintain databases to track the amount of incidental take authorized and effectiveness of conservation and mitigation measures.
- Provide recommended actions in recovery plan as section 7(a)(1) conservation recommendations.
- Prioritize staff time to address and minimize short- and long-term effects of all actions occurring in listed Central Valley salmon and steelhead habitats.
- Focus staff priorities, to the extent possible, away from section 7 compliance in watersheds not designated as a priority for recovery and direct efforts to recovery implementation
- Streamline consultations for those actions with little or no effect on recovery areas or priorities.
- Prioritize staff efforts to carefully and consistently consider short-term and long-term impacts to watershed processes when conducting jeopardy analysis for Federal actions in key listed Central Valley salmon and steelhead watersheds.
- Apply the VSP framework and recovery priorities to evaluate population and area importance in jeopardy and adverse modification analysis.
- Work with established conservation bank programs to influence conservation bank agreements and actions that provide measurable contributions to threats abatement and recovery.

Within this framework NMFS will utilize its authorities to encourage:

- Amendments to the Corps section 404 Clean Water Act exemptions for farming, logging, and ranching activities. Terminating section 404(f) exemptions for discharges of dredged or fill material into waters of the United States associated with certain normal agricultural activities (defined as logging, ranching, and farming) will allow interagency consultations in key Dependent and Independent watersheds and provide incidental take coverage for individuals/corporations/agencies engaged in those activities.
- The Federal Emergency Management Agency (FEMA) to fund upgrades for flood-damaged facilities to meet the requirements of the ESA and facilitate recovery.
- The Environmental Protection Agency (EPA) to prioritize action on pesticides known to be toxic to fish and/or are likely to be found in fish habitat; and to take protective actions, such as restrictions on pesticide use near water.
- The FHWA and Caltrans develop pile driving guidelines, approved by NMFS, for all bridge construction projects in Key Dependent, Independent, and other watersheds with extant listed Central Valley

salmon and/or steelhead populations.

- ❑ Development of section 7 Conservation Recommendations to help prioritize Federal funding towards recovery actions (NMFS, USFWS, NRCS, EPA, etc) during formal consultations.
- ❑ All Federal agencies who designate a non-Federal representative to conduct informal consultation or prepare a biological assessment ensure the associated documentation comports to 50 CFR 402.14(c) prior to initiating consultations with NMFS.
- ❑ All Federal agencies, or their designated representatives, to field review projects and actions upon project completion to determine whether or not the projects were implemented as planned and approved. Encourage all Federal agencies, or their designated representatives to report the initial findings of field review to NMFS.
- ❑ Encourage Federal agencies to coordinate and develop programmatic incidental take authorization for activities that contribute to the recovery of listed Central Valley salmon and steelhead, to streamline their permitting processes.
- ❑ Encourage all consulting agencies to provide biological assessments that comport to 50 CFR 402.14(c) for all projects in all watersheds where listed Central Valley salmon and/or steelhead are present and/or with designated critical habitat.

8.3.6 ESA Section 9

Section 9 prohibits any person from harming members of listed species including direct forms of harm such as killing an individual, or indirect forms such as destruction of habitat where individual rear or spawn. The recovery plan will assist NMFS' Enforcement personnel by targeting key watersheds essential for species recovery. Core recovery areas identified in this plan should be considered the highest priority

areas. NMFS PRD staff will work closely with NMFS Enforcement regarding the identification of threats and other activities believed to place Chinook salmon at high risk of take and/or extirpation. Actions will include the following:

- ❑ NMFS will conduct outreach and provide enforcement a summary of the recovery priorities and threats.
- ❑ NMFS will prioritize those actions and areas deemed of greatest threat or importance for focused efforts to halt illegal take of listed species.
- ❑ NMFS will develop a plan to outline responsibilities and priorities between PRD and enforcement to ensure activities by NMFS staff, when supporting enforcement, are focused on the highest recovery priorities.
- ❑ When a take threat has occurred in a high priority area, NMFS PRD will work with NMFS enforcement, to the extent feasible, with the development of a take statement.
- ❑ NMFS enforcement will work with the California Department of Fish and Game, in conjunction with the Joint Enforcement Agreement to increase patrols and landowner outreach in critical watersheds, particularly during droughts, when listed Central Valley salmon and steelhead are potentially at greater threat of unauthorized taking.
- ❑ Regular meetings between recovery staff and Enforcement will occur. NMFS Enforcement will place a high priority on identification and curtailment of threats in key populations identified for recovery.

8.3.7 ESA Section 10

Section 10 (a)(1)(A) provides permits for the authorization of take for scientific research, or to enhance the propagation or survival of listed species. Typically NMFS has authorized conservation hatcheries and research activities

under section 10(a)(1)(A). Section 10(a)(1)(B) authorized take that is incidental to otherwise lawful activities for non-federal entities. Requests for such a permit must be accompanied by a conservation plan that describes how the entity will minimize and mitigate take and the effects of the take. To improve the section 10 authorization process, NMFS will utilize its authorities to:

Section 10(a)(1)(a) Research Permits

- ❑ Prioritize permit applications that address identified research and monitoring needs in the recovery plan.
- ❑ Evaluate all proposed activities against the identified threats, recovery strategy, and recovery actions identified in the plan.
- ❑ Develop and maintain databases to track the amount of incidental take authorized and the effectiveness of conservation and mitigation measures.

Section 10(a)(1)(B) Habitat Conservation Plans

We recommend all future HCPs, where listed Central Valley salmon and steelhead are covered species, adopt the viability and threats assessment guidelines described in this recovery plan. Adoption of these guidelines will facilitate standardization and could help in the tracking of recovery actions and threats abatement. Additionally, adoption of the assessment protocols should streamline jeopardy analysis and assist applicants in identification of limiting factors and strategically targeting beneficial and conservation and mitigation opportunities and locations. Finally, adoption of the assessment protocols will facilitate consistency in the development of standards to determine the appropriate levels of mitigation necessary to ensure the continued existence of listed Central Valley salmon and steelhead. The Habitat Conservation Planning Handbook stresses the need for consistency of mitigation measures for a species and for specific standards. Although, not a preferred option (according to the USFWS/NMFS HCP Handbook), if offsite

mitigation is necessary this recovery plan can be used to target watersheds for recovery actions. In some circumstances off-site mitigation may provide greater opportunity for recovery than onsite mitigation (*i.e.*, if an HCP's covered activities occur in a non-focus watershed).

Within this framework NMFS will utilize its authorities to:

- ❑ Prioritize cooperation and assistance to landowners proposing activities or programs designed to achieve recovery objectives.
- ❑ Standardize monitoring methods in HCPs to the TRT research needs and the recovery plan template. Consistent data collection techniques and the ability to compare similar data sets over space and time will set the framework for the five year review and help track recovery progress.

Section 10(j) Experimental Populations

Among the significant changes made in the 1982 amendments to the ESA was the creation of section 10(j), which provides for the designation of specific populations of species listed as "experimental populations" so long as they are wholly separate from other non-experimental populations. Under section 10(j), reintroduced populations of endangered or threatened species established outside the current range but within the species' historical range may be designated, at the discretion of NMFS, as "experimental," lessening the ESA's regulatory authority over such populations. Because these populations are not provided full ESA protection, management flexibility is increased, local opposition is reduced, and more reintroductions are possible.

Two types of experimental population designations exist: essential and nonessential. An essential experimental population is a reintroduced population whose loss would be likely to appreciably reduce the likelihood of the survival of the species in the wild. These

populations are treated as threatened species (with special rules) for the purposes of section 9 of the Act. Therefore, they can be managed with greater flexibility with regard to incidental take and regulated take.

A nonessential experimental population is a reintroduced population whose loss would not be likely to appreciably reduce the likelihood of the survival of the species in the wild. These populations, besides being treated as threatened species, are treated as proposed species for the purposes of section 7. The establishment of experimental populations is a valuable tool for use in the recovery of some listed species

To facilitate the implementation of species reintroduction, and to minimize the regulatory prohibitions that may create opposition to reintroduction programs, all candidate reintroduction areas in the Recovery Footprint should be considered for 10(j) rule proposals. Additional analysis is needed to determine if specific populations should be proposed as essential or non-essential. However, we have evaluated reintroduction potential for several historic, currently unoccupied habitats and recommend that 10(j) rules be developed for the following areas:

Little Sacramento and McCloud Rivers

Species: Sacramento River winter-run Chinook salmon, CV spring-run Chinook salmon, and CV steelhead.

The 2009 NMFS biological opinion on OCAP includes an RPA requiring the U.S. Bureau of Reclamation to begin the reintroduction of Sacramento River winter-run Chinook salmon, CV spring-run Chinook salmon, and CV steelhead to the Little Sacramento and McCloud Rivers in 2012. The engineering, biological, cultural and sociopolitical challenges associated with reintroducing populations above one of the

largest dams in the country highlights the need to tailor flexible regulatory prohibitions. These populations should be considered for designation as experimental through section 10(j).

Upper Yuba River

Species: CV spring-run Chinook salmon, and CV steelhead

The upper Yuba River has long been recognized for offering perhaps the best opportunity to create a viable population in the Northern Sierra Diversity Group, that is wholly separate from other populations and many of the catastrophic risk factors other populations face. Several initiatives are underway to develop engineering alternatives to allow upstream passage, develop reintroduction plans, and collaborate with watershed stakeholders to develop a reintroduction strategy. Similar to passage challenges at Keswick and Shasta Dams, reintroducing fish above Englebright Dam on the Yuba River will require specific and flexible regulatory prohibition. These populations should be considered for designation as experimental through section 10(j).

American River

Species: CV steelhead

The 2009 NMFS biological opinion on OCAP includes an RPA requiring the U.S. Bureau of Reclamation to begin the reintroduction of CV steelhead to the upper American River in 2012. Similar to passage challenges at Keswick and Shasta Dams, reintroducing fish above Folsom Dam on the American River will require specific and flexible regulatory prohibition. These populations should be considered for designation as experimental through section 10(j).

San Joaquin River

Species: CV spring-run Chinook salmon

The San Joaquin River Settlement Agreement calls for a combination of channel and structural modifications along the San Joaquin River below Friant Dam, releases of water from Friant Dam to the confluence of the Merced River, and the reintroduction of spring-run Chinook salmon. With implementation of these actions, the San Joaquin River Watershed below Friant Dam has a high potential to support a spawning population of reintroduced spring-run Chinook salmon. However, this reintroduction is outside of the existing ESU boundaries, and implementation will face numerous challenges in terms of engineering, biology, and public support; requiring the need to consider specific and flexible regulatory prohibition. The reintroduced population of spring-run Chinook salmon should be considered for designation as experimental through section 10(j).

The San Joaquin River Settlement Agreement requires the USFWS to submit a permit to NMFS for reintroduction of spring-run to the San Joaquin River no later than Sept 30, 2010. NMFS is required to issue a permit by April 30, 2012, and for reintroduction no later than 12-31-2012.

8.3.8 Fisheries Management and EFH

Much of listed Central Valley salmon and steelhead habitat is located in areas identified as Essential Fish Habitat (EFH) for the Pacific Coast Salmon Fishery Management Plan (FMP) under the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA). NMFS will implement fishery regulations, through coordination with PFMC, to maintain salmon harvest levels at or below those necessary to allow for the recovery of listed salmon. NMFS anticipates the objectives and recovery strategies will serve as a guide when providing

conservation recommendations for actions that may adversely affect EFH. In addition, NMFS will work to implement fishery regulations to reduce bycatch of salmon in federally-managed fisheries.

8.3.9 Coordination with other NMFS Divisions and the PFMC

Other divisions within NOAA can contribute significantly to recovery. NMFS PRD staff will coordinate closely with the SWFSC, Habitat Conservation Division, and NOAA Restoration Center to assist in the development, review and funding of restoration projects.

In addition NMFS PRD staff will need to coordinate closely with the PFMC for establishing an ecosystem-based fishery management plan to prevent overfishing of listed Chinook salmon. The current management measures serve to:

- apportion ocean harvest equitably among treaty Indian, non-treaty commercial and recreational fisheries
- provide in-season adjustment flexibility so that the fishing can provide for spawning escapement that meets replacement curves
- provide in-season adjustments to manage for ESA listed species

Additional changes in management may be required to meet recovery directives.

8.3.10 Technical Assistance

Beyond NMFS' statutory authorities and obligations we are engaged in a significant amount of outreach to various constituencies where we provide technical assistance regarding listed salmon, their habitat needs, and various life history requirements. Due to the large proportion of private lands and the limited contributions of section 7, developing partnerships through providing technical assistance will be critical for recovery. Through this role NMFS shall focus efforts in key areas

critical for recovery through the following actions:

- ❑ Work with the individual cities and counties throughout the Central Valley to recommend city and county planning and policies protective of listed Central Valley salmon and steelhead.
- ❑ Continue working with Natural Resource Conservation Service, Resource Conservation Districts, and Reclamation Districts, to encourage improved agricultural practices as well as land use practices of rural residential landowners.
- ❑ Encourage Smart Growth policies and provide outreach and education to urban planners and builders. Encourage planning that accounts for natural events such as droughts, storm, flooding and climate change.
- ❑ Encourage State wide policies for urban and rural roads.
- ❑ Prioritize cooperation and assistance to landowners proposing activities or programs designed to achieve recovery objectives.
- ❑ Establish policies and compliance that preserve and protect stream flows required by specific life stages of listed Central Valley salmon and steelhead.
- ❑ Assemble a NMFS Water Rights Team that focuses on restoring and maintaining natural streamflow regimes across the ESUs/DPS.
- ❑ Work to assure funding and staff for full enforcement of laws, codes, regulations and ordinances across the listed Central Valley salmon ESUs and steelhead DPS.

9.0 Glossary

<i>Adaptive management</i>	An action-oriented approach to resource management that brings science and management together and allows managers to move forward in the face of uncertainty when dealing with complex ecological problems. Adaptive management tackles uncertainty about the system head-on by identifying clear objectives, developing conceptual models of the system, identifying areas of uncertainty and alternative hypotheses, learning from the system as actions are taken to manage it, updating the conceptual models, and incorporating what is learned into future actions.
<i>Alevin</i>	Newly hatched salmon that have not yet adsorbed their yolk sac. The alevin life stage comes before the fry stage.
<i>Alleles</i>	Any of the alternative forms of a gene that may occur
<i>Anadromous Fish</i>	Fish that are hatched in freshwater, then spend a part of their life cycle in the sea and return to their natal streams to spawn.
<i>California Central Valley Project Improvement Act</i>	Passed by the State legislature in 1933, authorized the sale of bonds to pay for the Central Valley Project. The Project was taken over by the Federal Government under the Rivers and Harbors Act of 1935(from Wikipedia). (CVPIA) - This federal legislation, signed into law on October 30, 1992, mandates major changes in the management of the federal Central Valley Project. The CVPIA puts fish and wildlife on an equal footing with agricultural, municipal, industrial, and hydropower users.
<i>CALFED Bay/Delta Authority</i>	A California State agency that coordinates the efforts of both the State and the Federal Government addressing hydrologic concerns within the Sacramento/San Joaquin River Delta System. This entity was begun in 1994 to streamline efforts to ensure water quality standards, reliability of water supplies, viability of native and protected species, eradication/control of invasive species, as well as the integrity of levees within the Delta system.
<i>Central Valley Project</i>	Now run by the U.S. Department of Reclamation, this entity controls water resources by impounding water from snowpack runoff for hydroelectric power generation, municipal and agricultural supplies and to control flooding as well as provide recreational opportunities to all. A primary function of the CVP is to move water from the north where

	there is an abundance to the southern part of the Central Valley where there are chronic shortages. (CVP) - Federally operated water management and conveyance system that provides water to agricultural, urban, and industrial users in California.
<i>Channel Complexity</i>	Measure of multiple components determining the makeup of a given waterway. Some of these would include slope, meander, bedload/substrate makeup (<i>i.e.</i> gravel, cobble, boulder, combination), presence/absence large instream woody material, thalweg, <i>etc.</i>
<i>Cladocerans</i>	Small aquatic crustaceans (<i>i.e.</i> "water fleas")
<i>Conceptual Model</i>	A qualitative model of the system and species life stages with the interrelations between the system and threats shown in diagrammatic form. Several threats are interlinked or independent and these can be illustrated on the model of the system. "(1) "Explicit statements of the hypothesized fundamental relationships underlying management decisions regarding environmental resources." [A Proposal for the Development of a Comprehensive Monitoring Assessment and Research Program, April 24, 1998, page 30]; (2) "A simple non-quantitative model, developed for the purpose of building a consensus regarding the most important ecological elements and linkages that characterize a stressed ecosystem." [Nick Aumen, Conceptual Modeling Workshop, UC Davis, June 17-18, 1998]
<i>Congressional Federal Register</i>	Daily publication of the official journal of the U.S. Government, containing public notices and other routine publications.
<i>Connectivity</i>	Spatial structure should have permanent or appropriate seasonal connectivity to allow adequate migration between spawning, rearing, and migration patches.
<i>Conservation-Reliant</i>	Species are dependent on enforced protections for survival.
<i>Conveyance</i>	A pipeline, canal (natural or artificial), or similar conduit that transports water from one location to another.
<i>Copepod</i>	Small aquatic crustacean.
<i>Crepuscular</i>	Relating to twilight.
<i>Critical Habitat</i>	The specific areas within the geographical areas occupied by the species, at the time it is listed, on which are found those physical or biological features (i) essential to the conservation of the species and (ii) which may require special management considerations or protection.

	Importantly, critical habitat “shall not include the entire geographical area which can be occupied by threatened or endangered species”.
<i>Delist</i>	To remove an animal or plant from the list of endangered and threatened wildlife and plants thereby removing the accompanying protection.
<i>Deme:</i>	A local population of organisms of one species that actively interbreed with one another and share a distinct gene pool. When demes are isolated for a very long time they can become distinct subspecies or species
<i>Diversity Group</i> (Recovery Unit)	Populations are categorized into diversity groups based on the geographical structure described in Lindley <i>et al.</i> (2007) (diversity group ≈ recovery unit)
<i>Distinct Population Segment</i> (DPS)	A subdivision of a vertebrate species that is treated as a species for purposes of listing under the Endangered Species Act (ESA). To be so recognized, a potential distinct population segment must satisfy standards specified in a FWS or NOAA Fisheries policy statement (See the February 7, 1996, Federal Register, pages 4722 – 4725). The standards require it to be separable from the remainder of and significant to the species to which it belongs.
<i>Efficacy</i>	Measure of the ability to produce desired outcome.
<i>Effluent</i>	Discharge or emission of a liquid or gas (usually waste material)
<i>Endangered Species</i>	Species that are at significant risk of extinction throughout all or much of its range.
<i>Endangered Species Act</i>	Federal legislation that provides protection for species at risk of extinction. Through federal action and by encouraging the establishment of state programs, the 1973 Endangered Species Act provides for the conservation of ecosystems upon which threatened and endangered species of fish, wildlife, and plants depend. Section 7 of the Endangered Species Act requires Federal agencies to insure that any action authorized, funded or carried out by them is not likely to jeopardize the continued existence of listed species or modify their critical habitat.
<i>Entrainment</i>	To draught and transport by the flow of a fluid.
<i>Ephemeral</i>	Transient, Brief, Temporary, Eposidic.
<i>Escapement:</i> <i>Spawning Escapement</i>	Adult fish that “escape” fishing gear to migrate upstream to spawning grounds. The quantity of sexually mature adult salmon (typically

measured by number or biomass) that successfully pass through a fishery to reach the spawning grounds. This amount reflects losses resulting from harvest, and does not reflect natural mortality, typically partitioned between enroute and pre-spawning mortality. Thus, escaped fish do not necessarily spawn successfully.

Essential Fish Habitat (EFH):

Those waters and substrate necessary for fish spawning, incubation, breeding, feeding, or growth to maturity. These areas include migration corridors and adult holding areas. Essential Fish Habitat must also include wetland/riparian shore that supports vegetation that projects shade/cover over waterways used by listed species.

“waters”: aquatic areas and associated physical, chemical, and biological properties used by fish.

“substrate”: includes sediment, hard bottom, structures underlying the waters, and associated biological communities.

“necessary”: habitat required to support a sustainable fishery and the managed species’ contribution to a healthy ecosystem.

“spawning, breeding, feeding or growth to maturity”: covers a species’ full life cycle.

Estuarine:

Relating to an estuary.

Estuary:

That area of water, usually at least partially enclosed, which joins marine and freshwater components. As such, these areas are heavily influenced by both tidal and riverine inputs. Commonly an arm of the sea at the lower end of a river. Estuaries are often enclosed by land except at channel entrance points.

Evolutionarily Significant Unit (ESU)

A Pacific salmonid stock that is substantially reproductively isolated from other stocks of the same species and which represents an important part of the evolutionary legacy of the species. Life history, ecological, genetic, and other information can be used to determine whether a stock meets these two criteria. NOAA Fisheries uses this designation. NMFS definition of a distinct population segment that is smallest biological unit that will be considered to be a “species” under the ESA. A population will be is considered to be an ESU if 1) it is substantially reproductively isolated from other conspecific population units, and 2) represents an important component in the evolutionary legacy of the species.

Exotic Species

(Also called Non-Indigenous Species or Non-Native Invasive Species [NIS]):

Plants and animals that originate elsewhere and migrate or are brought into an area. They may dominate the local species or have other negative impacts on the environment because they can often outcompete native species and they typically have no natural predators.

<i>Extant</i>	Existing, Surviving.
<i>Extirpation:</i>	Loss of a taxon from all of its range.
<i>Extirpated Species</i>	A species that no longer survives in regions that were once part of its range, but that still exists elsewhere in the wild or in captivity.
<i>Fish Ladder</i>	Structure that allows fish passage to areas upstream of obstructions (e.g. dams, locks). Fish ladders employ a series of stepped, terraced pools fed with spillover water cascading down the ladder. This allows fish to make incremental leaps upstream from pool to pool to access historical/ancestral habitat upstream. Water-filled staircase that allows migrating fish to swim upstream around a dam or obstacle.
<i>Fish Screens</i>	Physical exclusion structures placed at water diversion facilities to keep fish from becoming entrained, trapped and dying in a given water body.
<i>Fry</i>	The life stage of salmonids between alevin and parr. (sac fry or alevin) – The stage in the life of a fish between the hatching of the egg and the absorption of the yolk sac. From this stage until they attain a length of one inch the young fish are considered advanced fry. Early life stage of salmonids. Typically, juveniles that can swim and catch their own food. Next life stage after alevin, and before smolt. The third freshwater stage of salmonid development; when egg mass is no longer present and fish develops characteristic markings. (upon reaching 1.25 inches in length, they are sometimes called “fingerlings”).
<i>Genetic Drift</i>	The random change of the occurrence of a particular gene in a population; genetic drift is thought to be one cause of speciation when a group of organisms is separated from its parent population. Birgird Schindwein’s Hypermedia; the random fluctuation of an allele frequencies in a population resulting from the sampling of gametes to produce a finite number of individuals in the next generation.
<i>Gene(tic) Flow</i>	The rate of entry of non-native genes into a population, measured as the proportion of the alleles at a locus in a generation that originated from outside of the population. Can be thought of as the genetically successful stray rate into a population. See also stray rate and homing rate.
<i>Genetic Divergence</i>	The process of one species diverging over time into more than one species. Passing small random advantages characteristic changes over time from one generation to the next generations
<i>Genetic Fitness</i>	Generally depicted as n : The reproductive success of a genotype, usually measured as the number of offspring produced by an individual that survive to reproductive age relative to the average for the population.

<i>Genetic Introgression</i>	Introduction by interbreeding or hybridization of genes from one population or species into another.
<i>Genetic Robustness</i>	Demographic Robustness
<i>Habitats</i>	Areas that provide specific conditions necessary to support plant, fish, and wildlife communities. Habitat elements identified in the Ecosystem Restoration Program Plan include tidal perennial aquatic habitat, nontidal perennial aquatic habitat, delta sloughs, midchannel islands and shoals, saline emergent wetland, fresh emergent wetland, seasonal wetlands, riparian and riverine aquatic habitats, inland dune scrub habitat, perennial grassland, agricultural lands, freshwater fish habitat, and essential fish habitat. The natural abode of a plant or animal, including all biotic, climatic, and soil conditions, or other environmental influences affecting life.
<i>Heavy Metal</i>	A group that includes all metallic elements with atomic numbers greater than 20, the most familiar of which are chromium, manganese, iron, cobalt, nickel, copper and zinc but that also includes arsenic, selenium, silver, cadmium, tin, antimony, mercury, and lead, among others.
<i>Habitat</i>	Is the area where a particular species lives.
<i>Hybridization</i>	Is the process of mixing different species or varieties of organisms to create a hybrid.
<i>Hydrologic Unit</i>	A definitive geographical area, typically an entire watershed defined by the United States Geological Survey (USGS).
<i>Hyporheic</i>	Hyporheic describes that flow of water through the interstitial spaces in the substrate beneath the stream (river) bed. It is vitally important because of the function that hyporheic flow performs in bringing oxygen and other nutrients to developing eggs and alevins, and in removing wastes from redds.
<i>Immediacy</i>	There are varying degrees of immediacy, including, a species is intrinsically vulnerable to threats, or identifiable threats can be “mapped” and seen as increasing or decreasing, or the threats are reasonably predictable.
<i>Inbreeding Depression</i>	Is reduced fitness in a given population as a result of breeding of related individuals
<i>Independent Population:</i>	An independent population is any collection of one or more local breeding units whose population dynamics or extinction risk over a 100-year time period is not substantially altered by exchanges of individuals

with other populations. In other words, if one independent population were to go extinct, it would not have much impact on the 100-year extinction risk experienced by other independent populations. Independent populations are likely to be smaller than a whole ESU and they are likely to inhabit geographic ranges on the scale of entire river basins or major sub-basins.

Instream Flow Incremental Methodology

Equation to derive the **flow** needed for spawning and rearing salmon and steelhead

Invasive Species

See exotic species.

Irreversibility

The trend/probability of a process to continue in only one direction once a tipping threshold has been crossed or met

Iteroporous

The term iteroporous describes the condition in which a fish may spawn multiple times. Steelhead (*Oncorhynchus mykiss*) and Atlantic Salmon (*Salmo salar*) display this trait routinely while Pacific Salmon (*Oncorhynchus tshawytscha*, *O. gorbuscha*, *O. keta*, *O. nerka*., *O. kisutch*) without exception expire after spawning only once.

Jacks

Jacks are male salmonids that have spent only a year at sea but have returned to spawn. A less frequently used term for these individuals is *grilse*.

Jills

Jills (sometimes also called “jennys”) are female salmonids that have spent only a year at sea but have returned to spawn. This is a relative rarity within the population.

Kelt

“Spawned out” salmonid fish. Salmon or trout that remains in freshwater after spawning in the fall. A salmonid that survives spawning and may return to the ocean. This is extremely rare in salmon and uncommon in trout.

Metapopulation(s)

A population of sub-populations which are in turn comprised of local populations or demes. Individual sub-populations can be extirpated and consequently recolonized from other sub-populations. Stability in a metapopulation is maintained by a balance between rates of sub-population extinction and colonization.

Parr

First part of the smoltification stage in salmonid life history occurring after natal yolk sac has been re-absorbed and before the distinctive parr marks have completely faded. During this time the fish is actively feeding and growing while outmigrating from its natal stream on its way to the ocean.

<i>Parr Marks</i>	Parr marks are vertical oval bars on the flanks of salmon fry that fade completely as the fish go through the smoltification process
<i>Phenotypic</i>	Expression of (a) particular trait(s) in a particular specimen.
<i>Population(s)</i>	Multiple types (e.g. persistent, viable, independent, dependent) <ul style="list-style-type: none"> • Functionally Independent Populations: have a high likelihood of persisting over 100-year time scales and conform to the original definition of independent “viable salmonid population.” • Potentially Independent Populations: have a high likelihood of persisting in isolation over 100-year time scales, but are too strongly influenced by immigration from other populations to exhibit independent dynamics. • Dependent Population: At risk group that has a substantial likelihood of going extinct within a 100-year time period in isolation, yet receives sufficient immigration to alter their dynamics and extinction risk, and presumably increase persistence or occupancy.
<i>Predation:</i>	The act of acquiring sustenance and nutrition by killing and consuming living animals.
<i>Primary Constituent Elements (PCE)</i>	A physical or biological feature essential to the conservation of a species for which its designated or proposed critical habitat is based on, such as space for individual and population growth, and for normal behavior; food, water, air, light, minerals, or other nutritional or physiological requirements; cover or shelter; sites for breeding, reproduction, rearing of offspring, and habitats that are protected from disturbance or are representative of the species’ historic geographic and ecological distribution.
<i>Pyroclastic Flow</i>	Superheated mixture of debris, vapor, mud, <i>etc.</i> flowing downhill/away from a volcanic vent during an eruption event.
<i>Random-Walk-With-Drift Model</i>	A model that incorporates density independence and has often been used in population viability analysis. It is an important tool in conservation biology partly because its parameters are easily estimated from periodic observations of population size.
<i>Recovery Priority Number (RPM)</i>	A rank, ranging from a low of 18 to a high of 1C, whereby priorities are assigned to listed species and recovery tasks; assignment of rank is based on degree of threat, recovery potential, taxonomic distinctiveness, and presence of an actual or imminent conflict between the species and development activities.
<i>Recovery Viability Potential</i>	The potential of a population to be restored to viability using the four parameters that indicate viability. Viability of populations and ESUs

	depends on the demographic properties of the population or ESU, such as population size, growth rate, the variation in growth rate, and carrying capacity
<i>Redd</i>	Nest depression constructed by female salmonids facilitating increased hyporheic flow for alevins. A type of fish-spawning area associated with running water and clean gravel.
<i>Restoration Feasibility</i>	If the threats have undermined the integrity of the system to the point that it cannot be recovered, then the restorability has been reduced. The other end of the scale is if the system can be recovered once the threat is removed.
<i>Restoration Potential</i>	The potential for returning a damaged watershed or ecosystem to a condition or function that is (1) similar to pre-disturbance, or (2) self-sustaining and in equilibrium with the surrounding landscape and ecological processes necessary for carrying out the basic life history functions of target organisms. An area characterized as having a high restoration potential would be considered to have a high likelihood of returning to this condition or function. Conversely, an area with low restoration potential would have little to no likelihood of returning to this condition or function.
<i>Riparian</i>	The strip of land adjacent to a natural water course such as a river or stream. Often supports vegetation that provides the best fish habitat values when growing large enough to overhang the bank.
<i>Riverine</i>	Habitat within or alongside a river or channel.
<i>Scope</i>	The geographic area of the threat to the species or system. Impacts can be widespread or localized.
<i>Severity</i>	A measure of the level of damage to species or system(s) that can reasonably be expected within 10 years under current circumstances. Range of severity from total destruction down to slight impairment.
<i>Smolt:</i>	An anadromous fish that is physiologically ready to undergo the transition from fresh to salt water; age varies depending on species and environmental conditions.
<i>Smoltification</i>	Describes the process by which salmonid fish acclimate metabolically over time from aquatic to marine environments as they emigrate from their natal streams to the ocean. During this process, parr marks fade and the fish takes on a silver color.
<i>Species group</i>	Certain species or groups of species are given a particular attention based on three criteria that might be met by a species: 1) it is threatened,

endangered, or a species of special concern; 2) it is economically important, supporting a sport or commercial fishery; or 3) it is an important prey species”

<i>Stochastic Events</i>	Random, unpredictable events.
<i>Straying</i>	Occurs when some adult spawners spawn in a stream other than the one they were born in. Straying may be influenced by hatchery practices, water quality or water diversions.
<i>Thalweg:</i>	Defines the deepest continuous portion of a stream or waterway. Sometimes referred to as the “valley line” is often undercuts structures embedded in the streambank.
<i>Thermocline</i>	That layer in a body of water where the temperature difference is greatest per unit of depth. It is the layer in which the drop in temperature equals or exceeds one degree C. (1.8 degrees F) per meter (39.37 inches).
<i>Threat Abatement</i>	To reduce the amount, intensity or degree of a threat
<i>Trophic Levels:</i>	Hierarchical tiers within a food web system (<i>e.g.</i> top predator or primary producer).
<i>Viable Salmonid Population (VSP)</i>	An independent population of any Pacific salmonid (genus <i>Oncorhynchus</i>) that has a negligible risk of extinction due to threats from demographic variation (random or directional), local environmental variation, and genetic diversity changes (random or directional) over a 100-year time frame.
<i>Weir</i>	A fence-like fish trap placed across a stream or outlet forces fish to swim into waiting traps.

CENTRAL VALLEY SALMON AND STEELHEAD RECOVERY PLAN WATERSHED PROFILES

At first glance, California Central Valley's 28 major watersheds might seem very similar in physical characteristics and to have redundant habitat types. However, the Sacramento and San Joaquin River Basins that make up the two main watersheds in the Central Valley are surprisingly diverse. As already mentioned in the Recovery Plan, the Central Valley is made up of four distinct geological zones which create different watershed systems, which in turn are the basis for diverse fisheries.

An example of this is that the large number of historic salmon runs present before the 1850's, were likely a result of the plethora of habitat types and geological formations found in the Central Valley. These varying habitats supported different life history strategies leading to genetically distinct populations of salmon and steelhead. Central Valley salmon and steelhead developed different life history strategies by evolving with habitat factors that reflected differences in these watersheds such as: the availability of cold water, adequate substrate, cover, and flow. Fish ecologists believe that this variability in life history traits was caused by the limitations or availability of habitat features between watersheds, and geographic isolation of populations, which led to genetic separation and to independent salmonid populations within the Central Valley.

With the many habitat changes, and impacts to salmonids discussed in the Recovery Plan, improving habitat quality and availability of different habitats within a watershed and increasing the number of Central Valley watersheds that could support independent or important dependent populations is a cornerstone for salmon and steelhead recovery. Improvement in genetic diversity is and will be a direct result of maintaining and improving habitat complexity within watersheds. Since salmon and steelhead evolve to the habitats that they reside in, the loss of these habitats, or access to these habitats has been one of the primary road blocks to species population

differentiation, production, and thus to recovery. Therefore, the relationship of these watersheds to population recovery is one of the primary tasks for planners when tackling threats and restoration actions within watersheds.

The following watershed profiles characterize current watershed conditions, summarize key threats, identify factors affecting species, and identify priority restoration or recovery actions. The watershed profiles also characterize the current viability of extant populations, and the potential for the watershed to support populations that meet the viability criteria described in Table 4-1, Chapter 4 of the Recovery Plan (Recovery Goals, Objectives and Criteria). For watersheds that historically supported these species, but are currently unoccupied, the watershed profiles characterize existing conditions and consider the potential for supporting viable populations if fish are re-introduced.

The watershed profiles are generally categorized by biogeographic diversity groups based on the Central Valley Technical Recovery Team's (TRT) identification of four groups that Chinook salmon and steelhead historically inhabited in the Central Valley (Figure A). Diversity groups are intended to capture a wide variety of climatological, hydrological, and geological conditions; and important components of habitat, life history or genetic diversity that contribute to the viability of salmonid ESUs/DPSs (Lindley *et al.* 2007). The diversity groups are as follows:

- ❑ The **basalt and porous lava diversity group** composed of the upper Sacramento River and Battle Creek watersheds;
- ❑ The **northwestern California diversity group** composed of streams that enter the mainstem Sacramento River from the northwest;
- ❑ The **northern Sierra Nevada diversity group** composed of streams tributary to the Sacramento River from the east, and including the Mokelumne River; and
- ❑ The **southern Sierra Nevada diversity group** composed of streams tributary to the San Joaquin River from the east.

The basalt and porous lava region comprises the streams that historically supported winter-run Chinook salmon. All of these streams receive large inflows of cold water from springs through the summer, upon which winter-run Chinook salmon depended. This region excludes streams south of Battle Creek, but would include the part of the Upper Sacramento drainage used by winter-run, and part of the Modoc Plateau region. The Northern Sierra Nevada region includes the southern part of the Cascades region (i.e., the drainages of Mill, Deer, and Butte creeks) and extends south including the Cosumnes River. The Southern Sierra Region begins at the the Mokelumne River and

extends south to include the upper San Joaquin River. This split reflects the greater importance of snowmelt runoff in the southern part, and distinguishes tributaries to the Sacramento and San Joaquin Rivers. There are two additional diversity groups within the steelhead DPS (Central Western California and Suisun Bay) which are not described here in the watershed profiles as it is assumed that full recovery of the CV steelhead can be achieved without the presence of these populations.

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

The Cosumnes River Watershed can be characterized as having a *moderate to high* restoration potential, and a *low* contribution to recovery. Although the Cosumnes River is widely known as one of the last undammed watersheds in the Central Valley, available anadromous habitat in the Cosumnes River includes 35 miles river miles from Latrobe Falls at an elevation near 400 feet, downstream to the confluence with the Mokelumne River. Because of this low elevation, spawning is only likely to occur in wet water years, and the production of yearling emigrants is unlikely due to warm summer water temperatures. The Cosumnes River may provide important non-natal rearing habitat to CV steelhead from the Mokelumne River or other nearby steelhead-producing rivers. The most valuable portion of this habitat is within the 46,000 acres of the Cosumnes River Preserve, partnership with local landowners, private partners such as the Nature Conservancy, and federal, state and local government agencies. The Cosumnes River preserve is pursuing conservation strategies restore and protect the ecological processes within its boundaries.

Viability potential

CV steelhead - Low

The Cosumnes River is characterized as having a *low* potential to support viable population a of steelhead due to the lack of suitable spawning and rearing conditions. However, the lower reaches of the watershed probably provide important rearing habitat for steelhead from the Mokelumne River and other adjacent watersheds.

Key Threats and Stressors

Key threats and stressors to Central Valley steelhead in Cosumnes Creek include, but are not limited to the following:

- ❖ Loss of floodplain habitat, natural river morphology, and riparian habitat and instream cover affecting juveniles
- ❖ Predation in the lower intertidal reaches near the confluence with the Mokelumne River

Key Actions

- ❖ Work with local, State, and Federal flood control agencies, and the Cosumnes River Preserve to relocate levee alignments away from active stream channels and floodplains.
- ❖ Work with the CDFG and other stakeholders to reduce the abundance of non-native predatory fish species in the Cosumnes River and the Delta.

Watershed Description

The Cosumnes River is the last undammed river flowing from the Sierra Nevada mountains into the Central Valley. Originating at an elevation of 7,600 feet, the headwaters of the Cosumnes River flow through the El Dorado National Forest and support native trout fisheries and many other aquatic species. Descending towards the Central Valley, the river passes through blue oak, grassland, and vernal pool communities. The lower reaches of the river provide critical salmon spawning habitat and the broad floodplain of the lower river harbors valley oak riparian forest and freshwater wetlands used by thousands of resident and migratory birds. Andadromous fish access is limited to river reaches downstream from river mile 35 at Latrobe Falls.

Lands within the Cosumnes River Preserve are jointly owned by The Nature Conservancy, The Bureau of Land Management, Ducks Unlimited, the California Department of Fish and Game, State Lands Commission, the California Department of Water Resources, Sacramento County and various private owners. The Preserve is reestablishing riparian forest and perennial grasslands through active and passive restoration efforts. Valley oak, Oregon ash, Fremont's cottonwood, box elder, willow, wild rose, and elderberry are planted to create the diverse understory of trees and shrubs found in mature riparian forest.

Fisheries

The Cosumnes River Barrier Improvement project, funded in 1998, was a collaborative effort by the FFC, Department of Fish and Game (DFG), The Nature Conservancy (TNC), AFRP, CALFED, Rancho Murieta Community Services District (RMCS), Omochumnes/Hartnell Water district (OHWD), and a private landowner adjacent to the lower Cosumnes River. The focus of the project was fall-run Chinook salmon passage improvement, but is likely to include some ancillary benefits to steelhead, especially in wet years spawning may occur. The objectives of the project as originally proposed were to improve passage conditions at four low-flow barriers; two summer dams and a low flow crossing in the lower river beneath the historic spawning reach and a diversion dam in the middle of the spawning reach. During post project monitoring activities two additional potential barriers were discovered and included in the objectives. In total, improvements were made to six structures from River mile(RM) 6.75 through RM 34.5.

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Chinook salmon and steelhead were once abundant in the Mokelumne River. The building of Comanche Dam, the Woodbridge diversion as well as other structures caused an 85% loss of habitat accessibility by these anadromous fish. Dams, sedimentation from gold mining and loss of habitat access were the main reasons that much of the steelhead and Chinook salmon runs have severely declined since the early 1900's (Reynolds et al. 1990 in USFWS 1995). Current efforts include improvements to fish passage and flows such as the recent improvement of passage at the Woodbridge diversion structure.

Recent monitoring in the San Joaquin River watershed has detected self-sustaining populations of steelhead in the Stanislaus, Mokelumne, and Calaveras rivers (McEwan 2001). Additionally, steelhead (and their progeny) from the artificially propagated stocks from the Coleman NFH and the Feather River Hatchery steelhead programs are considered part of the listed C CVS ESU. Anadromous hatchery programs that release out-of-ESU steelhead stocks into the C CVS ESU are operated at Nimbus Hatchery and Mokelumne River Hatchery.

It is likely that steelhead numbers could be restored to the lower Mokelumne River in better numbers if temperature and flow standards are established that would provide for juvenile rearing. However, not much is known about steelhead numbers and current habitat uses in the Southern Sierra Diversity Group. Lindley et al. (2007) recommend that in order to assess the risk of extinction or develop effective recovery actions for steelhead in the Central Valley, determining the distribution of steelhead and assessing the relationship between resident and anadromous forms of *O. mykiss* is a fundamental need. Lindley et al. (2007) stress that any quantitative assessment of population viability would be inadequate unless the role resident fish play in population maintenance and persistence of *O. mykiss* in the Central Valley is known.

Viability Potential for Existing Populations

CV steelhead: **Low**

CV spring-run Chinook salmon: No population exists currently; the potential to support a viable population is considered low.

Potential for Historic Habitats to Support Spawning Populations

Above Comanche Dam:

CV steelhead – **Low to Moderate**

CV spring-run Chinook salmon – **Low to Moderate**

The upper Mokelumne River is characterized as having a **low to moderate** potential to support a spawning population of spring-run salmon and steelhead. Due to flow regulations at the Tiber Creek and West Point powerhouse, it is considered difficult to anticipate life history success for either of these species even if volitional passage or truck and haul programs were instigated because of low water quality as a result of these powerhouse facilities.

Key Threats and Stressors

Key threats and stressors to Central Valley steelhead in the Mokelumne River watershed include, but are not limited to the following:

- ❖ Passage impediments/barriers at Camanche Dam and Pardee Reservoir Dam affecting adult immigration and holding
- ❖ Flow conditions (i.e., low flows) associated with attraction, migratory cues, flood flows and the attraction of non-natal fish into the Mokelumne River affecting adult immigration and holding
- ❖ Competition for spawning habitat, physical habitat alteration associated with limited supplies of instream gravel, habitat suitability and spawning habitat availability affecting adult spawning
- ❖ Hatchery effects associated with redd superimposition, competition for habitat, and genetic integrity affecting adult spawning
- ❖ Water temperatures affecting adult spawning and embryo incubation
- ❖ Flow conditions (i.e., flow fluctuations, changes in hydrology) affecting adult spawning, embryo incubation, juvenile rearing and outmigration
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Hatchery effects on juvenile rearing and outmigration

Key Watershed Restoration and Recovery Actions

- ❖ Evaluate and, if feasible, develop and implement a fish passage program for Camanche and Pardee dams as generally described in Appendix B

- ❖ Evaluate pulse flow benefits for steelhead attraction and passage in the Mokelumne River; if pulse flows are determined to be effective for attracting steelhead, implement the most beneficial pulse flow regime
- ❖ Develop and implement a spawning gravel augmentation plan for the Mokelumne River
- ❖ Develop a Mokelumne River Steelhead Hatchery Genetic Management Plan to minimize adverse effects to the wild stock
- ❖ Manage cold water pools in Camanche and Pardee Reservoirs to provide suitable water temperatures for all steelhead life stages
- ❖ Develop and implement an instream flow management plan that fully considers all steelhead life history stages

Watershed Description

With its headwaters at 10,000 feet on the crest of the Sierra Nevada mountains, the Mokelumne River drains approximately 661 square miles from four counties (i.e., Amador, Calaveras, Sacramento, and San Joaquin (USFWS and The Trust for Public Land 2009). It is a major tributary to the Sacramento-San Joaquin Delta, entering the lower San Joaquin River northwest of Stockton. The median historical unimpaired runoff is 696 taf, with a range of 129 taf to 1.8 maf (USFWS 1995). The landscape of the Mokelumne River watershed is typical of the lower Sierra foothills, with rolling terrain interrupted by scattered rock outcrops and moderate to steep hillsides. The vegetation is predominantly grasslands and oak woodlands (EBMUD 2008).

The upper Mokelumne River watershed (upstream of Pardee Reservoir) measures about 570 square miles and is drained by numerous creeks (e.g., Jackson, Tiger and Sutter), feeding into the Mokelumne River (EBMUD 2009).

Geology

The topography of the upper watershed varies from the gently sloping plain of the eastern San Joaquin Valley to the gentle and moderately rolling hills and ridges of the western-most Sierra Nevada foothills (EBMUD 2008). Elevations range from 235 feet above mean sea level (msl) to about 700 feet msl on the ridge-crests adjacent to Pardee Dam. Major soil groups in the upper watershed include well-drained stony clays to stony silt loams, well-drained gravelly to cobbly loams, well-drained clays occupying moderate slopes, relatively young overlying soil deposits consisting of well-developed alluvia with resistant hardpans, and unconsolidated to slightly consolidated alluvia. All exposed sedimentary rocks and soils are subject to erosion and transport into the downstream reservoirs (e.g., Pardee and Camanche), largely as a function of slope.

Because rainfall in the watershed can mobilize contaminants and sediment in runoff, the presence of vegetation is a major factor in the prevention of erosion. Local sediments are the primary source of inorganic turbidity in Pardee and Camanche reservoirs (EBMUD 2008).

Hydrology

Almost 90 percent of precipitation occurs as rainfall during the months of November through April, and snowfall within the watershed is rare (EBMUD 2008).

Construction of Pardee Dam and Reservoir (1929) and Camanche Dam and Reservoir (1963) altered the hydrologic regime of the Mokelumne River, and the historic 100-year floodplain of the Mokelumne River is now within the area permanently flooded by Pardee and Camanche Reservoirs (EBMUD 2008). Watershed runoff is captured in three major impoundments (Camanche, Pardee, and Salt Springs Reservoirs) operated by East Bay Municipal Utilities District (EBMUD) and PG&E. These impoundments have a combined storage capacity of more than 750 taf. One other small impoundment in the watershed, the Lower Bear River Reservoir, stores 52 taf. Minimum flows below Camanche Dam range from between 100 to 325 cfs, as specified in FERC 2916-029, 1996 (Joint Settlement Agreement) (Reclamation 2008). Minimum flows below the Woodbridge Diversion Dam range from between 25 to 300 cfs (Reclamation 2008).

Land Use

The Mokelumne River watershed is a significant source of water for both consumption and energy production. The major land use in the upper watershed, owned both privately and publicly, is timber management. Much of the privately held land in the drainage area is undeveloped, and is currently left as open space or used for grazing (EBMUD 2008). Additionally, the Mokelumne River has a long history of water development. Within the watershed, East Bay Municipal Utility District (EBMUD) owns about 44 percent of the land area, which includes areas in the upper watershed extending from U.S. Highway 49 westward toward and including the Mokelumne River Day Use Area below Camanche Dam (EBMUD 2008a). Existing developments on the Mokelumne River upstream of Camanche Reservoir include facilities for hydroelectric, irrigation, and municipal use. Downstream of Camanche Reservoir, developments include both hydroelectric and irrigation facilities (USFWS 1995). EBMUD operates Camanche Reservoir together with Pardee Reservoir as part of an integrated system, and water releases are used to meet various demands for downstream users, including storage regulation for flood control and for the Mokelumne River Fish Hatchery,

hydroelectric generation, and instream flow requirements for salmon (The Trust for Public Land 2009).

Fisheries and Aquatic Habitat

Five species of anadromous fish are present in the Mokelumne River below Camanche Dam, including fall-run Chinook salmon, steelhead, American shad¹, striped bass and pacific lamprey (USFWS 1995; M. Workman, USFWS, pers. comm. 2009). Fall-run Chinook salmon and steelhead are the primary management focus in the river (EBMUD 2008b).

Steelhead historically occurred in the Mokelumne River (USFWS 1998), but as recently as 2007, native steelhead were believed to be extinct, and were maintained in the river by hatchery plants (Marsh 2007). In the San Joaquin Basin, anadromy in *Oncorhynchus mykiss* populations may be nonexistent or too low to detect while resident *O. mykiss* populations in the same rivers have remained strong (CDFG 2008). Because resident and anadromous *O. mykiss* juveniles can be difficult to differentiate, monitoring programs in these rivers typically report steelhead/rainbow trout captures as *O. mykiss*, rather than identifying the particular life history strategy of individual fish (CDFG 2008). Given the above considerations, in addition to the relatively recent, but extensive monitoring efforts that have been undertaken since implementation of the Joint Settlement Agreement² (1998), detailed findings regarding steelhead populations in the lower Mokelumne River are only beginning to emerge. Consequently, much of the information regarding anadromous salmonids habitat utilization in the Mokelumne River is based upon fall-run Chinook salmon.

Since the early 1900s, Chinook salmon in the lower Mokelumne River were adversely affected by poor water quality associated with winery and mine wastes, fish losses at unscreened diversions, and migration barriers due to dams (DFG 1991 in USFWS 1995). Runs up to 12,000 fish were recorded in the early 1940s (USFWS 1995). Spring-run Chinook salmon were probably present in the Mokelumne River prior to the

¹ Distribution is believed to be limited to reaches downstream of Woodbridge Dam (Michele Workman, USFWS, pers. comm. 2009).

² The Lower Mokelumne River Joint Settlement Agreement for the Lower Mokelumne River Project, FERC No. 2916, regarding flow and non-flow measures appropriate for the lower Mokelumne River was entered into by and between East Bay Municipal Utilities District, USFWS, and CDFG. The Agreement was intended to resolve: (1) pending FERC Proceeding No. 2916-004; and (2) pending Mokelumne River Water Rights Proceedings before the SWRCB.

construction of Pardee Dam in 1929. However, dams, poaching, and sedimentation caused by gold mining eliminated the spring-run Chinook salmon in the Mokelumne River (Reynolds et al. 1990 in USFWS 1995).

Wheaton et al. (2004) reports that *“the majority of salmonid spawning now takes place in a 14-km reach between Camanche Dam and Elliot Road (Merz and Setka, in press)”*. The annual upstream fall-run Chinook salmon migration in the Mokelumne River begins in September, peaks in November and tapers off by early January (EBMUD 2009; (CDFG 1991 in USFWS 1995). Fall-run Chinook salmon spawning generally occurs in late October through January (EBMUD 2009). Myrick (1998 and 2000 in Reclamation 2008) found steelhead from the Mokelumne River preferred water temperatures between 62.5°F and 68°F. However, the condition of the aquatic habitat and the variation of conditions in the lower Mokelumne River have resulted in widely varying population levels of these species (USFWS 1995).

The major barrier to upstream migrating Chinook salmon and steelhead adults on the Mokelumne River is Woodbridge Dam (USFWS 1995). Woodbridge Dam, a flashboard dam constructed on the lower Mokelumne River in 1910, contained no fish ladder until 1925. Fish passage was dependent upon river flows and the length of the irrigation season. Upstream migration of adult Chinook salmon was generally possible only after the flashboards were removed at the end of the irrigation season (October). The fish ladder proved to be ineffective and was reconstructed in 1955. Subsequent analyses of passage conditions indicated that migration of adult Chinook salmon past the dam was potentially impaired by spills that attract fish away from the fish ladder (CDFG 1991 in USFWS 1995). CDFG identified a shallow portion of the Mokelumne River near Thornton as a migration barrier to adult Chinook salmon at flows less than 60 cfs (CDFG 1991 in USFWS 1995). Historically, inadequate attraction and migration flows (generally less than 50 cfs) below Woodbridge Dam during October and November resulted in poor adult returns to the Mokelumne River and the Mokelumne River Fish Facility (USFWS 1995). However, since completion of the Joint Settlement Agreement (1998), flows during the fall do not decrease below 350 cfs in any water year type. The failure of returning adults to detect Mokelumne River outflow also may be exacerbated by diversion of proportionately large volumes of Sacramento River water into the lower Mokelumne River via the Delta Cross Channel (DCC), and reverse flows in the lower San Joaquin River and south Delta channels.

As previously discussed, historic upstream migration of adult Chinook salmon in the Mokelumne River was often delayed due to high water temperatures below Woodbridge Dam, which could persist until early November, even during a normal water year (CDFG 1991 in USFWS 1995). Passage at natural riffles is not as much of a

concern for steelhead as it is with Chinook salmon because steelhead are smaller and better swimmers and can better negotiate natural riffles and partial barriers (USFWS 1995). Poor water quality conditions below Camanche Reservoir had the potential to adversely affect Chinook salmon by inhibiting upstream migration of adult Chinook to spawning areas. Water quality problems in the Mokelumne River have been associated with heavy metal pollution from Penn Mine, drought conditions, and Pardee and Camanche Reservoir operations. Past fish kills at the Mokelumne River Fish Facility were attributed to Camanche Reservoir discharges containing toxic levels of copper and zinc, low dissolved oxygen levels, and high concentrations of hydrogen sulfide. These conditions were associated with low inflows from Pardee Reservoir; record low reservoir levels; and hypolimnetic mixing, which may have mobilized sediments during the late summer and fall turnover of the reservoir (CDFG 1991 in USFWS 1995).

Suitable water temperatures for Chinook salmon spawning in the Mokelumne River below Camanche Dam generally have not occurred until early November during a normal water year. Water quality standards have been recommended by CDFG, including water temperatures to protect aquatic resources, including adult Chinook salmon spawners (CDFG 1991 in USFWS 1995). Camanche Dam also prevented the natural recruitment of gravel from upstream sources to spawning areas below the dam. Net losses of spawning gravels and a general increase in the size of streambed materials have reduced the amount of suitable spawning area. In addition, armoring or compaction of spawning substrate has reduced spawning gravel quality (USFWS 1995). Suitable water temperatures for Chinook salmon incubation and emergence in the Mokelumne River below Camanche Dam generally have not occurred until early November during a normal water year. Potential stranding of juvenile salmonids as a result of flow fluctuations were evaluated in several reaches downstream of Camanche Dam based on predicted changes in wet surface area over a range of flows. The stranding potential increased at flows below 400 cfs (USFWS 1995).

As part of the Joint Settlement Agreement, water temperatures in the lower Mokelumne River were to be maintained to meet the life-history needs of aquatic organisms (e.g., fall-run Chinook salmon and steelhead). EBMUD opens the upper level outlet in Camanche Reservoir after lake turnover and closes the upper outlet when temperatures at Woodbridge Dam reach approximately 64°F to maintain the best possible release temperatures to meet the life-history needs of aquatic organisms, including steelhead. Using its best efforts, EBMUD also manages the hypolimnetic volume in Camanche Reservoir so that at the end of October, the volume has exceeded 28,000 acre-feet in every year except 2003. The Mokelumne River watershed received uncharacteristically high precipitation in April and May 2003 and high flood control releases were required

which diminished the cold-water pool during 2003 to 16,700 acre-feet (EBMUD et al. 2008).

Dry year flows in the lower Mokelumne River below Woodbridge Dam during the spring period are inadequate to effectively convey juvenile salmonids downstream and through the Delta (USFWS 1995). Juvenile Chinook salmon in the Mokelumne River are allowed to migrate naturally to the ocean in wet, normal and above normal water year types, but are trapped at Woodbridge Dam and trucked to Rio Vista or other suitable locations in the Delta during dry or critically dry years. In general, peak adult returns to the Mokelumne River indicate favorable rearing and emigration conditions during preceding wet years. Nearly all Chinook salmon produced at the Mokelumne River Fish Facility are trucked as yearlings to release locations in the western Delta. Major diversions affecting juvenile Chinook salmon emigrants from the Mokelumne River are the Woodbridge Canal diversion and the south Delta SWP and CVP export facilities. The Woodbridge Canal diversion was screened in 1968 and operates from April to October, depending on irrigation demands. The Woodbridge Canal fish screen was identified as not meeting NMFS and CDFG fish screen velocity and design criteria (USFWS 1995). However, as part of the Lower Mokelumne River Restoration Program, one of the project's key elements is to improve the fish screens and the fish bypass system for anadromous salmonids at the Woodbridge Dam (CALFED 2000).

Adult steelhead are likely to encounter the DCC gates in both an open and closed configuration throughout their extended spawning migration. NMFS (2009) believes that elevated levels of net negative flow present a risk to emigrating fish that have entered the central Delta through Georgiana Slough or, when the DCC is open, the Mokelumne River system. Closure of the DCC gates from November 1 through May 20 may block or delay adult salmonids that enter the Mokelumne River system and enter through the downstream side of the DCC. However, it is anticipated that closure of the DCC gates during this period will reduce diversion of Sacramento River water into the Central Delta, thereby improving attraction flows for adults in the mainstem Sacramento River (NMFS 2009).

Steelhead are reported to move out of the Mokelumne River during December and January (NMFS 2009). Steelhead smolts from the Mokelumne River system enter the Eastern Delta (NMFS 2009). The Mokelumne River fish can either follow the north or south forks of the Mokelumne River through the Central Delta before entering the San Joaquin River at RM 22. Some fish may enter the San Joaquin River farther upstream if they diverge from the South Fork of the Mokelumne River into Little Potato Slough (NMFS 2009). Smolts migrating naturally out of the Mokelumne River also are exposed to Delta flow patterns in the central and south Delta (USFWS 1995).

Anadromous salmonids are subject to loss as they cross the Delta during their downstream migration towards the ocean (NMFS 2009), and steelhead from the Mokelumne River Basin must pass several points of potential entrainment into the south Delta prior to reaching the western Delta (NMFS 2009). Reverse flows caused by CVP and SWP export pumping in the south Delta contribute to poor survival of juvenile Chinook salmon and steelhead that enter the central Delta from the Mokelumne River or from the Sacramento River via the DCC or Georgiana Slough. Mark-recapture studies indicate that juvenile Chinook salmon released in the lower Mokelumne River experience higher mortality than those released in the Sacramento River below the DCC under dry year conditions (USFWS 1987 in USFWS 1995). As shown by the Bureau et al. (2007), Perry and Skalski (2008) and Vogel (2008a) studies, individual fish risk entrainment into the channels of Georgiana Slough under all conditions and into the Mokelumne River system when the DCC gates are open as they migrate downstream in the Sacramento River. Estimated average survival is only 33 percent with a range of approximately 10 percent to 80 percent survival (NMFS 2009). Most of this loss is believed to be associated with predation, but may also include prolonged exposure to adverse water quality conditions represented by temperature or contaminants. Several years of salmonid survival studies utilizing both Coded Wire Tags (CWT) and acoustically tagged fish indicate that survival is low in the interior Delta waterways compared to the mainstem Sacramento River. Likewise, survival in the upper San Joaquin River is substantially lower than survival from Jersey Point to Chipps Island (VAMP studies), indicating that transiting the Delta interior is a risky undertaking for fish exiting from the San Joaquin River Basin or the east side tributaries (Mokelumne River Basin) (NMFS 2009).

CDFG has determined that the river reaches between Camanche Dam and the confluence with the Delta are of considerable importance for maintenance and restoration of Chinook salmon and steelhead (CDFG 1991). Over the past few years, Mokelumne River studies have used an extensive acoustic receiver array system deployed in the river to track the movement, survival, and habitat use of hatchery origin steelhead smolts, hatchery steelhead kelts and multiple life stages (>160mm) of the wild river population of *O. mykiss* (Workman et al. 2008). EBMUD, CDFG and USFWS continue to collaboratively work to improve conditions for the lower Mokelumne River. Restoration objectives have focused on providing additional salmonid spawning gravel, improving intergravel water quality, and increasing floodplain connectivity and providing the energy needed to sustain river rehabilitation in the first 1 mile below Camanche Dam (EBMUD 2009). Spawning gravel augmentation, side channel reconnection, riparian and educational projects have been undertaken. Woodbridge Irrigation District has completed the rebuilding of the dam at

Woodbridge with improved fish passage facilities and improved screening at the diversion (USFWS 2008).

Steelhead

Although steelhead historically had sustained annual runs up the Mokelumne River, no information exists on the size of these historic runs (USFWS 1995). The Mokelumne River Fish Hatchery was constructed in 1964 as mitigation for loss of spawning habitat between Camanche and Pardee Dam. The hatchery has received an average of about 500 Chinook salmon adults between 1967 and 1991 (USFWS 1995). The Mokelumne River Fish Hatchery has an annual production goal of 100,000 yearling fish, which are primarily from Feather River and American River stocks (Reclamation 2008). However, NMFS (1998; 1999) does not consider Mokelumne River Fish Installation stocks to be part of the Central Valley ESU. Mokelumne River rainbow trout (hatchery produced and naturally spawned) are genetically most similar to Mount Shasta Hatchery trout, but also show genetic similarity to the Northern California ESU (Nielsen 1997, as cited in NMFS 1997b).

More recently, monitoring has detected small, self-sustaining populations of steelhead (although influenced by the Mokelumne River Hatchery steelhead program) in the Mokelumne River (NMFS 2009). Since implementation of the Joint Settlement Agreement, East Bay Municipal Utilities District has monitored *O. mykiss* populations in the lower Mokelumne River using video monitoring as the Woodbridge Irrigation District Dam (WIDD) fish ladder, rotary screw traps in the lower Mokelumne River downstream of the WIDD, and conducted seasonal fish surveys from Camanche Dam downstream to WIDD (**Table 1**) (EBMUD et al. 2008). Steelhead redd surveys in the lower Mokelumne River are conducted between Camanche Dam and the Elliott Road Bridge (EBMUD et al. 2008).

Table 1. *O. mykiss* observed in the fisheries sampling conducted in the lower Mokelumne River from Camanche Dam downstream to Woodbridge Dam between 1998 and 2008 (Reproduced from EBMUD et al. 2008)

Watershed/Ecosystem Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

There is a general consensus in the available literature suggesting that habitat for steelhead in the American River below Nimbus Dam is impaired (Reclamation 2008; NMFS 2009; Water Forum 2005; Water Forum 2005a; SWRI 2001; CDFG 1991, 2001). Of particular concern are warm water temperatures, flow fluctuations, and limited flow-dependent habitat (e.g., low flows during summer and fall limiting predator refuge habitat for juveniles). It has been suggested that the environmental factor probably most limiting to natural production of steelhead in the lower American River is high water temperatures during the summer and fall (Water Forum 2005; Reclamation 2008). Structural modifications may be needed to alleviate this limiting factor, including, but not limited to enhancing or replacing the shutter system at Folsom Dam, dredging and/or construction of temperature control curtains in Lake Natoma, and installation of a temperature control device at the El Dorado Irrigation District diversion.

Based on general observations of habitat complexity in terms of the distribution and availability of mesohabitat types (e.g., riffles, runs, and pools), with respect to geomorphology, it does not appear that the lower American River is in a highly degraded state, although a specific study addressing this issue is needed. One known concern regarding habitat complexity in the lower American River is that recruitment of large woody debris is limited, primarily because the debris is removed in order to provide safer conditions for rafting and other recreation activities.

The presence of Nimbus and Folsom dams have the most influence on the restoration potential of the American River watershed. Dams produce extensive ecological disruptions, including alteration of flow regimes, sedimentation, and nutrient fluxes, modification of stream-channel morphology, spatial decoupling of rivers and their associated floodplains, disruption of food webs, and fragmentation and loss of habitat (Ligon *et al.* 1995, Levin and Tolimieri 2001). All of these disruptions have occurred in the American River watershed due to the construction of Nimbus and Folsom dams.

Between Folsom Lake and the next upstream fish barrier, approximately 57 miles of riverine habitat exists in the North, Middle, and South forks combined. Within this 57 miles (and in more upstream habitats), evaluations of habitat quality with respect to anadromous salmonid life history requirements are needed. An indication that these riverine habitats above Folsom Dam may still be of sufficient quality to support

anadromous salmonids is that populations of resident *O.mykiss* abundant enough to support recreational fisheries occur in all three forks, although the situation in the South Fork is complicated by the influence of stocking. The *O.mykiss* populations in the North and South Forks are entirely composed of wild fish.

Viability Potential for Steelhead in the Lower American River

The potential for the lower American River to support a viable population of steelhead is *low* based on the following discussion. Lindley *et al.* (2007) classifies the natural population of American River steelhead at a high risk of extinction because this population is mostly composed of steelhead originating from Nimbus Fish Hatchery. The small population size of only a few hundred in-river spawners (Hannon and Deason 2008) along with the complete loss of historic spawning habitat and degraded genetic composition (Garza and Pearse 2008) further support this classification. As noted above, warm water temperatures in the lower American River during the summer and fall are considered a major stressor to steelhead. Considering that both increased water demands and effects of climate change will lead to further deterioration of habitat conditions in the lower American River, including increased temperatures, the potential for wild steelhead to improve their from their low population status is limited.

Potential for Historic Habitats to Support Spawning Populations:

CV steelhead - **Moderate**

CV spring-run Chinook salmon – **Moderate**

The CV TRT assumed, based on the distance between forks, that the spring-run Chinook salmon that historically occurred in the North and Middle forks represented one independent population and the South fork spring-run represented a separate population (Lindley *et al.* 2004). Based on the TRT's assumption, we assume that spring-run Chinook salmon re-introduced to the North and Middle forks would represent one population and the South Fork would function as a separate population. This assumption applies to steelhead re-introductions as well. The North, Middle and South forks are characterized as having a **moderate** potential to support spawning populations of spring-run Chinook salmon and steelhead. This characterization is based on several conflicting factors, which are discussed for steelhead first and then for spring-run Chinook salmon.

First, historically, the American River watershed supported populations of summer-, fall-, and winter-run steelhead (Gerstung 1971). If steelhead were provided access to

and from historic habitat above Folsom Dam, and that habitat was restored to or maintained at a properly functioning level (McElhany et al. 2000), it is reasonable to assume that populations may become re-established. Fish passage around Folsom Dam would open up approximately 30 miles of riverine habitat in the North and Middle forks combined, and approximately 20 miles in the South fork, about twice the amount of habitat currently accessible to anadromous fish in the American River watershed. Second, recent genetic analyses of *O.mykiss* from above Folsom Dam indicate that those fish retain ancestral American River steelhead genetics (Garza and Pearson 2008), and thereby may serve as a source population for re-establishing anadromous steelhead above the dam. Third, the Middle Fork American River between Folsom Reservoir and Ralston Afterbay Dam (the first upstream barrier) currently supports naturally spawning populations of resident *O.mykiss*, an indication that that habitat is of sufficient quality to potentially support the anadromous form. *O.mykiss* also occur in the North (Garza and Pearse 2008) and South (<http://www.dfg.ca.gov/fishingpassport/guide.asp>) forks and it is likely that these fish are also reproducing naturally, although published accounts of this were not identified in the literature.

Factors which decrease the potential of historic habitats to support a spawning steelhead population include: (1) those habitats have been affected by past mining activities and more recent human development including, for example on the Middle Fork, the presence and operation of two storage reservoirs, five diversion dams, five power plants, and other related facilities (Reclamation 2009); and (2) providing upstream and downstream fish passage around Folsom Dam will involve considerable technologic, biologic, economic, social, and political issues.

The American River watershed above Folsom Dam is also characterized as having a **moderate** potential to support spawning populations of spring-run Chinook salmon, based on rationale similar to that presented above for steelhead. The strongest evidence suggesting that the habitat above Folsom Dam can support a spawning population of spring-run is that historically two independent populations occurred in the watershed, one in the North and Middle forks, and one in the South Fork (Lindley et al. 2004). However, as described for steelhead, these habitats have been altered by human development. It should be noted that our “moderate” characterization for spring-run Chinook salmon is made with less confidence than the steelhead characterization, because Chinook salmon are less plastic than *O.mykiss* in that they do not express a non-anadromous life history strategy, and subsequently, unlike for *O.mykiss*, there is no resident life form of spring-run Chinook salmon occurring in the watershed to indicate whether the habitat may or may not be suitable for the species.

The characterization of the potential for habitats accessible to anadromous salmonids before dam construction to support spawning populations if returned to those habitats could be made with more confidence and better support if evaluations of habitat quality with respect to anadromous salmonid life history requirements were available for all three forks. Such habitat evaluations are critical recovery actions for the American River watershed.

Key Threats and Stressors

Key threats and stressors to steelhead in the American River include the following:

- ❖ Nimbus and Folsom Dams (and smaller upstream dams) blocking access to historical spawning habitat;
- ❖ Warm water temperatures, particularly below dams, affecting juvenile rearing and outmigration and adult immigration and holding;
- ❖ Predation of juveniles;
- ❖ Loss of riparian habitat and instream cover affecting juvenile rearing and outmigration;
- ❖ Loss of floodplain habitat affecting juvenile rearing and outmigration;
- ❖ Loss of natural river morphology affecting juvenile rearing and outmigration;
- ❖ Competition for spawning habitat between natural- and hatchery-origin steelhead and the resultant effects on the genetic fitness of the natural population;
- ❖ Flow fluctuations affecting early life stages

Key Actions

- ❖ Conduct a passage feasibility study, including an assessment of potential salmonid habitat above Nimbus and Folsom dams.
- ❖ Implement physical and structural modifications to the American River Division of the CVP in order to improve water temperature management
- ❖ Evaluate the potential to replace the Nimbus Fish Hatchery broodstock with genetically more appropriate sources (e.g., the *O.mykiss* in the watershed above Folsom Dam which retain ancestral American River steelhead genetics).
- ❖ Develop a Nimbus Fish Hatchery Genetic Management Plan for steelhead.
- ❖ Evaluate Nimbus Fish Hatchery steelhead production and stocking practices to identify and implement measures that would promote restoration of wild steelhead in the lower American River.

- ❖ Develop State and national levee vegetation policies to maintain and restore riparian corridors in the American River (Corps vegetation management policy and FloodSAFE).
- ❖ Utilize bio-technical techniques that integrate riparian restoration for river bank stabilization instead of conventional rip rap in the American River.
- ❖ Inventory locations for creating shallow inundated floodplain habitat in the American River for multi-species benefits and implement where suitable opportunities are available.

Watershed Description

The American River drains a watershed of approximately 1,895 square miles (Reclamation 1996), and is a major tributary entering the Sacramento River and RM 60. The American River watershed drains about 1,900 square miles and ranges in elevation from 23 feet to more than 10,000 feet (USFWS 1995). The American River has historically provided over 125 miles of riverine habitat to anadromous and resident fishes. Presently, use of the American River by anadromous salmonids is limited to the 23 miles of river below Nimbus Dam (i.e., the lower American River) (Figure 1).

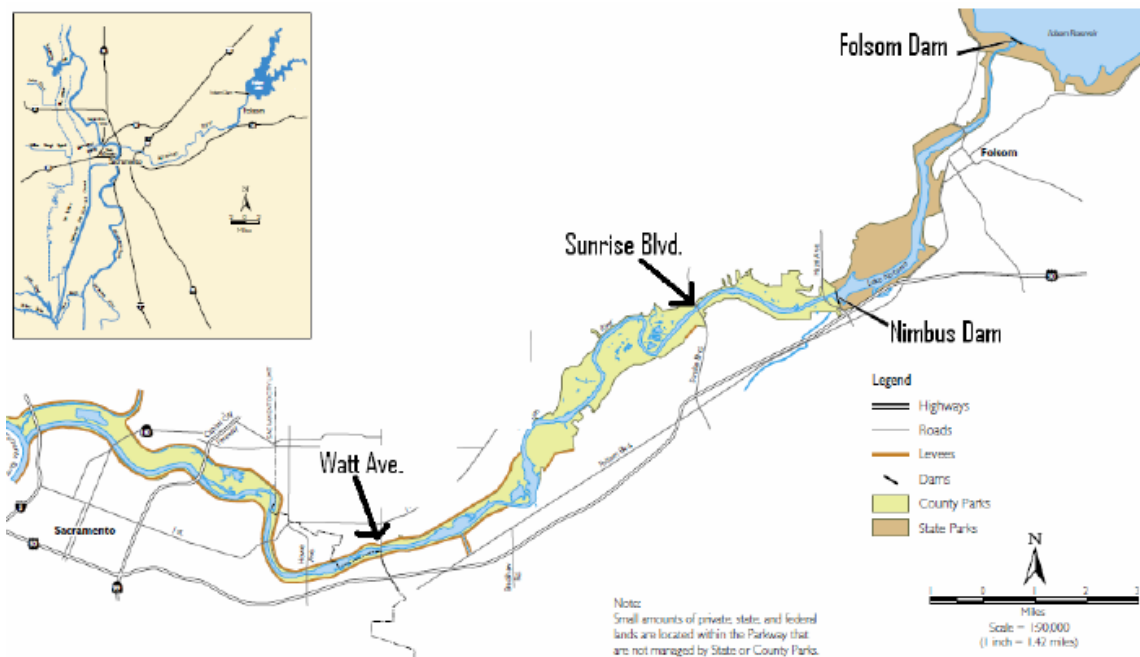

Figure 1. Map of lower American River. Source: NMFS 2009 (Modified from (Water Forum 2005).

Geology

As reported by SWRI (2001), from Folsom Dam to Fair Oaks, the American River floodplain is narrow. At Fair Oaks, the floodplain widens to about 1 to 5 miles, and the steep 125-foot high bluff of the Turlock Lake formation bounds the northern channel margin. Downstream, near Sacramento, the bluff height reduces to less than 10 feet and consists of the Riverbank Formation. The southern channel margin consists of a terrace of Recent-age alluvium that is lower than the northern bluff. The levees that have been constructed along both banks of the lower river are, therefore critical to flood control operations. The bed of the American River is primarily composed of gravel to cobble-sized material. However, gravel size can change seasonally and from year-to-year (SWRI 2001).

Hydrology

As reported by USFWS (1995), the American River accounts for approximately 15% of the total Sacramento River flow. Average annual precipitation over the watershed ranges from 23 inches on the valley floor to 58 inches at the river's headwaters. Snowmelt is the source of approximately 40% of the American River flow. Average historical unimpaired run-off at Folsom Dam, near the border between Sacramento and Placer counties, is 2.8 maf. The median historical unimpaired run-off is 2.5 maf, with a range of 0.3-6.4 maf. The American River has three major branches: the South Fork, the Middle Fork, and the North Fork. Today, 13 major reservoirs exist in the drainage with total storage capacity of 1.9 maf. Folsom Lake, the largest reservoir in the drainage, was constructed in 1956 and has a capacity of 974 taf. Folsom Dam, approximately 30 miles upstream from the mouth, is a major element of the Central Valley Project. The dam is operated by USBR as an integrated system to meet contractual water demands and instream flow and water quality requirements (USFWS 1995).

Completion and operation of Folsom and Nimbus dams resulted in higher flows during fall, significantly lower flows during winter and spring, and significantly higher flows during summer.

Land Use

The following discussion on the historical land use in the American River watershed was directly taken from the *Impacts on Lower American River Salmonids and Recommendations Associated with Folsom Reservoir Operations to Meet Delta Water Quality Objectives and Demands* (Water Forum 2005a). Prior to 1849, the riparian vegetation along the river formed extensive, continuous forests in the floodplain, reaching widths of up to 4 miles. Settlement of the lower American River floodplain by non-indigenous peoples and the resulting modifications of the physical processes shaping the river and

its floodplain have drastically altered the habitats along the river. Early settlers removed trees and converted riparian areas to agricultural fields. Hydraulic gold mining in the watershed caused deposits of 5-30 feet of sand, silt, and fine gravels on the riverbed of the lower American River. These deposits resulted in extensive sand and gravel bars in the lower river and an overall rising of the river channel and surrounding floodplain. This was later exacerbated by gravel extraction activities. As a result, the floodplain's water table has dropped, reducing the growth and regeneration of the riparian forest (Water Forum 2005a).

Additional habitat impacts resulted from the construction of Folsom and Nimbus Dams. These structures have blocked the main upstream sediment supply to the lower American River. This sediment deficit reduces the amount of material that can deposit into bars and floodplains in the lower reaches, resulting in less substrate for growth of cottonwoods and other riparian vegetation (Stromberg *et al.* 2007). Modification of river flows resulting from the operation of Folsom Dam and Reservoir has likely affected the potential for regeneration of cottonwood. Flows that had historically occurred during the seed dispersal period for cottonwood shifted from the late spring/early summer to late summer or no longer occur. Also, artificial flow fluctuations can cause the stranding of fish in ponds and depressions on the floodplain when high flows recede (Water Forum 2005a).

Since the 1970s, bank erosion, channel degradation and creation of riprap revetments have contributed to the decline of riparian vegetation along the river's edge, loss of soft bank and channel complexity, and reduced amounts of large woody debris in the river that are used by fish and other species. Currently, some of the large woody debris that does still accumulate in the river is removed to provide safer conditions for recreation activities such as swimming and rafting. In addition, there has been a decrease in overhanging bank vegetation called shaded riverine aquatic (SRA) habitat (Water Forum 2005a).

Urbanization throughout the greater Sacramento area has led to a replacement of agricultural land uses within the American River floodplain with urban land uses, and a corresponding increase in urban runoff (SWRI 2001). Based on data from 1992 through 1998 collected by the Ambient Monitoring Program, lower American River water quality exceeded State (California Toxics Rule) or Federal (EPA) criteria with respect to concentrations of four metals – lead, copper, zinc, and cadmium (SWRI 2001). High concentrations of these metals have adverse effects on fish. In particular, studies have demonstrated that fish fed diets contaminated with zinc exhibited reduced survival, growth, and increased incidence of disease (Farag *et al.* 1994, Bowen *et al.* 2006). It should be noted that zinc is easily bioaccumulated in stream invertebrates – an

important food source for juvenile salmonids while rearing in freshwater systems (Bowen *et al.* 2006).

Fisheries and Aquatic Habitat

Including the mainstem, and north, middle, and south forks, historically over 125 miles of riverine habitat were available for anadromous salmonids in the American River watershed (Yoshiyama *et al.* 1996). The construction of Nimbus Dam in 1955 blocked steelhead and spring-run Chinook salmon from all of their historic spawning habitat in the American River (Lindley *et al.* 2006). Hydrological and ecological changes associated with the construction of the dams contributed to the extirpation of summer steelhead and spring-run Chinook salmon, which were already greatly diminished by the effects of smaller dams (*e.g.*, Old Folsom Dam and the North Fork Ditch Company Dam) and mining activities (Yoshiyama *et al.* 1996).

Development of the American River watershed has modified the seasonal flow and water temperature patterns in the lower American River. Operation of the Folsom-Nimbus project significantly altered downstream flow and water temperature regimes. In addition, operation of Sacramento Municipal Utility District's Upper American River Project (UARP) since 1962, as well as Placer County Water Agency's Middle Fork Project (MFP) since 1967, altered inflow patterns to Folsom Reservoir (SWRI 2001). Completion and operation of Folsom and Nimbus dams resulted in higher flows during fall, lower flows during winter and spring, and higher flows during summer

Seasonal water temperature regimes also have changed with development in the American River watershed, particularly with the construction and operation of Folsom and Nimbus Dams. Prior to the completion of Folsom and Nimbus Dams in 1955, maximum water temperatures during summer frequently reached temperatures as high as 75°F to 80°F in the lower American River (Gerstung 1971). Although summer water temperatures are cooler in the lower river after Folsom Dam was constructed as compared to the pre-dam conditions, prior to habitat elimination resulting from the dam, rearing fish had access to cooler habitats throughout the summer at higher elevations.

Water temperature management for anadromous salmonids is an issue of concern in the lower American River. For example, the occurrence of a bacterial-caused inflammation of the anal vent (commonly referred to as "rosy anus") of American River steelhead has been reported by CDFG to be associated with warm water temperatures. Sampling in the summer of 2004 showed that this vent inflammation was prevalent in steelhead throughout the river and the frequency of its occurrence increased as the duration of

exposure to water temperatures over 65°F increased. At one site, the frequency of occurrence of the anal vent inflammation increased from about 10 percent in August, to about 42 percent in September, and finally up to about 66 percent in October (Water Forum 2005a). During the summer, mean daily water temperatures at Watt Avenue often exceed 68°F (NMFS 2009).

Predators of juvenile steelhead in the lower American River include both native (*e.g.*, pikeminnow) and non-native (*e.g.*, striped bass) fish as well as avian species. Some striped bass reportedly reside in the lower American River year-round, although their abundance greatly increases in the spring and early summer as they migrate into the river at roughly the same time that steelhead are both emerging from spawning gravels as vulnerable fry and are migrating out of the river as smolts (SWRI 2001). Striped bass are opportunistic feeders, and almost any fish or invertebrate occupying the same habitat eventually appears in their diet (Moyle 2002). Empirical data examining the effect of striped bass predation on steelhead in the American River have not been collected, although one such study was recently conducted in the Delta (CDWR 2008). Results of this study concluded that steelhead of smolt size had a mortality rate within Clifton Court Forebay that ranged from 78 ± 4 percent to 82 ± 3 percent over the various replicates of the study. The primary source of mortality to these steelhead is believed to be predation by striped bass. Although Clifton Court Forebay and the lower American River are dramatically different systems, this study does demonstrate that striped bass are effective predators of relatively large-sized steelhead. Considering that striped bass are abundant in the lower American River during the spring and early summer (SWRI 2001), when much of the steelhead initial rearing and smolt emigration life stages are occurring, striped bass predation on juvenile steelhead is considered to be a very important stressor to this population.

Steelhead

Between 1944 and 1947, annual counts of summer-run steelhead passing through the Old Folsom Dam fish ladder during May, June, and July at Old Folsom Dam (RM 27) ranged from 400 to 1,246 fish (Gerstung 1971). After 1950, when the fish ladder at Old Folsom Dam was destroyed by flood flows, summer-run steelhead perished in the warm water in areas below Old Folsom Dam. By 1955, summer-run steelhead (and spring-run Chinook salmon) were completely extirpated and only remnant runs of fall- and winter-run steelhead and fall-run Chinook salmon persisted in the American River (Gerstung 1971).

Estimates of historic run sizes for fall- and winter-run steelhead in the American River were not identified in the available literature. However, all three (summer, fall, and

winter) runs of steelhead were likely historically abundant in the American River considering: (1) the extent of available habitat; (2) the historic run size estimates of Chinook salmon before massive habitat degradation occurred; and (3) the reported historic run size estimates for summer-run steelhead in the 1940s which occurred even after extensive habitat degradation and elimination.

The following information on the current status of American River steelhead comes from the *Biological Opinion on the Long-Term Central Valley Project and State Water Project Operations Criteria and Plan* (NMFS 2009) and references therein.

The Central Valley steelhead DPS includes naturally-spawned steelhead in the American River but excludes steelhead spawned and reared at Nimbus Fish Hatchery. The current population size of about a few hundred in-river spawning steelhead (Hannon and Deason 2008) is much lower than estimates from the 1970s (Staley 1976), and is primarily composed of fish originating from Nimbus Hatchery. This means that the listed population (*i.e.*, naturally-produced fish) in the lower American River is at an abundance level lower than the estimates provided by Hannon and Deason (2008) and is likely on the order of tens.

In addition to small population size, other major factors influencing the status of naturally spawning steelhead in the American River include: (1) a 100 percent loss of historic spawning habitat resulting from the construction of Nimbus and Folsom Dams (Lindley *et al.* 2007), which has obvious and extreme implications for the spatial structure of the population; and (2) the operation of Nimbus Fish Hatchery, which has completely altered the diversity of the population.

Lindley *et al.* (2007) classifies the natural population of American River steelhead at a high risk of extinction because this population is reportedly mostly composed of steelhead originating from Nimbus Fish Hatchery. The small population size and complete loss of historic spawning habitat and genetic composition further support this classification.

Watershed/Ecosystem Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

The limiting factor for steelhead in the Auburn Ravine system is suitable spawning habitat. Due to the current out of basin water imports and related flow regimes, these streams provide spawning and rearing habitats that would otherwise be limited or absent. Rainbow trout are known to spawn here, however, steelhead spawning has not been confirmed. If suitable spawning habitat were to be established, it is possible that there would be more active use of this creek by steelhead.

To facilitate Auburn Ravine water deliveries to users, there are approximately 10 small seasonal diversion dams installed throughout Auburn Ravine. Most of the dams are less than 10 feet high and pond water for diversion into agricultural areas. Larger dams also divert water into major canals. Installation of the seasonal dams during the spring and removal during the fall reportedly can affect the upstream migration of some fish species (e.g., steelhead and fall-run Chinook salmon) (Jones & Stokes Associates 1999).

As reported by SARSAS (2009), Placer Legacy and NID are currently in the process of retrofitting the Lincoln Gaging Station and Hemphill Dam for fish passage. These dams will be retrofitted by the end of Summer 2009. Fish will then be able to reach the base of NID's Gold Hill Diversion Dam. NID has identified retrofitting Gold Hill Dam to facilitate fish passage as a focus for NID once fish are able to reach the dam (SARSAS 2009).

Viability Potential

CV steelhead: **Low**

The potential for Auburn Ravine and Coon Creek to support a viable population of steelhead is considered to be low due to the limited amount of habitat that provides

suitable spawning and year-round rearing habitats, at marginally suitable elevations. The existing population is largely supported by cold water imports from other watersheds.

Key Threats and Stressors

Key threats and stressors to steelhead in Auburn Ravine and Coon Creek include, but are not limited to the following:

- ❖ Passage impediments/barriers affecting adult immigration and spawning
- ❖ Flow conditions (i.e., low flows, flow fluctuations) associated with attraction and migratory cues into the Auburn Ravine and Coon Creek drainage affecting adult immigration and spawning
- ❖ Limited instream gravel supply and habitat availability affecting spawning
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Water temperature and water quality (e.g., agricultural and urban runoff) into the Auburn Ravine and Coon Creek drainage affecting juvenile rearing and outmigration
- ❖ Entrainment at individual diversions in the Auburn Ravine and Coon Creek drainages affecting juvenile rearing and outmigration
- ❖ Loss of natural morphology, riparian habitat and instream cover affecting juvenile rearing and outmigration
- ❖ Predation associated with non-site specific and structure-related habitats in the Auburn Ravine and Coon Creek drainage affecting juvenile rearing and outmigration

Key Actions

- ❖ Evaluate fish passage impediments and either remove or replace priority sites with state-of-the-art fish passage facilities that meet NMFS fish passage criteria. Passage impediments/barriers affecting adult immigration and spawning.
- ❖ Reduce juvenile entrainment throughout the watershed.
- ❖ Evaluate opportunities to maintain suitable water temperature and instream flows necessary to support spawning and rearing steelhead populations.
- ❖ Evaluate and implement spawning gravel supplementation projects.

Watershed Description

Auburn Ravine originates north of the City of Auburn and flows 29 miles to its confluence with the East Side Canal, draining an area of approximately 79 square miles.

The East Side Canal drains into the Cross Canal, which then drains into the Sacramento River just southeast (downstream) of the Feather River confluence. The elevation of the Auburn Ravine basin ranges from 1,600 to 30 feet above mean sea level (msl) (County of Placer 2002). Primary tributaries to Auburn Ravine include North, Dutch, and George's Ravines (County of Placer 2002).

The Coon Creek watershed originates in the foothills north and east of the City of Auburn, near Clipper Gap. The watershed east of SR 49 is primarily composed of two intermittent tributaries, Dry Creek and Orr Creek, which eventually merge approximately one mile west of SR 49 to form Coon Creek (County of Placer 2002). Primary tributaries to upper Coon Creek include Orr, Dry, and Rock Creeks, and Deadman Canyon. Doty Ravine is the primary tributary of Coon Creek. The Doty Ravine watershed originates in the Bald Hill area north of Newcastle and flows westerly for about 8.5 miles before leaving the upper watershed just east of McCourtney Road. Major tributaries to Doty Ravine include Sailor's Ravine and Caps Ravine (County of Placer 2002).

Geology

As reported by North Fork Associates (2003), the area immediately around Auburn consists of Jurassic and Triassic metavolcanic rocks. The remainder of the upper foothills is composed of Mesozoic granitic rocks. Pliocene nonmarine sediments occur between the granitic rocks to the east and Highway 65 between Roseville and Lincoln. These sediments form the Mehrten Formation, which consists of a variety of cemented material and is well known for supporting vernal pools along the east side of the Central Valley. Eocene deposits of the Ione Formation form small pockets associated with the Mehrten Formation. West of Highway 65 is a large amount of Pliocene and Pleistocene nonmarine sediments, which tend to form coarse, well drained soils. Further to the west, more recent alluvial fan deposits form coarse to fine grained soils. Soils in the upper and lower foothills of western Placer County include Auburn, Sobrante, Andregg, Caperton, Sierra, Exchequer, and Inks. The upper foothill soils are shallow to moderately deep and are typically well drained. Therefore, much of the rainfall in this region enters streams either through direct runoff or groundwater discharges. The Exchequer-Inks soils occur over shallow volcanic rock. Inks soils are formed from consolidated or cemented sediments derived from volcanic rock, and is one of the primary Mehrten Formation soils. Valley soils include San Joaquin, Cometa, Fiddymont, Kasberg, Ramona, Kilga, Redding, and Corning Series. Several of these are Alfisols and have dense, subsurface clay layers that impede water percolation. Wetlands are often found on these soils because they tend to hold water, especially in depressions (North Fork Associates 2003).

Hydrology

As reported by County of Placer (2002), water management practices in Auburn Ravine, Coon Creek, and Doty Ravine are different than most small East Side foothill tributary streams. Because these watersheds are relatively small, very little of the stream flow is from natural runoff. Coon Creek's hydrology is similar to Auburn Ravine, except that nearly all irrigation water is diverted out of the channel just downstream of Highway 65 during the irrigation season. Water in the Coon Creek channel downstream of this diversion point is primarily groundwater inflows or agricultural return flows (County of Placer 2002).

Historically, Auburn Ravine flows were ephemeral (Sierra Business Council 2003). Flows gradually declined through the spring, summer, and early fall until the first seasonal storm events occurred. Compared to the historical flow regime, current management practices produce higher flows year-round and more consistent flows during the spring and summer months (Table 2). Most of the instream flow in Auburn Ravine is water imported from the Yuba River, Bear River, and American River watersheds through various means, to meet domestic and agricultural needs in western Placer County and southeastern Sutter County (Sierra Business Council 2003). Discharges from PG&E's Wise Powerhouse dominate instream flows during the irrigation season, which extends from April 15 through October 15. Winter flows are dominated by discharges from wastewater treatment facilities and natural runoff. Current water management practices in Auburn Ravine likely provide cold water habitat for salmonids during time periods which historically lacked cold water habitat (Sierra Business Council 2003).

Table 2.. Estimated historic and existing streamflow regimes in Auburn Ravine (cfs)

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

Existing	117	120	132	66	88	82	114	99	43	30	39	84

Source: Jones & Stokes Associates 1999

The relatively cool water discharged from the Wise Powerhouse originates from the Drum-Spaulding Project on the Yuba and Bear rivers. PCWA also discharges up to 50 cfs of water from the North Fork American River into Auburn Ravine during the irrigation season. NID, PCWA, and South Sutter Water District, and their customers, divert water from Auburn Ravine primarily for irrigation purposes. Water

temperatures in Auburn Ravine during the irrigation season are heavily influenced by these discharges and diversions.

As reported by County of Placer (2002), the Placer County Wastewater Treatment Plant, discharges treated effluent into Rock Creek. Rock Creek joins Dry Creek about 50 yards downstream of the effluent outfall. Dry Creek continues to flow west to the confluence with Orr Creek, which flows from the northeast. Dry Creek and Orr Creek join together to form Coon Creek, which then flows generally westward to the Cross Canal before entering the Sacramento River. The upper half of the Coon Creek basin is characterized by a complex network of irrigation canals managed by NID to carry water imported from the Bear River (County of Placer 2002).

The maximum elevation of the Auburn Ravine watershed is approximately 1,000 feet above mean sea level (MSL). Therefore, precipitation in the watershed falls nearly exclusively as rainfall. The annual timing of rainfall is fairly consistent, with the majority of a water year's precipitation occurring between November and April. However, the amount of precipitation can vary greatly on an annual basis, and individual storm cells can deliver a large amount of rainfall in a relatively short period, even during drought periods (County of Placer 2002).

Winter flows vary widely between and among the Auburn Ravine and Coon Creek watersheds. Auburn Ravine's winter flow peaks can range from a few hundred cubic feet per second (cfs) to an estimated 100-year flow event exceeding 17,000 cfs. Coon Creek's peak flows can range from several hundred cfs in smaller events to more than 22,000 cfs in a hundred year event (County of Placer 2002). High flow events are not contained within the channel of Coon Creek and extensive overland flow occurs (County of Placer 2002).

The critical low flow period generally occurs in October when irrigation season ends and flows from imported sources cease or greatly diminish. Flows during this period (generally early October until winter rains are sufficient to generate additional natural stream flow) are often only a few cfs, resulting in a substantial decrease in aquatic habitat in the low gradient portions of the Auburn Ravine, Doty Ravine, and Coon Creek watersheds (County of Placer 2002).

Land Use

As reported by Placer of County (2002), portions of Auburn Ravine, Dutch Ravine, Doty Ravine, and Coon Creek were placer mined in the mid-to-late 1800s. This activity resulted in removal of riparian vegetation, excavation of soil, and redeposition of

tailings. Large quantities of sediment, generated by hydraulic mining, were washed into stream channels and most of this sediment was deposited on the valley floor. Trees were also removed for firewood, construction materials, and to facilitate grazing and farming. In the western portion of the watersheds, the creeks have been largely confined to narrow channels and the riparian plant community reduced to a narrow band along the banks.

Lower elevations, which were once dominated by marshlands, have been largely converted to irrigated agriculture. Stream channels have been converted to irrigation/flood canals, with some riparian vegetation within a generally open grassy levee system. Historic vernal pool grasslands have been largely replaced by farmland. Upstream, streams flow through non-native grassland (often grazed) and agricultural fields, with a thin margin of mixed native and non-native riparian species along the creeks. Grassland areas may include patches of valley oak woodland. Oak woodland and mixed oak woodland and scrub habitats become more predominant in the foothills, transitioning to heavier forested areas in the steeper portions of the watershed. These plant communities are affected significantly by the invasion of exotic plants, including a variety of non-native grasses and weedy species such as mustard, broom, and Himalayan blackberry. These species have largely replaced the native grass and forb habitats of the lower foothills (County of Placer 2002).

Auburn Ravine flows through the middle of the city of Auburn, where it is channelized and passes through a variety of culverts. The land adjacent to this portion of the watershed is highly urbanized. Immediately west of the City of Auburn, the character of the channel changes, adjacent land uses change, and water from various sources is discharged into the channel (County of Placer 2002).

The primary ecological and land use concern in the Auburn Ravine and Coon Creek watersheds is the conversion of existing land uses from agriculture to urban and suburban development. Stream and riparian zone areas would face further ecological stress due to the conversion of adjacent upland habitats to urban and suburban development. Additionally, it is anticipated that water quality will decline with urbanization of the surrounding watersheds. Sustaining commercial agriculture, with its open space component, is a primary goal of habitat conservation, as planned urban development and uncontrolled annexation of agricultural lands continues (County of Placer 2002).

Urban development is least likely to occur along Coon Creek above Gladding Road due to large parcel sizes, current General Plan designations, a lack of urban services and environmental constraints. Auburn Ravine is experiencing the greatest pressures from

urban encroachment with the expansion of housing tracts in the Lincoln area. Development could be a major constraint on fishery restoration as most land in the watershed is in private ownership and has no permanent protection (Bear River Watershed Group Website 2009).

Due to large parcel sizes, particularly along Coon Creek upstream of Gladding Road, blue oak woodlands are relatively intact and unfragmented, thus providing large patch sizes for terrestrial species. The Auburn Ravine's upper watershed is more fragmented due to the predominance of the rural resources land designation. The potential for subdivision development in the upper Coon Creek watershed is generally low under current General Plan designations and is unlikely to occur in the future because of a lack of urban services and environmental constraints. The dominant land use in the portion of the watersheds west of Lincoln is rice farming. This land use drives the current water management practices and the timing and flow volumes of water that is delivered during the spring, summer, and early fall (County of Placer 2002).

Fisheries and Aquatic Habitat

As reported by County of Placer (2002), Auburn Ravine provides a diversity of aquatic habitats, including shallow, fast-water riffles, glides, runs and pools. Near its headwaters in the City of Auburn, Auburn Ravine is highly restricted to its natural channel and passes through several culverts. From the western edge of the City of Auburn to west of Lozanos Road, Auburn Ravine is confined in a narrow canyon and has a steep gradient. Stream habitat units in this reach are primarily cascades and pool-riffle complexes, while the substrate consists of bedrock, sands, and cobbles. Just east of Gold Hill Road, the channel gradient in Auburn Ravine decreases to less than 2 percent and the stream habitat is dominated by pools, riffles, and runs, while the substrate is dominated by sands and gravels. Near the City of Lincoln, the stream gradient decreases to less than one percent and the stream habitat shifts from pool-riffle complexes with mixes of gravels and sands to dune-ripple complexes dominated by coarse sand. The lowermost seven miles of Auburn Ravine are confined within naturally erosion-resistant banks and man-made levees, and are dominated by dune-ripple complexes and a sandy substrate (County of Placer 2002).

Aquatic habitat surveys of Auburn Ravine, within and downstream of the City of Lincoln, indicate that a large percentage of the stream is dominated by sandy and silty substrates. Sandy and silty substrates also dominate the middle reaches of Coon Creek and portions of Doty Ravine. These substrate types are characterized by low instream productivity and low habitat diversity. The sources of these sediment inputs are not apparent, but the small grain size and continuously shifting nature of these substrate

types contribute to what are considered low quality fish habitats. These substrate types eliminate, for all practical purposes, the potential for Chinook salmon and steelhead spawning in areas downstream of the Highway 65 Bridge in Lincoln (County of Placer 2002).

Without the water imported into these watersheds, most would be dry, or nearly so, for several months of the year. Due to the current water delivery schedules and flow volumes, there are riparian and aquatic habitats along tens of miles of stream channel length that would otherwise be absent. As a result, these streams may support aquatic species that would not otherwise have found suitable habitat in this region. At the same time, these enhanced flow regimes provide habitat for non-native species; for example, the regular flow regime may enhance conditions for Himalayan blackberry, a non-native species that crowds out native plants (County of Placer 2002).

Flows and water temperatures in Auburn Ravine are influenced by discharges from the Lincoln Wastewater Treatment and Reclamation Facility (WWTRF) and the Auburn Wastewater Treatment Plant (WWTP). These discharges likely are warmer than the receiving waters in Auburn Ravine. Another factor influencing Auburn Ravine water temperature is the amount of overhanging riparian vegetation. The lack of riparian buffers along the downstream reaches of Auburn Ravine likely contributes to elevated water temperatures.

To facilitate Auburn Ravine water deliveries to users, there are approximately 10 small seasonal diversion dams installed throughout Auburn Ravine. Most of the dams are less than 10 feet high and pond water for diversion into agricultural areas. Larger dams also divert water into major canals. Installation of the seasonal dams during the spring and removal during the fall reportedly can affect the upstream migration of some fish species (e.g., steelhead and fall-run Chinook salmon) (Jones & Stokes Associates 1999).

As reported by SARSAS (2009), Placer Legacy and NID are currently in the process of retrofitting the Lincoln Gaging Station and Hemphill Dam for fish passage. These dams will be retrofitted by the end of Summer 2009. Fish will then be able to reach the base of NID's Gold Hill Diversion Dam. NID has identified retrofitting Gold Hill Dam to facilitate fish passage as a focus for NID once fish are able to reach the dam (SARSAS 2009).

Steelhead

Historically, low elevation streams such as Auburn Ravine likely were essentially dry during the summer and fall, at least in the foothill sections. Therefore, streams such as

Auburn Ravine likely were not conducive to supporting significant or consistent steelhead populations. Local area residents have reported that steelhead routinely spawned near Auburn (Jones & Stokes Associates 1999).

Documented evidence of steelhead spawning (e.g., observations of steelhead actively spawning or confirmed steelhead redds) in Auburn Ravine has not been located, however, the presence of juvenile rainbow trout captured during electrofishing surveys and seining suggests that at least rainbow trout successfully spawn in Auburn Ravine (CDFG 2005, unpublished data).

Currently, information regarding steelhead presence and habitat utilization in Auburn Ravine is either limited or not readily available. Steelhead were not collected during the 1997 fish survey, although juvenile fishes were collected in upper reaches during the 1998 and 1999 surveys (Jones & Stokes Associates 1999). The 1998 survey reported that some of the captured juvenile fish exhibited the iridescent silvery sides typical of smolting salmonids (Jones & Stokes Associates 1999); however, it can be difficult to determine whether juvenile fish are anadromous or resident forms of the species. The juvenile fishes collected during the 1999 survey reportedly did not exhibit any obvious visual characteristics of emigration associated with the anadromous form (i.e., steelhead) (Jones & Stokes Associates 1999).

CDFG (2005, unpublished data) conducted two-pass electrofishing surveys on a total of seven reaches in Auburn Ravine during the fall/winter of 2004 and the spring of 2005. During the 2004 fall/winter survey, a total of 689 fish were collected in Auburn Ravine, 309 of which were identified as steelhead/rainbow trout. Of the 674 fish collected during the 2005 survey, 253 were identified as steelhead/rainbow trout. The CDFG survey results indicate that Auburn Ravine may constitute a probable steelhead spawning area given the presence of very small juveniles during spring. Auburn Ravine, both upstream and downstream of the tunnel outlet, may represent a year-round rearing area for juvenile steelhead, given the presence of both YOY and larger juveniles during November, December, and April.

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Because of the extensive changes that have happened to Dry Creek's channel morphology, restoration of this creek has potential but will be tricky. Throughout the watershed, reaches have been straightened, floodplain area reduced, reaches dredged, and riparian vegetation removed, resulting in eroding banks, sediment deposition, lack of cover, lack of pools and riffles, lack of riparian vegetation, and barriers to fish passage. Additionally, placer mining in Secret, Strap, and Miners Ravines accelerated stream incision down to the bedrock in the upper reaches. However, Dry Creek does support a relatively healthy riparian corridor upstream of Folsom Road to the confluence with Miners and Secret ravines (ECORP Consulting 2003), and thus, the focus for restoration should be in those areas along that reach that can support stream cover and natural channel processes.

Viability Potential

CV steelhead: **Low**

The potential for Dry Creek to support a viable population of steelhead is considered to be low due to the limited amount of habitat that provides suitable spawning and year-round rearing habitats, at marginally suitable elevations.

Key Threats and Stressors

Key threats and stressors to steelhead in Dry Creek include but are not limited to the following:

- ❖ Passage impediments/barriers in the Dry Creek watershed affecting adult immigration and holding

- ❖ Elevated water temperatures and water quality (agricultural and urban runoff) affecting adult immigration and holding, spawning and embryo incubation, juvenile rearing and outmigration
- ❖ Flow fluctuations affecting spawning
- ❖ Physical habitat alteration associated with limited supplies of instream gravel, habitat suitability and spawning habitat availability affecting adult spawning
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Loss of natural morphology, riparian habitat and instream cover affecting juvenile rearing and outmigration

Key Actions

- ❖ Evaluate fish passage impediments and either remove or replace priority sites with state-of-the-art fish passage facilities that meet NMFS fish passage criteria. Passage impediments/barriers affecting adult immigration and spawning.
- ❖ Reduce juvenile entrainment throughout the watershed.
- ❖ Evaluate opportunities to maintain suitable water temperature and instream flows necessary to support spawning and rearing steelhead populations.
- ❖ Evaluate and implement spawning gravel supplementation projects.

Watershed Description

The following information on the Dry Creek watershed is summarized from the *Dry Creek Watershed Coordinated Resource Management Plan* (ECORP Consulting 2003).

Dry Creek originates in the Sierra Nevada Foothills, drains approximately 101 square miles, and is approximately 17.6 miles long (ECORP Consulting 2003) and is hydraulically connected to the Sacramento River *via* the Natomas East Main Drainage Canal. The Dry Creek watershed covers a range from just west of Auburn (Placer County) west to Steelhead Creek (north of Sacramento, Sacramento County), and south to Folsom (Sacramento County). The mainstem drainage system is composed of 1.3 miles of intermittent drainage, 20.3 miles of first-order perennial, and 21.6 miles of second-order perennial streams.

Elevations in the Dry Creek watershed ranges from approximately 1200 feet above mean sea level (msl) down to approximately 30 feet above msl. Below Elverta Road, Dry Creek diverges into two channels (i.e., the Main Fork and the North Fork). The Main Fork lies to the south and contains flow year-round. The North Fork is several feet higher than the Main Fork and functions as an overflow channel (Foothill

Associates 2003). Tributaries to Dry Creek include Secret Ravine, Miners Ravine, Strap Ravine, Antelope Creek, Clover Valley Creek, and Linda Creek.

Geology

Soils within the Dry Creek watershed are variable, depending upon landscape position and underlying geology. Most soils are formed from either granitic or volcanic parent material, and often include a clay pan, hard pan, or other consolidated layer that impedes water permeability. Shallow soils and rock outcrops are fairly common at higher elevations. At lower elevations, soils are generally on flatter lands and underlain by a claypan or hardpan, have low permeabilities, finer texture (e.g., silts and clays), low soil strength, and high shrink-swell potential. These soils often require artificial drainage for development or agriculture. Additionally, areas of the watershed are underlain by Mehrten Formation that may present infiltration impediments and support vernal pool ecologies (ECORP Consulting 2003).

Hydrology

The headwaters of three major Dry Creek tributaries, Antelope Creek, Secret Ravine, and Miners Ravine, begin in the foothills of the Sierra Nevada mountain range at 900 to 1200 feet above mean sea level. Secret Ravine converges with Miners Ravine just upstream from Eureka Road in Roseville, CA. Antelope Creek enters Dry Creek just south of Atlantic Boulevard, also in Roseville. Linda Creek and Strap Ravine are lower gradient streams that begin near Granite Bay at a mean sea level elevation of 300 to 500 feet. Linda Creek is tributary to Cirby Creek. Cirby Creek then flows into Dry Creek just downstream of Royer Park in Roseville. The Dry Creek mainstem begins at the confluence of Secret Ravine and Miners Ravine and flows down to about 30 feet above mean sea level into Steelhead Creek (i.e., the Natomas East Main Drainage Canal) in Sacramento County (ECORP Consulting 2003).

Numerous canals, aqueducts, siphons, reservoirs, ponds, dams, pipelines, and other natural and non-natural water features significantly influence local hydrology within the Dry Creek watershed. Modification of the watershed's hydrology is compounded by modification of the instream configuration by channelization, levees, dredging, and reduced floodplain area. These modifications also result in altered stream flow where flow is faster in some areas (i.e., channelized conveyances), contributing to erosion and faster peak flow timing, but slower in other areas (i.e., behind dams and other impeding structures), contributing to flooding and sediment deposition.

Several historically intermittent drainages (e.g., Strap Ravine, upper portions of many tributaries) are currently perennial drainages due to nuisance flows (e.g., flows from artificial outfalls, irrigation runoff, and irrigation drainage). These flows may contribute to water quality degradation through associated pollutants and higher water temperatures.

A major facility discharging into the Dry Creek mainstem is the Roseville Wastewater Treatment Plant (Roseville WWTP). Discharges from the Roseville WWTP have minimal impacts to Dry Creek during wet months, however, they can compose a high proportion of flows during dry months (i.e., greater than 50% of total flow at the Vernon Street Bridge). As development continues to expand within this region, treated effluent discharges will likely increase. A new regional wastewater treatment plant is being built outside of the Dry Creek watershed by the City of Roseville. It is estimated that approximately 15,000 Roseville WTP customers will be transferred to the new facility.

From 1997 through 2008, the highest peak flow on Dry Creek at the Vernon Street Bridge was 7,950 cfs, occurring on Jan 22, 1997 (USGS Website 2009). From 2000 through 2008, annual daily mean flows at the Vernon Street Bridge ranged from 48.8 cfs in 2007 to 131.3 cfs in 2006 (USGS Website 2009).

The climate in which the Dry Creek watershed is located is considered a Mediterranean climate with a warm, dry season during April through October; and a wet, mild season from November through March. Annual precipitation is approximately 20 to 25 inches per year, with peak rainfall occurring during December through February. Summer stream flows are generally composed of flow from springs and urban runoff, and irrigation drainage and effluent from wastewater treatment systems.

Land Use

Various land uses in the Dry Creek Watershed over the past 150 years have resulted in direct and indirect impacts to channel morphology. Historical land uses include placer mining, quarry development, agricultural development, and urbanization. Dramatic levels of urbanization have occurred since the 1950s, particularly in the Roseville and Rocklin areas. Many roads traverse the stream valleys, modifying floodplain areas and channels where bridges and culverts have been installed for crossings. Streams have been channelized, moved or straightened to fit floodplain developments and riparian vegetation has been removed mechanically or by use of herbicides, resulting in bank instability and erosion (ECORP Consulting 2003).

Generally, the middle portion of the Dry Creek watershed has been subject to extreme development pressure by relatively recent growth, primarily within the cities of Roseville and Rocklin. The upper and lower portions of the watershed are anticipated to experience similar growth in the coming years. Such development generally has been perceived to have exacerbated normal historical flooding conditions lower in the watershed, particularly in Sacramento County, by contributing greater and faster flood flows during storm events. In addition, water quality concerns have arisen, due to the perceived increase in sedimentation and potential contamination from non-point sources.

Within the Dry Creek Watershed, much of the native vegetation has been removed and either replaced with non-native species (e.g., landscaping, agriculture), developed, or left bare. The reduction in native vegetation has contributed to significant degradation of the watershed water resources. Reduction of riparian habitat and/or replacement with non-native species (e.g., ornamentals) occurs within all tributaries of the watershed. This has contributed to bank destabilization and erosion, higher water temperatures, and reduction in suitable habitat for aquatic life.

Historically, livestock traffic compaction and off-road recreational vehicle activities have contributed to bank destruction. In many areas, channels have been deepened, straightened, and/or re-located to accommodate roads, to create agricultural land, for sewage treatment ponds, to convey flows, and for other developments. This channelization and reconfiguration has resulted in reduced area for overbank flow and reduced channel meandering. Whether by erosive processes, historical placer mining or channel reconfiguration, these deepened channels have lowered the shallow groundwater table, particularly in the upper tributary reaches (ECORP Consulting 2003).

Fisheries and Aquatic Habitat

As discussed above, land use impacts have affected the form and function of stream channels throughout the Dry Creek Watershed, which in turn have impacted riparian and aquatic communities. Much of the focus of these impacts have been in the middle and lower reaches of the watershed, particularly Secret Ravine, Miners Ravine, and the mainstem of Dry Creek, due to their importance in sustaining salmonid populations and riparian habitat (ECORP Consulting 2003). Throughout the watershed, reaches have been straightened, floodplain area reduced, reaches dredged, and riparian vegetation removed, resulting in eroding banks, sediment deposition, lack of cover, lack of pools and riffles, lack of riparian vegetation, and barriers to fish passage. Additionally, placer mining in Secret, Strap, and Miners Ravines accelerated stream

incision down to the bedrock in the upper reaches. However, Dry Creek does support a relatively healthy riparian corridor upstream of Folsom Road to the confluence with Miners and Secret ravines (ECORP Consulting 2003).

Below the confluence with Secret and Miners ravines, aquatic habitat is characterized by low gradient, slow moving water, dominated by sand/silt substrate. Water temperatures appear to be 5.6 °C (10 °F) warmer than upstream of the confluence. Available fish habitat is limited to undercut banks, overhanging vegetation, and some instream woody debris. Habitat is much more complex in Secret Ravine, with an abundance of pool habitat, large woody debris, and suitable spawning habitat.

Preliminary water temperature data collected by CDFG in 1999 and 2000 indicate that mean daily summer water temperatures above the confluence never reached 21.1 °C (70°F). This is in contrast to mean daily summer water temperatures below the confluence, which peaked at over 26.7 °C (80°F) in 1999. The Roseville WWTP has recorded mean daily water temperatures of greater than 31 °C in the mainstem of Dry Creek during the summer (period of record was 1998 through June 2003) (ECORP Consulting 2003).

Tributaries within the Dry Creek Watershed are known to support anadromous salmonids and other areas likely historically supported anadromous salmonids, but now either have passage barriers or severely degraded habitat. The mainstem of Dry Creek is not suitable fish habitat, but is considered to be a migratory corridor for anadromous salmonids. Linda Creek has two sites that might be suitable for spawning and rearing, however, most of the habitat is generally degraded with steep eroding banks and high summer water temperatures. Cirby Creek is heavily urbanized and likely no longer supports salmonids. Antelope Creek has two potential spawning areas, but these areas also are degraded. Rock dams and beaver dams act as barriers to fish passage in Antelope Creek, although a few fish have been found in this tributary. Miners Ravine still supports salmonids, however many reaches are heavily degraded. Secret Ravine also still supports salmonids and has the highest quality fisheries habitat in the Dry Creek watershed (ECORP Consulting 2003).

Given the increase in summer streamflows compared to historical conditions, the potential for improvement of existing juvenile steelhead rearing habitat exists, but primarily only within the uppermost portions of Dry Creek (i.e., Secret Ravine) (ECORP Consulting 2003). Several studies and projects have been implemented to improve fish passage and restore aquatic life habitat in Miners Ravine, Secret Ravine, and

Cirby/Linda Creek. For example, riparian trees have been planted along Dry Creek by the City of Roseville in association with the Dry Creek Reforestation Project.

Steelhead

General information on the historical presence of anadromous salmonids in Dry Creek is available through many small-scale inventory surveys and anecdotal information. A review of this information suggests that suitable salmonid habitat is available at select sites (Sierra Business Council 2003), and that the system currently hosts a self-sustaining population of steelhead (Ayres et al. 2003; Sierra Business Council 2003). All spawning habitat and accounts of spawning anadromous salmonids have been reported to be located upstream of the Dry Creek WWTP.

The CDFG Native Anadromous Fish and Watershed Branch initiated a reconnaissance-level assessment of steelhead distribution and abundance, relative to stream habitat conditions, in 1998 and 1999. At that time, steelhead escapement to the upper Dry Creek watershed was estimated at a few hundred fish, with the most suitable spawning and rearing habitat in Secret Ravine and to a lesser extent, Miners Ravine. Monitoring of juvenile salmonid emigration also was conducted by CDFG during 1999 and 2000. During both years, juvenile steelhead (and Chinook salmon) were collected in rotary screw traps located immediately downstream of the confluence of Secret and Miners ravines (ECORP Consulting 2003).

During the fall/winter of 2004 and the spring of 2005, CDFG conducted two-pass electrofishing surveys on a total of seven reaches in Dry Creek, as well as in several reaches in Miners and Secret ravines. During the 2004 fall/winter survey, no steelhead/rainbow trout were captured in Dry Creek or Miners Ravine. However, 41 steelhead/rainbow trout were captured in Secret Ravine. During the 2005 spring survey, no steelhead/rainbow trout were identified in Dry Creek or Miners Ravine, but 95 steelhead/rainbow trout were captured in Secret Ravine (CDFG 2005, unpublished data). During the 2005 spring survey in Secret Ravine, five pit-tagged steelhead/rainbow trout were re-captured from the 2004 fall/winter survey. All of these fish were re-captured in the same reach of Secret Ravine as when they were originally captured and tagged during the 2004 fall/winter survey. Growth rates for these fish were quite variable, as shown in **Table 3**.

Table 3. Steelhead/rainbow trout growth in Secret Ravine

Length at Capture (mm)	Time to Re-capture (days)	Length at Re-capture (mm)	Growth (mm)
91	187	168	77
95	204	155	60
88	204	154	66
90	204	188	98
79	204	143	64

Data source: (CDFG 2005, unpublished data)

Based on analysis of data from the 2004/2005 surveys conducted by CDFG, the findings are consistent with previous studies and anecdotal information suggesting that Dry Creek is utilized as a migratory corridor for anadromous salmonid passage upstream to spawning and rearing habitat in the upstream tributaries (Secret Ravine and Miners Ravine) (CDFG 1998). Catch data also is consistent with information presented in the Dry Creek Watershed Coordinated Resource Management Plan (ECORP Consulting 2003), which states that the mainstem of Dry Creek is not suitable anadromous salmonid habitat and is considered only as a migratory corridor to upstream areas containing suitable spawning and rearing habitat.

Watershed Restoration and Potential to Support Viable Populations

Watershed/Ecosystem Restoration

For currently occupied habitats between below Oroville Dam, it is unlikely that habitats can be restored to pre-dam conditions, but many of the processes and conditions that are necessary to support a population of CV spring-run Chinook and CV steelhead can be improved and sustained with extensive long-term human intervention, including improvements to water temperature management, habitat availability, spatial distribution and separation of spring- and fall-run Chinook salmon hatchery management. Implementation of the Settlement Agreement for the Oroville FERC license is expected address these factors and considerable improve the habitat in the lower Feather River.

Viability Potential for Existing Populations

CV spring-run Chinook salmon - **Moderate**

CV Steelhead - **Moderate**

CV spring-run Chinook salmon and CV steelhead are produced by the Feather River Hatchery, but also spawn in the river downstream from the Fish Barrier Dam approximately 8 miles to the Thermalito Afterbay Outlet. The majority of the spawning occurs in the upper three miles of river downstream from the Feather River Hatchery. T CWT information from these hatchery returns indicates substantial introgression has occurred between fall-run and spring-run Chinook salmon populations within the Feather River system due to hatchery practices which has compromised the genetic integrity of spring-run Chinook salmon. Lindley *et al.*, (2007) characterized CV spring-run Chinook salmon and CV steelhead populations in the Feather River as data deficient. However, the existing spring-run Chinook population in the Feather River, including the hatchery fish, may be the only remaining representatives of this important ESU component and that the Feather River hatchery spring-run Chinook stock may play an important role in the recovery of spring-run Chinook in the Feather River Basin.

The lower Feather River, below Oroville Dam, is characterized as having a moderate potential to support a viable independent population of CV spring-run Chinook and a moderate potential to support a viable population of steelhead. This is primarily based on the presence of a hatchery supported populations that are known to reproduce naturally in the Low Flow Channel between river mile 59 and 67. The recently signed Settlement Agreement for Licensing of the Oroville Facilities (March 2006) includes the Lower Feather River Habitat Improvement Plan, which requires the development and

implementation of numerous programs and projects that will improve the ecological condition of the Lower Feather River, in a manner that is expected to improve the quality and quantity of CV spring-run Chinook salmon and CV steelhead habitat for the next 50 years. Most significantly, the Settlement Agreement includes measures to improve the short- and long-term genetic management of the Feather River Hatchery, measures to physically separate and isolate CV spring-run Chinook salmon from CV fall-run Chinook salmon, and measures that will increase the spatial availability of spawning habitat for CV steelhead.

Potential for Historic Habitats to Support Spawning Populations

CV Steelhead - **Low**

South Fork Feather:

CV Spring-run Chinook salmon – **Low**

CV Steelhead - **Low**

With the exception of the North Fork Feather River, the upper watershed and areas of historic habitat above Oroville Dam are characterized as having a low potential to support spawning populations of CV spring-run Chinook salmon and CV steelhead. Although discrete reaches of habitat are available in the upper watershed that are capable of supporting these fish, the areas are fragmented by the extensive presence of up-river hydroelectric facilities, which would significantly limit efforts to successfully reintroduce fish and manage their up and downstream migration. The North Fork Feather River, primarily the reach from the vicinity of Seneca, California, downstream to the confluence with the East Branch Feather River, near Belden California. NMFS conducted field reconnaissance of this historic habitat and concluded that water temperatures, summer holding pools and spawning gravel existed to support a population of 2,000 to 3,000 adults (NMFS 2009).

Key Threats and Stressors

Key threats and stressors to Central Valley spring-run Chinook salmon and steelhead in the Feather River include, but are not limited to the following:

- ❖ Passage impediments/barriers at the Fish Barrier Dam and at the Oroville Dam affecting adult immigration and holding
- ❖ Flow conditions (i.e., low flows) associated with attraction and migratory cues into the Feather River affecting adult immigration and holding
- ❖ Water temperatures affecting adult immigration and holding, spawning, juvenile rearing and outmigration
- ❖ Passage impediments/barriers and hatchery effects related to redd superimposition, competition for habitat, hybridization/genetic integrity affecting spawning
- ❖ Physical habitat alternation associated with limited supplies of instream gravel, habitat suitability and spawning habitat availability affecting adult spawning
- ❖ Loss of natural river morphology, loss of riparian habitat and instream cover affecting juvenile rearing and outmigration
- ❖ Predation effects on juvenile rearing and outmigration

Key Actions

- ❖ Determine the feasibility of providing access to habitat above the Fish Barrier Dam and above Oroville Dam.
- ❖ Provide access to suitable habitat in the Feather River basin to create new geographically isolated independent populations of Spring-run Chinook salmon and steelhead.
- ❖ Implement actions to enhance habitat conditions and improve access within the area above Oroville Dam, including increasing minimum flows, providing passage at upstream dams, and assessing feasibility of passage improvement at natural barriers.
- ❖ Design and conduct a trap-and-haul pilot program to evaluate adult distribution, survival, spawning, and production in habitats above Oroville Dam.
- ❖ Develop a hatchery management plan for the Feather River Fish Hatchery, including specific criteria for operating as either an integrated or segregated hatchery.
- ❖ Develop a spring-run Chinook salmon conservation hatchery program at the Feather River Fish Hatchery.
- ❖ Implement the use of a temporary weir in the Feather River to spatially segregate spring-run Chinook salmon and fall-run Chinook salmon during spawning.

- ❖ Develop a spawning gravel budget, identify gravel starved areas, and implement an augmentation plan in the Feather River.
- ❖ Identify stream reaches that have been most altered by anthropogenic factors and reconstruct natural channel geometry scaled to current channel forming flows in the Feather River.
- ❖ Implement Facilities Modifications(s) to achieve Feather River water temperatures at least as protective as those specified in Table 2 of the Settlement Agreement For Licensing of the Oroville Facilities (March 2006) (<http://orovillereicensing.water.ca.gov/settlement%20agreement.html>).
- ❖ Increase Feather River stream flows as needed to reduce water temperatures for steelhead juvenile rearing

Watershed Description

The Feather River Watershed is located at the north end of the Sierra Nevada and encompasses an area of about 5,900 square miles (DWR 2007). The upper Feather River Watershed above Oroville Dam is approximately 3,600 square miles, and comprises approximately 68 percent of the Feather River Basin. Downstream of Oroville Dam, the watershed extends south and includes the drainage of the Yuba and Bear rivers (Figure 2). The Yuba River flows into the Feather River near the City of Marysville, 39 river miles downstream of the City of Oroville. The Bear River flows into the Feather River about 55 river miles downstream of the City of Oroville. Approximately 67 miles downstream of the City of Oroville, the Feather River flows into the Sacramento River near the town of Verona (DWR 2007).

Geology

The watershed is bounded by the volcanic Cascade Range to the north, the Great Basin on the east, the Sacramento Valley on the west, and higher elevation portions of the Sierra Nevada on the south (DWR 2007). Downstream of Oroville Reservoir, the Feather River emerges from the Sierra Nevada and enters the Sacramento Valley. The Feather River below Thermalito Diversion Dam to Verona is mostly an alluvial stream flowing across its own sedimentary deposits of clay, silt, sand, and gravel. By far, historic hydraulic mining of Eocene gold-bearing gravel deposits caused the largest impact on the Feather River channel. Massive amounts of erosional debris, including cobbles, gravel, sand, silt, and clay, were washed into the river. Mining debris still profoundly affects the present-day Feather River. Both the human-modified cobble banks and clay rich slickens have increased bank stability. Between the cities of Oroville and Gridley, cobbles and coarse gravel dredge tailings constitute most of the banks, slowing the bank erosion process. Between Honcut Creek and the mouth of the Feather River, the

meandering process has slowed, and the river is wide and shallow, with low sinuosity and a sand bed. Most of the reach is mapped as glides or long pools, with low mesohabitat variability. The lower Feather River meander belt (Figure 2) consists of recent alluvium and stream channel deposits. Of the two, the alluvium is older, but both consist of river deposits, including floodplain deposits, point bar deposits, channel fill, oxbow lake deposits, tributary delta deposits, and hydraulic mining debris. The deposits range in size from clay, silt, and sand to gravel, cobbles, and boulders. Coarse deposits predominate near the City of Oroville and fine deposits predominate from Gridley downstream to the mouth of the Feather River. Older alluvial deposits not directly linked to the present Feather River form terraces on both sides of the active stream channel. These deposits are typically higher in elevation, more resistant to erosion and define the boundaries of the active meander belt (DWR 2007).

The most common parent material for the soils downstream of Oroville Dam is river alluvium, with some soils derived from debris deposited during the hydraulic mining period. The predominant soil types or textures in the 100-year floodplain are characterized as fine sandy loam, loamy sand, and loam to silt loam. Minor soil types are clay, clay loam, sandy clay loam, sandy loam, silt loam, silty clay, sand and gravel, and river wash. Many of the soils are further divided by occurrence of flooding, such as occasionally flooded to frequently flooded. The soils range from shallow to very deep, with most being moderately deep to very deep. Floodplain soils are conducive to agriculture and many areas of riparian floodplain and fluvial terraces have been converted to irrigated crops and orchards (DWR 2007).

Hydrology

Climate in the region follows a Mediterranean pattern, with cool wet winters and hot dry summers. Air temperatures range from below zero to above 100 degrees Fahrenheit (°F). Approximately 95 percent of the annual precipitation occurs during the winter months. Precipitation ranges from more than 90 inches at the orographic (i.e., mountain) crest near Bucks Lake, 33 inches at the City of Oroville, to less than 20 inches in the eastern headwaters. Precipitation above 5,000 feet occurs primarily as snow, which regularly accumulates in excess of 5 to 10 feet during winter. There are infrequent summer thunderstorms, predominantly in the eastern third of the watershed. These storms can produce significant rainfall of short duration over a relatively small area (DWR 2007).

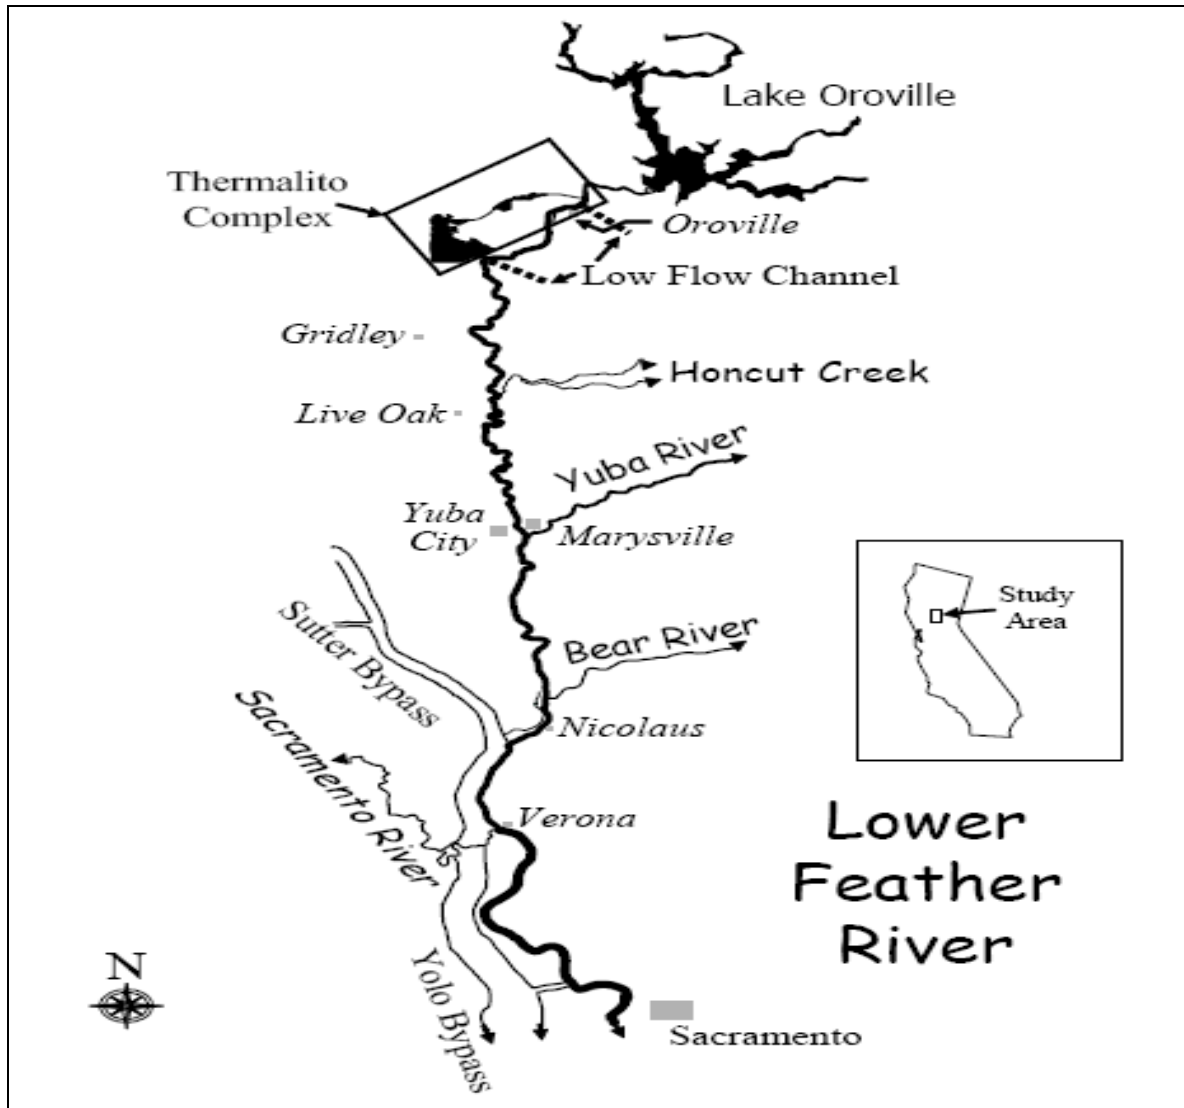

Figure 2. The Lower Feather River (Source: DWR 2006)

The Feather River is considered to be a major tributary to the Sacramento River and provides about 25 percent of the flow³ in the Sacramento River (DWR 2007). The average annual yield of the upstream Feather River Basin at Oroville is about 4.2 million acre-feet (maf), with runoff generally occurring between January and June. Summer inflows into Oroville Reservoir are sustained at about 1,000 cfs by snowmelt and accretions from springs and groundwater in the upper watershed. Due to several diversions upstream, actual annual inflow into Oroville Reservoir is about 4.0 maf.

³ As measured at Oroville Dam.

Annual flows are variable and depend upon precipitation. From 1979 to 1999, annual inflows ranged from a minimum of 1.7 maf to as high as 10 maf (DWR 2007).

Feather River flows are altered by hydroelectric, water storage, and diversion projects upstream of the Oroville Facilities⁴, Oroville Reservoir operations, and by diversions from the Thermalito Afterbay to meet service area entitlements (DWR 2007). Upstream projects alter Feather River flows through operation of storage facilities and by diversions from the river and its tributaries. Water diversions to meet service area entitlements occur primarily during the irrigation months, April to October. Water also is required during all months of the year to meet State Water Project (SWP) water contractors' requests, with the highest requests typically occurring from June through August, and the lowest occurring during January. Water available for delivery varies depending on hydrologic conditions and operating requirements (DWR 2007).

Oroville Reservoir, operated by the California Department of Water Resources (DWR) and the keystone of the SWP, is the lowermost reservoir on the Feather River and the upstream limit for anadromous fish (USFWS 1995). With a storage capacity of more than 3.5 maf, Oroville Reservoir is located at the confluence of the West Branch and the North, Middle, and South Forks of the Feather River, upstream from the Yuba and Bear River tributaries at an elevation of 900 feet above msl (YCWA and Reclamation 2007). Water is released from Oroville Dam through a multilevel outlet to provide appropriate water temperatures for the operation of the Feather River Hatchery and to protect downstream fisheries. Approximately 5 miles downstream of Oroville Dam, water is diverted at the Thermalito Diversion Dam into the Thermalito Power Canal, thence to the Thermalito Forebay and another powerhouse, and finally into the Thermalito Afterbay. Water can be pumped from the Thermalito Diversion Pool back into Oroville Reservoir to generate peaking power. The Oroville-Thermalito complex (Figure 3), completed in 1968, provides water conservation, hydroelectric power, recreation, flood

⁴ The Oroville Facilities were developed as part of the State Water Project (SWP), a water storage and delivery system of reservoirs, aqueducts, power plants, and pumping plants. The Federal Power Act (FPA) license for the Oroville Facilities (issued by the FERC, on February 11, 1957) expired on January 31, 2007. The California Department of Water Resources (DWR) sought a new federal license to continue generating hydroelectric power while continuing to meet existing commitments and comply with regulations pertaining to water supply, flood control, the environment, and recreational opportunities. FERC issued an annual license to DWR for Project No. 2100 for a period effective February 1, 2007 through January 31, 2008, or until the issuance of a new license for the project or other disposition under the FPA, whichever came first. If issuance of a new license (or other disposition) did not take place on or before January 31, 2008, pursuant to 18 C.F.R. 16.18(c), an annual license under section 15(a)(1) of the FPA will be renewed automatically without further order or notice by FERC, unless FERC orders otherwise (FERC 2007).

control, and fisheries benefits. The other major impoundment in the watershed is Lake Almanor, with a storage capacity of more than 1.1 maf. A number of other small- to moderate-sized impoundments, including Mountain Meadows Reservoir, Bucks Lake, Little Grass Valley Reservoir, Lake Davis, Frenchman Lake, Butt Valley Reservoir, Sly Creek Reservoir, and Antelope Lake, store an additional 450 taf or more (USFWS 1995).

Under an agreement with the CDFG, Feather River flows between the Thermalito Diversion Dam and the Thermalito Afterbay outlet are regulated at 600 cfs, except during flood events when flows have been as high as 150,000 cfs (DWR 1983). This section is often referred to as the "low-flow" river section. Water is released through a powerhouse, then through the Fish Barrier Dam to the Feather River Hatchery, and finally into the low-flow section of the Feather River. Thermalito Afterbay has a dual purpose as an afterbay for upstream peaking power releases to ensure constant river and irrigation canal flows, and as a warming basin for irrigation water being diverted to rice fields. Thus, water temperatures in the approximately 14 miles of salmon spawning area from the Thermalito Afterbay outlet to the mouth of Honcut Creek (referred to as the "high-flow" section) are always higher than those in the 8 miles of the low-flow section (USFWS 1995).

Land Use

Human activity over time has resulted in decreased vegetative cover from logging and grazing, channel clearing, levee construction and water diversions. These activities have contributed to the increased sediment load in the Feather River Watershed (Plumas County Flood Control and Water Conservation District 2004). Current land use patterns within the watershed are diverse, but the principal land use activities include recreation, agriculture, timber production, hydropower generation, and livestock grazing. About 4 percent (i.e., approximately 70 square miles) of all land in Butte County consists of urban uses (DWR 2007).

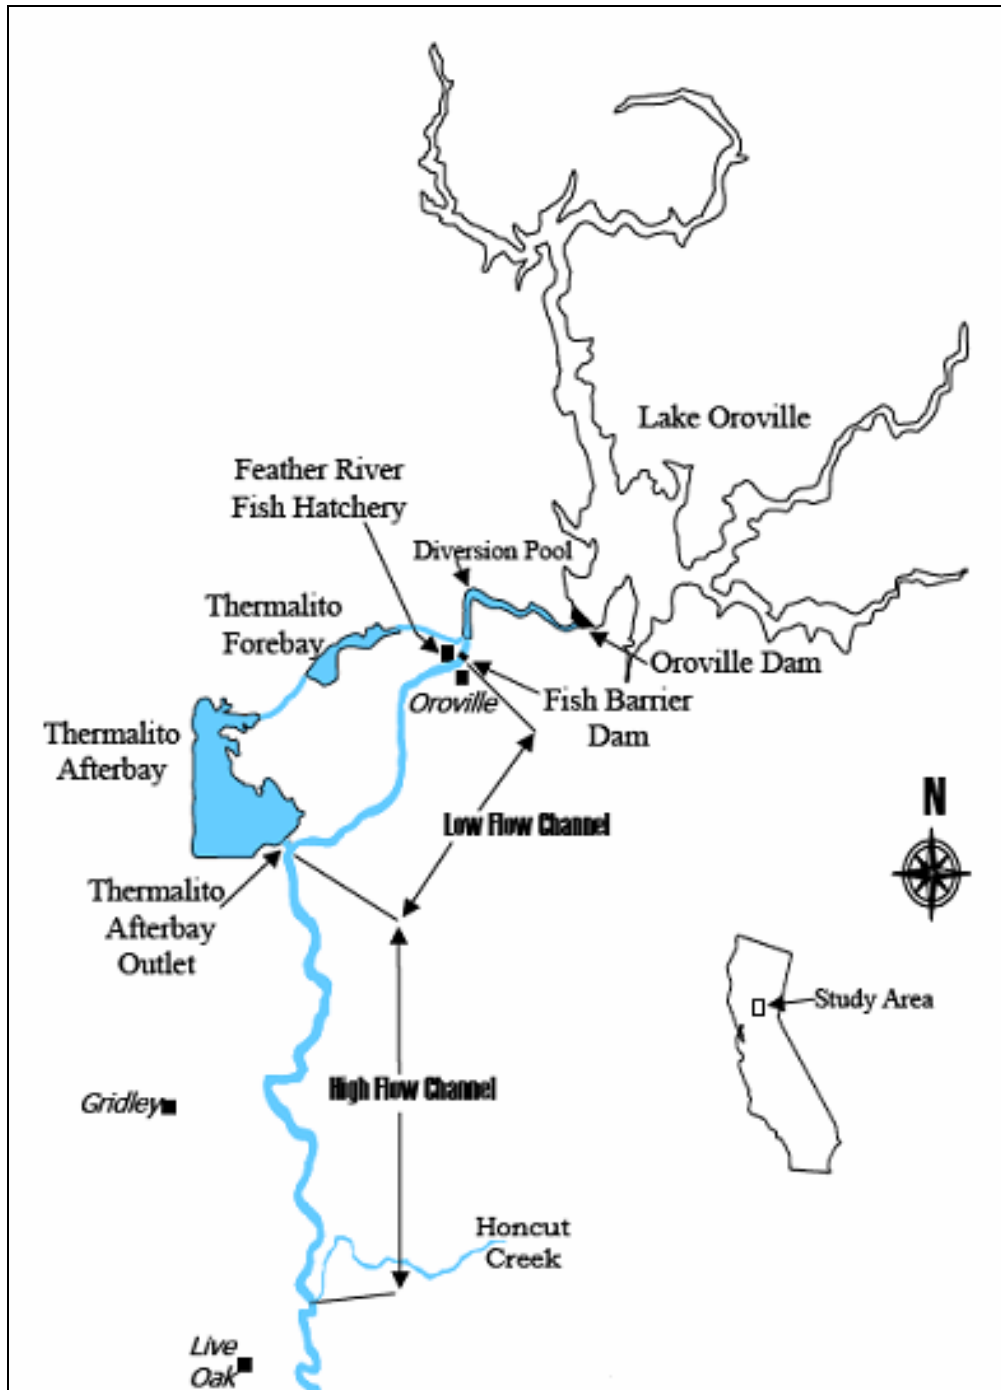

Figure 3. Oroville-Thermalito complex (Source: Modified from DWR 2006)

Fisheries and Aquatic Habitat

The Feather River Watershed is reported to have contained about 211 miles of historic anadromous fish habitat, and currently contains about 64 miles of habitat for Chinook salmon and steelhead (USFWS 2009). Spring-run historically ascended to the very

highest elevation headwaters of the Feather River watershed prior to the construction of numerous hydroelectric power projects and diversions (Clark 1929). Spring-run Chinook salmon were reported to have occurred in the West Branch Feather up to Stirling City, and the North Fork past the present day site of Lake Almanor. In the Middle Fork, spring-run Chinook salmon were reported as far upstream as the natural barrier at Bald Rock, and potentially to Feather Falls located on the Fall River, a tributary to the Middle Fork (CDFG 1998). Spring-run may have ascended to the vicinity of Forbestown on the South Fork (Yoshiyama *et al.* (1996).

Based on broad-scale mesohabitat surveys, the major tributaries in the upper Feather River—the West Branch of the North Fork Feather River (West Branch), the North Fork Feather River (North Fork), the Middle Fork Feather River (Middle Fork), and the South Fork Feather River (South Fork)—generally provide suitable habitat for all life stages of Chinook salmon and steelhead (DWR 2005). For both Chinook salmon and steelhead, spawning and embryo incubation is the life stage for which the smallest amount of suitable habitat is available in the upper Feather River. The greatest amount of suitable habitat is available for the following life stages: (1) Chinook salmon juvenile rearing and downstream movement; (2) steelhead adult immigration and holding; (3) steelhead fry and fingerling rearing and downstream movement; and (4) steelhead smolt emigration. Overall, the North Fork appears to be the most suitable for occupancy of anadromous salmonids, while the South Fork appears to be the least suitable (DWR 2005). Water temperatures, at the locations for which water temperature data were available, approached or exceeded potentially stressful levels generally from May through October (DWR 2005). However, water temperature data loggers were generally located at low elevations near the tributary/reservoir boundary, which is the location within tributaries that is typically believed to experience the highest water temperatures (DWR 2005). In general, the upper Feather River appears to be suitable for migratory Chinook salmon and steelhead based on available mesohabitat data, water temperature profiles, and the current distribution of resident rainbow trout populations (DWR 2005). However, if these upper tributaries become accessible to anadromous salmonids in the future, additional data is required to definitively determine the suitability of habitat in the upper Feather River (DWR 2005).

The lower Feather River commences at the Low Flow Channel (LFC), which extends eight miles from the Fish Barrier Dam (RM 67) to the Thermalito Afterbay Outlet (RM 59) (Figure 3). As described above, flows in this reach of the river are generally regulated at 600 cfs (DWR 1983). Average monthly water temperatures typically range from about 47°F in winter to about 65°F in summer. The majority of the LFC flows through a single channel contained by stabilized levees. Side-channel or secondary channel habitat is extremely limited, occurring primarily in the Steep Riffle and Eye

Riffle areas between RM 60 and 61. The channel banks and streambed consist of armored cobble as a result of periodic flood flows and the absence of gravel recruitment. However, there are nine major riffles with suitable spawning size gravel, and approximately 75 percent of the Chinook salmon spawning takes place in this upper reach (Sommer *et al.* 2001). Releases are made from the coldwater pool in Oroville Reservoir and this cold water generally provides suitable water temperatures for spawning in the LFC (DWR 2001).

The lower reach extends 15 miles from the Thermalito Afterbay Outlet (RM 59) to Honcut Creek (RM 44) (Figure 4). Releases from the outlet vary according to operational requirements. In a normal year, total flow in the lower reach ranges from 1,750 cfs in fall to 5,000-8,000 cfs in spring. Water temperature in winter is similar to the Low Flow Channel but increases to 74°F in summer. Higher flows dramatically increase the channel width in this reach. Numerous mid-channel bars and islands braid the river channel, creating side-channel and backwater habitat. The channel is not as heavily armored and long sections of riverbanks are actively eroding. In comparison to the LFC, there is a greater amount of available spawning areas, which are isolated by longer and deeper pools (DWR 2001).

Spring-run Chinook Salmon

NMFS (2009) reports that four independent populations of spring-run Chinook salmon historically occurred in the upper tributaries (*i.e.*, North, Middle and South forks, and the West Branch) of the Feather River Watershed, but they are now extinct. However, a hatchery population currently occurs in the lower Feather River below Oroville Dam (see below).

A naturally-spawning dependent population of spring-run Chinook salmon currently is restricted to accessible reaches of the lower Feather River (CDFG 1998; NMFS 2009). Approximately two-thirds of the natural Chinook salmon spawning in the Feather River occurs between the Fish Barrier Dam and the Thermalito Afterbay Outlet (RM 67 to 59), and one-third of the spawning occurs between the Thermalito Afterbay Outlet and Honcut Creek (RM 59 to 44) (DWR 2007).

Chinook spawning typically occurs from September through December. Spring-run Chinook salmon spawning may occur a few weeks earlier than fall-run spawning, but currently there is no clear distinction between the two, because of the disruption of spatial segregation by Oroville Dam. Thus, the spawning and embryo incubation life stage of spring-run Chinook salmon in the Feather River generally occurs during the same months (*i.e.*, September through February) as fall-run Chinook salmon spawning

and embryo incubation (DWR 2004d; Moyle 2002). Because of hatchery overproduction and the inability to physically separate spring-run and fall-run Chinook salmon adults, significant redd superimposition occurs in the lower Feather River and this concurrent spawning has led to hybridization between the spring- and fall-run Chinook salmon in the Feather River (NMFS 2009).

Most juvenile Chinook salmon emigrate from the lower Feather River within a few days of emergence, and 95 percent of the juvenile Chinook have typically emigrated from the Oroville Facilities project area by the end of May (DWR 2007). However, spring-run Chinook salmon juveniles reportedly can rear in their natal streams for up to 15 months (Moyle 2002). Adult Chinook salmon exhibiting the typical life history of the spring-run are found holding at the Thermalito Afterbay Outlet and the Fish Barrier Dam as early as April (DWR 2007).

Over the past several decades, Chinook salmon are reported to be the most numerous fish species in the lower Feather River, and between 30,000 and 170,000 Chinook salmon spawn in the lower Feather River annually (DWR 2007). Significant numbers of spring-run Chinook salmon, as identified by run timing, return to the Feather River Fish Hatchery (FRFH) (NMFS 2009). Between 1967 and 2008, the highest annual hatchery spring-run Chinook salmon escapement was 8,662, occurring in 2003 (CDFG 2009). From 1986 to 2007, the average number of spring-run returning to the FRFH was 3,992, compared to an average of 12,888 spring-run returning to the entire Sacramento River Basin. More recently, FRFH spring-run Chinook salmon escapement from 2005 through 2008 was 1,774, 2,061, 2,674, and 1,418, respectively (CDFG 2009). Coded Wire Tag (CWT) information from hatchery returns indicates substantial introgression has occurred between spring-run and fall-run populations within the Feather River system due to hatchery practices. Because Chinook salmon have not always been temporally separated in the hatchery, spring- and fall-run Chinook salmon have been spawned together, thus compromising the genetic integrity of the spring-run and early fall-run stocks (NMFS 2009). The number of naturally spawning spring-run in the Feather River has been estimated only periodically since the 1960s, with estimates ranging from 2 fish in 1978 to 2,908 in 1964. However, the genetic integrity of this population is questionable because of the significant temporal and spatial overlap between spawning populations of spring-run and fall-run Chinook salmon (Good et al. 2005).

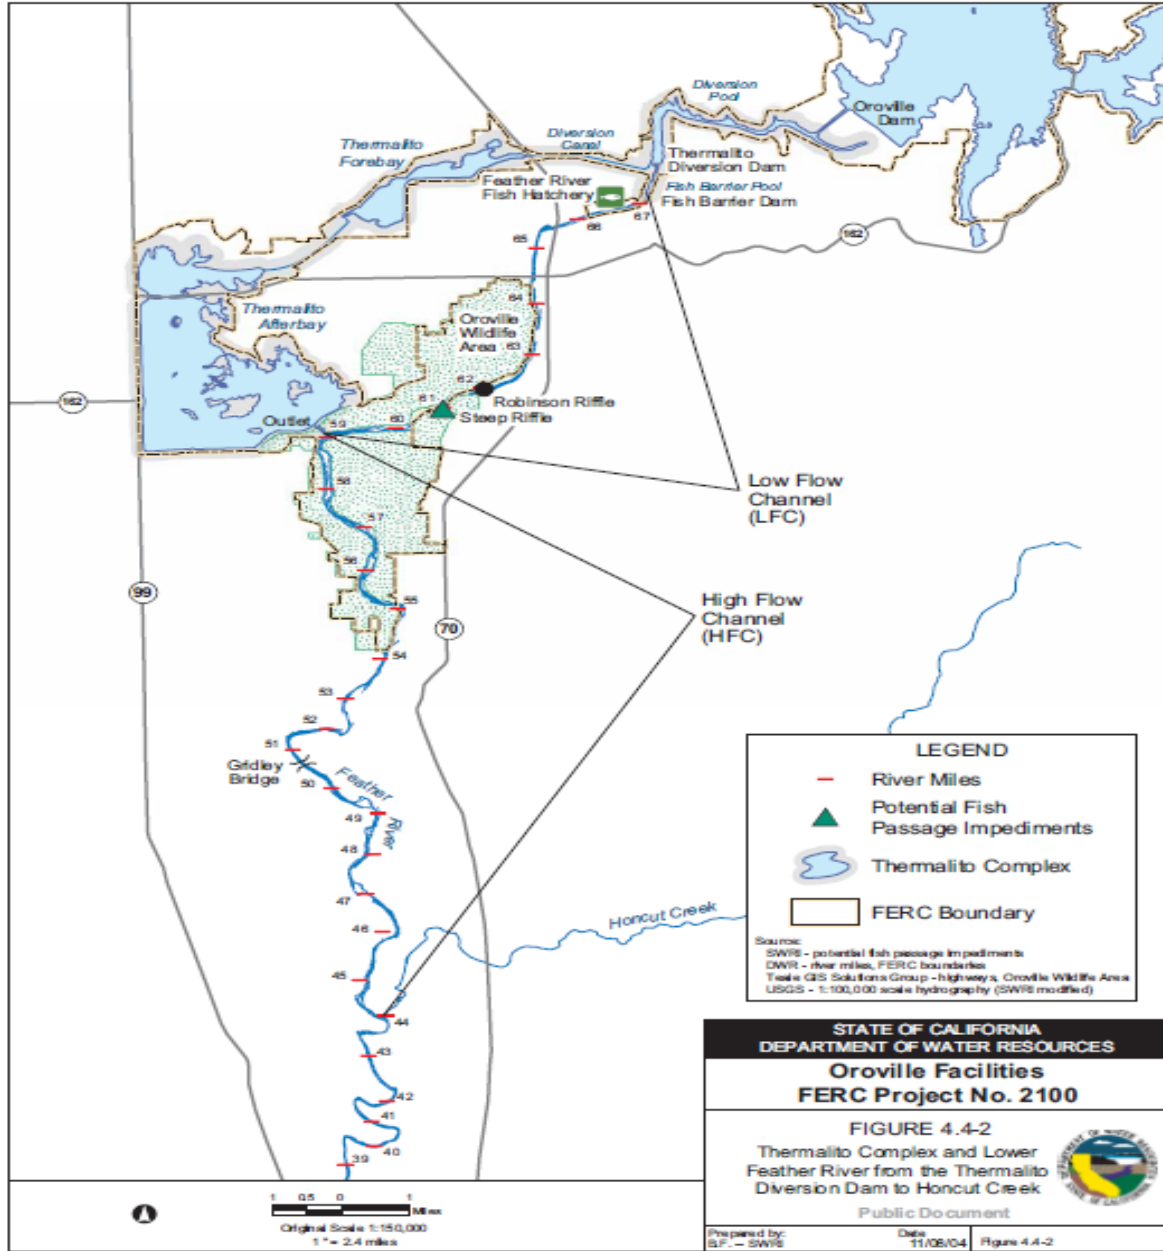

Figure 4. Thermalito complex and lower Feather River from Thermalito Diversion Dam to Honcut Creek (Source: DWR 2007)

Steelhead

NMFS (2009) reports that existing wild steelhead stocks in the Central Valley are mostly confined to the upper Sacramento River and its tributaries (e.g., Antelope, Deer, and Mill creeks and the Yuba River). However, some wild steelhead are produced in the Feather River (McEwan and Jackson 1996).

Most of the natural steelhead spawning in the Feather River occurs in the LFC, particularly in the upper reaches near Hatchery Ditch, a side channel located between RM 66 and RM 67 (Figure 4) (DWR 2007). Adult steelhead typically ascend the Feather River from September through April (Busby *et al.* 1996; Cavallo 2004 pers. comm.; McEwan 2001; Moyle 2002), where spawning takes place rather quickly. The majority of the steelhead spawning and embryo incubation life stage in the Feather River generally lasts from December through May (Busby *et al.* 1996; Cavallo 2004 pers. comm.; McEwan 2001; Moyle 2002). The residence time of adult steelhead in the Feather River after spawning and the extent of adult steelhead post-spawning mortality is currently unknown. It appears that most of the natural steelhead spawning in the Feather River occurs in the LFC, particularly in the upper reaches near Hatchery Ditch. Limited steelhead spawning also occurs below the Thermalito Afterbay Outlet (DWR 2007). So on after emerging from the gravel, a moderate percentage of the fry appear to emigrate (DWR 2007). The remainder of the population rears in the river for at least six months to one year (McEwan 2001; Moyle 2002), then reportedly emigrate from January through June (Cavallo 2004 pers. comm.). Studies have confirmed that juvenile rearing (and probably adult spawning) is most concentrated in small secondary channels within the LFC. The smaller substrate size and greater amount of cover (compared to the main river channel) likely make these side channels more suitable for juvenile steelhead rearing. Currently, this type of habitat comprises less than 1 percent of the available habitat in the LFC (DWR 2001 in DWR 2007).

Since 2001, DWR has conducted redd dewatering and juvenile salmonid stranding surveys to assess the impact of water operations on the population of juvenile salmonids in the lower Feather River. Objectives of this long-term study are to determine the number of redds dewatered by reductions in flow; identify potential ponding areas; determine the relative abundance of stranded salmonids; and determine the biological significance of redd dewatering and juvenile stranding (DWR 2006).

Between January 6 and April 3, 2003, a total of 13 weekly redd surveys were conducted and 108 steelhead and 75 redds were observed during this sampling period (DWR 2005). Redd construction likely began sometime in late December, peaked in late January, and was essentially complete by the end of March. During January, February, and March, steelhead constructed, at minimum, 45, 26, and 4 redds, respectively. The surveys revealed that nearly half (48 percent) of all redds were constructed in the uppermost reach of the lower Feather River (between RM 66 and RM 67), between the Table Mountain Bicycle Bridge and Lower Auditorium Riffle. This section of river maintained 36 redds per mile, more than 10 times more than any other reach surveyed. Hatchery Ditch alone had 26 redds constructed within it, 5 times more redds than were constructed in any other location (DWR 2005). Attempts were not made to estimate the

number of adult steelhead spawning (DWR 2005). Difficulties associated with identifying all steelhead redds indicated only the minimum number of spawning steelhead for the 2002–2003 spawning period. Assuming one female per redd and a male-to-female ratio of 1.2:1, the minimum number of males and females expected to have spawned was 88 and 75, respectively, for a total of 163 steelhead (DWR 2005). Physical characteristics of constructed redds in both the High Flow Channel and LFC appeared suitable for successful spawning and egg incubation. High flows in the High Flow Channel during three weeks in February may have reduced spawning in the High Flow Channel or forced steelhead to spawn near the river margin. There was no evidence that any redds were dewatered after the flow reduction. It is unknown whether a flow of 8,000 cfs (experienced on February 20, 21, and 22) would scour recently constructed redds in the High Flow Channel (DWR 2005).

Watershed Restoration Potential and Contribution to Recovery

Watershed restoration

The upstream limit of anadromous fish access in the Bear River is the South Sutter Irrigation District's diversion dam, approximately 15 miles above the confluence with the lower Feather River (USFWS 1995).

The lower Bear River continues to support remnant and/or “stray” wild and/or hatchery-sustained salmon, and in the past it supported both steelhead and sturgeon as well (Bear River Watershed Group Website 2009). Inadequate streamflow in the Bear River prevents the establishment of a self-sustaining steelhead population (JSA 2004).

Viability Potential

CV steelhead: **Low**

The potential for the Bear River to support a viable population of steelhead is considered to be low due to the limited amount of habitat that provides suitable spawning and year-round rearing habitats, at marginally suitable elevations. The existing population is largely supported by cold water imports from other watersheds. The Bear River does provide CV steelhead with valuable winter rearing habitat, particularly in the lower reaches near the confluence with the Feather River.

Key Threats and Stressors

Key threats and stressors to Central Valley steelhead in the Bear River include, but are not limited to the following:

- ❖ Loss of natural river morphology, riparian habitat, floodplain habitat and instream cover affecting juvenile rearing and outmigration
- ❖ Flow conditions (i.e., low flows and flow fluctuations) associated with attraction and migratory cues in the Bear River affecting adult immigration and holding, spawning, embryo incubation, juvenile rearing and outmigration
- ❖ Water temperature affecting adult immigration and holding, embryo incubation
- ❖ Physical habitat alternation associated with limited supplies of instream gravel, and suitability of available habitat affecting adult spawning
- ❖ Water quality affecting embryo incubation, juvenile rearing and outmigration
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Entrainment at individual diversions affecting juvenile rearing and outmigration

Key Actions

- ❖ Coordinate with local, State, and Federal flood management agencies to move existing levee alignments away from active river channels and flood plains. To increase floodplain habitat availability.
- ❖ Evaluate fish passage impediments and either remove or replace priority sites with state-of-the-art fish passage facilities that meet NMFS fish passage criteria. Passage impediments/barriers affecting adult immigration and spawning.
- ❖ Reduce juvenile entrainment throughout the watershed.
- ❖ Evaluate opportunities to maintain suitable water temperature and instream flows necessary to support spawning and rearing steelhead populations.
- ❖ Evaluate and implement spawning gravel supplementation projects.

Watershed Description

As reported by the Bear River Watershed Group Website (2009), the Bear River rises on the west side of the Sierra Nevada just below Lake Spaulding at an elevation of 5,500 feet. From there it flows southwest about 65 miles to its confluence with the Feather River at RM 12 of the Feather River, draining portions of Nevada, Placer, Sutter and Yuba counties. The 292 square mile Bear River watershed includes over 990 miles of streams, creeks, and rivers, and reaches 20 miles across at its greatest width. It can be divided into three major reaches, the upper Bear River, middle Bear River and lower Bear River (Bear River Watershed Group Website 2009).

The Upper Bear River extends from its headwaters above Bear Valley to Rollins Lake at approximately 3,300 feet elevation. The middle Bear River extends from Rollins Dam about 15 miles downstream at 2,100 foot elevation; then another 10 miles to Lake Combie at 1,600 foot elevation; then another 17 miles to New Camp Far West Reservoir at the 300 foot elevation. The lower Bear River extends from New Camp Far West Reservoir 16 miles to its confluence with the Feather River at 23 foot elevation (Bear River Watershed Group Website 2009).

Geology

The Bear River is an example of an “underfit” stream—a stream whose channel was formed by a larger flow than presently existed (Johnson 2002). The deep V-shaped canyon of the Bear River reflects the work of a much larger river at some point in the past. Researchers have studied glacial stratigraphy of the Bear River, and the features indicate that at least two and probably three glacial advances occupied both the South Yuba and Bear valleys (Johnson 2002). These advances are believed to have ground through a narrow ridge separating the South Fork of the Yuba River from the Bear River, just downstream of what is now Lake Spaulding. Water from the upper watershed of the Bear River then began to flow into the Yuba River drainage (James 1995). Outwash deposits extend downstream from Bear Valley and grade into coarse channel lag gravel and boulders upstream of the Drum Powerhouse (NID 2008). This capture reflects a structural advantage to the Yuba River drainage, such as a lower base level and softer material that is less resistant to erosion (Johnson 2002). The Bear River contains surface basin deposits, which are composed of stream channel and floodplain deposits, and dredger tailings. These deposits consist of highly permeable boulders, gravels, cobbles and sands (Onsoy et al. 2005). The Bear River contains an estimated 125 million cubic meters (160 million cubic yards) of mining sediment, which, in combination with restricting levees, has caused the lower Bear River to change from wide and shallow to deeply incised (Sierra Club Website 2007). In addition, mercury

imported from the Coastal Ranges is found in sediments within the historic gold mining areas downstream of Spaulding Reservoir on both the Yuba and Bear rivers (May et al. 2000).

Hydrology

The main tributaries of the Bear River include Steephollow and Greenhorn creeks above Rollins Lake, and Wolf and Little Wolf creeks between Lake Combie and Camp Far West Reservoir (Bear River Watershed Group Website 2009). Rock Creek drains into Camp Far West Reservoir. Dry Creek runs through the Spenceville Wildlife Area and into the Bear River below Wheatland. Yankee Slough, from the south, and Best Slough, from the north, enter the Bear just below the confluence with Dry Creek (Bear River Watershed Group Website 2009).

The largest impoundment in the Bear River watershed, Camp Far West Reservoir, is operated by the South Sutter Water District and has a storage capacity of 104 thousand acre-feet (taf). Other small impoundments in the watershed include Rollins Lake and Lake Combie, which store an additional 70 taf or more (USFWS 1995).

The Bear River watershed is one of the most heavily managed watersheds in California for water conveyance. By the late 1800's, hydraulic mining had largely given way to inter-basin water and hydropower development which served agricultural water supply and power generation needs throughout the western foothills region and beyond. By the turn of the 20th century, much of the region's contemporary water infrastructure was in place. Flows are currently largely controlled by the Nevada Irrigation System and PG&E (Bear River Watershed Group Website 2009).

In the 1960's, when growth in the foothills area increased, some of the original water and hydropower infrastructure was replaced or expanded while several new dams, powerhouses, and conveyance works were added. Throughout this period, the Bear River became the region's hydraulic workhorse, conveying water for consumption and energy generation from the upper Yuba, upper American, and its own headwaters and tributaries into the middle and lower Bear, the lower American, and the associated foothill creek-ravine region (Bear River Watershed Group Website 2009). The drainage pattern of the middle and lower reaches of the Bear River is illustrated in **Figure 5**.

Bear River below Rollins:

Principal storage, diversion, conveyance, and hydropower facilities

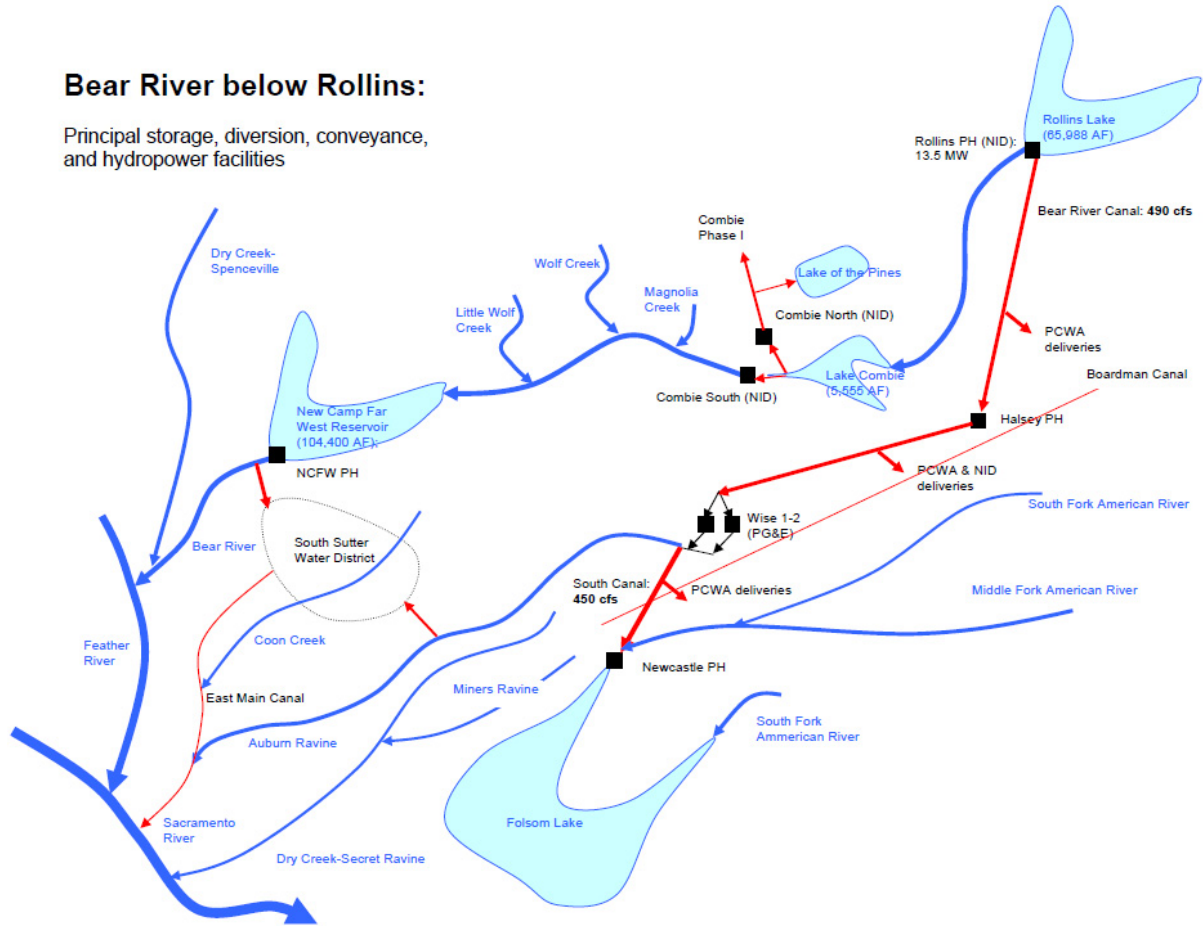

Figure 5. Schematic of the Middle and Lower Reaches of the Bear River
 Source: Bear River Watershed Group Website 2009

Land Use

Much of the lower Bear River is under private ownership. While the condition of riparian habitat has not been investigated, it is likely that some riparian habitat has been degraded due to agricultural encroachment into the riparian zone. The upper Bear River includes approximately eight miles of relatively undeveloped river from its spring-fed headwaters above Bear Valley to Rollins Lake (Bear River Watershed Group Website 2009).

The Bear River was far more heavily impacted by hydrologic mining than the Yuba or American rivers and, unlike the Yuba or American rivers, contains a large volume of mining sediment stored in its main channel which is subjected to continual erosion. As mentioned above, it is estimated that 125 million cubic meters (160 million cubic yards) of mining sediment is stored in the lower Bear River. The high volume of mining

sediment, in combination with restricting levees, has caused the lower Bear River to change from wide and shallow to deeply incised (Sierra Club Website 2007).

Fisheries and Aquatic Habitat

The upstream limit of anadromous fish access in the Bear River is the South Sutter Irrigation District's diversion dam, approximately 15 miles above the confluence with the lower Feather River (USFWS 1995).

The lower Bear River continues to support remnant and/or "stray" wild and/or hatchery-sustained salmon, and in the past it supported both steelhead and sturgeon as well (Bear River Watershed Group Website 2009). Inadequate streamflow in the Bear River prevents the establishment of a self-sustaining steelhead population (JSA 2004). Minimum releases below Rollins Lake (10 cfs) and Lake Combie (5 cfs) from approximately June to November result in warm water temperatures that are suitable only for bass or other warm water species (Bear River Watershed Group Website 2009). However, during periods of high flows, steelhead are known to utilize the river for limited spawning (JSA 2004). Because environmental conditions do not support a self-sustaining population of steelhead in the Bear River, those steelhead that do spawn during high flow years have likely originated from the Feather River Fish Hatchery. The present system of diversions results in abnormal flow fluctuations, in contrast to historical natural seasonal flow variations.

In addition to inadequate flows, due to the past accumulation of mining sediments and the presence of overly-constrictive levees, the lower reach has become narrow and incised and will likely require physical remediation as part of any flow-related restoration effort, in addition to eradication of invasive plant species such as Giant arundo (Bear River Watershed Group Website 2009). Downstream gravel recruitment has been limited for many years and also would have to be actively supplemented to provide suitable habitat conditions for anadromous fish. In addition, New Camp Far West Reservoir is both shallow and warm and may not be able to provide releases or through-flows when needed (i.e., during late summer and early fall) at water temperatures that are suitable to salmonids downstream; the result will depend upon the particular reservoir storage and mixing, as well as the volume, timing, source, and temperature of any upstream flow improvements (Bear River Watershed Group Website 2009).

Continued high levels of mercury in present day river sediments indicate that the majority of the estimated 2.5 million pounds of the heavy metal that were lost in the Bear River Watershed during 32 years of hydraulic mining are still present, trapped in

the 1.5 billion cubic yards of sediment stripped from hillsides (Bear River Watershed Group Website 2009).

Steelhead

As discussed above, the Bear River does not support a self-sustaining population of steelhead; steelhead that do spawn in the Bear River, during favorable environmental conditions, likely originated from the Feather River Fish Hatchery.

Watershed Restoration and Potential to Support Viable Populations

Watershed/Ecosystem Restoration

In most regulated rivers in the Central Valley, key factors affecting anadromous salmonid habitat in the lower section of the river (i.e., the section below the dam) include warm water temperatures, flow fluctuations, flow dependent habitat availability, and a lack of rearing habitat. With implementation of the Yuba Accord, a set of agreements that has resolved years of litigation over lower Yuba River flows, concerns regarding water temperature and flow in the river have in large part been addressed. However, loss of floodplain and riparian habitat remains a major restoration concern.

Historically, the Yuba River was connected to vast floodplains and included a complex network of channels, backwaters and woody material. The legacy of hydraulic and dredger mining is still evident on the lower Yuba River where, for much of the river, dredger piles confine the river to an unnaturally narrow channel. The consequences of this unusual and artificial geomorphic condition include reduced floodplain and riparian habitat and resultant limitations in fish habitat, particularly for rearing juvenile salmonids. As such, lower Yuba River habitat restoration must include projects aimed at increasing availability of floodplain and riparian habitats.

Other potential restoration actions in the lower river are to: (1) improve fish passage at Daguerre Point Dam through dam removal or fish ladder improvements; and (2) augment spawning gravels in the narrows reach, a bedrock section immediately downstream of Englebright Dam with little to no suitable spawning habitat. However, it should be noted that gravel supply downstream of the narrows reach is not limited. A more complete description of the status of lower Yuba River habitat and restoration needs is presented in CALFED and YCWA (2005).

Viability Potential for Existing Populations

CV spring-run Chinook salmon - Moderate
CV steelhead - Moderate

The potential for the lower Yuba River to support a viable salmonid population is characterized as *moderate* for spring-run Chinook salmon and for steelhead. These characterizations are based on several conflicting factors. Factors which increase the potential for the lower Yuba River to support viable populations of spring-run Chinook salmon and steelhead include that: (1) flow and water temperature conditions are generally suitable to support the life stage requirements of these species; (2) the river does not have a hatchery on it, and thus the genetic integrity of spring-run Chinook salmon and steelhead is largely uncompromised by hatchery influence, although some straying of both species from the Feather River Hatchery into the Yuba River does occur; and (3) spawning habitat availability is not limited.

Factors which have a negative influence on the potential for the lower Yuba River to support viable populations of spring-run Chinook salmon and steelhead include: (1) both species are confined below Englebright Dam and thus are confined to spawn in habitats that historically did not support that life stage; (2) although fish exhibiting spring-run Chinook salmon phenotypes return to the Yuba River annually, the origin, genetic makeup, and the relationship with fall-run Chinook salmon is unknown (DWR, YCWA, and Reclamation 2007); (3) the abundance of adult spring-run Chinook salmon

(about 1,000 fish⁵) is sufficiently low to place the population at a moderate risk of extinction (see Table 4-1 in the Recovery Plan); and (4) recent genetic analysis of *O.mykiss* from the lower Yuba River indicate that most of those fish exhibit a resident life history strategy, rather than the anadromous strategy characteristic of steelhead (Zimmerman et al. 2008).

Potential for Historic Habitats to Support Spawning Populations

South Yuba River:

CV Spring-run Chinook salmon - Moderate

CV Steelhead – Moderate

Middle Yuba River:

CV Spring-run Chinook salmon – Moderate

CV Steelhead - Moderate

North Yuba River:

CV Spring-run Chinook salmon – High

CV Steelhead – High

The potential for both the South and Middle Yuba rivers to once again support populations of spring-run Chinook salmon and steelhead is characterized as *moderate*. This characterization is largely based on results of the Upper Yuba River Watershed Chinook Salmon and Steelhead Habitat Assessment published by DWR in 2007 (DWR 2007). Results of that study indicated that with water management operations prior to fall of 2004, the South Yuba River would likely be too warm to support spring-run Chinook salmon and steelhead. However, the authors noted that changes in Lake Spaulding release strategies initiated during fall of 2004 would likely result in colder South Yuba River water temperatures. Subsequently, the authors suggested further study would be needed to assess whether water temperatures cold enough to support spring-run Chinook salmon and steelhead would occur in the river with the modified Lake Spaulding release strategies initiated in 2004. Under current operations, 5 cfs is released from Lake Spaulding during the summer. It is likely that with higher summer releases, the availability of suitable water temperatures for spring-run Chinook salmon and steelhead in the South Yuba River would increase. DWR (2007) also indicated that potential spawning sites are available in the South and Middle Yuba rivers.

⁵ Although precise estimates of adult spring-run Chinook salmon abundance are not available, past testimony by the USFWS and recent data collected by CDFG suggest that the population is composed of about 1,000 fish (DWR, YCWA, and Reclamation 2007).

In addition the presence of suitable spawning habitats on the Middle Yuba River, DWR (2007) found that water temperatures would provide suitable thermal conditions to support all life stages of spring-run Chinook salmon and steelhead. However, most suitable spawning habitats in the Middle Yuba River are located upstream of Our House Dam (DWR 2007), and fish passage at that location would need to be provided. Without the fish passage issue at Our House Dam, the Middle Yuba River would have a high potential to support spawning populations spring-run Chinook salmon and steelhead. As indicated in DWR (2007), if flows were increased to 50 cfs, approximately 1,650 spring-run Chinook salmon and 2,640 steelhead could spawn in thermally suitable habitat in the Middle Yuba River

The potential for the North Yuba River to support populations of spring-run Chinook salmon and steelhead is characterized as *high*. This characterization is based on information presented in DWR (2007) and on general observations which suggest that flows and water temperatures in the upper watershed both below and above New Bullards Bar Reservoir could provide suitable conditions for anadromous salmonids. DWR (2007) identified 13 potential spawning sites in the Yuba River downstream of the South Yuba River mouth. The presence of potential spawning habitats on the North Yuba River above New Bullards Bar Reservoir has not been evaluated. Detailed habitat assessments with respect to the life stage-specific requirements of spring-run Chinook salmon and steelhead are needed above New Bullards Bar Reservoir.

Key Threats and Stressors

Key threats and stressors common to Central Valley spring-run Chinook salmon and steelhead in the Yuba River watershed include, but are not limited to the following:

- ❖ Passage impediments/barriers at Englebright Dam and Daguerre Point Dam, affecting adult immigration and holding
- ❖ Passage impediments/barriers at Englebright Dam affecting adult spawning, redd superimposition, competition for habitat, hybridization and genetic integrity
- ❖ Hatchery effects associated with redd superimposition, competition for habitat and genetic integrity affecting adult spawning
- ❖ Physical habitat alternation associated with limited supplies of instream gravel, reduced spawning habitat availability and habitat suitability affecting adult spawning
- ❖ Flow conditions (i.e., flow fluctuations) and water quality effects on embryo incubation

- ❖ Entrainment effects from individual diversions in the Yuba River and Daguerre Point Dam affecting juvenile rearing and outmigration
- ❖ Non-site specific and structure related predation effects affecting juvenile rearing and outmigration
- ❖ Loss of natural river morphology, riparian habitat and instream cover, and floodplain habitat affecting juvenile rearing and outmigration

Key Actions

- ❖ Implement actions to: (1) enhance habitat conditions including providing flows and suitable water temperatures for successful upstream and downstream passage, holding, spawning and rearing; and (2) improve access within the area above Englebright Dam, including increasing minimum flows, providing passage at Our House, New Bullards Bar, and Log Cabin dams, and assessing feasibility of passage improvement at natural barriers.
- ❖ Design and conduct an experimental fish passage program to evaluate adult distribution, survival, spawning, and production in habitats above Englebright Dam. This short-term experimental re-introduction program could include trap and haul techniques.
- ❖ If the experimental fish passage program demonstrates that passage above Englebright Dam can substantively contribute to the long-term viability of the ESU/DPS, then develop and implement long-term fish passage programs. This long-term program would rely on volitional passage instead of an indefinite trap and haul operation.
- ❖ Investigate the feasibility of fish passage alternatives at Englebright Dam, including dam removal, volitional passage, or trap and haul.
- ❖ Develop hydro-electric license re-opener clauses for FERC projects with triggers based on reintroduction of anadromous fish to project watershed.
- ❖ Develop hydro-electric license re-opener clauses for FERC projects with triggers based on reintroduction of anadromous fish to project watershed.
- ❖ Implement gravel injection program below Englebright Dam to restore geofluvial processes.
- ❖ Create and restore side-channel habitats to increase the quantity and quality of off-channel rearing (and spawning) areas in the Yuba River.
- ❖ Implement projects to increase Yuba River floodplain habitat availability to improve habitat conditions for juvenile rearing (NMFS 2007b).

Watershed Description

The Yuba River Watershed drains 1,339 square miles of the western slope of the Sierra Nevada and includes portions of Sierra, Placer, Yuba, and Nevada counties (YCWA *et al.* 2007). The watershed is comprised of the North, Middle and South Forks of the Yuba River. There also are several other small- to moderate-sized impoundments in the watershed, including Lake Spaulding, Bowman Lake, Jackson Meadows Reservoir, Englebright Reservoir, Lake Fordyce, and Scotts Flat Reservoir. The North Fork of the Yuba River flows into New Bullards Bar Reservoir and is joined by the Middle Fork about 5 miles downstream from the 645-foot New Bullards Bar Dam. The South Yuba begins with runoff near Donner Pass high in the Sierra Nevada, and its source is Lake Angela at 7,190 feet. The South Yuba River extends for 64 miles before joining the other two forks at Englebright Dam and Reservoir to form the main stem of the lower Yuba River (SYRCL 2009). The main stem of the lower Yuba River is a tributary of the Feather River, which drains into the Sacramento River. The lower Yuba River consists of the approximately 24-mile stretch of river extending from Englebright Dam, the first impassible fish barrier along the river, downstream to the confluence with the Feather River near Marysville, California.

Geology

The watershed rises from an elevation of about 88 feet to about 8,590 feet above mean sea level (msl), and is bordered by the basins of the Feather River to the north, the Truckee River to the east, and the Bear River and American River to the south (SYRCL 2009). Above 6,000 feet, ponderosa pine, sugar pine, Douglas fir, white fir, and incense cedar thrive, and precipitation in the watershed can range from 50 to 70 inches each year (SYRCL 2009). The upper Yuba River tributaries (North Yuba, Middle Yuba, and South Yuba Rivers) are steep, mountain drainages that flow through narrow, deeply incised canyons alternating between bedrock and alluvial reaches. Alluvial reaches store considerable volumes of sediment in the channel bed, active bars, and infrequent well-vegetated floodplains and terraces (Curtis *et al.* 2005). Bedrock reaches have minimal channel storage, although patchy alluvium may be found in deep pools or behind bedrock constrictions or large boulders (Curtis *et al.* 2006). A stratum of serpentine traverses the Yuba River Watershed in a direction generally parallel with the crest of the Sierras. This stratum is generally softer and more easily eroded than adjoining strata (Department of Agriculture 1901).

Large volumes of sediment, derived from past upstream hydraulic-mining activities, are currently stored in several upland tributaries that flow into the Middle Yuba and South Yuba Rivers. A significant part of the Yuba River sediment load is deposited in

New Bullards Bar Reservoir (Brown and Thorpe, 1947; Dendy and Champion, 1978), in Englebright Reservoir (Childs et al. 2003; Snyder et al. 2004; Snyder et al. 2004), and behind Log Cabin Dam and Our House Dam (YCWA 1989).

Hydrology

New Bullards Bar Reservoir, located on the North Yuba River, is operated by the Yuba County Water Agency (YCWA) and is the principal storage facility of YCWA's Yuba River Development Project (Yuba Project). The reservoir has a total storage capacity of 966 TAF with a minimum pool of 234 TAF (as required by YCWA's FERC license), thus leaving 732 TAF of capacity that can be regulated. A portion of this regulated capacity, 170 TAF, normally must be held empty from September through April for flood control (YCWA *et al.* 2007).

Englebright Dam and Reservoir were constructed in 1941 to capture sediment produced by upstream hydraulic mining activities, and is located downstream of New Bullards Bar Dam at the confluence of the Middle and South Yuba rivers. With a storage capacity of approximately 70 TAF, Englebright Dam and Reservoir essentially serves as a re-regulating afterbay for New Bullards Bar Reservoir and fluctuates on a frequent basis. Most of the water from Englebright Dam is released through the Narrows I and II powerhouses for hydroelectric power generation (USFWS 1995). The 0.2-mile reach of river between the dam and the two powerhouses typically does not contain much water except when the reservoir is spilling. Deer Creek flows into the Yuba River at approximately RM 22.7. The 0.7-mile reach of river downstream of the Narrows I and II powerhouses to the mouth of Deer Creek is characterized by steep rock walls, long deep pools, and short rapids. Below this area, the river cuts through 1.3 miles of sheer rock gorge called the Narrows, where the river forms a large, deep, boulder-strewn pool (USFWS 1995). YCWA and PG&E coordinate the operations of Narrows I and II for hydropower efficiency and to maintain relatively constant flows in the lower Yuba River. The Narrows I Powerhouse typically is used for low-flow reservoir releases, or to supplement the Narrows II Powerhouse capacity during high flow reservoir releases. Because of the recreational and power generation needs, the storage level within the reservoir seldom drops below 50 TAF (YCWA *et al.* 2007).

The river canyon opens into a wide floodplain at the downstream end of the Narrows where large quantities of hydraulic mining debris have been deposited during past gold mining operations. This 18.5-mile section is typified as open valley plain. Dry Creek flows into the Yuba River at RM 13.6, approximately two miles upstream of Daguerre Point Dam (YCWA *et al.* 2007). Daguerre Point Dam, located 12.5 miles downstream from Englebright Dam, is the major diversion point on the lower river. The open valley

plain continues 7.8 miles below Daguerre Point Dam to beyond the downstream terminus of the Yuba Goldfields. This section is composed primarily of alternating pools, runs, and riffles with a gravel and cobble substrate. By virtue of the quality and size of the substrate, this section contains most of the suitable Chinook salmon spawning habitat found in the lower Yuba River (USFWS 1995). The remaining 3.5 miles of the lower Yuba River extending to the confluence with the Feather River is bordered by levees and is subject to backwater influence of the Feather River (USFWS 1995).

Operations of New Bullards Bar Reservoir can be described in terms of: (1) water management operations (i.e., baseflow operations), (2) storm runoff operations, and (3) flood control operations. Baseflow operations describe normal reservoir operations when system flows are controlled through storage regulation. These operations occur outside periods of flood control operations, spilling, bypassing uncontrolled flows into Englebright Reservoir, or outside periods of high unregulated inflows from tributary streams downstream from Englebright Dam. Storm runoff operations occur during the storm season, typically between October and May. Storm runoff operations target Englebright Reservoir operations, because it is the downstream control point for releasing water into the lower Yuba River. Storm runoff operations guidelines for Englebright Reservoir specify target storage levels and release rates. During flood control operations, the seasonal flood pool specified in the Corps flood operation manual for New Bullards Bar Reservoir is kept evacuated for flood protection, and to avoid unnecessary flood control releases. Reservoir releases may be required to maintain flood control space between September 15 and June 1 (YCWA *et al.* 2007).

Instream flow requirements are specified for the lower Yuba River at the Smartville Gage (RM 23.6), located approximately 2,000 feet downstream from Englebright Dam, and at the Marysville Gage (RM 6.2). The annual unimpaired flow at the Smartville Gage on the lower Yuba River has ranged from a high of 4.93 MAF in 1982 to a low of 0.37 MAF in 1977, with an average of about 2.37 MAF per year (1901 to 2005).⁶ In general, runoff is nearly equally divided between runoff from rainfall during October through March and runoff from snowmelt during April through September. Below the Smartville Gage, accretions, local inflow, and runoff contribute, on average, approximately 200 TAF per year to the lower Yuba River.

⁶ The forecasted seasonal unimpaired flow at Smartville is estimated each year by DWR and reported monthly in Bulletin 120, *Water Conditions in California*. The unimpaired flow at Smartville controls YCWA contractual delivery obligations to senior water right holders on the lower Yuba River, and is used to calculate the Yuba River Index (YRI), defined in RD-1644, and the North Yuba Index (NYI), defined in the Yuba Accord (YCWA *et al.* 2007).

Land Use

The upper basins of the Middle Yuba and South Yuba rivers have been extensively developed for hydroelectric power generation and consumptive uses by Nevada Irrigation District (NID) and PG&E. Total storage capacity of about 307 TAF on the Middle Yuba and South Yuba rivers and associated diversion facilities enable both NID and PG&E to export an average of approximately 410 TAF per year from the Yuba River Basin to the Bear River and American River basins. In addition, the South Feather Water and Power Agency exports an average of about 70 TAF per year from Slate Creek (a tributary to the North Yuba River) to the Feather River Basin. The operations in these upper basins can significantly reduce the water supply available to the lower Yuba River, particularly during dry and critical water years (YCWA *et al.* 2007).

The Corps and YCWA own storage facilities in the Yuba Region. Englebright Dam and Daguerre Point Dam were originally constructed by the California Debris Commission, a unit of the Corps, for debris control and now are operated and maintained by the Corps. Englebright Reservoir is used extensively for recreation. The Yuba Project, constructed and operated by YCWA, is a multiple-use project that provides flood control, power generation, irrigation, recreation, and protection and enhancement of fish and wildlife. It includes New Bullards Bar Reservoir, New Colgate Powerhouse, and Narrows II Powerhouse. Englebright Dam and Reservoir and Daguerre Point Dam are not parts of the Yuba Project. However, Englebright Dam and Reservoir are used to regulate power peaking releases from the New Colgate Powerhouse, and Daguerre Point Dam is used by YCWA to divert water to its Member Units. Water projects operated by PG&E, NID, and South Feather River Water and Power Agency export up to approximately 530 TAF of water per year into adjacent basins. Once exported, this water is not available to the lower Yuba River.

Fisheries and Aquatic Habitat

The lower Yuba River downstream of Englebright Dam provides successful spawning habitats for Chinook salmon and is home to one of the last self-sustaining runs of wild steelhead in the Central Valley. While biological data suggests that the Yuba River upstream of Englebright also historically supported anadromous fish species, this habitat was altered by past hydraulic mining practices and dam construction (DWR 2009). In the lower Yuba River, adult spring-run Chinook salmon are reported to hold over the summer in the deep pools and cool water downstream of the Narrows I and Narrows II powerhouses, or further downstream in the Narrows Reach (CDFG 1991a; SWRCB 2003), where water depths can exceed 40 feet (YCWA *et al.* 2007).

Within freshwater environments, juvenile salmonids select specific microhabitats where water depth and velocity fall within a specific range or where certain hydraulic properties occur. In general, juvenile Chinook salmon have been observed throughout the lower Yuba River, but with higher abundances above Daguerre Point Dam. This may be due to larger numbers of spawners, greater amounts of more complex, high-quality cover, and lower densities of predators such as striped bass and American shad, which reportedly are restricted to areas below the dam (YCWA *et al.* 2007). The primary rearing habitat for juvenile steelhead/rainbow trout also is upstream of Daguerre Point Dam. Juvenile trout (age 0 and 1+) abundances were substantially higher upstream of Daguerre Point Dam, with decreasing abundance downstream of Daguerre Point Dam. Large juveniles and resident trout up to 18 inches long also have been commonly observed in the lower Yuba River upstream and downstream of Daguerre Point Dam (SWRI *et al.* 2000).

Spring-run Chinook Salmon

Relatively small numbers of Chinook salmon that exhibit spring-run phenotypic characteristics have been observed in the lower Yuba River (CDFG 1998). Although precise escapement estimates are not available, the USFWS testified at the 1992 SWRCB lower Yuba River hearing that “...a population of about 1,000 adult spring-run Chinook salmon now exists in the lower Yuba River” (San Francisco Bay RWQCB 2006). However, annual escapement estimates Chinook salmon in the lower Yuba River conducted since 1992 indicate that 108 spring-run Chinook salmon were observed in 2001, but not in recent years (i.e., 2002 through 2008) (CDFG 2009).

Since 2000, Chinook salmon redd surveys in the lower Yuba River have been conducted during late August through September by CDFG. In the lower Yuba River, Chinook salmon redds have been observed in the Garcia Gravel Pit Reach (primarily above Parks Bar) by mid-September. The number of Chinook salmon redds observed by CDFG during September has ranged between 66 and 288 during 2000 through 2005, although redd superimposition during some years has precluded accurate redd counts (YCWA *et al.* 2007).

The installation of a VAKI Riverwatcher fish imaging system in the North and South Fish Ladders at Daguerre Point Dam in 2003 has provided an opportunity to count Chinook salmon as they migrate through the lower Yuba River (YCWA *et al.* 2007). During 2005, the year in which the VAKI system operated continuously during the February through June period, 1,021 Chinook salmon (including grilse) were observed (CDFG, preliminary, unpublished data). Only four Chinook salmon were observed passing Daguerre Point Dam during the month of February; most Chinook salmon

passing Daguerre Point Dam during this period were observed during the month of June. The recent VAKI system observations have not been used to attempt to estimate the total spring-run Chinook salmon escapement in the lower Yuba River. Also, the origins of the early migrating and spawning fish and their genetic relationship with fall-run Chinook salmon are unknown. Hatchery-reared spring-run Chinook salmon were planted in the lower Yuba River during the 1970s and adipose fin-clipped (e.g., hatchery) Chinook salmon have been observed both by the VAKI system and during carcass surveys.

Steelhead

Historical information on Central Valley steelhead populations is limited, but historical declines in steelhead abundance have been attributed largely to dams that eliminated access to most of their historic spawning and rearing habitat and restricted steelhead to unsuitable habitat below the dams. In the Yuba River, definitive population estimates do not exist for steelhead, but it is likely that the river supported large steelhead runs in the 1800s (USFWS 1995). Hydraulic mining and diversion and storage dams significantly reduced steelhead populations. For example, from 1910 to 1949 there was complete or nearly complete blockage of upstream migration at Daguerre Point Dam (Dunn et al. 1992 in USFWS 1995). Many of the freshwater habitat factors cited for declines in spring-run Chinook salmon runs generally apply to steelhead as well, because of their need for tributaries and headwater streams where cool, well-oxygenated water is available year round.

CDFG estimated that only approximately 200 steelhead spawned in the lower Yuba River annually before New Bullards Bar Reservoir was completed in 1969. From 1970 to 1979, CDFG annually stocked 27,270–217,378 fingerlings, yearlings, and sub-catchables from Coleman National Fish Hatchery into the lower Yuba River (CDFG 1991b). Based on angling data, CDFG estimated a run size of 2,000 steelhead in the lower Yuba River in 1975. The current status of this population is unknown, but it appears to be stable and able to support a significant sport fishery (McEwan and Jackson 1996). The Yuba River is managed for natural steelhead production (CDFG 1991b).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Water temperature imports to Butte Creek from the upper West Branch Feather River deliver cold water that is capable of supporting CV spring-run Chinook salmon. Because of the low elevation of holding and spawning habitat, historic water temperatures were likely too warm to support over summering adult spring-run Chinook salmon, and it is not likely that a self sustaining population of CV spring-run Chinook salmon existed prior to the import of this cold water. The cold water import essentially creates the cold habitat conditions that allow spring-run Chinook salmon to oversummer, spawn and successfully occupy Butte Creek. The success of numerous restoration efforts that have been undertaken on Butte Creek are illustrated by the abundance of CV spring-run Chinook salmon that have been observed since 1998. Once impaired by numerous dams with poor fish passage facilities, no dedicated fish flows, and unscreened diversions, Butte Creek now provides state-of-the-art fish ladders and screens, and dedicated instream flows. Water temperatures continue to pose threats to holding adult spring-run Chinook salmon and may limit habitat availability for steelhead.

Viability potential

CV spring-run Chinook salmon - **High**

CV Steelhead - **Moderate**

Butte Creek is characterized as having a *high* potential to support a viable independent population of spring-run Chinook and a *moderate* potential to support a viable population of steelhead.

Because the Butte Creek spring-run fish population is now considered persistent and viable, the watershed is considered a *conservation stronghold* for all life stages of spring-run Chinook salmon. Butte Creek is one of the most productive spring-run Chinook salmon streams in the Sacramento Valley (DWR 2005), and is one of only three streams (in addition to Deer and Mill creeks) that harbor a genetically distinct, sustaining population of spring-run Chinook salmon (CDFG 1998, as cited in CDFG 2008). Therefore, the viability of the Central Valley spring-run Chinook salmon ESU is reliant upon sustaining the Butte Creek spring-run Chinook salmon population. Lindley *et al.*, (2007) characterized the Butte Creek population as being at a low risk of extinction due to the abundance of the population, positive production trends, and a very low hatchery influence. Recent years have seen a sharp reduction in adult abundance, but the population still remains strong and should still be considered at moderate to low risk of extinction.

In addition, due to the low elevation habitat available to spring-run Chinook salmon in Butte Creek, climate change and potentially warmer water temperatures in the future may become a key threat to their recovery. If summer water temperatures warm even by one or two degrees (°C), it is unlikely that Butte Creek spring-run Chinook salmon would persist (Williams 2006). With a rise in air temperatures of 2 °C, the 25°C isotherm might just rise to the upper limit of the historical distribution of spring-run Chinook salmon in Butte Creek (Lindley et al. 2007). These threats currently are being evaluated and will be addressed over the next five years through the issuance of a new FERC license of the operation of the DeSabra-Centerville Hydroelectric project. Water temperature improvements are expected to reduce maximum water temperatures by as much as 1 to 2 degrees Celsius and reduce the frequency of heat events that trigger adult mortality.

The status of steelhead in Butte Creek is unknown. Although water temperatures are adequate to support summer rearing, and *O. mykiss* are present in high densities through the reach between lower Centerville Diversion Dam and the Centerville Powerhouse, high quality spawning and rearing habitat is essentially limited to only

about 5 miles of stream. Further monitoring of steelhead in the system, as well as, studying the habitat use and needs of steelhead for Butte Creek is needed to develop a recovery strategy for this Creek. However, given that spring-run Chinook salmon are productive in Butte Creek, the potential to support a viable steelhead population appears to moderate at the least.

Key Threats and Stressors

Key threats and stressors to spring-run Chinook salmon and steelhead in Butte Creek include, but are not limited to the following:

- ❖ Water temperatures affecting adult immigration and holding and embryo incubation
- ❖ Passage impediments/barriers affecting adult immigration and holding
- ❖ Predation of juveniles in the Butte Sink and Sutter Bypass
- ❖ Flow fluctuations and turbidity affecting spawning and embryo incubation
- ❖ Summer instream recreation activities stressing holding adults
- ❖ Loss of natural river morphology, riparian habitat and instream cover affecting juvenile rearing and outmigration
- ❖ Lack of certainty regarding a long-term flow agreement with irrigation districts (T. Parker, USFWS, pers. comm. 2009)
- ❖ Upper watershed condition and fire risk

Key Restoration Actions

- ❖ Develop, implement and evaluate a Butte Creek flow test for the PG&E DeSabra-Centerville Hydroelectric Project to determine the flow conditions that optimize coldwater holding habitat and spawning distribution.
- ❖ Install state-of-the-art fish ladders at DWR weir 2 and Willow Slough weir.
- ❖ Maintain state-of-the-art fish passage facilities at diversions in Butte Creek to meet NMFS' passage criteria.
- ❖ Enhance watershed resiliency in Butte Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce local water temperatures, or increase riparian shade (U.S. Forest Service Long-term Anadromous Fish Conservation Strategy).

Watershed Description

The following information on the Butte Creek watershed is generally summarized from the *Butte Creek Watershed Project: Existing Conditions Report* (Butte Creek Watershed Conservancy 1999).

Butte Creek originates in the Jonesville Basin, Lassen National Forest, on the western slope of the Sierra Nevada Mountains, and drains about 800 square miles in the northeast portion of Butte County. The Butte Creek Watershed encompasses approximately 510,000 acres and lies predominantly in Butte County with smaller portions in Tehama, Glenn, Colusa and Sutter Counties. Butte Creek enters the Sacramento Valley southeast of Chico and meanders in a southwesterly direction to the initial point of entry into the Sacramento River at Butte Slough. Butte Creek also enters the Sacramento River through the Sutter Bypass and Sacramento Slough.

In addition to Butte Creek and its tributaries, the watershed includes a series of dams, diversions and canals mostly located in the valley portion of the watershed and in the middle and lower canyon portions of Butte Creek. The Sutter Bypass section of Butte Creek begins downstream of the Butte Slough Outfall. Butte Creek (named Butte Slough in this section) splits into two channels, known as the East and West Borrow Canals, as it enters the Sutter Bypass near Highway 20. Generally, Butte Creek enters the Sacramento River via Sacramento Slough immediately upstream of the mouth of the Feather River near Verona.

Geology

The following information on geology in the Butte Creek watershed was taken from or summarized from the *Butte Creek Watershed Project: Existing Conditions Report* (Butte Creek Watershed Conservancy 1999).

The geology of the headwaters area in the Butte Meadows Basin is composed of volcanic rocks, associated with the Pliocene volcano Mt. Yana. The area contains andesitic rocks, basaltic rocks, and pyroclastic formations (Tuscan Formation).

As Butte Creek leaves the Butte Meadows area, it begins to incise into the Pre-Cretaceous metavolcanic and (older) Paleozoic marine sedimentary and metasedimentary geologic structures, known as the Sierra Nevada Basement Series or Basement Complex. These rocks underlie the volcanic structures that dominate the drainage basin. This formation is composed of massive greenstones, tuffaceous schists, dark schistose metasedimentary and metavolcanic rocks of the "Calaveras Formation",

slates, dark phyllite, quartzite, serpentine, and greywacke. It is in this area that the interface between the Tuscan (mudflow) Formation and the underlying Basement Series geology, in part containing the "Tertiary Auriferous gravels", begins to become exposed. The Tertiary Auriferous gravels are ancient, gold-bearing (auriferous) stream deposits, with their deposition occurring in the Tertiary period of the geologic time scale. Cape Horn, a geologic feature that dominates the canyon landscape, is visible 3/4 of a mile downstream of the Inskip Creek confluence. This outcropping of more resistant metavolcanic material has forced Butte Creek to flow around the rock outcrop, while the Butte Creek Canal, some 180 feet above the creek, enters a tunnel through the rock itself.

The middle section of the Butte Creek canyon downstream of the confluence with Clear Creek, is an area of extensive faulting of the Basement Series, where mining activity and settlement concentrated during the Gold Rush. There are many mines in the area, identified on USGS 7.5' quadrangles (Dix, Royal Drift, Black Diamond, etc.). The natural topography of the inner gorge of Butte Creek Canyon in the area around the Forks of Butte (the confluence with the West Branch of Butte Creek) has been modified by the mining of the stream and terrace gravel in the area of the confluence itself. Tailing piles and old sluice channels are scattered along the banks. The interface between the Tuscan and Basement Series rocks was exploited extensively on the Platte Ravine, off the West Branch of Butte Creek, accounting for headcuts and some hardrock tunneling in this area. Although many of the cutbanks in the area now have 100+ year old trees growing out of them, the landscape is still visibly altered.

The predominant geologic unit in the watershed, the Tuscan Formation, covers all other geologic formations in the mid-section of the watershed and effectively "caps" the landscape. Its estimated 300 cubic miles of material are spread out over a range of 2,000 square miles, covering an area from Oroville to Red Bluff. This formation was created by a mudflow deposit of late Pliocene age and is composed of angular to surrounded volcanic and metamorphic fragments, up to 3 meters in diameter, in a matrix of gray-tan volcanic mudstone. Downstream of the Centerville Diversion Dam, Butte Creek is entrenched in the metamorphic and igneous rocks that comprise the Basement complex of the Sierra Nevada. The sides of the creek show signs of past mining, with tailings piles and tunnels through bedrock banks.

The geologic character of Butte Creek changes markedly about 1.25 miles upstream of Helltown Bridge. At this location the Sierran Basement geology is covered by the Chico Formation (a unit of Cretaceous age associated with the inland seas of the Sacramento Valley). The Chico Formation is composed of fossiliferous marine sandstone. Gravel bars begin to form on the insides of meander bends, and the banks are covered with

vegetation as roots more easily penetrate the softer sandstone. Due to a large landslide sometime within the last 11,000 years, the creek is forced up against the west side of the canyon just downstream of Helltown Bridge, cutting deeply into the Chico Formation, leaving well-exposed tan sandstone cliffs. Directly below this landslide area begins a unit known as the Modesto Formation, composed of gravel, sand, silt and clay derived from the Tuscan and Chico Formations. The Modesto Formation is perched atop the Chico Formation along Butte Creek, and is prevalent along the canyon bottom, leading to the Sacramento Valley. Although mining debris are visible further upstream, the Modesto Formation area reveals the first obvious signs of dredge tailings. These tailings, consisting of cobble-sized and larger rocks, sit in piles where they were left after being sluiced through by gold miners. The tailings continue down the canyon along Butte Creek.

Hydrology

The following information on hydrology in the Butte Creek watershed was taken from or summarized from the *Butte Creek Watershed Project: Existing Conditions Report* (Butte Creek Watershed Conservancy 1999).

The hydrology of Butte Creek has been extensively modified and developed. It contains multiple hydropower diversions and imports water from other watersheds. Figure 6 displays the main hydrologic features (e.g., streams, diversions, powerhouses) within the Butte Creek watershed. There are three main sections of Butte Creek (upper, middle and lower).

Upper Butte Creek (i.e., Butte Meadows)

After Butte Creek flows through the Butte Meadows Basin, it transitions through the steep Butte Creek Canyon some 25 miles to the point where it enters the valley floor near Chico. In this section Butte Creek flows in a north-northeast to south-southwest direction, and is characterized by numerous small tributaries and springs, and deep, shaded pools interspersed throughout the upper section of the canyon above Centerville with flora dominated by pine and fir. The creek averages a drop of over 100 feet per mile in this section. The canyon section below Centerville has a shallower gradient and a riparian canopy of alder, oak, sycamore and willow. PG&E owns and operates two hydroelectric power generation dams (Butte Creek Head Dam and Centerville Head Dam) in the canyon.

Middle Butte Creek (i.e., Butte Canyon)

After Butte Creek leaves the canyon near Chico, it flows through a portion of the Sacramento Valley known as the Butte Creek Valley Section that extends to the Butte Slough Outfall, where Butte Creek first enters the Sacramento River. Four dams and numerous diversions in the valley section remove water to irrigate rice fields and orchards. The upstream-most diversion, Parrott-Phelan, diverts water year-round, but most diversions operate during April through September. Dams also impound and divert water for wildlife and agricultural uses in the lower portion of the section (Butte Sink). These dams include: Sanborn Slough, White Mallard Dam, East-West Diversion weir, and weirs number 1 through 5.

Lower Butte Creek (i.e., Butte Valley)

The Sutter Bypass section of Butte Creek, also known as Butte Basin, extends downstream of the Butte Slough Outfall for approximately 40 miles. Butte Creek (named Butte Slough in this section) splits into two channels, known as the East and West borrow pits, as it enters the Sutter Bypass near Highway 20.

The tributaries that enter each of the three Butte Creek reaches (*i.e.*, Butte Meadows, Butte Creek Canyon and Butte Creek Valley Section) are listed in an upstream-downstream order in Table 4.

Land Use

As described in the *Butte Creek Watershed Project: Existing Conditions Report* (Butte Creek Watershed Conservancy 1999), the diversity in the terrain encompassed by the Butte Creek Watershed has resulted in very diverse landownership and land uses. The land use map displayed in Figure 6 identifies the general land uses present in the Butte Creek Watershed as of 1997. The map displays broad land use designations and presents numerous generalizations; consequently, it should be only used in a broad or regional context. The areas assigned to each of the 13 land use categories in Figure 6 are quantified in terms of acreage and percent of the total watershed area in Table 2. Most of the lands in the Butte Creek watershed were allocated to grazing and agricultural use (64%), with the remaining lands almost equally split between commercial, industrial and residential use (13.1%) and forest related uses (13%). It is likely that in the recent 10 years these percentages may have changed somewhat due to the increase in residential development at the expense of grazing and agricultural use.

Unknown	59.2	0.01
Total watershed acreage	517,848	100

Fisheries and Aquatic Habitat

Butte Creek is unique among the remaining spring-run Chinook salmon independent populations in that all of the holding and spawning area for spring-run Chinook salmon is below 285 m (931 ft) elevation, by contrast to Deer and Mill creeks which do not have passage barriers and where spring-run Chinook salmon hold and spawn in areas above that elevation (CDFG 2008). Due to the lower elevation habitat, Butte Creek exhibits water temperatures above the ideal temperatures for holding and spawning Chinook salmon (Ward et al. 2003, as cited in CDFG 2008). According to CDFG (2008), minimum instream flow levels need to be established in Butte Creek in order to assure the continued viability of fisheries resources. The extensive temperature modeling above the DeSabra Centerville dam has helped managers mitigate for this lack of cold water downstream. The cold water can be released when need because the managers now know where that colder water is in the thermocline.

Salmonids currently have access to approximately 53 miles of Butte Creek (DWR 2005). The upstream limit of migration is considered to be Quartz Bowl Falls, a 15 foot tall waterfall located at an elevation of approximately 900 feet. Fish passage through Butte Creek is affected by about 22 major structures and an estimated 60 to 80 minor structures (DWR 2005). Salmon have been observed upstream from Quartz Bowl Falls

and below the Centerville Head Dam on three occasions in the past 25 years, when spring flows were in excess of 2,000 cfs (e.g., during 1998 and 2003) (DWR 2005).

Extensive habitat evaluations have been conducted throughout Butte Creek have identified and quantified habitat upstream from the Quartz Bowl that is suitable for CV spring-run Chinook salmon production (Holtgrieve and Holtgrieve 1995). For many years, this habitat was thought to be blocked by Centerville Diversion Dam, but recent evaluations by DFG have concluded that natural, historic passage to these areas was not likely due to the presence numerous waterfalls and high gradient reaches that start approximately one mile upstream from Centerville Diversion Dam (CDFG 1998, NMFS 2006).

Since the early 1990s, restoration actions in Butte Creek have focused on improving instream flow during the critical spring immigration period, thereby increasing the likelihood that fish will succeed in reaching the upstream holding and spawning areas, even in dry years. Currently, the minimum flow deemed necessary to allow for spring-run Chinook salmon upstream passage is estimated at 80 cfs (CALFED 2006).

PG&E's minimum instream flow requirement at the Lower Centerville Diversion Dam is 40 cfs from June 1 to September 14. Average monthly flows from June through September (1998-2002) were between 46 cfs and 49 cfs. During the onset of the spring-run Chinook salmon spawning period in mid-September of 2004, PG&E, in consultation with CDFG and NMFS, increased flows to 60 cfs (PG&E 2005). Flows in Butte Creek begin to increase during the steelhead spawning period from November through April. Because there are no large storage facilities on Butte Creek, flow regimes during the winter months when agriculture diversions are not occurring tend to mimic the historic hydrology of the watershed.

Based on an analysis of the percentage of available spring-run Chinook salmon spawning habitat, CDFG (2008) recently recommended new minimum instream flows for Butte Creek from Centerville Head Dam downstream to Parrot-Phelan Diversion Dam, related to the FERC relicensing of the DeSabra-Centerville hydropower project. CDFG's analysis of spring-run Chinook salmon spawning habitat was conducted using a 2-dimensional hydraulic and habitat model (USFWS 2003, as cited in CDFG 2008), an analysis of historical regulated flow data, including inter-basin water transfer from the West Branch of the Feather River to Butte Creek data (CDFG 2008b, as cited in CDFG 2008), and water quality (e.g., temperature) benefits (CDFG 2008b, as cited in CDFG 2008). Spawning habitat was identified as a limiting-factor for spring-run Chinook salmon in Butte Creek based on a considerable amount of redd superimposition observed during data collection efforts by the USFWS (USFWS 2003; USDOJ 2008, as

cited in CDFG 2008). CDFG (2008) suggest that their minimum instream flow recommendations for Butte Creek would allow for greater dispersal of spring-run Chinook salmon redds and reductions in redd superimposition. CDFG's (2008) recommended minimum flows in Butte Creek for each month of the year for normal and dry water year types are presented below.

CDFG's recommended minimum instream flows (cfs)

<u>Month</u>	<u>Normal</u>	<u>Dry</u>
Oct	100	75
Nov	100	75
Dec	100	75
Jan	100	75
Feb	100	75
Mar 1-14	100	75
Mar 15-31	80	75
Apr	80	75
May	80	65
Jun	40	40
Jul	40	40
Aug	40	40
Sep	100	75

In addition to efforts to implement new minimum instream flow requirements, significant restoration efforts have been conducted in Butte Creek to remove passage barriers, rehabilitate fish passage structures, screen unscreened diversions, and improve riparian habitat conditions.

Spring-run Chinook Salmon

From 2005 through 2008, Butte Creek spring-run Chinook salmon escapement was 10,625, 4,579, 4,943 and 3,935, respectively (CDFG 2009). Between 1960 and 2008, the highest annual spring-run Chinook salmon escapement was 20,259, occurring in 1998 (Table 6).

Table 6. Adult Spring-run Chinook salmon population estimates for Butte Creek from 1960 to 2008.

Year	Adult Estimate	Year	Adult Estimate	Year	Adult Estimate
1960	8,700	1977	100	1994	474
1961	3,082	1978	128	1995	7,500
1962	1,750	1979	10	1996	1,413
1963	6,100	1980	226	1997	635

1971	470	1988	1,290	2005	10,625
1972	150	1989	1,300	2006	4,579
1973	300	1990	250	2007	4,943
1974	150	1991		2008	6,000
1975	650	1992	730		
1976	46	1993	650		

Water temperatures between the Parrot-Phelan Diversion Dam and the Centerville Head Dam in Butte Creek frequently exceed the reported optimum temperatures for spring-run Chinook spawning. Water temperatures frequently exceed 59°F from July through September. During 2002 and 2003 elevated water temperatures, in conjunction with a large number of adult spring-run Chinook salmon returns, resulted in an outbreak of Columnaris (*Flavobacterium columnare*). 1,699 pre-spawning mortalities were observed from June 26, 2002 to September 19, 2002 from the Parrot-Phelan Diversion to the Centerville Head Dam. During 2003, an estimated 17,294 adult spring-run Chinook salmon migrated to Butte Creek, of which an estimated 11,231 died prior to spawning (Ward *et al.* 2003).

Juvenile Chinook salmon rear in the Butte Creek Canyon downstream of Centerville Head Dam for up to one year. Although summer flows of 40 cfs generally keep water temperature below 68°F throughout most of the reach (Kimmerer and Carpenter, 1989), water temperature often exceeds 76°F in the canyon between Butte Creek Head Dam and Centerville Head Dam in July and August. Moreover, water temperatures could be of concern during the late spring, particularly in the lower reaches of Butte Creek.

Studies in Butte Creek (Ward *et al.* 2003) found the majority of spring-run migrants to be fry moving downstream primarily during December, January, and February, and that these movements appeared to be influenced by flow. Small numbers of spring-run juveniles remain in Butte Creek above the Parrot-Phelan Diversion Dam prior to emigrating in the spring (Ward *et al.* 2004).

Steelhead

As reported by the Butte Creek Watershed Conservancy (1999), steelhead have been reported in Butte Creek principally through reports by CDFG wardens of angler catches. However, no estimate of steelhead abundance in Butte Creek is known to be available (Butte Creek Watershed Conservancy 1999; FERC 2008).

Adult steelhead ascend Butte Creek during the late fall and winter. Steelhead spawning occurs in tributaries such as Dry Creek and in the mainstem of Butte Creek above Parrott-Phelan diversion during winter and spring (generally December through April). As reported by the Butte Creek Watershed Conservancy (1999), the spawning area for steelhead in Butte Creek extends from the Centerville Head Dam downstream to the vicinity of the Western Canal Siphon crossing. Steelhead generally spawn upstream of the Parrott-Phelan diversion. Spawning gravel in the reach of the creek from the Centerville Head Dam downstream to the vicinity of Helltown is extremely limited, with the major gravel beds existing below the Centerville Powerhouse (Butte Creek Watershed Conservancy 1999). The Sutter Bypass is reportedly used by juvenile steelhead as rearing habitat (Butte Creek Watershed Conservancy 1999).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

A small dependent population of spring-run Chinook salmon continues to occur in Big Chico Creek, but relies on extant independent populations for its continued survival. The run size is under 500 returning adults annually and is considered a remnant population. Steelhead do occur in Big Chico Creek along with resident trout. The numbers of steelhead have not been estimated, however, they are believed to use the foothill zone to spawn except in low water years they spawn in the lower river.

Big Chico Creek is a small watershed with substantial urban impacts in the lower watershed. Big Chico Creek contains marginally suitable habitat for salmon that most likely was opportunistically used in the past by salmon and steelhead (Yoshiyama et al. 1996). The middle and upper watershed areas however, are not urbanized and much effort by local groups and land owners has been made to secure conservation easements along this portion of the river corridor. These easements protect the riparian zone from the impacts of development long term. To keep this small population of spring-run and steelhead persistent in this watershed, there are several restoration actions that could help the watershed: 1) improve fish passage through Iron Canyon 2) improve habitat function in the lower habitat through riparian and off channel improvements.

One of the limiting factors for the dependent population of spring-run Chinook salmon is fish passage through Iron Canyon which lies approximately 7 miles from the town of Chico. This ladder provides access for spring-run salmon into the upper watershed where cooler water is found in the late summer. The ladder connects Big Chico Creek through a section of the valley that was impacted by a previous earthquake. There are plans to improve this fish ladder, which would be an important restoration activity for this watershed to assist the current population to remain viable.

Viability potential

CV spring-run Chinook salmon: **Low to Moderate**

CV Steelhead: **Low to Moderate**

Big Chico Creek is characterized as having a *low to moderate* potential to support a persistent spring-run Chinook salmon. The Big Chico Creek spring-run population is considered an important dependent component of the Northern Sierra Diversity Group spring-run population. With successful restoration efforts, namely in the lower sections of the river and through improvements in the Iron Canyon fish ladder, the dependent population of spring-run will be supported to travel up the system where cooler pools exist at Higgins hole, an important summer holding area. Because the numbers of spring-run in this system vary from numbers below 50 up to 500 fish, the extinction risk for this dependent population is high. Implementation of key recovery actions could

improve conditions to reduce the risk of extinction. Even with effective restoration, the effective population size of 50 to 500 spawning adults, may never increase. However, because this is an important dependent population, maintaining habitat factors that increase the chances of survival, even if it never reaches dependent status, is important to the overall health of the ESU.

The Big Chico Creek watershed probably will also have a *low to moderate* potential to support a viable population of steelhead, with restoration efforts in the lower watershed. Steelhead likely are able to extend further upstream in the Big Chico Creek Watershed than spring run and therefore have access to better habitats. The potential for Big Chico Creek to support a viable steelhead population is higher than for spring-run because of the greater amount of habitat availability.

Key Threats and Stressors

Key threats and stressors to spring-run Chinook salmon and steelhead in Big Chico Creek include, but are not limited to the following:

- ❖ Physical passage impediments and flow-based barriers at Iron Canyon, City of Chico Swimming Holes and associated dams affecting adult immigration and holding
- ❖ Water temperatures affecting adult immigration and holding, spawning and embryo incubation
- ❖ Habitat suitability and spawning habitat availability affecting adult spawning
- ❖ Loss of floodplain habitat and natural river morphology affecting juvenile rearing and outmigration
- ❖ Passage impediments related to the reverse flows caused by M&T pumps affecting juvenile outmigration

Key Actions that would help support persistent dependent populations

- ❖ Restore the lower watershed riparian corridor through native riparian planting and improve off channel refugia
- ❖ Improve the Iron Canyon Fish Ladder so that salmonids can pass at low summer flows

Watershed Description

Big Chico Creek Watershed (Figure 7) is located within Butte and Tehama Counties, encompassing an area of approximately 72 square miles (USFWS 1995). The headwaters

of Big Chico Creek originate from the southwest slope of Colby Mountain at an elevation of approximately 5,400 feet. Big Chico Creek is approximately 45 miles in length and enters the Sacramento River west of the City of Chico (USFWS 1995). The watershed also encompasses three smaller drainages to the north including Sycamore, Mud, and Rock creeks (USFWS 1995; USFWS 2007).

Geology

The Great Valley geomorphic province lies to the west and the Sierra Nevada geomorphic province lies to the east and south. Rocks from the Cascade Range and Great Valley provinces are exposed along Big Chico Creek, and include Upper Cretaceous marine sedimentary rocks of the Chico Formation, Miocene volcanic rocks of the Lovejoy Basalt, and Pliocene volcanic and sedimentary rocks of the Tuscan Formation (USFWS 2006). In response to tectonic uplift and tilting, Big Chico Creek eroded through the Tuscan Formation and exposed the older Lovejoy Basalt. Continued downcutting through the very hard and resistant basalt resulted in the formation of a steep-sided, narrow canyon, primarily oriented along two primary joint sets within the basalt (USFWS 2006). Where the creek has cut entirely through the basalt into the softer Chico Formation, the steep canyon walls have been prone to instability due to

Figure 7. The Big Chico Creek Watershed (Source: CDFG 2001). Undercutting and the loss of support (Guyton and DeCourten 1978 in USFWS 2006). Upstream of Higgin's Hole (RM 23), the Big Chico Creek stream channel has cut through metamorphic rock, creating a narrow canyon with big boulders, bedrock potholes, and spectacular waterfalls (USFWS 1995).

Hydrology

The main channel of Big Chico Creek begins in Chico Meadows, fed by a number of springs that originate from Colby Mountain, and flows 45 miles to its confluence with the Sacramento River (CDFG 2001). Big Chico Creek can be divided into three zones: (1) the upper zone extends from the headwaters and Higgin's Hole; (2) the middle zone extends from Higgin's Hole to Iron Canyon; and (3) the lower zone extends from Iron Canyon to the Sacramento River (Maslin 1997). The unimpaired average annual yield is approximately 54,000 acre-feet (USFWS 1995). Above Five-Mile Diversion, base flows in Big Chico Creek during the summer (i.e., June-October) typically range from 20 to 25 cfs. However, most of this base flow is lost to infiltration in the region of the creek's outwash fan (i.e., roughly the city of Chico), therefore, by late summer of most years surface flow does not extend downstream of Rose Avenue (USFWS 1995).

Mud Creek and Rock Creek join Big Chico Creek about 0.75 miles before it enters the Sacramento River. These two tributaries differ from Big Chico Creek, in that: (1) these two creeks receive precipitation primarily as rain, rather than snow; and (2) their channel structure is shorter and dendritic, draining from the surface of the tilted Tuscan formation at relatively lower elevations than most of the Big Chico Creek drainage. Accordingly, they are seasonal (flowing from about November to June in the Central Valley portion of their channels) and warm up more rapidly during the spring (USFWS 1995).

Flowing 26 miles before entering Big Chico Creek, Mud Creek is a spring-fed stream that is one of the primary tributaries in the Big Chico Creek Watershed. Richardson Springs (Figure 7) serves as a barrier to upstream fish migration in Mud Creek (BCCECR in CDFG 2001). An outflow weir at Lindo Channel diverts excess flows through a diversion channel to Sycamore Creek, where it then flows into Mud Creek (Maslin, Analysis of the Sycamore in CDFG 2001).

Land Use

Most of Big Chico Creek is bordered by private land with smaller holdings by the United States Forest Service and the Bureau of Land Management (USFWS 1995). Big Chico Creek flows through Bidwell Park (the third largest municipal park in the United States), downtown Chico, and the California State University campus (USFWS 1995). The headwaters of Mud and Rock creeks are in privately held forest land; foothill reaches are mostly pastured brush land or woodland; and Central Valley reaches traverse agricultural land. Both Mud and Rock creeks have minor agricultural diversions (USFWS 1995). In addition, Mud Creek is impounded for domestic water

supply at Richardson Springs. The Sycamore Diversion passes floodwater from Big Chico Creek to Mud Creek (USFWS 1995).

Fisheries and Aquatic Habitat

The lowermost 24 miles of Big Chico Creek are identified as providing both historic and current aquatic habitat for anadromous salmonids (USFWS 2008). It has been reported that Big Chico Creek is important for providing aquatic habitat for adult spring-run Chinook salmon holding and spawning, while Mud, Rock and Sycamore creeks have been shown to be important non-natal rearing areas for salmonids (Big Chico Creek Watershed Alliance 1997).

Unless otherwise specified, the following information on fisheries and aquatic habitat in Big Chico Creek comes directly from the Big Chico Creek Watershed Existing Conditions Report (Big Chico Creek Watershed Alliance 2000).

In the lower reach of Big Chico Creek (known as Iron Canyon) that is located approximately 13 miles upstream of the confluence with the Sacramento River (DWR 2002), the valley narrows abruptly and the stream gradient increases. At its upper end, the basalt near the area from Bear Hole to Brown's Hole in Bidwell Park is undercut and large boulders have tumbled into the creek bed, possibly by a rock slide that occurred as a result of the 1906 San Francisco earthquake (DFG 1958 in USFWS 2006). During periods of normal creek flow, this debris field of boulders acted as an impassable barrier to upstream movement of fish and represented the most downstream barrier to fish passage. In 1958, CDFG constructed a fish ladder to provide pools of water for the fish to traverse the blocked area and reach the cooler pools to hold over the summer for fall spawning (DFG 1958 in USFWS 2006; Big Chico Creek Watershed Alliance 2008). The ladder was comprised of seventeen weirs, which reportedly were constructed to bypass a 14-foot-high waterfall created by the debris field (USFWS 2006). Since the original construction, the limited fish passage that does occur beyond the Iron Canyon Fish Ladder is believed to occur during higher flows (USFWS 2006). Over time, the fish ladder has fallen into disrepair. The Big Chico Creek Watershed Alliance (2008) has been working together with the resource agencies to fund construction of a rehabilitated fish ladder. In 2007, the final designs and specifications for rehabilitation of the structure were completed. If funding is secured, it is anticipated that the project would be constructed in the summer/ fall of 2010 (Big Chico Creek Watershed Alliance 2008).

Upstream of Iron Canyon and approximately four miles downstream of Web Hollow Creek (Figure 7), the canyon narrows and consists of large boulders, bedrock potholes, and waterfalls. Near Higgin's Hole (RM 23), there is a considerable waterfall that is

believed to be the uppermost barrier to anadromous fish passage (CDFG 2001). In very unusual years when migration corresponds exactly with high flow, salmon or steelhead may pass through this canyon to the waterfall at Bear Lake, but there is only one record of salmon being sighted at Bear Lake (Big Chico Creek Watershed Alliance 2000).

In Mud Creek, the main fish passage barrier is the 69-foot waterfall at Richardson Springs, which stops all upstream movement of fish, at the upstream extent of the valley zone. The Mud Creek foothill zone is extremely short, only extending from the top of the waterfall 1.1-mile to another series of falls. In Rock Creek, the upstream end of the valley zone for many years has been the diversion dam about 0.3 miles upstream of the Anderson Fork confluence.

Additional fish passage barriers in the Big Chico Creek watershed (depending on flow conditions) include the Lindo Channel Weir, a diversion dam at stream mile 18 in Rock Creek, a diversion dam between Ponderosa Way and Higgin's Hole, and various undersized culverts. Higgin's Hole is the upstream limit for spring-run Chinook salmon and steelhead, approximately 0.5 to 1 mile above the crossing of Ponderosa Way (Yoshiyama *et al.* 1996). The size of the waterfalls and the scenic nature of the upstream canyon preclude construction of fishways (USFWS 1995).

Historically the foothill zone of Big Chico Creek was dominated by migratory fish including spring-run Chinook salmon and steelhead. However, there are no accurate records of historical fish populations in the watershed. Anecdotal accounts suggest existence of former populations of steelhead and spring-run Chinook salmon in both Mud and Rock creeks. However, it is unlikely that either creek could sustain its own salmon or steelhead population indefinitely; historical populations were likely lost in each series of drought years and then re-established by strays from Big Chico Creek. Although no formal counts have ever been conducted, it is likely that only a few adult salmonids stray into Mud and Rock Creeks under present conditions.

During the winter and early spring, juvenile Chinook salmon of all races move from the Sacramento River where they were spawned into tributaries for rearing (Maslin *et al.* 1997). Some move upstream substantial distances (e.g., to Hicks Lane in Mud Creek; to Highway 99 in Rock Creek), although they are more numerous closer to the Sacramento River confluence. Maslin *et al.* (1998) estimated that approximately 50,000 juvenile Chinook salmon from the Sacramento River reared in Mud and Rock creeks, including an estimated 10,000 winter-run Chinook salmon. Juvenile Chinook salmon rearing in the tributaries reportedly grow faster and are in better condition than those remaining in the Sacramento River, and smolt and emigrate earlier than they would in the mainstem Sacramento River (Maslin *et al.* 1997; 1998). However, some tributary-rearing

juveniles get trapped by receding water, particularly in low water years (Maslin *et al.* 1998).

Spring-Run Chinook Salmon

NMFS (2009) indicates that a dependent population of spring-run Chinook salmon continues to occur in Big Chico Creek, but relies on extant independent populations for its continued survival. CDFG (2007) also reports that the creek currently exhibits only a remnant non-sustaining population of spring-run Chinook salmon and, thus, Big Chico Creek is not currently used as a population trend indicator.

As reported by the Big Chico Creek Watershed Alliance (2000), Big Chico Creek spring-run Chinook salmon spend the summer in deep pools from Iron Canyon to Higgin's Hole and spawn in adjacent riffles when temperatures drop during early Fall. Relatively high water temperatures limit the ability of holding spring-run Chinook salmon to tolerate additional stressors such as harassment by swimmers, particularly during drought years when water temperatures tend to be higher and salmon are over-summering in pools downstream of the Iron Canyon ladder. Due to elevated water temperatures in the area where adults are forced to spawn, their offspring develop rapidly; nearly all juveniles emigrate by the following spring (unlike Deer and Mill Creeks where many juveniles emigrate during the wet season more than a year after being spawned) (Big Chico Creek Watershed Alliance 2000).

The average annual run-size of Big Chico Creek spring-run Chinook salmon is believed to have been less than 500 fish during the 1950s and 1960s, but is now considered to be only a remnant population (CDFG 1993 as cited Yoshiyama *et al.* 1996). GrandTab data for Big Chico Creek spring-run Chinook salmon is available for some of the years between 1960 and 2008⁷. Between 1962 and 1969, escapement was 200, 500, 100, 50, 50, 150, 175, and 200, respectively (CDFG 2009). Between 1993 and 2008, escapement was 38, 2, 200, 2, 2, 369, 27, 27, 39, 0, 81, 0, 37, 299, 0, 0, respectively (CDFG 2009). For years not mentioned, escapement data either was not available or was intermittently available. During 2006, the most recent year that spawning fish were observed, about 83 percent (248) of estimated adults that returned to spawn in Big Chico Creek were found above the Iron Canyon Fish Ladder (USFWS 2007). In this diversity group, spring-run Chinook salmon populations seem to persist in Antelope and Big Chico creeks, albeit at

⁷ Data availability for Big Chico Creek during this period has been dependent on funding availability and other considerations (T. Parker, USFWS, pers. comm. 2009).

an annual population size in the tens or hundreds of fish, with no returning spawners in some years (NMFS 2009).

Steelhead

Existing wild steelhead stocks in the Central Valley are mostly confined to the upper Sacramento River and its tributaries (e.g., Antelope, Deer, and Mill creeks and the Yuba River) (NMFS 2009). However, populations also may exist in Big Chico and Butte creeks (McEwan and Jackson 1996).

As reported by the Big Chico Creek Watershed Alliance (2000), adult steelhead usually spawn in the foothill zone of the Big Chico Creek Watershed, but during low-flow years they may spawn in the valley zone. Historically, steelhead were probably predominant when the habitat was more suitable for anadromous salmonids. The decline of steelhead has permitted their replacement by resident rainbow trout. Studies have not been conducted to determine whether the rainbow trout are migratory (i.e., steelhead) or resident fish. Additionally, there have been no reported occurrences or estimates of steelhead spawning in Big Chico Creek (Big Chico Creek Watershed Alliance 2000).

Watershed/Ecosystem Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of CV spring-run Chinook salmon and CV steelhead in Deer Creek. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed is in good condition. Those actions that are required are localized in nature and when fully implemented have a high likelihood of restoring good fish passage conditions. In particular, long-term fish passage improvements should be addressed by installing state-of-the-art passage facilities at the Cone-Kimball, Stanford Vina, and Deer Creek Irrigation District dams, and existing dam structures should be replaced with inflatable bladder dams that can be installed during the irrigation season and lowered during periods of high stream flow and bedload transport. In the upper watershed Federal land management practices are guided by a long-term anadromous fish conservation strategy. Private timberland management plans lack a comprehensive anadromous habitat protection strategy.

Viability Potential

CV spring-run Chinook salmon - **High**

CV Steelhead - **High**

Deer Creek is characterized as having a *high* potential to support a viable independent population of spring-run chinook and a *high* potential to support a viable steelhead population.

Deer Creek, along with Mill Creek and Butte Creek, is recognized as supporting one of three remaining self-sustaining CV spring-run Chinook populations. Habitat used for holding and spawning is located at high elevations and habitat is considered to be high quality (CDFG 1998). The high elevation habitats in Deer Creek are isolated from fall-run Chinook salmon by low summer and fall flows and high water temperatures that prevent geographic co-occurrence and maintains genetic and phenotypic diversity of the population. The NMFS TRT did not conclude as to whether Mill and Deer creeks are independent of one another, although they did conclude that spring-run Chinook salmon in these streams are currently independent from other spring-run Chinook salmon populations and represent a significant lineage within Central Valley Chinook ESU.

When considering watersheds in the Central Valley that contribute current viable populations for Spring-run chinook, Deer Creek is considered a conservation stronghold for the ESU. Lindley *et al.* (2007) classified the Deer Creek spring-run Chinook salmon population as having a low risk of extinction. Over the past three

years poor ocean conditions combined with drought, and other stressors have affected the abundance of the Deer Creek population and the extinction risk may be trending toward moderate to high. With the implementation of key recovery actions, the watershed has a high potential for sustaining a population at a low risk of extinction (Lindley et al. 2007)) for the following reasons: (1) Deer Creek contains a sufficient amount holding and spawning habitat to support a population with an effective size greater than 500 adults or a census population near 2,500 (see Table 4-1 of the Recovery Plan), based on our review of historic and recent abundance; (2) hatchery influence is low and expected to decrease over time, (3) the number and magnitude of recovery actions needed within the Deer Creek watershed are limited and localized.

Deer Creek also supports all life history stages of steelhead, although not is much is known about the long term viability of steelhead in the ESU. The carrying capacity of steelhead in Deer Creek is not known, the watershed historically supported strong populations that likely persisted at low levels of extinction prior to water development on the valley floor. Deer Creek has a high potential to support a viable, self sustaining steelhead population because of the extensive (25 miles) or suitable spawning and rearing habitat, the existing occurrence of *O. mykiss* throughout Deer Creek at high densities (up to several thousand rearing fish per mile (Mike Berry, CDFG, pers. com., 2005)), and the limited number and localized nature of watershed-specific recovery actions.

The anadromous fish habitats in Deer Creek (along with Mill, Antelope, Battle and Butte Creeks) are probably the best remaining habitat above the Central valley for anadromous salmonids, and serve as important anchors for their recovery. It is also worth noting that aquatic resources in the Deer Creek watershed have regional significance for a number of reasons. There are diversion structures in the valley section of Deer Creek, however, as opposed to 90% of the rivers draining into the Sacramento Basin, there are no major water impoundments along the Deer Creek corridor. Unlike many other rivers in the Central Valley which find relief in the Sacramento River because their channels have been blocked by dams and diversions, anadromous fish have been able to maintain passage, and native fish communities have survived in the free flowing sections. Deer Creek is also considered essential to the recovery and perpetuation of the wild stocks of winter-run steelhead in the Central Valley (Reynolds et. al. 1993; McEwan and Jackson 1996) in part because of its current habitat conditions.

In Deer Creek the primary focus for spring-run Chinook salmon restoration is on improving flow conditions for upstream migrating adults so they can access important holding and spawning habitat (Mills and Ward 1996) and for outmigration fry. To this end, water exchange programs are underway or in development with cooperating

irrigation districts. The programs are intended to develop and operate wells to offset bypass flows needed for spring-run Chinook salmon and to implement water use efficiency measures to reduce irrigation water demand.

How will Deer Creek help to buffer the negative effects of climate change for salmonids in the Central Valley?

Under the expected climate warming of around 5°C, substantial salmonid habitat would be lost in the Central Valley, with significant amounts of habitat remaining primarily in the Feather and Yuba rivers, and remnants of habitat in the upper Sacramento, McCloud, and Pit rivers, Battle and Mill creeks, and the Stanislaus River (Lindley et al. 2007). Under the less likely but still possible scenario of an 8°C warming, spring-run Chinook salmon habitat would be found only in the upper-most reaches of the north fork Feather River, Battle Creek, and Mill Creek (Lindley et al. 2007).

In addition, while warming may pose as a key threat to spring-run Chinook salmon in Deer Creek, suitable water temperature conditions should persist longer in Deer Creek (and Mill Creek), where fish can reach higher altitudes (Williams 2006). Some existing or potential habitat should also remain for some time below various dams that currently release cool water through the summer (Williams 2006).

Key Threats and Stressors

Key threats and stressors to spring-run Chinook salmon and steelhead in Deer Creek include, but are not limited to the following:

- ❖ Agricultural diversion dams impeding or blocking passage of immigrating adults
- ❖ Elevated water temperatures affecting adult immigration and holding
- ❖ Low flows affecting juvenile outmigration, and attraction and migratory cues of immigrating adults
- ❖ Possible catastrophic event (e.g., fire or volcanic activity)
- ❖ Loss of genetic and life history diversity from steelhead hybridization with out-of-basin rainbow trout that are planted into reaches of Deer Creek upstream from the Upper Deer Creek Falls.

Key Restoration Actions

- ❖ Develop and implement a water exchange agreement with the Deer Creek Irrigation Company and the Stanford-Vina Irrigation District and dedicate fish passage flows (AFRP Website 2005).
- ❖ Construct state-of-the-art inflatable dams and install fish ladders that meet NMFS' adult fish passage criteria at the Cone-Kimball Diversion, Stanford-Vina Dam, and the Deer Creek Irrigation District Dam.
- ❖ Implement watershed restoration actions that reduce sedimentation and thermal loading in low gradient headwater habitats of Deer Creek Meadows, and Gurnsey Creek.
- ❖ Enhance watershed resiliency in Deer Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire.
- ❖ Revise inland fishery management practices to eliminate to the stocking of out-of-basin rainbow trout in Deer Creek in all waters upstream of Upper Deer Creek Falls.

Watershed Description

As reported by DWR (2009), Deer Creek is an eastside tributary to the Sacramento River that flows in a southwesterly direction for approximately 60 miles and drains 134 square miles. Deer Creek originates near the summit of Butt Mountain at an elevation of approximately 7,320 feet. It initially flows through meadows and dense forests and then descends rapidly through a steep rock canyon into the Sacramento Valley. Upon emerging from the canyon, the creek flows 11 miles across the Sacramento Valley floor, entering the Sacramento River at approximately 1 mile west of the town of Vina at an elevation of approximately 180 feet (DWR 2009).

Geology

Deer Creek is located within the southernmost extension of the Cascade Range. As reported in Armentrout et al. (1998), the Tuscan formation of the Pliocene age, comprised primarily of mudflows, dominates the geology. This formation dips gently and thins toward the southwestern portions of the watersheds. Geologic diversity is supplied by several influences. These include andesitic plugs that intrude the Tuscan formation along two linear trends, relatively minor exposures of marine sedimentary rocks, and at lower elevations, quaternary sediments of the Sacramento Valley. Glacial processes shaped some of the higher elevation landforms.

Soils generated from these parent materials are generally productive; erosion rates range from low to moderate on the andesitic soils to high to very high on the rhyolitic soils. Mass wasting is evident in the Deer Creek watershed, dominated by debris flows in colluvium-filled hillslope hollows. Failures are episodic and triggered by extreme precipitation events. Surface erosion, especially on the rhyolitic soils, is the other major source of sediment (Armentrout et al. 1998).

The soils of the Deer Creek watershed are derived from volcanic breccia, including basalt, andesite, dacite and rhyolite. Dominant soils in the Deer Creek watershed are of the Lyonsville and Jiggs association, Cohasset series, McCarthy series and the Windy series. The Lyonsville soils are generally found along ridges, are moderately deep and well-drained. The Jiggs soils are derived from volcanic flow of rhyolite and are somewhat excessively drained. The Lyonsville and Jiggs soils are mapped together because they both have erosive properties due to their rhyolitic component. The Cohasset soils are derived from weathered andesite and breccia. They are generally found on slopes of canyons in mountainous areas, and are moderately deep, moderately coarse textured, and have a granular structure. The Windy soils are well-drained soils derived from basic volcanic rocks, andesite and basaltic rocks from volcanic flows, and in some places are cemented together with tuffaceous material. These soils are found in mountainous areas (Armentrout et al. 1998).

Hydrology

As reported in Armentrout et al. (1998), precipitation varies from 25 to nearly 80 inches per year, over the range in elevation (approximately 180 to 7320 feet msl) in the Deer Creek watershed. Deer Creek produces on average 228,700 acre ft of water per year. Peak flows from the watershed are dominated by rain-on-snow events.

The majority of annual flow events occur in December, January and February when snow could be expected to be present in the transient snow zone (above about 3,000 feet in elevation). Earlier peaks (September through November) are most likely rain events with little snow influence. Later peaks (mid-March through May) indicate snowmelt generated peaks. The recorded maximum flow on Deer Creek was 23,800 cfs on December 10, 1937 (Armentrout et al. 1998).

There are three diversion dams and four diversion ditches on the 10 miles of stream between the canyon mouth of Deer Creek and the Sacramento River. During low flow periods, the existing water rights are sufficient to dewater the stream. Late spring and early summer diversions have resulted in flows low enough to block access for late-migrating adults (Armentrout et al. 1998).

Land Use

As reported by Armentrout et al. (1998), the Deer Creek watershed is relatively long and narrow, with moderate to steep slopes. Extended low gradient channel types are uncommon on the mainstem, restricted to Deer Creek Meadows and reaches in the Valley floor. Steep slopes adjacent to the main channel historically served as barriers to human activity, and recent land use allocations have protected these areas such that the main stem is essentially undisturbed. However, the presence of Highway 32 along portions of Deer Creek is a notable exception. In addition, timber harvest and grazing have impacted many of Deer Creek's tributary streams. These impacts have resulted in increased sedimentation to the Deer Creek watershed. The Lassen National Forest, through their Land and Resource Management Plan (USFS 1992), is decommissioning roads throughout the forest that are no longer in use. One of the primary reasons for this decommissioning is to reduce sediment load to anadromous watersheds such as Deer and Mill creeks.

Currently, approximately half of the forest lands in the region are in private ownership, providing support to local economies. Historically, range management was a major land use in the watershed. In the upper watershed, the number of animals grazing has declined substantially over the past hundred years, but ranching still provides limited employment. Pressure has increased on ranchers and growers to convert their lands to residential development (Armentrout et al. 1998).

Recreational activities in the watershed have steadily increased over the past decades with the increased population in the region. Lassen National Park and Forest Service Campgrounds in the Deer Creek watershed are sites of concentrated use. State Highway 32 provides easy access to stretches of Deer Creek, and is a major site of recreational fishing (Armentrout et al. 1998).

Fisheries and Aquatic Habitat

Deer Creek contains approximately 40 miles of anadromous fish habitat, with approximately 25 miles of adult spawning and holding habitat, most of which is on public lands managed by the Lassen National Forest. Unlike most tributary streams of the Sacramento and San Joaquin rivers that now have major water storage facilities that inundate or block miles of historical anadromous spawning habitat, headwater stream habitat in Deer Creek is still available for utilization by anadromous fish (Armentrout et al. 1998). Deer Creek provides approximately 42 miles of anadromous habitat extending from the confluence with the Sacramento River upstream to Upper Deer Creek Falls. Like the anadromous reaches of Mill Creek, the habitat is utilized and/or

available to fulfill one or more riverine life history requirements for both spring-run Chinook salmon and winter-run steelhead.

Until 1943, when a ladder was built to provide access to habitat upstream of the falls, Lower Falls (at a reported height of 16 feet) was the upstream limit to migration (Cramer and Hammack 1952). Construction of the ladder effectively provided access to an additional five miles of habitat which is now an important area for adult holding and spawning. In the early 1950's, a fish ladder was also built at Upper Falls, although upstream habitat was not considered suitable for spring-run Chinook salmon (Armentrout et al. 1998). The ladder currently remains closed for a variety of reasons during the adult spring-run Chinook salmon upstream migration period. In some years, anadromous fish have been observed above Upper Falls, but habitat appears to be utilized only on rare occasions when a few hardy fish are capable of surmounting the falls under suitable conditions (Armentrout et al. 1998).

Evaluations of Central Valley anadromous fishery resources (Reynolds et. al. 1993; McEwan and Jackson 1996; Harvey-Arrison 2008) have consistently identified insufficient instream flows, and elevated water temperatures particularly during the adult spring-run Chinook salmon upstream migration and holding period (May-September) as factors limiting anadromous fish production in the Deer Creek watershed. Recognition of these limitations has led to the establishment of the Deer Creek Watershed Conservancy, and development of cooperative programs between local, state and federal agencies, water users, and landowners to implement water exchange and other programs to sustain spring-run Chinook salmon and steelhead in Deer Creek.

Spring-run Chinook Salmon

Estimates of spring-run Chinook salmon abundance in Deer Creek are available since 1963 (CDFG Grandtab 2008) (Table 7). During the previous 17 years (1992-2008), spring-run Chinook salmon counts in Deer Creek have ranged from 140 to 2,759 salmon. From 2005 through 2008, Deer Creek spring-run Chinook salmon escapement was 2,239, 2,432, 644, and 140, respectively (CDFG 2009). Between 1940 and 1964, an average of 2,200 spring-run Chinook salmon was counted annually using fish ladder counts and carcass surveys. These historical surveys were often expansions of partial weir counts and incomplete carcass surveys and are not comparable to current survey efforts (Harvey-Arrison 2008).

Table 7. Adult spring-run Chinook salmon population estimates for Deer Creek from 1963 to 2008. Estimates are not available for all years.

Year	Adult Estimate	Year	Adult Estimate	Year	Adult Estimate
1963	2,302	1979	-	1995	1,295
1964	2,874	1980	1,500	1996	614

Spring-run Chinook salmon have been documented migrating upstream on Deer Creek from March through early July. Because data is limited, adult immigration timing and immigration peaks are not well known. In 1944 the peak period of adult immigration was during April, and from 1945-1948 the peak period was during May (Cramer and Hammack 1952). According to Cramer and Hammack (1952), the end of adult spring-run Chinook salmon counts made in Deer Creek (from 1940 through 1948) were always brought about by the lack of sufficient water below irrigation diversions for salmon to ascend readily, in addition to the onset of lethal water temperatures (Armentrout et al. 1998). From available data compiled for Deer Creek and Mill Creek (Fisher 1994), the peak spring-run migration appears to occur earlier in Deer Creek than in Mill Creek (Armentrout et al. 1998).

More recent data regarding the abundance of adult spring-run Chinook salmon is available from snorkel surveys to count holding adults. In late July 2007, a total of 644 adult spring-run Chinook salmon was observed (Harvey-Arrison (2008) (Table 8). Twenty-four miles of stream were surveyed from the Upper Deer Creek Falls downstream to within 2 miles of Dillon Cove (Figure 8). This encompasses the known holding habitat of adult spring-run Chinook salmon in Deer Creek (Harvey-Arrison 2008). Only 1% of the spring-run Chinook salmon population held between Upper Falls and Lower Falls in 2007 (Table 9). Normally, up to 28 % of the population holds in this reach. In 2006, only 3% held upstream of Lower Falls. Attraction flows in the Lower Falls fish ladder has been declining in recent years. The stream channel upstream of the ladder is slowly degrading, reducing the amount of flow being diverted into the ladder.

In addition, the supporting wall of the lowermost weir was lost in the 1997 flood, further decreasing the attraction flow for fish. A long-term solution is being explored to improve performance of the ladder by providing more flow through the ladder (Harvey-Arrison 2008).

The Lassen National Forest conducted spring-run Chinook salmon redd surveys in Deer Creek in October 2007. A total of 403 complete redds, 21 practice redds, 18 carcasses and 87 live fish on redds was observed (Harvey-Arrison 2008) (Table 8). As with Mill Creek, this spawner survey is a one-time pass, scheduled after the peak of spawning activity. The redd-to-holding fish ratio in 2007 was 1.6, or one redd for every 1.6 fish counted in the snorkel survey. Ratios of redds to holding spring-run Chinook salmon in Deer Creek for the past 11 years have ranged from 1.1 to 2.5, with an average of 2 fish per redd (Harvey-Arrison 2008).

As reported by Harvey-Arrison (2008), base flow within spring-run Chinook salmon holding and spawning habitat (measured at the DCV gage) during 2007 ranged from 255 cfs in early May to 74 cfs by the time of spawning. The average base flow during the same time periods for the previous 115 years of record are 395 cfs and 96 cfs, respectively (Harvey-Arrison 2008).

Water temperatures in Deer Creek are recorded at six locations at elevations ranging from 1,500 ft to 3,200 ft. Two recorders failed in 2007, representing thermal conditions at 1,700 ft. elevation and 2,000 ft. elevation. Water temperatures exceeded 2006 values at all locations recorded (Table 9). Water temperatures exceeded optimal values for spring-run Chinook salmon holding at all locations and may have reduced spawning success in 2007. Water temperatures were below tolerance limits for successful spawning after September 2 upstream of A-Line Bridge. At the lowest elevation of

spring-run Chinook spawning in Deer Creek, water temperatures were suitable for successful spawning after September 19 (Harvey-Arrison 2008).

During 2007, bi-monthly Chinook salmon rearing surveys were conducted in Deer Creek. Two locations were sampled (A-line Bridge and Ponderosa Way, Figure 8). Data from the rearing surveys were used to compare relative growth and occurrence of rearing spring-run Chinook salmon juveniles with fall-run and spring-run Chinook salmon juveniles captured downstream at the rotary screw trap (RST) location (Harvey-Arrison 2008a).

Studies in Butte Creek (Ward *et al.* 2003) found the majority of spring-run migrants to be fry moving downstream primarily from December through February associated with flow events, with small numbers of juveniles remaining to rear and migrate as yearlings later in the spring. Juvenile spring-run Chinook salmon emigration patterns in Deer Creek are similar to patterns observed in Butte Creek, with the exception that Deer Creek juveniles typically exhibit a later young-of-the-year migration and an earlier yearling migration (Lindley *et al.* 2004).

The RST, located approximately 9 miles upstream of Deer Creek's confluence with the Sacramento River, was operated from mid-December 2007 through late-March 2008. However, a combination of low flows, shallow water and a damaged live car reduced sampling efficiencies during this period. During this limited sampling period, 23 broodyear (BY) 2006 yearling spring-run Chinook salmon were captured, ranging in size from 66 mm fork length up to 101 mm fork length. A total of 1,197 BY 2007 young-of-year (YOY) Chinook salmon were captured during February and March, ranging in size from 32 mm to 52 mm fork length (Harvey-Arrison 2008a).

According to Lindley *et al.*, (2004) the best available information suggests that Mill and Deer creek spring-run Chinook salmon populations were never very large historically. Hanson *et al.*, (1940) estimated that Mill Creek could support about 3000 and Deer Creek about 7500 spring-run Chinook salmon spawners. Large numbers of spring-run Chinook salmon once migrated past Mill and Deer creeks on their way to upper Sacramento tributaries, and Mill and Deer creeks may have received significant numbers of strays, causing their dynamics to be linked to that of the up-river tributary populations. The NMFS TRT did not conclude as to whether Mill and Deer creeks are independent of one another, although they did conclude that spring-run Chinook salmon in these streams are currently independent from other spring-run Chinook salmon populations and represent a significant lineage within Central Valley Chinook ESU.

Steelhead

Steelhead begin migration into Deer Creek during the late-fall and winter, primarily when flows increase from storms. Ladder counts at Clough Dam, on Mill Creek, between 1953 and 1963, show that adult steelhead migrate upstream from September through June (Van Woert 1964). Harvey (1995) observed two distinct migration peaks in Van Woert's (1964) data. The largest peak occurred from late-October to mid-November, and accounted for 30 percent of the run. A smaller peak occurred in the first 2 weeks of February, and accounted for 11 percent of the run. Because Deer Creek is in the same geographic region as Mill Creek, and runoff patterns are similar, historic

steelhead migration timing was probably likely to be similar. Chinook salmon emigration studies on Deer and Mill Creeks have incidentally captured emigrating steelhead in rotary screw traps. Steelhead generally are captured from November through June, with most fish captured from December through March.

The three diversion dams on the 10 miles of stream between the canyon mouth of Deer Creek and the Sacramento River can provide passage impediments to adult steelhead during low flow periods. All of the diversion structures have CDFG designed and operated fish ladders and screens (Deer Creek Conservancy Website 2007).

The Upper Falls fish ladder is functioning during the time steelhead would be migrating upstream (Deer Creek Conservancy Website 2007). As previously discussed, the ladder is closed during the time when spring-run Chinook salmon would be migrating upstream because very little holding habitat exists above this point.

Steelhead habitat in the upper watershed is considered to be excellent with an abundance of spawning gravel (DWR 2005; USFWS 1999).

Water temperatures throughout the Deer Creek watershed are suitable for juvenile steelhead rearing except for the summer months when temperatures in the lower watershed become too high to support juvenile steelhead rearing. Cold water refugia are likely available during the summer months in the upper watershed.

The explicit time period when juvenile steelhead emigrate from Deer Creek has not been documented. However, it is likely that it occurs from October through May as seasonal flows increase. The extent to which flow fluctuations from water diversions in Deer Creek may cause juvenile stranding is currently unknown.

As described above, during 2007-2008 RST monitoring was conducted sporadically between mid-December and late-March. The Deer Creek RST was in operation a total of 32 days. A total of 18 outmigrating steelhead was captured in the Deer Creek RST between December and March, ranging in size from 58 mmfl to 282 mm (fork length) (Harvey-Arrison 2008a).

With the exception of some limited data on juvenile outmigration (mentioned above), little is known about the winter-run steelhead in Deer Creek and the distribution and abundance of their habitat. Considering steelhead life-history requirements, however, their range within the system is likely to include the range described for spring-run Chinook salmon, and may actually extend beyond this range (i.e., into potentially suitable upstream habitat or tributaries). Because steelhead are, on average, smaller in

size than Chinook salmon and can utilize smaller substrate for spawning, potential habitat exists for them beyond the known range of Chinook salmon.

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of CV spring-run Chinook salmon and CV steelhead in Mill Creek. With the exception of impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed is in good condition. Those actions that are required are localized in nature and when fully implemented have a high likelihood of restoring or maintaining good fish passage conditions. A water exchange agreement already is in place between the CDFG and water users on Mill Creek. Although the agreement improves fish passage conditions for CV spring-run Chinook salmon, a comprehensive hydraulic fish passage evaluation and monitoring plan has not been developed to assess the effectiveness of the agreement. Long-term verification of the flows, and an evaluation of existing dams for fish passage suitability are needed to ensure passage is provided at a wide range of stream flows and water year types. In the upper watershed Federal land management practices are guided by a long-term anadromous fish conservation strategy. Private timberland management plans lack a comprehensive anadromous habitat protection strategy.

Viability potential

CV spring-run Chinook salmon - **High**

CV Steelhead - **High**

Mill Creek is characterized as having a *high* potential to support a viable independent population of spring-run chinook and a *high* potential to support recovery of a viable population of steelhead.

Mill Creek, along with Deer Creek and Butte Creek, is recognized as supporting one of three remaining self-sustaining CV spring-run Chinook populations. Habitat used for holding and spawning is located at high elevations and is considered to be high quality (CDFG 1998). The high elevation habitats in Mill Creek are isolated from fall-run Chinook salmon by low summer and fall flows. High water temperatures prevent geographic co-occurrence and is the thermal gradient that maintains genetic and phenotypic diversity of the populations. The NMFS TRT did not conclude as to whether Mill and Deer creeks are independent of one another, although they did conclude that spring-run Chinook salmon in these streams are currently independent from other spring-run Chinook salmon populations and represent a significant lineage within Central Valley Chinook ESU.

When considering watersheds in the Central Valley that contribute current viable populations for spring-run Chinook salmon, Mill Creek is considered a conservation stronghold for the ESU. Lindley *et al.* (2007) classified the Mill Creek spring-run Chinook salmon population as having a moderate risk of extinction. Over the past three years, the abundance of the Mill Creek population has been in steep decline, and the extinction risk may be trending toward moderate to high. With the implementation of key recovery actions, the watershed has a high potential for sustaining a population at a low risk of extinction (Lindley et al. 2007) for the following reasons: (1) Mill Creek contains a sufficient amount of holding and spawning habitat to support a population with an effective size greater than 500 adults or a census population greater than 2,500; (2) hatchery influence is low and expected to decrease over time, (3) the number and magnitude of recovery actions needed within the Mill Creek watershed are limited and localized.

Mill Creek also supports all life history stages of steelhead, although not is much is known about the long term viability of steelhead in the DPS. Mill Creek has a high potential for supporting a viable, self sustaining steelhead population because of the extensive (25 miles) or suitable spawning and rearing habitat.

The anadromous fish habitats in Mill Creek (along with Deer, Antelope, Battle and Butte Creeks) are probably the best remaining habitat above the Central valley for anadromous salmonids, and serve as important **anchors** for their recovery. It is also worth noting that aquatic resources in the Mill Creek watershed have regional significance for a number of reasons. There are diversion structures in the valley section of Mill Creek, however, as opposed to 90% of the rivers draining into the Sacramento Basin, there are no major water impoundments along the Mill Creek corridor. Unlike many other rivers in the Central Valley which find relief in the Sacramento River because their channels have been blocked by dams and diversions, anadromous fish have been able to maintain passage, and native fish communities have survived in the free flowing sections. Deer Creek is also considered essential to the recovery and perpetuation of the wild stocks of winter-run steelhead in the Central Valley (Reynolds et. al. 1993; McEwan and Jackson 1996) in part because of its current habitat conditions.

In Mill Creek the primary focus for spring-run Chinook salmon restoration is on maintaining flow conditions for upstream migrating adults so they can access important holding and spawning habitat (Mills and Ward 1996) and for outmigration fry. To this end, water exchange programs are underway or in development with cooperating irrigation districts. The programs are intended to develop and operate wells to offset bypass flows needed for spring-run Chinook salmon and to implement water use efficiency measures to reduce irrigation water demand.

How will Mill Creek help to buffer the negative effects of climate change for salmonids in the Central Valley?

Under the expected climate warming of around 5°C, substantial salmonid habitat would be lost in the Central Valley, with significant amounts of habitat remaining primarily in the Feather and Yuba rivers, and remnants of habitat in the upper Sacramento, McCloud, and Pit rivers, Battle and Mill creeks, and the Stanislaus River (Lindley et al. 2007). Under the less likely but still possible scenario of an 8°C warming, spring-run Chinook salmon habitat would be found only in the upper-most reaches of the north fork Feather River, Battle Creek, and Mill Creek (Lindley et al. 2007).

Key Threats and Stressors

Key threats and stressors to Central Valley spring-run Chinook salmon and steelhead in Mill Creek include, but are not limited to the following:

- ❖ Elevated water temperatures affecting adult immigration and holding
- ❖ Low flows affecting attraction and migratory cues of immigrating adults

- ❖ Possible catastrophic events (e.g., fire or volcanic activity)

Key Restoration Actions

- ❖ Implement a Mill Creek anadromous fish passage study (AFRP Website 2005) that will evaluate fish passage at all agricultural diversions to determine if they meet NMFS' fish passage criteria. Design and install state-of-the-art fish passage facilities at diversions that currently do not meet the passage criteria.
- ❖ Conduct a study designed to determine adult fish passage flows at critical riffles and fish ladders in Mill Creek. Develop a water exchange agreement with all Mill Creek water users to allow implementation of those flows.
- ❖ Enhance watershed resiliency in Mill Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce local water temperatures, or increase riparian shade and reduce sources of chronic road-related erosion of sediment (Mill Creek Conservancy Watershed Report, U.S. Forest Service Long-term Anadromous Fish Conservation Strategy).
- ❖ Eliminate sources of chronic sediment delivered to Mill Creek from roads and other near stream development by out-sloping roads, constructing diversion prevention dips, replacing under-sized culverts and applying other storm proofing guidelines.
- ❖ Work with State and Federal water acquisition programs to develop *dedicated instream water*; participate in the lower Mill Creek Watershed Restoration Project (AFRP Website 2005).

Watershed Description

Mill Creek is an eastside tributary to the Sacramento River that flows in a southwesterly direction for approximately 60 miles and drains 134 square miles (DWR 2009). The creek originates near a thermal spring area in Lassen Volcanic National Park (LVNP) at an elevation of approximately 8,200 feet. It initially flows through meadows and dense forests and then descends rapidly through a steep rock canyon into the Sacramento Valley. Upon emerging from the canyon, the creek flows 8 miles across the Sacramento Valley floor, entering the Sacramento River about 1 mile north of the town of Tehama, near Los Molinos, at an elevation of approximately 200 feet (DWR 2009).

Geology

Mill Creek is located within the southernmost extension of the Cascade Range. As reported by Armentrout et al. (1998), the Tuscan formation of the Pliocene age, comprised primarily of mudflows, dominates the geology. This formation dips gently and thins toward the southwestern portions of the watersheds. Overlaying the Tuscan formation are flows of rhyolite, which form the Mill and Lost Creek Plateaus. Geologic diversity is supplied by several influences. These include andesitic plugs that intrude the Tuscan formation along two linear trends, relatively minor exposures of marine sedimentary rocks, and at lower elevations, quaternary sediments of the Sacramento Valley. Glacial processes shaped some of the higher elevation landforms.

Soils generated from these parent materials are generally productive; erosion rates range from low to moderate on the andesitic soils to high to very high on the rhyolitic soils. Mass wasting is evident in the Mill Creek watershed, dominated by debris flows in colluvium-filled hillslope hollows. Failures are episodic and triggered by extreme precipitation events. Surface erosion, especially on the rhyolitic soils, is the other major source of sediment. Erosion from recent volcanic deposits in and near LVNP within the headwaters of Mill Creek contributes turbidity to Mill Creek nearly year round (Armentrout et al. 1998).

The headwaters of Mill Creek are cutting through an ancient andesitic stratocone (layered andesitic lavas and pyroclastic deposits that were erupted at 600-400 ka). The hydrothermal system associated with this ancient volcano has altered the more permeable pyroclastic rocks in the center of it to mostly clay. This has enhanced erosion locally and is a significant contributor to the fine-grained sediment load of Mill Creek.

The soils in the Mill Creek Watershed range in parent material from volcanic breccia, including basalt, andesite, and rhyolite, to metamorphic rock. Dominant soils in the Mill Creek watershed are Toomes soils and Supan soils (Armentrout et al. 1998). The Toomes series is a well drained, shallow to very shallow, extremely rocky soil. The erosion hazard is moderate to severe, depending on the slope. Much of the watershed is composed of colluvial land which is characterized by steep slopes and is highly erosive due to loose rock and soil material. Therefore catastrophic events such as large rain events, stand reducing fires, and volcanic activity could lead to mass wasting events that could potentially devastate the fishery. So, management actions to address these threats, such as good fire plans need to be in place to avert this risk to the population.

Hydrology

The range in elevation in the Mill Creek watershed influences precipitation which varies from 25 to nearly 80 inches. Mill Creek produces on average 215,000 acre ft (or 2.56 ft/acre) of water per year. Peak flows from the watershed are dominated by rain-on-snow events.

The majority of annual flow events occur in December, January and February when snow could be expected to be present in the transient snow zone (above about 3,000 feet in elevation). Earlier peaks (e.g., September, October and November) are most likely rain events with little snow influence. Later peaks (mid-March through May) indicate snowmelt generated peaks. The recorded maximum flow on Mill Creek occurred on December 11, 1937. This storm was far above the gauge height (maximum at that time of 14,000 cfs), and was first calculated by USGS at 23,000 cfs, but later revised to 36,400 cfs.

Morgan and Growler Hot Springs are located along Mill and Canyon Creeks just north of Highway 36. The last additional geothermal input into Mill Creek occurs just north of the town of Mill Creek. These springs have a seasonal and diurnal variation but contribute about 10-15 % to the stream flow (Armentrout et al. 1998). Arsenic is added to Mill Creek by the Morgan/Growler hydrothermal system but the clay from the altered volcanics act as a stabilizing influence and adsorbs 70% of the arsenic by the time the stream reaches Highway 36 (Armentrout et al. 1998).

There are three diversion dams on Mill Creek. Two are operated by LMMWC and one is operated by the Clough and Owens ranches. During low flow periods the existing water rights are sufficient to dewater the stream. Late spring and early summer diversions have resulted in flows low enough to block access for late-migrating adult salmonids. Low flows may also prevent downstream migrating smolts from reaching the Sacramento River (McEwan and Jackson 1996).

Land Use

As reported by Armentrout et al. (1998), extended low gradient channel types are uncommon on the Mill Creek mainstem, and are restricted to upper Mill Creek and reaches in the Valley floor. Steep slopes adjacent to the main channel historically served as barriers to human activity, and recent land use allocations have protected these areas such that the mainstem is essentially undisturbed. However, timber harvest and grazing have impacted many of Mill Creek's tributary streams.

Approximately half of the forest lands in the region are in private ownership, providing support to local economies. Historically, range management was a major land use in the watershed. In the upper watershed, the number of animals grazing has declined substantially over the past hundred years, but ranching still provides limited employment. Pressure has increased on ranchers and growers to convert their lands to residential development (Armentrout et al. 1998).

The Lassen National Forest, through their Land and Resource Management Plan (USFS 1992), is decommissioning roads throughout the forest that are no longer in use. One of the primary reasons for this decommissioning is to reduce sediment load to anadromous watersheds such as Mill and Deer creeks.

Recreational activities in the watershed have steadily increased over the past decades with the increased population in the region. Lassen National Park and Forest Service Campgrounds in the Mill Creek watershed are sites of concentrated use.

Fisheries and Aquatic Habitat

As reported by Armentrout et al. (1998), Mill Creek (in addition to Antelope and Deer Creeks) still support the majority of their original native aquatic species assemblages. The three watersheds have been rated as having high "biotic integrity" (defined as "the ability to support and maintain a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of the natural habitat of the region") (Moyle and Randall 1996 as cited in Armentrout et al. 1998).

Unlike most tributary streams of the Sacramento and San Joaquin rivers that now have major water storage facilities that inundate or block miles of historical anadromous spawning habitat, headwater stream habitat in Mill Creek is still available for utilization by anadromous fish. Within the boundary of the Lassen National Forest, an estimated total of 43 miles of anadromous fish habitat is present in Mill Creek. From its origin in Lassen Valley National Park (LVNP) to its confluence with the Sacramento River, Mill Creek is approximately 58 miles long. Nearly all of the mainstem aquatic habitat is utilized and/or available to spring-run Chinook salmon and winter-run steelhead for one or more life history requirements (Armentrout et al. 1998).

Evaluations of Central Valley anadromous fishery resources (Reynolds et. al. 1993; McEwan and Jackson 1996; Harvey-Arrison 2008) have consistently identified insufficient instream flows as one factor limiting anadromous fish production in the Mill Creek watershed. This has led to progressive cooperative programs between

agencies and water users including the irrigation district, landowners, the local Conservancy, DWR and CDFG in the Mill Creek watershed to develop and operate wells, or to obtain water rights (lease or purchase) to offset bypass flows needed for spring-run Chinook salmon and steelhead.

Elevated water temperatures during the adult spring-run Chinook salmon upstream migration and holding period (May-September) also have been identified as a limiting factor, particularly at elevations \leq 2,100 feet msl.

Spring-run Chinook Salmon

The spring-run salmon population currently represents a good example of a viable population of fish in the Central Valley. The factors that contribute to this persistent viable spring-run population are cold water inputs from the upper watershed, relatively intact riparian habitat, and unimpeded corridor. Although the watershed lies in the Lassen National Forest, where cutting has occurred, many of the road systems have been decommissioned, so sedimentation rates, with the exception of high flood events or areas that have been burned, should be considered to be at the historic baseline. Therefore, the spring-run populations are experiencing conditions still close to ideal for their evolutionary life history trajectory.

In terms of population abundance, much good data has been collected. As reported by Harvey-Arrison (2008), Mill Creek spring-run Chinook salmon populations have been monitored since the late 1940's (Table 10). Various counting methods have been employed, including carcass and redd counts, electronic counters and fish traps. The natural turbidity of Mill Creek makes annual counts by direct observation impractical. The most consistent data available is a trapping station at the Clough dam that operated from 1954 thru 1963 (Van Woert 1964, as cited in Harvey-Arrison 2008). During this 10 year period, spring-run Chinook salmon counts ranged from 1,203 to 3,485. Since the removal of Clough dam in 1997, redd counts have been used to estimate returning spring-run Chinook salmon. For the past 11 years, estimates of spring-run Chinook salmon have ranged from 202 to 1,594, and have been above 900 salmon from 2002 through 2007 (Harvey-Arrison 2008). From 2005 through 2008, estimated Mill Creek spring-run Chinook salmon escapement was 1,150, 1,002, 920, and 362, respectively (Harvey-Arrison 2008; CDFG 2009).

Table 10. Adult spring-run Chinook salmon population estimates for Mill Creek from 1960 to 2008. Estimates are not available for all years.

Year	Adult Estimate	Year	Adult Estimate	Year	Adult Estimate
1960	2,368	1977	460	1994	723
1961	1,245	1978	925	1995	320

1971	1,000	1988	572	2005	1,150
1972	500	1989	563	2006	1,002
1973	1,700	1990	844	2007	920
1974	1,500	1991	319	2008	306
1975	3,500	1992	237		
1976	-	1993	61		

Based on observations of spring-run Chinook salmon adults holding and/or spawning, the known range of salmon habitat extends a distance of approximately 48 miles from near the Little Mill Creek confluence (C. Harvey 1996, personal communications, as cited in Armentrout et al. 1998) upstream to within 1/2 mile of the LVNP boundary (personal observation of adult holding, as cited in Armentrout et al. 1998). Although adults have been reported spawning in "Middle Creek" (Armentrout et al. 1998), a small tributary located approximately 2 miles downstream of the park boundary, suitable spawning habitat on the mainstem of Mill Creek extends to near Morgan Hot Springs (approximately three miles downstream of LVNP).

Mill Creek spring-run Chinook salmon redd survey results from 2007 are provided in Table 11 (Harvey-Arrison 2008). Forty-one miles of spring-run Chinook salmon spawning habitat were surveyed beginning upstream of the Highway 36 Bridge downstream to the Steel Tower Transmission Lines (Figure 9). Reaches with the highest number of redds observed include Canyon Camp to Sooner Place, and Sooner Place to McCarthy.

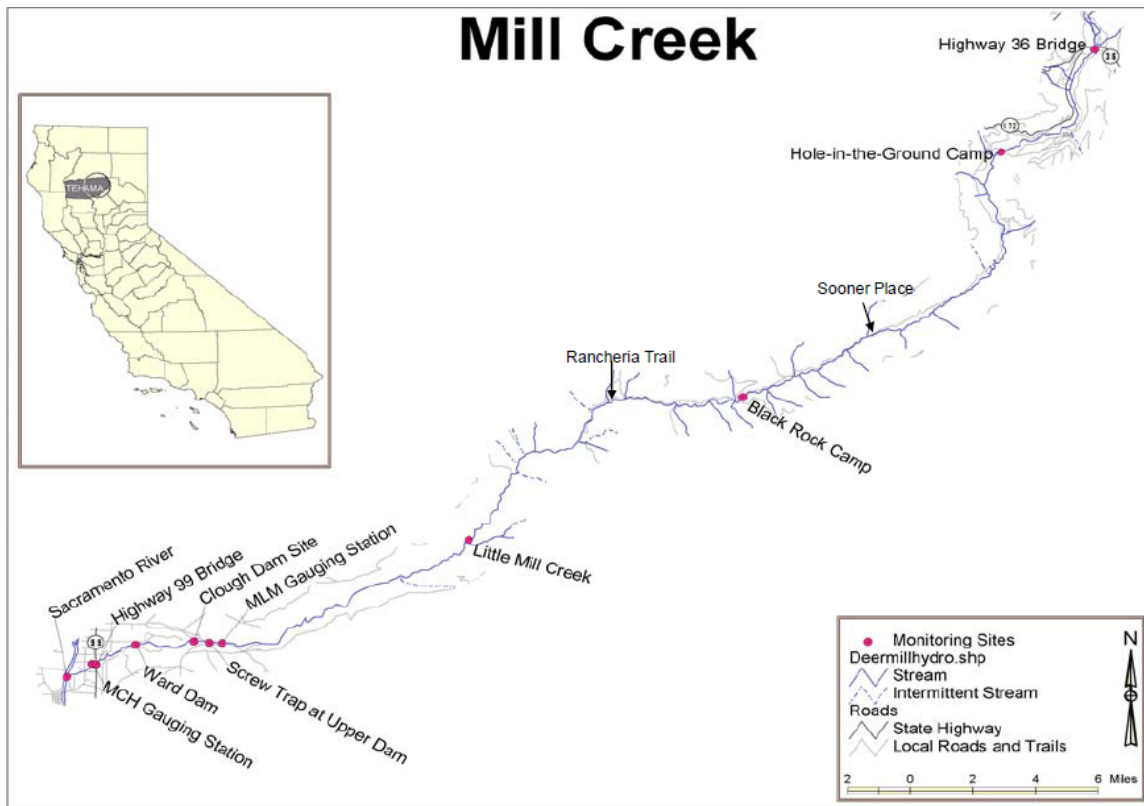

Figure 9. Map of spring-run Chinook salmon holding and spawning habitat in Mill Creek Source: Harvey-Arrison 2008

Water temperature recorders are located in six locations in spring-run Chinook salmon holding and spawning areas in Mill Creek, ranging from 4800 ft. elevation to 1000 ft. elevation. Table 12 shows the number of days at each elevation that water temperatures exceeded upper tolerance limits for normal egg development and adult salmon survival for both

2007 and 2006. These exceedence periods have an effect on the population in terms of growth and survival, particularly in the egg and incubation stages. Mill Creek water temperatures were higher in 2007 than 2006. In 2007, exceedence of optimal water temperatures occurred at elevations below 2800 ft. In 2006, water temperatures remained at levels supporting normal egg viability above 2100 ft elevation (Harvey-Arrison 2008).

Table 12. Water temperature exceedence and spring-run Chinook salmon spawning distribution in Mill Creek, May through September, 2006 and 2007

Location	Elevation (ft)	% Spawning Salmon 2007	Number of Days Mean Daily Temperature Exceeds:					
			≥59.0°F normal egg viability		≥63.5°F reduced egg viability		≥68.0°F partial mortality

Studies in Butte Creek (Ward *et al.* 2003) found the majority of spring-run migrants to be fry moving downstream primarily from December through February associated with *flow events*, with small numbers of juveniles remaining to rear and migrate as yearlings later in the spring. Juvenile spring-run Chinook salmon emigration patterns in Mill Creek are similar to patterns observed in Butte Creek, with the exception that Mill Creek juveniles typically exhibit a later young-of-the-year migration and an earlier yearling migration (Lindley *et al.* 2004).

Steelhead

Steelhead begin migration into Mill Creek during the late-fall and winter, primarily when flows increase from storms. Ladder counts at Clough Dam, on Mill Creek, between 1953 and 1963, show that adult steelhead migrate upstream from September through June (Van Woert 1964). Harvey (1995) observed two distinct migration peaks in Van Woert's (1964) data. The largest peak occurred from late-October to mid-November, and accounted for 30 percent of the run. A smaller peak occurred in the first 2 weeks of February, and accounted for 11 percent of the run. Based on observations using a video weir in Mill Creek from March 6 through June 18, 2007, peak upstream and downstream steelhead passage occurred from May 8-10, 2007 (Killam and Johnson 2008). This may represent the presence of two runs of steelhead in Mill Creek, with one run exiting the system while another run is entering the system during May (Killam and Johnson 2008).

Chinook salmon emigration studies on Deer and Mill Creeks have incidentally captured emigrating steelhead in rotary screw traps. Steelhead generally are captured from November through June, with most fish captured from December through March. Harvey-Arrison (2008a), reported that during the 2007-2008 juvenile steelhead outmigration monitoring period, 297 steelhead were captured in the Mill Creek RST from mid-October 2007 through early June 2008.

Steelhead counts in Mill Creek are available from 1953 to 1963, 1980, 1993, and 1994, for adult fish that passed Clough Dam. From 1953 to 1963, between 417 and 2,269 steelhead, with an annual average of 911 steelhead were counted at Clough Dam (Van Woert 1964). In 1980, 280 steelhead were counted, and in the 1993 to 1994 migration season, 34 steelhead were estimated. Moore (2001) used snorkel and foot surveys in January, March, and April to count adult steelhead and steelhead redds in Mill Creek. These surveys observed 15 adult steelhead and 31 redds in about 3 to 4 percent of the accessible anadromous habitat in Mill Creek. The observations do not represent a population estimate because the entire amount of habitat was not surveyed, and surveys may have missed the peak spawning period.

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Relatively few restoration actions are needed to restore watershed and ecosystem function for the purpose of supporting the freshwater life history stages of CV spring-run Chinook salmon and CV steelhead in Antelope Creek. With the exception of

impaired stream flows and fish passage conditions on the valley floor below agricultural diversions, habitat in the upper watershed in good condition. Those actions that are required are localized in nature and when fully implemented have a high likelihood of restoring good fish passage conditions. Antelope Creek is diverted into several channels below the Edward Diversion Dam and a single migration channel and fish passage flows need to be established to ensure that adult salmon and steelhead have unimpeded access to upstream spawning habitat and juveniles have unimpeded downstream migration. Fish screens with suitable bypass flows also need to be installed at the Edward Dam. In the upper watershed Federal land management practices are guided by a long-term anadromous fish conservation strategy. Private timberland management plans lack a comprehensive anadromous habitat protection strategy.

Viability potential:

CV spring-run Chinook salmon - **Moderate**

CV Steelhead - **High**

Antelope Creek is characterized as having a **moderate** potential to support a viable independent population of spring-run chinook population. Lindley *et al.* (2007) did not classify the viability of CV spring-run Chinook salmon in Antelope Creek, but instead characterized the population as dependant upon other populations for its existence (Lindley *et al.* 2004). We characterized the existing viability potential using the numeric population abundance and hatchery risk criteria described in Lindley *et al.* (2007) for evaluating extinction risk, and concluded that despite low hatchery influence, the effective population size is less than 50, the census population is less than 250 adults, and the current extinction risk for this population is high. However, considering historic observations and estimates of adult abundance of up to 500 fish, implementation of key recovery actions could improve population viability.

Antelope Creek has a **high** potential to support a viable population of CV steelhead. Although comprehensive population abundance data are not available, the widespread presence of *O. mykiss* throughout the Antelope Creek watershed (up to several thousand fish per mile in some reaches (Mike Berry, pers. com. 2005)); the quality of existing spawning and rearing habitat, Federal land management strategies that protect, maintain, and restore anadromous habitat within important parts of the upper watershed; and the small channel characteristics with up to 20 miles of suitable steelhead spawning habitat and water temperatures that support spawning and rearing, contribute to the high potential to support a viable anadromous population of steelhead.

Antelope Creek is believed to support a natural population of spring-run Chinook salmon as well as steelhead. CDFG (1998) states that the Antelope Creek spring-run population is not persistent, and the Central Valley Technical Recovery Team considers the Antelope Creek population to be dependant upon the populations in Deer, Mill and Butte creeks (70 FR 37160 (June 28, 2005)). In addition, the upper reaches of Antelope Creek are still fairly undeveloped and contain good habitat for Chinook salmon and steelhead trout. Antelope Creek has the potential to produce a sustainable population of 2,000 spring-run Chinook salmon, although inadequate flows due to two low head diversion dams prevent runs from realizing this potential (Rectenwald 1998).

In Antelope Creek, the primary focus for anadromous salmonid restoration is on improving flow conditions and fish passage for upstream migrating adults so they can access important holding and spawning habitat, and for outmigrating fry.

Key Threats and Stressors

Key threats and stressors to Central Valley spring-run Chinook salmon and steelhead in Antelope Creek include, but are not limited to the following:

- ❖ Agricultural diversion dams impeding or blocking adult immigration
- ❖ Water diversions entraining juveniles
- ❖ Low flow conditions affecting immigrating adults
- ❖ Poorly defined migration channels downstream from canyon mouth
- ❖ Noxious weeds invading downstream areas affecting juvenile rearing and outmigration
- ❖ Possible catastrophic event (e.g., fire or volcanic activity)

Key Actions that would help support persistent dependent populations

- ❖ Restore instream flows during upstream and downstream migration periods.
- ❖ Develop water exchange agreements provide alternative water supplies to Edwards Ranch and Los Molinos Mutual Water Company in exchange for instream fish flows
- ❖ Restore connectivity of the migration corridor during upstream and downstream migration periods
- ❖ Implement Edwards and Penryn fish passage and entrainment improvement projects and
- ❖ Identify and define or construct a defined stream channel for upstream and downstream fish migration

- ❖ Restore the lower watershed riparian corridor

Watershed Description

Antelope Creek originates in the Lassen National Forest in Tehama County at an elevation of about 6,800 feet. The creek flows southwest from the foothills of the Cascade Range and enters the Sacramento River at RM 235, 9 miles southeast of the town of Red Bluff. The Antelope Creek drainage encompasses approximately 123 square miles (USFWS 1995).

Geology

Antelope Creek is located within the southernmost extension of the Cascade Range. The Tuscan formation of the Pliocene age, comprised primarily of mudflows, dominates the geology (Armentrout et al. 1998). This formation dips gently and thins toward the southwestern portions of the watershed. Geologic diversity is supplied by several influences. These include andesitic plugs that intrude the Tuscan formation along two linear trends, relatively minor exposures of marine sedimentary rocks, and at lower elevations, quaternary sediments of the Sacramento Valley. Glacial processes shaped some of the higher elevation landforms.

Soils generated from these parent materials are generally productive; erosion rates range from low to moderate on the andesitic soils to high to very high on the rhyolitic soils. Mass wasting is evident in the Antelope Creek watershed, dominated by debris flows in colluvium-filled hillslope hollows. Failures are episodic and triggered by extreme precipitation events. Surface erosion, especially on the rhyolitic soils, is the other major source of sediment. However, Antelope Creek has less rhyolitic soils than nearby watersheds including Deer Creek and Mill Creek and thus, has lower surface erosion rates and less mass wasting than these other watersheds (Armentrout et al. 1998).

Hydrology

The Antelope Creek watershed produces on average 110,800 acre ft (1.41 ft/acre) of water per year. The majority of annual flow events occur during December through February when snow could be expected to be present in the transient snow zone (i.e., above about 3,000 feet in elevation). Earlier peaks (September through November) are most likely rain events with little snow influence. Later peaks (mid-March through May) indicate snowmelt-generated peaks.

In wettest years, average flows in winter months range from 200 to 1,200 cfs. In the driest years, flows in winter average 50 cfs. In all but the wettest years, summer and early fall flows average from 20 to 50 cfs. The natural flow pattern is altered by diversions in the lower creek from spring through fall. Flows are typically diverted from April 1 through October 31 (County of Butte Website 2007).

There are two diversions on Antelope Creek, both located at the canyon mouth. One is operated by the Edwards Ranch, which has a water right of 50 cfs, and the other is operated by the Los Molinos Mutual Water Company (LMMWC), which has a water right of 70 cfs (USFWS 1995, CDFG 1998). Unimpaired natural flows are often less than the combined water rights of the two diverters, resulting in a total dewatering of Antelope Creek (92 cfs from 1940 to 1980) during critical migration periods (USFWS 1995). Although diversions typically occur between April 1 and October 31, in 2009 Edwards Ranch diverted water during January (P. Bratcher, CDFG, pers. comm. 2009). The stream can potentially be dewatered when both diversions operate. Late spring and early summer diversions have resulted in stream flows low enough to block access for late-migrating adult salmonids. In addition, flow from Antelope Creek can move through a different channel (i.e., New Creek), further impacting instream flow in Antelope Creek (P. Bratcher, CDFG, pers. comm. 2009).

Land Use

The middle and upper portions of Antelope Creek are narrow, with moderate to steep slopes (Armentrout et al. 1998). Extended low gradient channel types are uncommon on the mainstem, restricted to McClure Place, Paynes Place, and reaches in the Valley floor. Steep slopes adjacent to the main channel historically served as barriers to human activity, and recent land use allocations have protected these areas such that the mainstem is essentially undisturbed. Timber harvest and grazing have impacted many of Antelope Creek's tributary streams (Armentrout et al. 1998).

Approximately half of the forest lands in the region are in private ownership, providing support to local economies. Historically, range management was a major land use in the watershed. In the upper watershed, the number of animals grazing has declined substantially over the past hundred years, but ranching still provides limited employment. Pressure has increased on ranchers and growers to convert their lands to residential development (Armentrout et al. 1998).

Recreational activities in the watershed have steadily increased over the past decades with the increase in the human population in the region. Sites of concentrated recreational use in the Antelope Creek watershed include Lassen National Park, Forest

Service campgrounds, and the Tehama Wildlife Area. The Tehama Wildlife Area is located approximately one hour east of Red Bluff, California, and contains 46,862 acres of oak woodland, grassland and chaparral. Recreational activities in the Tehama Wildlife Area include hunting, camping, fishing, and wildlife viewing (CDFG Website 2009).

Fisheries and Aquatic Habitat

Antelope Creek provides approximately 30 miles of anadromous fish habitat from its confluence with the Sacramento River upstream and 2 and 3 miles of habitat on the North and South Forks of Antelope Creek, respectively, above their confluence (Armentrout et al. 1998). CDFG habitat surveys and water temperature monitoring have identified limited, but adequate adult holding and spawning habitat for CV spring-run Chinook salmon, most of which is located in the Mainstem of Antelope Creek, near the confluence with the North and South Fork. Antelope Creek fish habitat is relatively unaltered above the valley floor but lack of adequate migratory attraction flows into the Sacramento River to this habitat prevents optimum use by anadromous fish (DWR 2009).

Two water diversions exist at the canyon mouth of Antelope Creek. Flow in Antelope Creek is typically diverted April 1 through October 31. In 1976 two fish screens were installed on the LMMWC diversion dam. Fish screens were design to keep salmon and steelhead from being lost in the diversions (Rectenwald 1998). A fish ladder at Edwards Irrigation Dam was constructed in 2007 and is reported to be adequate for fish passage. Currently, Paynes Crossing (Middle Slab) is a passage impediment during springs when there is low flow (Brenda Olson, USFWS, personal communication).

The lower reach of the stream is usually dry when both diversions are operating. Such flows affect migrating adult steelhead at the end and beginning of the run and smolts that are migrating in the spring. Also, adult spring-run are unable to enter the stream during the irrigation and diversion season (Rectenwald 1998). In 2007 and 2008, rescues of spring Chinook salmon juveniles and steelhead have been necessary due to an early irrigation season (Brenda Olson, USFWS, personal communication).

Anadromous salmonid habitat in the Antelope Creek watershed occurs at elevations of 1600 feet and below, resulting in an increased susceptibility to warmer water temperatures and potentially less optimal conditions for anadromous salmonids, compared to some of the other Northern Sierra Nevada watersheds (i.e., Mill and Deer creeks) (P. Bratcher, CDFG, pers. comm. 2009).

Spring-run Chinook Salmon

Historically, Antelope Creek supported “a few hundred” adult fish (Hallock 1956; Van Woert 1959). Hayes and Lingquist (1966) estimated the run to be about 500 fish annually. From 2005 through 2008, Antelope Creek spring-run Chinook salmon escapement was estimated at 82, 102, 26 and 2 fish, respectively (Table 13) (CDFG 2009). Between 1993 and 2008, the highest annual spring-run Chinook salmon escapement was 154, occurring in 1998 (CDFG 2009).

The range of spring-run Chinook salmon in the Antelope Creek watershed extends from upstream of Judd Creek on the North Fork, to Buck’s Flat on the South Fork, downstream to approximately Facht Place on the mainstem (Harvey-Arrison 2008). Approximately 16 miles of suitable holding and spawning habitat is available to spring-run Chinook salmon (Harvey-Arrison 2008).

Antelope Creek was snorkel surveyed to count holding adult spring-run Chinook salmon in July 2007 (Harvey-Arrison 2008). A total of 26 adult Chinook salmon were observed. Sixteen miles of stream were surveyed including the North Fork from 0.8 miles upstream of Judd Creek’s confluence to the South Fork confluence, the South Fork from the South Antelope Gun Club to the North Fork confluence, and the mainstem from the North and South Fork confluence to Facht Place (Table 13 and Figure 10).

One spawning survey was completed in October 2007, covering the same reaches as the holding survey, except it omitted the North Fork upstream of Judd creek and the mainstem downstream of Canyon Mouth. A total of 10 redds, 0 carcasses and 3 live salmon was observed (Table 14 and Figure 10) (Harvey-Arrison 2008).

Steelhead

Steelhead begin migration into Antelope Creek during the late-fall and winter, primarily when flows increase from storms. Ladder counts at Clough Dam, on Mill Creek, between 1953 and 1963, show that adult steelhead migrate upstream from September through June (Van Woert 1964). Harvey (1995) observed two distinct migration peaks in Van Woert=s (1964) data. The largest peak occurred from late-October to mid-November, and accounted for 30 percent of the run. A smaller peak occurred in the first 2 weeks of February, and accounted for 11 percent of the run. Because Antelope Creek is in the same geographic region as Mill Creek, and runoff patterns are similar, historic steelhead migration timing was probably likely to be similar.

Little is known about the winter-run steelhead in Antelope Creek, including their population status and annual run size, or their distribution in the creek and utilization of habitat. Although steelhead have been observed in Antelope Creek, records of population estimates have not been noted (Rectenwald 1998), and adult counts are limited. Moore (2001) used snorkel and foot surveys from March through May to count adult steelhead and steelhead redds in Antelope Creek. These surveys observed a total of 47 steelhead and 52 redds in about 53 percent of the accessible anadromous habitat in Antelope Creek. These numbers do not represent a population estimate because the entire amount of habitat was not surveyed, and surveys may have missed the peak spawning period. In 2007/2008, DFG installed a video camera and observed 140 adult CV steelhead moving through the newly constructed fish ladder at the Edwards Diversion.

Considering steelhead life-history requirements, however, their range within the system is likely to include the range described for spring-run chinook salmon, and may actually extend beyond this range. Because steelhead are, on the average, smaller in size than salmon and can utilize smaller substrate for spawning, habitat potentially exists for them beyond the known range of salmon (Armentrout et al. 1998).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Battle Creek has had persistent spawning populations of spring-run Chinook salmon and steelhead in the reaches currently accessible on the North Fork and South Fork in recent years, although the populations have been relatively small. Currently, the Battle Creek Watershed has five dams blocking upstream migration of salmonids to much of the suitable and historic habitat; however, there is a major restoration project planned, the Battle Creek Salmon and Steelhead Restoration Project (Restoration Project), to begin implementation summer of 2009. The Restoration Project, once complete, will open up 21 miles of currently blocked historical habitat, and will restore and enhance a total of nearly 50 miles of habitat.

Early fisheries investigators claimed that Battle Creek was the most important salmon-producing tributary to the Sacramento River when its ecosystem had its original form and function before settlement in the 1850's (Rutter 1904; CDFG 1993c *as cited in* Kier Associates 1999). It is anticipated that the Battle Creek watershed, once restored, will be a conservation stronghold for spring-run and winter-run salmon and steelhead (Battle Creek AMP). Battle Creek provides the only remaining currently accessible habitat (post Restoration Project) in the Sacramento River watershed, other than the Sacramento River, that is thought to be suitable for populations of winter-run Chinook salmon. Also, Battle Creek offers the best opportunity for restoration of wild steelhead populations in the upper Sacramento River (McEwan and Jackson 1996). Battle Creek has been identified as having high potential for successful fisheries restoration, because of its relatively high and consistent flow of cold water (Newton et al. 2008). It has the highest base flow (i.e., dry-season flow) of any tributary to the Sacramento River between the Feather River and Keswick Dam (Ward and Kier 1999, as cited in Newton et al. 2008). As these cold water inputs and good flows still exist, this system, if restored, will allow access by fish to these key areas upstream where cold water is more available.

Viability potential

CV winter-run Chinook salmon - High
CV spring-run Chinook salmon - High
CV steelhead - High

Battle Creek is characterized as having a High potential to support viable independent populations of winter-run and spring-run Chinook salmon and steelhead.

Implementation of key recovery actions (completing the Restoration Project) could improve population viability by reducing the risk of extinction to low, based on achieving an effective population size of greater than 500 spawning adults, or a census population size of greater than 2500, as described by Lindley *et al.* (2007) as criteria for assessing the level of extinction risk for Pacific salmonids.

Factors that increase the potential for these species to see increased populations or reintroduction success in this watershed, are: (1) historically, Battle Creek was a uniquely important salmon-producing watershed due to the large numbers and composition of Chinook salmon that were produced there (Kier Associates 1999); (2) McEwan and Jackson stated (1996) that Battle Creek offers the best opportunity for restoration of wild steelhead populations in the upper Sacramento River; (3) presence of a cold, spring-fed stream system that has exceptionally high flows during the dry season.; and (4) a memorandum of agreement between CDFG, USFWS and NMFS has been undertaken as a component to success for population viability to occur.

Battle Creek is therefore, a great candidate to lead to a strong contribution toward population viability for spring-run, winter-run and for steelhead.

How will Battle Creek help to buffer the negative effects of climate change for salmonids in the Central Valley?

Under the expected climate warming of around 5°C, substantial salmonid habitat would be lost in the Central Valley, with significant amounts of habitat remaining primarily in the Feather and Yuba rivers, and remnants of habitat in the upper Sacramento, McCloud, and Pit rivers, Battle and Mill creeks, and the Stanislaus River (Lindley et al. 2007). Under the less likely but still possible scenario of an 8°C warming, spring-run Chinook salmon habitat would be found only in the upper-most reaches of the north fork Feather River, Battle Creek, and Mill Creek (Lindley et al. 2007).

Battle Creek offers important cold water inputs for spring-run and steelhead populations, that could prove to provide some of the Central Valley's best protection against extinction for these species as climate change effects take place.

Key Threats and Stressors

Key stressors to Central Valley spring-run Chinook salmon and steelhead in Battle Creek include, but are not limited to the following:

- ❖ Passage impediments/barriers by hydropower dams affecting immigrating adults
- ❖ Hatchery effects (competition) on juvenile rearing and outmigration
- ❖ Flow conditions (e.g., low flows) and associated high water temperatures affecting immigrating, holding and spawning adults, as well as rearing and outmigrating juveniles
- ❖ Entrainment of rearing and outmigrating juveniles at hydropower diversions [RP will take care of this more or less

Key Restoration Actions for Battle Creek to support viability

- ❖ Install state-of-the-art fish ladders at, or remove small dams on the North Fork of Battle Creek to provide fish passage (which is part of the Restoration Project, planned for implementation summer of 2009).
- ❖ Install state-of-the-art ladders at, or remove small dams on the South Fork of Battle Creek to provide fish passage (part of the Restoration Project, currently funding has not been allocated for these actions).
- ❖ Increase streamflows as specified in the Restoration Project.
- ❖ Develop HGMPs and control hatchery release timing, numbers and locations in Battle Creek to minimize adverse effects to wild stock. Conduct feasibility study of moving and/or modifying Coleman Hatchery operations to prevent adverse impacts to listed species in Battle Creek.
- ❖ Increase flow releases from remaining diversion dams affecting anadromous fish on Battle Creek as per the Battle Creek Restoration Project (CALFED 2007).

Watershed Description

Battle Creek enters the Sacramento River (at river mile 273) approximately five miles southeast of the Shasta County town of Cottonwood. It flows into the Sacramento Valley from the east, draining a watershed of approximately 360 square miles (DWR 2009). The watershed includes the southern slopes of the Latour Buttes, the western slope of Mt. Lassen, and mountains south of Mineral, California (Ward and Moberg 2004). Nearly 350 miles of streams in the Battle Creek watershed drain land at elevations as high as 10,400 feet and cascade steeply down through basalt canyons and foothills to the confluence with the Sacramento River (Ward and Moberg 2004).

Battle Creek is comprised of three main branches - the North Fork (approx. 29.5 miles in length from headwaters to confluence), the South Fork (approximately 28 miles in length from headwaters to confluence), and the mainstem valley reach (approximately

15.2 miles from the confluence of the North and South forks to the Sacramento River), in addition to numerous tributaries (Kier Associates 1999).

Geology

The geology of Battle Creek is unique among the tributaries to the upper Sacramento River downstream of Shasta Dam, but quite similar to tributaries upstream of Shasta Dam (Kier Associates 1999) (Figure 11).

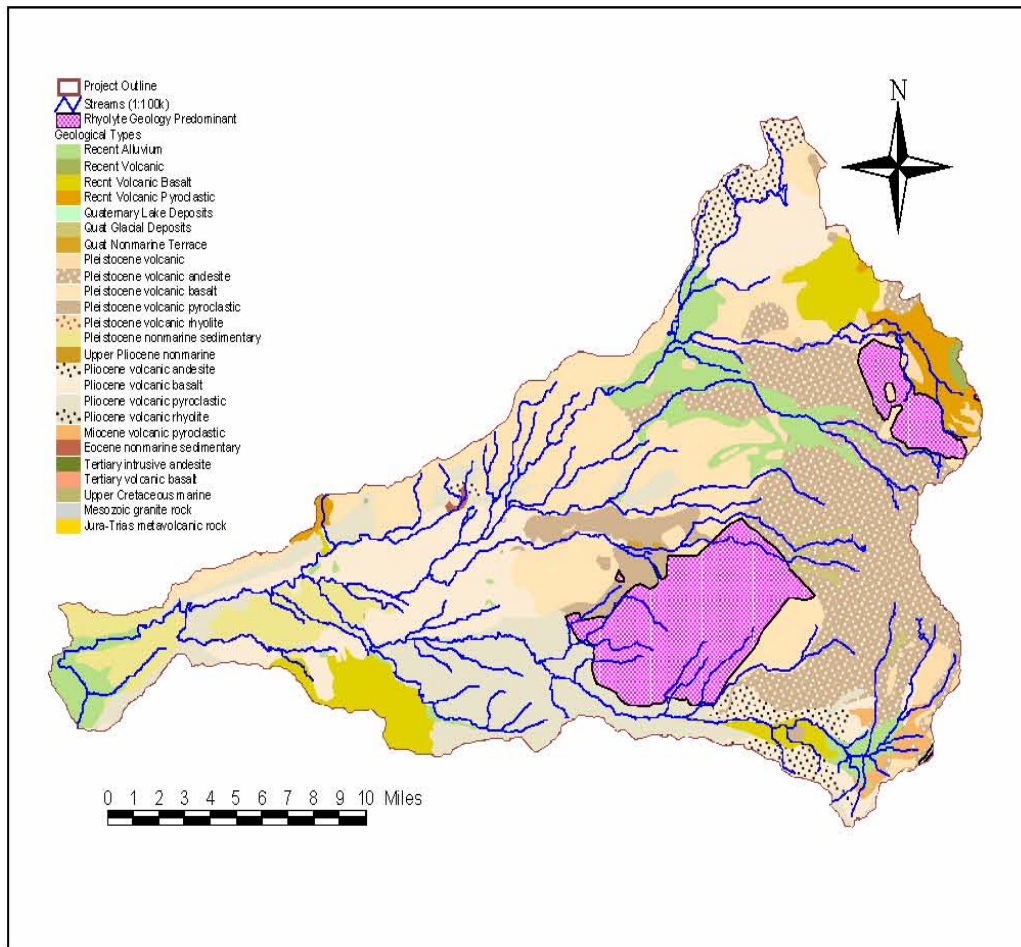

Figure 11. Battle Creek geologic types and location of rhyolitic soils (purple)

Source: Ward and Moberg 2004

Hydrology

Battle Creek has the largest base flow during the low flow season of any of the tributaries to the Sacramento River between the Feather River and Keswick Dam on the Sacramento River (Kier and Associates 1999). The spring-fed nature of Battle Creek ensures that an average September flow of 255 cfs reaches the Sacramento River (USGS

1995 as cited in Kier Associates 1999). Battle Creek and its tributaries drain the volcanic slopes of Mt. Lassen located at the top and center of the watershed (NPS circa 1998 as cited in Kier Associates 1999). The large snowfields on this 10,000 foot peak maintain stream flow until late in the summer (Kier Associates 1999). The volcanic formations and ancient stream channels buried by lava flows store a portion of the wet season runoff and convey it to the streams in the dry season via numerous cold springs (USGS 1956; NPS circa 1998; CDM n.d.; California Mines and Geology Redding Area Geologic Map; Koll Buer, DWR, Red Bluff, California, pers. comm. as cited in Kier Associates 1999).

There are two agricultural diversions in the valley reach of Battle Creek, including the Orwick Diversion (50 cfs) and the Gover Diversion (approximately 50 cfs) which are both considered to be pre-1914 water rights and enable year-round diversions. In addition, the diversions for Coleman National Fish Hatchery (CNFH) are located in the valley reach, and the amount of diversion varies seasonally (Kier Associates 1999). Irrespective of these diversions, Battle Creek remains hydraulically connected year-round, including the dry season and low flow conditions, to the Sacramento River (Kier Associates 1999). During the wet-season, the valley reach of Battle Creek has a natural unimpaired stream flow pattern (Kier Associates 1999).

Above the valley reach, Battle Creek has been extensively developed to produce hydroelectric power using a continuous series of small “run of the river” diversions (Kier Associates 1999). The structures that divert water for hydroelectric power production in the North Fork of Battle Creek include three diversion dams: (1) Wildcat Dam; (2) Eagle Canyon Dam; and (3) North Battle Creek Feeder Dam. These three dams are located downstream of natural barriers to upstream fish migration. The South Fork of Battle Creek also has three hydroelectric diversion dams downstream of natural barriers: (1) Coleman Dam; (2) Inskip Dam; and (3) South Diversion Dam.

Land Use

Land use in Battle Creek ranges from rural residential development to undeveloped wilderness areas of Lassen National Park, and is predominated by industrial timber harvesting, livestock ranch lands, grape growing, and other agricultural development (Ward and Moberg 2004). Private land adjacent to the anadromous reaches of Battle Creek is managed by relatively few landowners for agriculture and cattle grazing (Ward and Moberg 2004).

Timber harvest occurs on both publicly managed lands and privately owned lands. Sierra Pacific Industries is a major landowner in the Battle Creek watershed. Lassen

National Forest also manages land for timber harvest in the upper elevation portions of the watershed. Long-term sediment monitoring studies have been conducted by the USFS and timber companies (Ward and Moberg 2004). Fine sediment in the upper watershed shows a higher percentage of fines compared to other nearby streams (e.g., Deer, Mill and Antelope creeks) (Ward and Moberg 2004). Significant timber harvest during 2005-2009 contributed high amounts of fine sediment (M. Woodhouse, pers. comm., 2009.).

Current controversy includes the active lawsuit between concerned citizens and a proposed timber harvest plan for 900 acres near Manton, California. In 2007 this clearcutting plan for over 90% of the proposed project area was approved by the state; a subsequent lawsuit was filed and the controversy is yet to be resolved (January 15, 2008 Tehama County Superior Court, State of California) (T. Parker, USFWS, pers. comm. 2009).

Fisheries and Aquatic Habitat

Historically all four runs of Chinook salmon, including winter-run, spring-run, fall-run, and late-fall-run, occurred in Battle Creek (Yoshiyama et al. 1996; Yoshiyama et al. 1998). No reliable records exist that documented the number of winter-run Chinook salmon entering Battle Creek (Kier Associates 1999). Systematic counts were not made during the high-flow winter months when adult winter-run Chinook salmon migrate upstream (Kier Associates 1999).

The Coleman National Fish Hatchery (CNFH) was established in 1942 to mitigate the loss of natural salmon to historic spawning areas. The hatchery production goal included 250,000 winter-run Chinook salmon annually (USFWS 2008). In 1998, the winter-run propagation program was relocated from CNFH to the Livingston Stone Fish Hatchery on the Sacramento River. Winter-run Chinook salmon still have access to Battle Creek above the Coleman National Fish Hatchery (CNFH) weir from a fish ladder that is opened during the peak of the winter-run Chinook migration period (Ward and Kier 1999). However, if a winter-run Chinook salmon population exists in Battle Creek, its population size is unknown, likely very small, and is potentially mainly or entirely composed of strays from the mainstem Sacramento River.

As reported by Newton et al. (2008), since the early 1900's, a hydroelectric power generating system of dams, canals, and powerhouses, now owned by Pacific Gas and Electric Company (PG&E), has operated in the Battle Creek watershed in Shasta and Tehama Counties, California. The hydropower system has had severe impacts upon anadromous salmonids and their habitat (Ward and Kier 1999, as cited in Newton et al.

2008). The Central Valley Project Improvement Act's Anadromous Fisheries Restoration Program outlined several actions necessary to restore Battle Creek, including the following: "to increase flows past PG&E's hydropower diversions in two phases, to provide adequate holding, spawning, and rearing habitat for anadromous salmonids (USFWS 2001a, as cited in Newton et al. 2008)." CALFED, PG&E, and other contributors funded the Battle Creek Salmon and Steelhead Restoration Project (Restoration Project). The Restoration Project will provide large increases in minimum instream flows in Battle Creek, remove five dams, and construct fish ladders and fish screens at three other dams (Newton et al. 2008).

As reported by Newton et al. (2008), PG&E is required under its current FERC license to provide minimum instream flows of 3 cfs downstream of diversions on North Fork Battle Creek (North Fork) and 5 cfs downstream of diversions on South Fork Battle Creek (South Fork). Beginning in 1995, the CVPIA Water Acquisition Program (1995 to 2000) and ERP (2001 to present) contracted with PG&E to increase minimum instream flows in the lower reaches of the North Fork and South Fork (Newton et al. 2008). In general, flows are increased to 30 cfs (plus or minus 5 cfs) below Eagle Canyon Dam on the North Fork and below Coleman Diversion Dam on the South Fork (Newton et al. 2008). Increased flows were not provided on the South Fork in 2001 and most of 2002, due in part to lack of funds (Newton et al. 2008). Based on an agreement in 2003, flows can be redistributed between the forks to improve overall conditions for salmonids, based on water temperatures and the distribution of live Chinook salmon and redds (Newton et al. 2008).

As reported by Newton et al. (2008), the ERP-funded Interim Flow Project will continue until the Restoration Project construction begins (currently scheduled for 2009). The intent of the Interim Flow Project is to provide immediate habitat improvement in the lower reaches of Battle Creek to sustain current natural salmonid populations while implementation of the more comprehensive Restoration Project moves forward (Newton et al. 2008).

Central Valley Spring-Run Chinook

At the start of CNFH operations, a failed spring-run propagation effort collected 227, 1,181, 468, and 2,450 spring-run from Battle Creek in the years from 1943 to 1946, respectively, indicating that a large population was present in the creek (Kier Associates 1999). From 1946 to 1956, Battle Creek spring-run Chinook salmon numbered approximately 2,000 fish in most years (Yoshiyama et al. 1996). Escapement data for Battle Creek spring-run Chinook salmon is unavailable from 1960 to 1994 and 1997 to 1998. However, in 1995 and 1996, estimated adult spring-run Chinook salmon

escapement was 66 and 34 fish, respectively (USFWS 1996; Croci and Hamelberg 1998). From 1999 through 2008, Battle Creek spring-run Chinook salmon escapement was estimated to be 70, 40, 100, 144, 100, 70, 80, 154, 291, and 101, respectively (CDFG 2009).

As reported by Newton et al. (2008), linear regression techniques indicate that the spring-run Chinook salmon population in Battle Creek increased by about 13 fish per year, on average, from 1995 to 2007. This suggests that environmental conditions in Battle Creek have been suitable to maintain and lead to a modest increase in the population; interim flows, provided by PG&E, CVPIA, and CALFED since 1995 have likely been a primary contributing factor to this increase (Newton et al. 2008).

Table 15 displays total escapement estimates in Battle Creek of all four runs of Chinook salmon and rainbow trout/steelhead passing upstream of Coleman National Fish Hatchery (CNFH) barrier weir. Total estimated escapement includes Chinook salmon and steelhead passed during the CNFH broodstock collection and spawning program prior to March and fish passed through the barrier weir fish ladder between March 1 and August 31 (period of ladder operation was shorter in some years). Maximum potential spring-run Chinook salmon estimates include all unclipped salmon passing during the ladder operation period. Estimated spring-run Chinook salmon escapement is a reduced estimate based on apportioning some Chinook salmon to the winter, fall, and late-fall runs (Newton et al. 2008).

The current *upper* limits of spring-run Chinook salmon in the Battle Creek watershed are Eagle Canyon Dam on the North Fork and Coleman Diversion Dam on the South fork (e.g., Newton et al. 2007, 2008).

As reported by Newton et al. (2007), during 2006 the upstream-most observation of a Chinook salmon on the North Fork was a carcass observed at RM 5.06. During 2007 the upstream-most observation of a Chinook salmon on the North Fork was a carcass observed at RM 4.65 (Newton et al. 2008). During both 2006 and 2007, the upstream-most observation of a live Chinook salmon on the South Fork was immediately below Coleman Diversion Dam, which blocks fish passage (Newton et al. 2007, 2008).

In 2006, the upstream-most Chinook salmon redd observed on the North Fork was located at about RM 4.6. The upstream-most redd observed on the South Fork was located at about RM 2.5, immediately downstream of Coleman Diversion Dam. In 2007 the upstream-most Chinook salmon redd observed on the North Fork was located at approximately RM 3.8. The upstream-most redd on the South Fork was located at about RM 2.1, downstream of Coleman Diversion Dam (Newton et al. 2008).

Table 15. Multi-year summary of total estimated escapement in Battle Creek of all four runs of Chinook salmon and rainbow trout/steelhead passing upstream of Coleman National Fish Hatchery (CNFH) barrier weir

Year	Winter Chinook	Spring Chinook		Fall Chinook	Late-fall Chinook	Rainbow trout / steelhead	
		Maximum	Estimate			Clipped	Unclipped
1995		66				161 ^a	
1996		35				317 ^a	
1997		107				344 ^a	
1998		178				469 ^a

Central Valley Steelhead

Escapement estimates of Battle Creek clipped and unclipped rainbow trout/steelhead passing upstream through the CNFH barrier weir fish ladder between March and August from 1995 through 2007 are presented in Table 15 (Newton et al. 2008). Clip status was not used to differentiate hatchery- and natural-origin adult steelhead until 2001 because CNFH did not begin marking all of their production until brood year 1998. Battle Creek is one of the few Central Valley streams where quantification of the abundance of steelhead/rainbow trout is actually provided. The basis of the estimation of the annual run size is the number of adults passing the CNFH barrier weir. The total estimated number of steelhead entering Battle Creek based upon these estimates increased every year from 1995 through 2002 (Newton et al. 2008). Although the total number of adult steelhead estimated to be entering Battle Creek has declined since 2002, the proportion of un-clipped (i.e., “naturally-produced”) steelhead relative to the total run has increased substantially. Since 2005 the annual run of steelhead in Battle Creek has been comprised almost entirely of un-clipped steelhead.

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

As reported in the Cow Creek Watershed Assessment (SHN 2001), Cow Creek has been identified by DFG and USFWS as a candidate for restoration of anadromous fisheries. The Working Paper on Restoration Needs, compiled by the Anadromous Fish Restoration Program Core Group in 1995, identified Cow Creek and its tributaries as in “relatively good condition” regarding salmon and steelhead spawning habitat (WSRCD and Cow Creek Management Group 2001). During several DFG fish surveys in 2002 and 2003 primarily Terri Moore (DFG unpublished data) noted that there are sections throughout the watershed that appear to have suitable water temperatures year-round (primarily in the upper reaches of Old Cow and South Cow creeks). Overall, the habitat appeared to be suitable for spawning adult and rearing juvenile steelhead trout, with no definite barriers to anadromy. Moore further noted that there is no obvious reason for the absence of adult steelhead in the upper reaches of South Cow Creek. Yet, many sections of the watershed do not have suitable habitat, insufficient flows (*e.g.* irrigation and hydropower diversions – over 20 unscreened diversion in the watershed), resulting in water temperatures in holding pools that become too warm for spring-run Chinook salmon by midsummer (California Agriculture 2006). In addition, water temperatures and flows for rearing steelhead are less suitable than other nearby watersheds. Extensive restoration is needed in the Cow Creek Watershed for a population to persist. There have been an increase in focus on restoration in the system, particularly

addressing passage and entrainment issues, as well as the large hydropower project has filed decommission plans, which will return flows to their natural state, as well as remove passage impediments and entrainment concerns for these areas.

Viability potential

CV spring-run Chinook salmon: **low**

CV Steelhead: **moderate**

The Cow Creek Watershed is characterized as having a *low* potential to support a viable independent population of spring-run Chinook salmon population and would be considered to have a high risk of extinction according to criteria described in Lindley *et al.* (2007). In addition, the watershed is considered to have a *moderate* potential to support a viable population of steelhead. Implementation of key recovery actions could improve population viability by reducing the risk of extinction to moderate, based on achieving an effective population size of 50 to 100 spawning adults, or a census population size of 250 to 2500, as described by Lindley *et al.* (2007) as criteria for assessing the level of extinction risk for Pacific salmonids (see Table 4-1 in the Recovery Plan).

Key Threats and Stressors

Key stressors to steelhead in Cow Creek include but are not limited to the following:

- ❖ Passage impediments/barriers affecting adult immigration and holding and spawning
- ❖ Flow conditions (i.e., low flows) associated with attraction and migratory cues into Cow Creek affecting adult immigration
- ❖ Barriers in Cow Creek and resultant effects associated with redd superimposition, competition for habitat, hybridization/genetic integrity affecting adult spawning
- ❖ Elevated water temperatures and poor water quality affecting adult immigration and holding, spawning, embryo incubation, and juvenile rearing and outmigration
- ❖ Changes in flow conditions (low flows) in Cow Creek affecting juvenile rearing and outmigration
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Entrainment at individual unscreened permanent and temporary water diversions affecting juvenile rearing and outmigration

- ❖ Loss of natural river morphology, riparian habitat and instream cover, and floodplain habitat affecting juvenile rearing and outmigration
- ❖ Predation affecting juvenile rearing and outmigration
- ❖ Hatchery effects associated with trout stocking in upper Cow Creek affecting the genetic integrity of steelhead

Key Actions

- ❖ Decommission the PG&E Kilarc-Cow Hydroelectric Project; including reintroducing natural instream flows in the project reach and obliterating instream facilities that encumber upstream and downstream fish passage, or entrain juvenile outmigrants.
- ❖ Investigate measures to increase flows in Cow Creek and tributaries, such as: (1) investigating opportunities to increase irrigation efficiency; (2) managing vegetation to improve water supply and timing of supply; (3) purchasing water or water rights from willing sellers; (4) removing or laddering diversions; (5) providing alternate water sources during important periods; and (6) implementing a conjunctive use program
- ❖ Conduct feasibility analyses and prioritize screening and laddering five agricultural diversions in Cow Creek
- ❖ Install water temperature recorders at select locations in Cow Creek; develop recommendations for minimum instream flow based on temperature needs
- ❖ Implement projects to increase floodplain habitat availability to improve juvenile rearing habitat, and restore instream and riparian habitat in Cow Creek.
- ❖ Implement actions (e.g., spawning gravel augmentation) designed to increase spawning habitat availability and complement flows in Cow Creek.
- ❖ Enhance watershed resiliency in Cow Creek by identifying and implementing projects that would reduce the potential for, and magnitude of, a catastrophic wildfire, and restore forested areas within the watershed including riparian areas.

Watershed Description

The Cow Creek watershed encompasses approximately 425 square miles and has an average annual discharge of more than 500 thousand acre-feet (USFWS 1995). Cow Creek flows southwest from the base and foothills of Mt. Lassen and enters the Sacramento River at RM 280 (USFWS 1995, USFWS 2000). Most of the Cow Creek tributaries originate at 5,000 to 7,000 feet in elevation, and have steep gradients in their upper reaches. The landscape in the higher elevations consists predominately of mixed conifer forest of ponderosa pine, Douglas-fir, incense cedar, and California black oak

(USFWS 1995). The oak-digger pine association is predominant in the lower foothills, while the valley floor is dominated by oak grassland and pasture (USFWS 1995).

Geology

As reported by USFWS (2000), Cow Creek and its tributaries carve into diverse layers of geologic features. The eastern high of the Cow Creek watershed elevation reaches are the result of relatively recent volcanic activity, with the last eruption series occurring from 1915-1917 (Alt and Hyndman 1975 *as cited in* USFWS 2000). Encrusted lava rocks along with loose volcanic debris were deposited over more ancient (Cretaceous) marine sandstone and shale formations (USFWS 2000). Over time the Cow Creek tributaries have sliced through the blanket of volcanic deposits and eroded into the underlying sandstone and shale producing extensive alluvial deposits (Alt and Hyndman *as cited in* USFWS 2000). Gradient-transition points (i.e., head-cuts or knick-points) are evident in all five of the main tributaries at approximately 1000 feet elevation, forming notable waterfalls. These erosional deposits are the source of rich, well-draining soils that support lush forests and agricultural development (USFWS 2000).

Hydrology

The Cow Creek watershed is a dendritic system and can be divided into five main tributary subbasins, including Little Cow Creek, Oak Run Creek, Clover Creek, Old Cow Creek and South Cow Creek (USFWS 2000) (**Table 16**). The following subbasin descriptions come from USFWS (2000).

Table 16. Summary data for tributaries of the Cow Creek basin

Stream Name	Basin Area (square miles)	Stream Length
Little Cow Creek	148	36
Oak Run Creek	42	23.5
Clover Creek	54	27.5
Old Cow Creek	80	32.9
South Cow Creek	78	28.5
Main Stem Cow Creek	29	15
Total to Sacramento River	430	47.8

Source: (USFWS 2000)

Little Cow Creek

Also known as North Cow Creek, this subbasin drains 148 square miles. The headwaters (Cedar Creek, North Fork, and Mill Creek) originate at an elevation of roughly 5900 feet on the west slopes of Tolladay Peak, Snow Mountain and Clover Mountain. Little Cow Creek flows for 36 miles southwesterly, and then southerly prior to joining the Cow Creek mainstem at Hwy 44.

Oak Run Creek

Oak Run Creek is the smallest of the five main tributaries, draining 42 square miles. Oak Run Creek originates at an elevation of approximately 3200 feet. Oak Run Creek flows 23.5 miles southwesterly to its confluence with the Cow Creek mainstem in Palo Cedro.

Clover Creek

Clover Creek drains 54 square miles and originates at approximately 5500 feet on the south slope of Clover Mountain. Clover creek flows 27.5 miles from its headwaters to its confluence with the mainstem of Cow Creek.

Old Cow Creek

Old Cow Creek drains 80 square miles and originates at an elevation of 6500 feet in the Latour Demonstration State Forest. Old Cow Creek flows 32 miles and joins with Hunt Creek, Glendenning Creek, Canyon Creek and Coal Gulch prior to entering South Cow Creek three miles east of Millville.

South Cow Creek

South Cow Creek drains a 78 square mile basin and originates at an elevation of 5800 feet in the Latour Demonstration State Forest. South Cow Creek flows 28.5 miles to its confluence with Old Cow Creek near Hwy 44. Its larger tributaries include Atkins Creek, Beal Creek, Hamp Creek, and Mill Creek.

Land Use

Settlers were initially drawn to the Cow Creek watershed for its agricultural potential, due to its fertile floodplains (USACE 1971). Irrigation in the Cow Creek basin began soon after its settlement and continues today with a complex series of diversions and lift-pumps in all of the main tributaries. Diversions and pumps carry water to fields, pasturelands and residences in the upper and lower elevation areas. The lowland area primarily supports livestock ranches. Private and public timberlands dominate the eastern upland parts of the basin (above 2000 ft). Mining activity was limited to the northern portion of the basin along Little Cow Creek, where the Afterthought Mine

near Ingot (Hwy 299) was a source for gold and copper ore from 1862 to 1952 (Albers and Robertson 1961 *as cited in* USFWS 2000). Hydro-power plants were established on Old Cow Creek (Kilarc Reservoir and Powerplant) and South Cow Creek (Olsen Diversion) in the early 1900s to provide electricity for copper smelting, businesses and residents (Allen 1979 *as cited in* USFWS 2000). There are also multiple small individual hydropower setups throughout the watershed, including on Clover Creek (P. Bratcher, pers. comm., 2009).

Fisheries and Aquatic Habitat

As reported by USFWS (1995), primary limiting factors for anadromous salmonids include low fall and summer flows, caused in part by irrigation diversions. Irrigation diversions also affect steelhead by delaying or blocking adult immigration and entraining juveniles. Loss of habitat and water diversions in the Cow Creek watershed is largely due to activities associated with livestock production (USFWS 1995).

As reported by USFWS (1995), agricultural diversions in the Cow Creek watershed are unscreened, and ditches are unlined and poorly maintained. Habitat surveys conducted by DFG in 1992 identified several permanent and temporary irrigation diversions in the various tributary streams, including 13 diversions in South Cow Creek, 10 diversions on Old Cow Creek, one on Clover Creek, and two on North Cow Creek (USFWS 1995). No surveys were conducted on Oak Run Creek. According to DFG, no summary data readily exist for information on diversion rights (i.e., ownership, magnitude, and duration). Steelhead are directly affected by water diversions because they impede upstream migration of adults and entrain downstream migrating juveniles. Agricultural diversions and Pacific Gas and Electric Company's hydropower diversions on South Cow Creek also reduce summer flows important for juvenile steelhead rearing (USFWS 1995).

As reported by USFWS (1995), livestock grazing has reduced riparian vegetation and eroded streambanks in the various tributary streams and in the mainstem Cow Creek, degrading the quality of spawning gravel in Cow Creek. Habitat surveys conducted by DFG in 1992 identified stream sections within the various tributaries where excessive erosion has occurred. Fencing these stream sections to protect the riparian corridor has been recommended for approximately 42,600 feet of stream on South Cow Creek, 45,600 feet on Old Cow Creek, 39,120 feet on Clover Creek, and 19,500 feet on North Cow Creek (Harvey pers. comm., as cited in USFWS 1995). Population growth in the towns of Palo Cedro, Bella Vista, Oak Run, and Millville is resulting in increased demand for domestic water and is affecting riparian habitat within the Cow Creek watershed (Reynolds et al. 1993, as cited in USFWS 1995).

According to data collected during 2002 and 2003, water temperatures appear to be suitable for salmonids year-round in the upper reaches of Old Cow and South Cow creeks. Stressful and lethal water temperatures were observed in the lower reaches, but may not affect steelhead adult immigration or emigrating steelhead smolts because water temperatures are relatively cool between October and June (Moore 2003).

Steelhead

As reported in the Cow Creek Watershed Assessment (SHN 2001), steelhead populations have not been estimated in Cow Creek. No specific studies have been conducted on Cow Creek to estimate the size of the steelhead spawning run, although CDFG estimated that Cow Creek supported annual spawning runs of 500 steelhead (SHN 2001). Adult steelhead have been observed in North Cow, Old Cow and South Cow creeks; however, it is unknown what percentage of the steelhead run utilizes the other tributaries (SHN 2001). Most steelhead spawning in South Cow Creek probably occurs above South Cow Creek diversion. The best spawning habitat occurs in the 5-mile reach of stream extending from about 1.5 miles below South Cow Creek Diversion Dam to 3.5 miles above the diversion dam (Healy 1997, as cited in SHN 2001). Additional spawning habitat occurs upstream of this reach, but it is much less abundant. Sightings of adult steelhead have been made at the South Cow Creek Campground (approximately 8.5 miles upstream of the South Cow Creek Diversion Dam) and in Atkins Creek, located just upstream from the campground (SHN 2001).

During February – April of 2002 snorkel surveys were conducted in South Cow Creek, but no steelhead adults, carcasses or redds were identified (Moore 2003). During February – April of 2003, snorkel surveys and one walking survey in South Cow Creek, and one snorkel survey in Old Cow Creek were conducted to identify steelhead adults, carcasses and redds. Seven adult steelhead and two possible redds were identified in South Cow Creek (Moore 2003).

Watershed Restoration and Potential to Support Viable Populations

Watershed/Ecosystem Restoration

For currently occupied habitats between Keswick Dam and Red Bluff, it is unlikely that habitats can be restored to pre-dam conditions, but many of the processes and conditions that are necessary to support a population of Sacramento River winter-run Chinook can be improved and sustained with extensive long-term human intervention, including improvements to water temperature management and spawning gravel. The potential to restore ecological processes capable of supporting steelhead and spring-run is low, primarily because water temperatures and flow regimes that are applied to support the summer spawning of winter-run Chinook salmon discourage anadromy for steelhead, and because the potential to physically separate spring-run Chinook salmon from fall-run salmon is complicated by overlapping migration and spawning periods.

Viability Potential for Existing Populations

Sacramento River winter-run Chinook salmon – **Moderate**
CV spring-run Chinook salmon - **Low to Moderate**
CV steelhead - **Low to Moderate**

Lindley *i.e.*, (2007) characterized the Sacramento River winter-run Chinook salmon population that spawns below Shasta and Keswick dams as having a moderate risk of extinction according to PVA and a low risk based on other factors (abundance, hatchery influence, and production). However, recent population trends have seen a decline in abundance, and hatchery influence is increasing, exceeding 18% in 2005. Because the population may continue to rely on contributions of hatchery fish, the population viability potential for this population is moderate.

Lindley did not characterize or CV spring-run Chinook salmon and steelhead populations in the upper, mainstem Sacramento River, although there is developing information that suggests that some spring-run may be present in the river. Additionally, large numbers of resident *O. mykiss* are present, but little is known about potential anadromy in this population. We consider both populations to be data deficient and believe that additional information needs to be collected to better understand the potential for the river to support a viable population. The potential to support viable steelhead and spring-run populations is low to moderate, primarily because water temperatures and flow regimes that are applied to support the summer spawning of winter-run Chinook salmon discourage anadromy for steelhead, and because the potential to physically separate spring-run Chinook salmon from fall-run salmon is complicated by overlapping migration and spawning periods.

Potential for Historic Habitats to Support Spawning Populations:

Little Sacramento River:

- Sacramento River winter-run Chinook salmon - **Moderate**
- CV Spring-run Chinook salmon – **High**
- CV Steelhead - **High**

McCloud River:

- Sacramento River winter-run Chinook salmon - **High**
- CV Spring-run Chinook salmon – **High**
- CV Steelhead - **High**

Pit River:

- Sacramento River winter-run Chinook salmon - **Low**
- CV Spring-run Chinook salmon – **Low**
- CV Steelhead - **Low**

DFG (1998) reports in their report to the fish and game commission on the status of spring-run Chinook salmon in the Central Valley, that there are no precise estimates of spring run abundance upstream of the present day site of Shasta Dam, this was the

principle spawning area of the Sacramento River basin, and the numbers of fish must have been high.

For currently unoccupied historic habitats, the Little Sacramento River has a high potential to support spawning adults due to number of connected miles of suitable spawning and rearing habitat, especially for CV spring-run Chinook salmon and CV steelhead. The McCloud has a high potential to support Sacramento River winter-run Chinook salmon, CV spring-run Chinook salmon, and CV steelhead due to the number of connected miles of suitable spawning and rearing habitat. The Pit River has a low potential due to the extensive presence of hydroelectric facilities that inundate or substantially effect historic habitat. The restoration potential for areas above Shasta Dam characterizes the habitat as if it were to be made accessible to anadromous fish and does not take into consideration the significant challenges associated with the presence of Shasta Dam and the reservoir.

How will the Upper Sacramento River help to buffer the negative effects of climate change for salmonids in the Central Valley?

Under the expected climate warming of around 5°C, substantial salmonid habitat would be lost in the Central Valley, with significant amounts of habitat remaining primarily in the Feather and Yuba rivers, and remnants of habitat in the upper Sacramento, McCloud, and Pit rivers, Battle and Mill creeks, and the Stanislaus River (Lindley et al. 2007). Under the less likely but still possible scenario of an 8°C warming, spring-run Chinook salmon habitat would be found only in the upper-most reaches of the north fork Feather River, Battle Creek, and Mill Creek (Lindley et al. 2007).

The upper Sacramento River most likely will offer important cold water inputs for and steelhead populations, that could prove to provide some of the Central Valley's protection against extinction for these species as climate change effects take place.

Key Threats and Stressors

Key threats and stressors to winter-run Chinook salmon in the upper Sacramento River include, but are not limited to the following:

- ❖ Passage impediments/barriers affecting adult immigration and holding and spawning (Keswick and Shasta Dams)
- ❖ Flow conditions affecting embryo incubation
- ❖ Predation of juveniles due to GCID, RBDD and other structures
- ❖ Short-term inwater construction affecting embryo incubation

- ❖ Water quality affecting embryo incubation
- ❖ Water temperatures affecting spawning and embryo incubation
- ❖ Loss of natural morphologic function affecting juvenile rearing and outmigration
- ❖ Habitat suitability affecting spawning

Key Actions

- ❖ Conduct habitat evaluations and feasibility studies for reintroducing winter-run Chinook salmon, spring-run Chinook salmon, and steelhead to habitat above Shasta Dam, including assessing habitat suitability and passage logistics).
- ❖ Design and conduct an experimental fish passage program evaluating adult distribution, survival, spawning, and production in habitats above Shasta Dam.
- ❖ If the experimental fish passage program demonstrates that passage above Shasta dam can substantively contribute to the long-term viability of the ESU/DPS, then develop and implement long-term fish passage programs.
- ❖ Implement a river flow management plan that balances carryover storage needs with instream flow needs for winter-run Chinook salmon based on runoff and storage conditions, including flow fluctuation and ramping criteria (USFWS 2001).
- ❖ Develop a long-term strategy for monitoring and regulating discharges from agricultural lands to protect waters within the Central Valley, including enforcing the regulations (SWRCB website).
- ❖ Improve and maintain containment of contaminants from Iron Mountain Mine.
- ❖ Use the best available data regarding winter-run Chinook salmon spawning habitat availability as a key consideration for determining Keswick Dam releases.
- ❖ Conduct periodic (e.g., every 5 years) spawning gravel assessments in the upper Sacramento River (i.e., above RBDD) and implement gravel augmentation projects, as necessary.
- ❖ Achieve the daily average water temperature targets described in the Biological Opinion on the Long-Term Central Valley Project Operations Criteria and Plan (NMFS 2004).

Watershed Description

The upper Sacramento River watershed includes sub-basins above Shasta Dam and (Little Sacramento River, McCloud, and Pit Rivers) and areas below the Shasta and Keswick Dams downstream to the vicinity of Red Bluff. The areas above Shasta Reservoir include nearly 5,000 square miles of steep mountainous terrain, mid to high gradient stream channels, forested by mixed conifers at high elevations and oak woodlands, scattered pines and brush at lower elevations. Watershed condition,

geology, hydrology, land ownership and land use are diverse. The Little, or Upper, Sacramento is a spring-fed river draining Mt. Shasta. The Little Sacramento River is a moderate-size basin (2370 km²) and well-isolated from the McCloud River (Lindley *et al.*, 2004). The Little Sacramento River supported winter-run Chinook salmon as well as spring-run Chinook salmon (Yoshiyama *et al.*, 1996). Lindley *et al.*, (2007) concluded that the Little Sacramento was large enough and well-isolated enough to have supported an independent population of spring-run Chinook salmon. Access to the Little Sacramento is presently blocked by Keswick and Shasta dams.

The McCloud River is spring-fed tributary to the Lower Pit River and drains Mt. Shasta, and was swift, cold and tumultuous before hydropower development (Moyle *et al.*, 1982). The McCloud River supported winter-run and spring-run Chinook salmon and steelhead. The area above 500 m elevation is isolated from other areas historically used by spring-run chinook salmon. Lindley *et al.* (2007) concluded that the McCloud River was large enough and well-isolated enough to have supported an independent population of spring-run chinook salmon. Access to this watershed is now blocked by Keswick and Shasta dams.

The upper Pit River, Fall River and Hat Creek are documented to have contained spring-run Chinook salmon (Yoshiyama *et al.*, 1996). The middle and upper Pit is relatively low gradient, meandering across a flat valley floor, and is warm and turbid (Moyle *et al.*, 1982). Large falls block access shortly above the confluence of the Fall River (Yoshiyama *et al.*, 1996). The Fall River arises from springs at the edge of a lava field, and subsequently has a fairly large discharge of clear water. Hat Creek is similar to the Fall River. The whole region is above 500 m, and Hat Creek and the Fall River are within 50 km of each other. Based on the similarity and proximity of Hat Creek and the Fall River, and the fairly short lengths of accessible habitat within the tributaries, Lindley *et al.* (2004) decided that this area probably was occupied by a single population that had significant substructure. Access to this watershed is presently blocked by Keswick and Shasta dams on the Sacramento River, and numerous other hydroelectric facilities throughout much of its length. Unlike the Little Sacramento and McCloud Rivers, the Pit River is significantly impaired by hydro development and much of the historic habitat is either inundated by reservoirs or dewatered.

The Sacramento River reach below Keswick Dam is the most urbanized and industrialized of the four Sacramento River reaches, while also supporting agriculture. It has three water control structures (i.e., Keswick, Anderson-Cottonwood Irrigation District, and Red Bluff Diversion dams). The broad alluvial portion of the reach between Redding and Balls Ferry has the potential to support significant tracts of

riparian forest. Along much of the reach, however, riparian forests are confined to narrow corridors at the base of canyon walls (SRCAF 2003).

Geology

The upper Sacramento River watershed geology above Shasta Reservoir is dominated by the Cascade Range Geomorphic Province to the west and the Modoc Plateau Geomorphic Province to the East. The Cascade region contains some of the highest peaks in California, and includes several active volcanic formations. The Modoc region is dominated high elevation plateaus with a basalt geology.

As reported by SRCAF (2003), the geologic characteristics of the upper Sacramento River reach vary greatly. From Keswick Dam to Redding the river flows through volcanic and sedimentary formations. The canyon is relatively narrow in this area with little floodplain and a correspondingly narrow riparian corridor. From Redding to the Cow Creek confluence there are limited areas where the river has meandered over a broader floodplain of alluvium derived from the Klamath Mountains and the Coast Ranges. From the Cow Creek confluence to near Red Bluff the river is almost entirely controlled by the Tuscan Formation (DWR 1981, as cited in SRCAF 2003). Here the channel is often narrow and deep, between high canyon walls. Table Mountain, a 2-mile long volcanic plateau adjacent to the river, and steep-sloped Iron Canyon (RM 250-253) are both examples of Tuscan Formation outcrops. At Red Bluff the river flows out onto the broad alluvial floodplain of the Sacramento Valley (SRCAF 2003).

As reported by SRCAF (2003), the bed material and floodplain deposits of this portion of the Sacramento River consist generally of well-rounded material composed of various metamorphic, sedimentary, and igneous rocks. The size of this material ranges from clay fines to boulders (DWR 1981, as cited in SRCAF 2003). Since the closure of Shasta Dam in December 1943, the transport of sediment from reaches upstream of the dam has ceased, resulting in an armored channel surface below the dam as the river has transported sediments out of the area (DWR 1981, as cited in SRCAF 2003).

Other factors influencing the sediment supply in this reach include: (1) the urbanization of the Redding-Anderson area, resulting in reduced bank erosion due to the installation of bank protection and levees; and (2) large quantities of sand and gravel being mined at locations in and adjacent to the Sacramento River and its tributaries (DWR 1981, as cited in SRCAF 2003).

Hydrology

As reported by USFWS (1995), the Sacramento River is the largest river system in California, yielding 35% of the state's water supply. The median historical unimpaired run-off above Red Bluff is 7.2 million acre-feet (maf), with a range of 3.3-16.2 maf (USFWS 1995). Most of the Sacramento River flow is controlled by the U.S. Bureau of Reclamation's Shasta Dam, which stores up to 4.5 maf of water (USFWS 1995). As reported by SRCAF (2003), the Keswick-Red Bluff Reach is highly influenced by the altered hydrology resulting from the operation of the Central Valley Project (CVP). The operation of the CVP in this reach includes Shasta and Keswick Dams on the mainstem of the Sacramento River, as well as the diversion of Trinity River and Clear Creek water to Keswick Reservoir via the Spring Creek tunnel (SRCAF 2003).

As reported by SRCAF (2003), CVP operations reduce flood peaks during the winter and spring and increase discharge between floods during the summer and autumn. For example, without the CVP, a 100-year flood is calculated to be about 336,000 cubic feet per second (cfs) at Bend Bridge (SRCAF 2003). Under the controlled operation of the CVP, however, this is reduced to 202,000 cfs (SRCAF 2003). A smaller 2-year flood is reduced from 110,000 cfs to 70,800 cfs (TNC 1996, as cited in SRCAF 2003). During July, August, and September, the mean monthly flows of the Sacramento River at Keswick since 1963 are nearly 400 percent higher than the mean monthly flows prior to 1943 (DWR 1981, as cited in SRCAF 2003). The effect of these changes to hydrology is most obvious directly below the dams. The principal west side tributaries to the Sacramento River in the Keswick-Red Bluff Reach include Clear, Cottonwood, and Dibble Creeks. These creeks flow from the valley floor and parts of the Klamath Mountains to the Sacramento River. Main east side tributaries include Churn, Stillwater, Cow, Bear, Ash, Battle, and Paynes Creeks. Battle and Paynes Creeks originate in the Cascade Mountains east of Redding and flow through confined canyons before joining the Sacramento River (SRCAF 2003).

Land Use

Land ownership in the upper sub-basins above Shasta Reservoir is up to 50 percent public and land use is dominated by timber management, hydroelectric energy production, grazing, and agriculture. Historic land use included extensive mineral management.

As reported by SRCAF (2003), the Keswick-Red Bluff Reach has a variety of land uses—urban, residential, industrial, and agricultural. About 35 percent of the area is in agriculture, and about 12 percent is urban, residential, or industrial. Predominant

agricultural crops include walnuts, mixed pasture and prunes. Industrial land uses within this reach include lumber mills and gravel removal operations. Residential and commercial land uses in the cities of Redding, Anderson, and Red Bluff are common as well. In addition, this reach has the most recreational facilities on the Sacramento River (SRCAF 2003). Historically, the river between Redding and Anderson supported several gravel mining operations (SRCAF 2003).

Fisheries and Aquatic Habitat

The distribution of Sacramento River winter-run spawning and rearing historically is limited to the upper Sacramento River and its tributaries, where spring-fed streams provided cold water throughout the summer, allowing for spawning, egg incubation, and rearing during the mid-summer period (Slater 1963, Yoshiyama *et al.* 1998). CV spring-run Chinook salmon and CV steelhead also occurred in these tributaries. The headwaters of the McCloud, Pit, and Little Sacramento Rivers, and Hat and Battle Creeks, historically provided clean, loose gravel; cold, well-oxygenated water; and optimal stream flow in riffle habitats for spawning and incubation. These areas also provided the cold, productive waters necessary for egg and fry development and survival, and juvenile rearing over the summer. Approximately, 299 miles of tributary spawning habitat in the upper Sacramento River is now inaccessible to winter-run (NMFS 2009). Yoshiyama *et al.* (2001) estimated that in 1938, the Upper Sacramento had a “potential spawning capacity” of 14,303 redds. Most components of the winter-run life history (*e.g.*, spawning, incubation, freshwater rearing) have been compromised by the habitat blockage in the upper Sacramento River.

CDFG (1998) reports that Clark (1929) characterized CV spring-run Chinook salmon habitat above Shasta Dam as ideal. Yoshiyama (1996) concluded that CV spring-run Chinook salmon would have had access to habitat in the Little Sacramento River as far upstream as the vicinity of Box Canyon Dam, near Mount Shasta. Spring-run Chinook salmon also could have ascended as high as Lower Falls, on the McCloud River but probably stopped near Big Spring (Wales 1939 as reported in CDFG 1998); and ascended the Pit River to the Fall River (Yoshiyama 1996), Hat and Kosk Creek, and the lower one mile of Burney Creek (CDFG 1998). Much of the historic spawning habitat in the Little Sacramento and McCloud Rivers is still present above Shasta Reservoir without significant reductions in amount or connectivity. The Pit River has an extensive hydroelectric footprint, and much of the historic habitat is currently impounded, dewatered or otherwise affected by the presence and operation of facilities.

The ACID Dam (RM 298.5) was constructed in 1917 about three river miles downstream of the current Keswick Dam. Originally the ACID Dam was a barrier to upstream fish

migration until 1927 when a poorly designed fish ladder was installed (NMFS 1997). The ACID Dam is only installed during the irrigation season which typically runs from early April to October or early November. As mentioned above, the fish ladder providing passage around the dam was poorly designed and although winter-run Chinook salmon were able to negotiate the ladder, it did present a partial impediment to upstream migration. However, a new fish ladder installed in 2001 appears to be operating effectively (CDFG 2004). The high volume releases from the ACID's canal downstream of the dam may create false attraction flows for migrating adult salmon where they could be stranded (NMFS 1997).

The proportion of the spawning run that is affected by ACID Dam is uncertain. Although data on the spatial distribution of winter-run Chinook salmon spawning indicate that since the ladder improvements in 2001, an average of 42.13% spawn between Keswick Dam and ACID Dam (CDFG 2004), data on the temporal distribution of winter-run Chinook salmon upstream migration suggest that in wet years about 50 percent of the run has passed the RBDD by March, and in dry years, migration is typically earlier, with about 72 percent of the run having passed the RBDD by March (CUWA and SWC 2004).

The RBDD at RM 243 has 11 gates which are raised or lowered to control the level of Lake Red Bluff, enabling gravity diversion into the Tehama Colusa Canal (TCC). Permanent fish ladders are located on each abutment of the dam, however, the ladders are inefficient in allowing upstream migration of adult salmonids (NMFS 1997). In several radio tagging studies of adult winter-run Chinook salmon, 43 to 44 percent of tagged fish were blocked by the dam (NMFS 1997). Tagged winter-run Chinook salmon that eventually passed the dam were delayed by an average of 125 hours in one study (Vogel *et al.* 1988 in NMFS 1997) and 437 hours in a previous study (see NMFS 1997). At present, the dam gates are kept in the raised position from September 15 through May 14 allowing free passage for about 85 percent of the run (NMFS 1997). However, there are intermittent closures during this time period of up to 10 days. The remaining portion of the run (migrating upstream past May 15) is likely to be delayed or blocked from passing the dam. NMFS' Biological Opinion on the Long-term Operations of the CVP and SWP (2009) requires that Reclamation operate the RBDD with gates out year-round by May 15, 2012. This will be accommodated with construction of a pumping plant and fish screen to divert water for irrigation, with an initial capacity of 2,180 cfs (Tehama-Colusa Canal Authority 2008).

As reported by NMFS (2009), during recent years the majority of winter-run Chinook salmon (*i.e.*, > 50 percent since 2007) spawn in the area from Keswick Dam downstream to the ACID Dam (approximately 5 miles). Keswick Dam re-regulates flows from Shasta

Dam and mixes it with water diverted from the Trinity River through the Spring Creek tunnel. When the gates are down at RBDD, or flashboards in at the ACID Dam, access to the upper Sacramento River basin, including tributaries, can only be achieved through the RBDD and ACID Dam fish ladders. Both of these diversions' fish ladders allow salmonids to pass upstream.

Sacramento River winter-run Chinook salmon

The upper Sacramento River contains the only existing habitat for Sacramento River winter-run Chinook salmon. As reported by NMFS (2009), historical winter-run population estimates, which included males and females, were as high as over 230,000 adults in 1969, but declined to under 200 fish in the 1990s (Good *et al.* 2005). A rapid decline occurred from 1969 to 1979 after completion of the RBDD. Over the next 20 years, the population eventually reached a low point of only 186 adults in 1994. At that point, winter-run Chinook salmon were at a high risk of extinction, as defined by Lindley *et al.* (2007). However, several conservation actions, including a very successful captive broodstock program (i.e., Livingston Stone National Fish Hatchery (LSNFH)), construction of a temperature control device (TCD) on Shasta Dam, maintaining the RBDD gates up for much of the year, and restrictions in ocean harvest, have likely prevented the extinction of wild winter-run Chinook salmon.

In recent years, the carcass survey population estimates of winter-run Chinook salmon included a high of 17,205 (Table 17) in 2006, followed by a precipitous decline in 2007 that continued in 2008, when less than 3,000 adult fish returned to the upper Sacramento River. The preliminary total escapement estimate for winter-run Chinook salmon in 2008 is 2,850 (CDFG 2009).

Table 17 also provides data on the cohort replacement rate (CRR), which is similar to the SRR recommended by Anderson *et al.* (2009), that is, the ratio of the number of recruits returning to the spawning habitat divided by the number of spawners producing those recruits. As discussed, above, the majority of winter-run spawners are 3 years old. Therefore, NMFS calculated the CRR using the spawning population of a given year, divided by the spawning population 3 years prior.

A conservation program at LSNFH located at the base of Keswick Dam annually supplements the in-river production by releasing on average 250,000 winter-run smolts into the upper Sacramento River. The LSNFH operates under strict guidelines for propagation that includes genetic testing of each pair of adults and spawning less than 25 percent of the hatchery returns. This program and the captive broodstock program

(phased out in 2007) were instrumental in stabilizing winter-run following very low returns in the 1990s.

Table 17. Winter-run population estimates from RBDD counts (1986 to 2001) and carcass counts (2001 to 2008), and corresponding cohort replacement rates for the years since 1986 (CDFG 2004, CDFG 2007, CDFG 2009, NMFS 2009)

a Population estimates were based on RBDD counts until 2001. Starting in 2001, population estimates were based on carcass surveys.

b The majority of winter-run spawners are 3 years old. Therefore, NMFS calculated the CRR using the spawning population of a given year, divided by the spawning population 3 years prior.

c JPE estimates were derived from NMFS calculations utilizing RBDD winter-run counts through 2001, and carcass counts thereafter for deriving adult escapement numbers. Only estimated to RBDD, does not include survival to the Delta.

d CDFG (2009)

e NMFS (2009b) preliminary estimate to Reclamation

Recently, Lindley *et al.* (2007) determined that the winter-run Chinook salmon population, which is confined to spawning below Keswick Dam, is at a moderate extinction risk according to population viability analysis (PVA), and at a low risk according to other criteria (*i.e.*, population size, population decline, and the risk of wide ranging catastrophe). However, concerns of genetic introgression with hatchery populations are increasing. Hatchery-origin winter-run from LSNFH have made up more than 5 percent of the natural spawning run in recent years and in 2005, it exceeded

18 percent of the natural run. If this proportion of hatchery origin fish from the LSNFH exceeds 15 percent in 2006-2007, Lindley *et al.* (2007) recommends reclassifying the winter-run population extinction risk as moderate, rather than low, based on the impacts of the hatchery fish over multiple generations of spawners. In addition, data used for Lindley *et al.* (2007) did not include the significant decline in adult escapement numbers in 2007 and 2008, and thus, does not reflect the current status of the population size or the recent population decline. Furthermore, the current drought conditions in the Central Valley were not incorporated into the analysis of the winter-run population status in Lindley *et al.* (2007) as a potential catastrophic event.

In consideration of the almost 7-fold decrease in population in 2007, coupled with the dry water year type in 2007, followed by the critically dry water year type in 2008 (which could be qualified as a high-risk catastrophe) and likely a similar forecast for 2009, NMFS concludes that winter-run Chinook salmon are at high risk of extinction based on population size (NMFS 2009).

CV spring-run Chinook Salmon

The status of the spring-run population within the mainstem Sacramento River appears to have declined from a high of 25,000 in the 1970s to the current low of less than 800 counted at RBDD (Figure 12). Significant hybridization with fall-run has made identification of a spring-run in the mainstem very difficult to determine, and there is speculation as to whether a true spring-run still exists below Keswick Dam. This shift may have been an artifact of the manner in which spring-run were identified at RBDD. Fewer spring-run are counted today at RBDD because an arbitrary date, September 1, is to determine spring-run and gates are opened longer for winter-run passage (NMFS 2009). It is unknown if spring-run still spawn in the Sacramento River mainstem, but the physical habitat conditions below Keswick Dam is capable of supporting spring-run, although in some years high water temperatures can result in substantial levels of egg mortality. Current redd surveys have observed 20-40 salmon redds in September, from Keswick Dam downstream to the Red Bluff Diversion Dam. This is typically when spring-run spawn, however, there is no peak that can be separated out from fall-run spawning, but these redds also could be early spawning fall-run. Additionally, even though habitat conditions may be suitable for spring-run occupancy, spring-run Chinook salmon depend on spatial segregation and geographic isolation from fall-run Chinook salmon to maintain genetic diversity. With the onset of fall-run Chinook salmon spawning occurring in the same time and place as potential spring-run Chinook salmon spawning is likely to have caused extensive introgression between the populations (CDFG 1998)

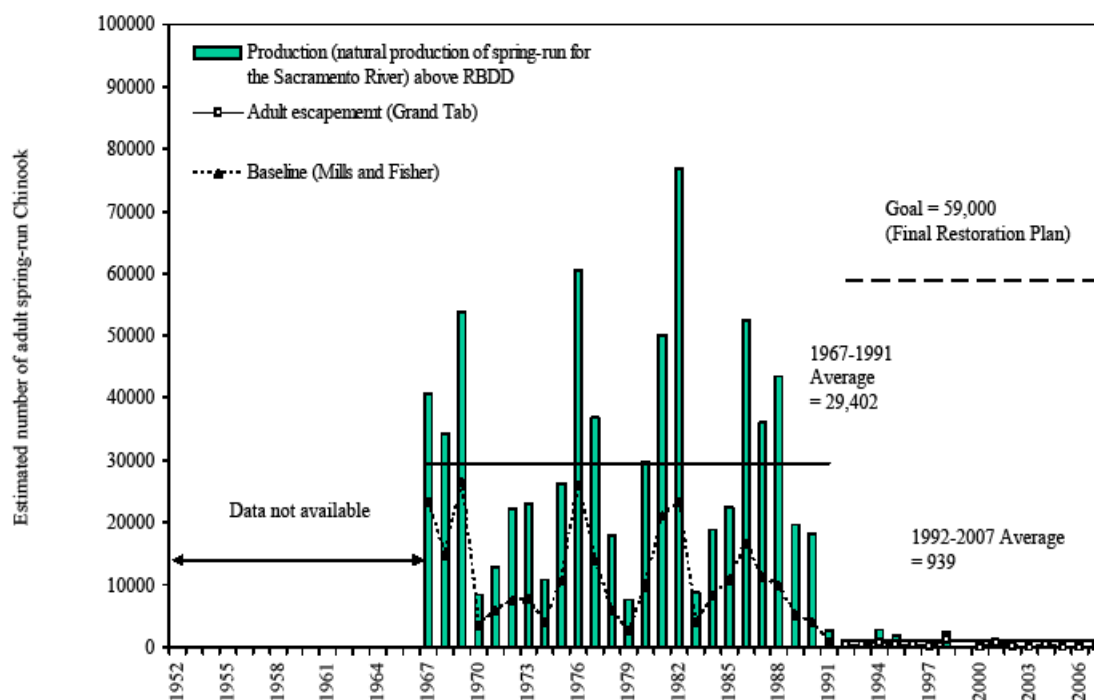

Figure 12. Estimated yearly spring-run escapement and natural production above RBDD (Hanson 2008)

CV steelhead

Estimates of CV steelhead abundance in the mainstem Sacramento River typically use the RBDD counts for historical trend data. Since 1991, the RBDD gates have been opened after September 15, making estimates of CV steelhead pass RBDD unreliable. Based on counts at RBDD, adult migration into the upper Sacramento River can occur from July through May, but peaks in September, with spawning occurring from December through May (Hallock 1998). Since the RBDD gates started operation in 1967, the CV steelhead abundance in the upper Sacramento River has declined from 20,000 to less than 1,200 (Figure 13). CV steelhead passage above RBDD after 1991 can be estimated based on the average of the 3 largest tributaries (*i.e.*, Battle Creek, Clear Creek and Cottonwood Creek). The average of these tributaries for the last 14 years (1992 through 2005) is 1,282 adults, which represents a continuous decline from the 1967 through 1991 average RBDD count of 6,574 (Figure 13). The decline in CV steelhead abundance is similar to winter-run and spring-run declines.

Actual estimates of CV steelhead spawning in the mainstem Sacramento River below Keswick Dam have never been made due to high flows and poor visibility during the winter time. Aerial redd surveys conducted for winter-run have observed resident O.

mykiss spawning in May and late-falls spawning in January. Since resident trout redds are smaller than steelhead redds and late-fall salmon spawn at the same time as steelhead, it would seem likely that CV steelhead redds could be observed. A CV steelhead monitoring plan is being developed by CDFG with a goal of determining abundance in the Sacramento River (Jim Hopelain per.com 2008).

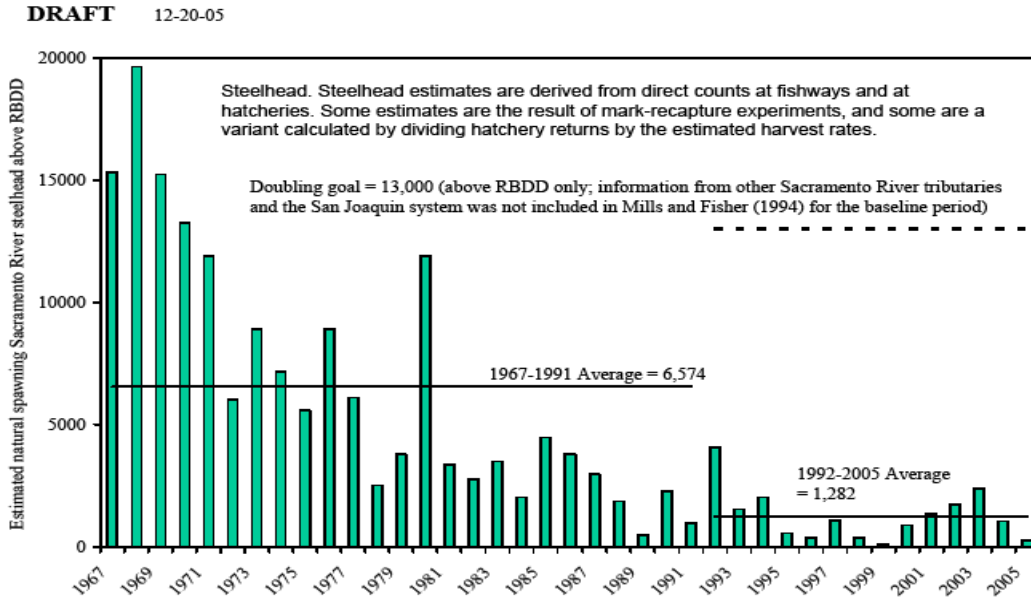

Figure 38. Estimated yearly number of natural spawning of steelhead on the Sacramento River, upstream of the RBDD (Mills and Fisher, 1994). Data for 1992-2005 is from CDFG, Red Bluff.

Figure 13. Estimated yearly number of natural spawning CV steelhead on the Sacramento River upstream of the RBDD 1967-2005. Data from 1992 to 2005 is based on tributary counts from CDFG, Red Bluff (Hanson 2008).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Putah Creek Watershed can be characterized as having a *moderate* restoration potential and/or contribution to recovery. Because steelhead were sporadically reported to occur downstream of the Putah Diversion Dam, it is unclear what recovery could occur with steelhead unless passage was improved (Moyle and Crain 2003).

Viability potential

CV steelhead - Moderate

Putah Creek is characterized as having a **moderate** potential to support viable populations of steelhead. This characterization is based on the following factors: (1) cold instream flow releases from Monticello Dam create habitats conditions that can support all freshwater life history stages of steelhead; (2) there is approximately 5 to 10 miles of spawning and yearly rearing habitat downstream from Monticello Dam; (3) only minor fish passage impediments prohibit fish from accessing suitable spawning habitat.

Key Threats and Stressors

Key threats and stressors to Central Valley steelhead in Putah Creek include, but are not limited to the following:

- ❖ Passage impediments/barriers by Solano Dam and Montecello dams affecting immigration and holding
- ❖ Low flow conditions and flow fluctuations affecting adult immigration and holding, juvenile rearing and outmigration, and embryo incubation
- ❖ Physical habitat alteration (i.e., limited instream gravel supply) affecting spawning
- ❖ Loss of floodplain habitat, natural river morphology, and riparian habitat and instream cover affecting juveniles

Key Actions

- ❖ Conduct technical fish passage evaluations at Solano Dam and design and construct state-of-the-art fish passage facilities consistent with NMFS fish passage criteria.
- ❖ Conduct anadromous fish habitat and flow evaluations and implement instream flow requirements downstream from Monticello Dam that maximize the habitat availability for steelhead migration, spawning and rearing.
- ❖ Conduct a spawning gravel assessment and develop and implement a spawning gravel supplementation program sufficient to support at least 500 spawning adult steelhead.
- ❖ Work with local, State, and Federal flood control agencies to relocate levee alignments away from active stream channels.

Watershed Description

The watershed of Putah Creek begins in the Coast Ranges at Cobb Mountain in Lake County at an elevation of 4,700 feet, and flows down to the Central Valley where it empties into the Yolo Bypass near sea level (Lower Putah Creek Coordinating Committee 2005). Putah Creek is the southernmost major drainage entering the Sacramento Valley from the west. The Putah Creek watershed is defined by two subbasins, the lower and upper Putah Creek watersheds (Lower Putah Creek Coordinating Committee 2005).

Lower Putah Creek is located in the southwestern corner of the Sacramento Valley and flows 26 miles across the valley floor from the Putah Diversion Dam to the Toe Drain in

the Yolo Bypass. Putah Diversion Dam is a reregulating reservoir below Monticello Dam. The upper Putah Creek subbasin is defined by the portion of the watershed located upstream of Monticello Dam, which forms Lake Berryessa. Lake Berryessa captures runoff from 90 percent of the watershed. The upper watershed occupies about 600 square miles within the Coast Ranges (Lower Putah Creek Coordinating Committee 2005).

Geology

Four major rock units characterize the Coast Ranges, including areas in which the Putah Creek watershed has formed: (1) the Franciscan formation; (2) the Great Valley sequence; a relatively thin (1 mile or more thick) layer of black igneous rock and unusual green serpentinite (between the Franciscan and Great Valley units) that is believed to have originated in the Earth's mantle from beneath the continental crust; and (4) a fossil-filled sandstone and mudstone layer that is younger than the other formations and lays over the top of them (Lower Putah Creek Coordinating Committee 2005). The upper Putah Creek watershed area is formed within the steep mountain slopes formed by sandstone and shale, local areas of serpentinite, and areas of volcanic rocks. As Putah Creek emerges from the mountains it enters the Central Valley, which was formed by the filling of an inland sea with thousands of feet of marine deposits, and with alluvial deposits from the Coast Ranges and the Sierra Nevada (Lower Putah Creek Coordinating Committee 2005).

Over the geologic timescale, high-flow events in Putah Creek have transported large quantities of erosive sandstone and other parent material from the mountains to the valley floor (Lower Putah Creek Coordinating Committee 2005). These high-flow events would deposit large-sized alluvium near the base of the mountains, forming the Putah Creek fan, and finer sediments were transported farther east onto the valley floor, providing the basis for the formation of productive agricultural soils that exist today (Lower Putah Creek Coordinating Committee 2005).

Hydrology

Hydrologic conditions in Putah Creek have been significantly modified since the construction of Monticello Dam and other Solano Project facilities (Putah Diversion Dam and Putah South Canal). Prior to the completion of Monticello Dam and other Solano Project facilities, runoff events were large and escaped the confinement of the stream banks, and caused extensive flooding along the creek (Lower Putah Creek Coordinating Committee 2005). Following the construction of the Solano Project

facilities, Putah Creek's hydrologic regime became highly regulated (Lower Putah Creek Coordinating Committee 2005).

The seasonal instream flow and release patterns from Monticello Dam have become regulated through the May 2000 Putah Creek Accord (Accord) (Solano County Superior Court 2000). The Accord is intended to balance the competing uses for water and create as natural of a flow regime as feasible from the Putah Diversion Dam to the connection at the East Toe Drain in the Yolo Bypass. The focus of the Accord is on the protection and enhancement of native resident and anadromous fish populations and maintenance of riparian vegetation. Four functional flow requirements are set forth in the Accord pertaining to juvenile rearing flows, spawning flows for native resident fishes, supplemental flows for anadromous fishes, and drought-year flows. Table 18 shows the basic required flow regimes specified by the Accord as prescribed for "normal" and "drought" conditions (Lower Putah Creek Coordinating Committee 2005).

Land Use

The lower Putah Creek watershed is comprised of public and private lands. Private lands within and adjacent to the riparian corridor account for 78% of the creek and creek-side parcels, while 21.2% of the parcels within and adjacent to the creek are designated as public lands (Lower Putah Creek Coordinating Committee 2005). Land use consists of agriculture, idle farmland, and urban uses (i.e., residential, commercial, and industrial).

Fisheries and Aquatic Habitat

Prior to the mid-1800s, Putah Creek flowed out of the mountains spreading to the Sacramento Valley and deposited a delta-like sheath of silts, sands, and cobbles by major flood events (Lower Putah Creek Coordinating Committee 2005). With each major flood event, the sediment deposition elevated the creek bed, resulting in Putah Creek changing its course, leaving levee-like strips of gravel flanking the channel (Lower Putah Creek Coordinating Committee 2005). These natural levees were overtopped as the creek sought new configurations (Lower Putah Creek Coordinating Committee 2005).

During the Euro-American settlement, riparian vegetation was removed along the creek to accommodate agricultural practices (Shapovalov 1946 *as cited in* Lower Putah Creek Coordinating Committee 2005). Riparian vegetation removal narrowed the riparian corridor and resulted in elevated water temperatures (Lower Putah Creek Coordinating Committee 2005). Flood control modifications reduced flow velocities and increased

the ratio of still to flowing water by widening the channel and eliminating floodplains within incised channels (Marovich, R., pers. comm. 2003 *as cited in* Lower Putah Creek Coordinating Committee 2005). The combination of these alterations increased habitat for introduced warmwater species (e.g., common carp, small mouth bass, etc.) (Lower Putah Creek Coordinating Committee 2005). The Solano Projects altered the flow regime, and further altered physical channel characteristics (e.g, channel structure, sediment transport, etc) and biological characteristics (e.g., species diversity, trophic structure, etc.) (Lower Putah Creek Coordinating Committee 2005).

Table 18. Summary of flows at or near Putah Diversion Dam before and after construction of the Solano Project, and the Putah Creek Accord release schedule

Variable	Flow (cfs)

Steelhead

Anadromous steelhead are considered to have historically spawned in the upper tributaries flowing into Putah Creek above the Berryessa Valley (now Lake Berryessa). Steelhead were sometimes reported to occur downstream of the Putah Diversion Dam, but the reports are unconfirmed (Moyle and Crain 2003). Migratory rainbow trout with a steelhead-like life history continue to spawn in the upper tributaries (Moyle, pers. comm., 2003, as cited in Lower Putah Creek Coordinating Committee 2005).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Existing conditions in Stony Creek preclude the annual production of spring-run Chinook salmon and steelhead (H.T. Harvey and Associates 2007a). Excessively low flows and warm water temperatures in Stony Creek during all life stages prevents the successful production of spring-run Chinook salmon and steelhead (H.T. Harvey and Associates 2007a). Any efforts to improve habitat conditions for anadromous salmonids in Stony Creek should consider the potential effects of climate change, which may prohibit successful production of coldwater fish in this low elevation watershed.

Viability potential

CV spring-run Chinook salmon - Low

CV steelhead - Low

Stony Creek is characterized as having a **low** potential to support viable populations of spring-run Chinook salmon and steelhead. This characterization is based on the following factors: (1) the system does not currently support populations of spring-run Chinook salmon and steelhead; (2) water diversions limit instream flows; (3) the watershed is at a relatively low elevation (Lindley et al. 2004), and thus, instream flow inputs are in the form of rainfall, not snowmelt; and (4) water temperatures under the current climate may already be beyond the thermal requirements of coldwater species such as spring-run Chinook salmon and steelhead, and climate change is expected to increase water temperatures in the Central Valley (Lindley et al. 2007).

Key Threats and Stressors

Key threats and stressors to Central Valley steelhead in Stony Creek include, but are not limited to the following:

- ❖ Passage impediments/barriers by Black Butte and North Diversion dams affecting immigrating adults
- ❖ Water temperature and/or water quality changes in Stony Creek affecting adult immigration and holding, juvenile rearing and outmigration, and embryo incubation

Key Actions

- ❖ Additional threats and stressors are displayed in Appendix A of the Recovery Plan
- ❖ Provide anadromous fish passage above Black Butte Dam. (We aren't considering it in the footprint)
- ❖ Enhance watershed resiliency in Stony Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce local water temperatures, or increase riparian shade.
- ❖ Evaluate water releases from Black Butte Dam, water exchanges with the Tehama-Colusa Canal and interim and long term water diversion solutions at RBDD

- ❖ Install water temperature recorders at select locations in Stony Creek; develop recommendations for minimum instream flow based on temperature needs

Watershed Description

Originating in the Coast Ranges (USFWS 1995), Stony Creek is the second-largest west-side tributary to the Sacramento River and drains approximately 740 square miles along California's Coastal Range in Tehama, Glenn, Colusa, and Lake Counties. The Stony Creek watershed has three reservoirs (Black Butte, Stony Gorge, and East Park), which have a combined storage capacity of more than 260 thousand-acre-feet (taf) (GCRC 2009). Typically, the watershed is discussed as two separate sections, the Upper Stony Creek Watershed and the Lower Stony Creek Watershed, with Black Butte Dam and its associated ridgeline forming the boundary (H.T. Harvey and Associates 2007a). The upper watershed encompasses approximately 473,915 acres including the Grindstone Creek, Briscoe Creek, Upper and Middle Stony Creek watersheds, while the lower watershed is approximately 24,497 acres in size (H.T. Harvey and Associates 2007a).

Geology

Upper Stony Creek

The Upper Stony Creek Watershed overlies mechanically weak volcanic, metamorphic and metasedimentary rocks of the Franciscan Complex (Swanson and Kondolf 1991 *as cited in* H.T. Harvey and Associates 2007a). The west side of the north-south trending linear valley marks the contact between the Franciscan Complex and younger sedimentary marine sandstones and conglomerates of the Great Valley Sequence, tertiary volcanic rocks, and alluvial deposits of Pleistocene and Holocene age (H.T. Harvey and Associates 2007a). The older non-marine alluvial deposits consist of consolidated inter-bedded gravel, sandstones, and siltstones (H.T. Harvey and Associates 2007a).

Lower Stony Creek

The majority of the Lower Stony Creek Watershed is comprised of alluvial fan deposits of the Pleistocene and Holocene epochs (H.T. Harvey and Associates 2007a). Releases from Black Butte Dam enter lower Stony Creek near the apex of the Stony Creek alluvial fan, and lower Stony Creek flows entirely through these Pleistocene and Holocene Stony Creek alluvial fan deposits, until near Mills Orchard, where the fan deposits become interbedded with finer-grained Sacramento River floodplain deposits (H.T. Harvey and Associates 2007a).

The alluvial fan surface's broad, concave-upward topography typically drains rainfall-derived runoff away from, not into the lower Stony Creek channel. The alluvial fan surface does not contribute flow to the channel so it is not technically within the watershed (H.T. Harvey and Associates 2007a). The Lower Stony Creek Watershed area is therefore a narrow band, which includes the currently active channel area and formerly active channel and floodplain terraces inset within the broader inactive fan deposits (H.T. Harvey and Associates 2007a).

Hydrology

Upper Stony Creek Watershed

Streamflows in the Upper Stony Creek Watershed are regulated by East Park and Stony Gorge reservoirs before flowing into Black Butte Lake. The main tributary streams drain eastward from their headwaters into a broad north-south trending valley through which Stony Creek flows northerly for about 30 miles to its confluence with Grindstone Creek, then flows northeasterly for about 10 miles to Black Butte Lake (Swanson and Kondolf 1991 *as cited in* H.T. Harvey and Associates 2007a).

East Park and Stony Gorge reservoirs impound water for irrigation and have no flood control capacity. These reservoirs likely attenuate flood peaks from the upper watershed to some degree, but their primary effect on the hydrology of the system is increasing summer base flows downstream. These reservoirs do not significantly reduce the sediment yield from the upper basin because they do not intercept sediment from tributaries with the greatest sediment yield, notably Grindstone Creek (H.T. Harvey and Associates 2007a).

Lower Stony Creek Watershed

Flows from Lower Stony Creek Watershed are controlled by releases made from Black Butte Lake for flood control and irrigation, and irrigation diversions. Black Butte Lake is operated from April to October for irrigation by the U.S. Bureau of Reclamation, while the U.S. Army Corps of Engineers (USACE) operates the reservoir from November to March for flood control purposes (H.T. Harvey and Associates 2007a).

Since the construction of Black Butte Dam in 1963 the frequency and extent of flooding along lower Stony Creek has been significantly reduced (H.T. Harvey and Associates 2007a). However, there are now higher and more variable summer and early fall flows, attributed to irrigation releases. Flows are often sustained through late fall. In 2007,

H.T. Harvey and Associates (2007b) conducted a detailed analysis of hydrologic changes due to Black Butte Dam. Their analysis showed that the dam reduced the duration of flows larger than 15,000 cfs by an average of about 1 day per year since 1963, while the duration of flows between 14,000 and 15,000 cfs has increased by an average of 0.62 days per year (H.T. Harvey and Associates 2007b).

Land Use

Upper Stony Creek Watershed

The majority of the Upper Stony Creek Watershed is publicly owned (i.e., Mendocino National Forest) (H.T. Harvey and Associates 2007a). The landscape of the Upper Stony Creek Watershed reflects the inhabitation and management of several cultures and eras, including Native American residence and Euro-American settlement (USDA 1995 *as cited in* H.T. Harvey and Associates 2007a). Mining, timber harvesting, agriculture and grazing, water management, and recreational land use practices can be observed in the Upper Stony Creek Watershed.

Lower Stony Creek Watershed

Compared to the Upper Stony Creek Watershed, the Lower Stony Creek Watershed is smaller in area. By contrast, approximately 96% of the land within the lower watershed is privately owned. Land uses include agriculture, grazing, gravel mining and rural residences (USBR 1998 *as cited in* H.T. Harvey and Associates 2007a). Some public land, associated with diversion canals and other types of infrastructure also exists within the lower watershed (H.T. Harvey and Associates 2007a).

Fisheries and Aquatic Habitat

The upper limit of anadromous fish access in Stony Creek is Black Butte Dam. The existing opportunistic use by salmonids of Stony Creek is currently limited both spatially and temporally, due to unsuitable water temperatures and flows. Only fall-run Chinook salmon have life history requirements nearly compatible with the existing conditions of lower Stony Creek. Improvements to water temperature and flows sufficient to support annual production of fall-run Chinook salmon also would enhance periodic rearing of non-natal Chinook salmon and steelhead trout (H.T. Harvey and Associates 2007a).

Stony Creek does not currently support a sustained annual cycle of anadromous salmonid production. When connected with the Sacramento River, Lower Stony Creek

provides non-natal rearing habitat for steelhead and all four runs of Chinook salmon (H.T. Harvey and Associates 2007a).

Steelhead

Data on the relative abundance of fishes in lower Stony Creek comes from trapping and netting by the U. S. Bureau of Reclamation from 2001-2004 (Corwin and Grant 2004). From a total catch of 64,962 fish, two were juvenile steelhead (H.T. Harvey and Associates 2007a). As reported by H.T. Harvey and Associates (2007a), 53 stranded juvenile steelhead were rescued from Lower Stony Creek in March 1997.

While natal rearing by salmonids in Stony Creek occurs during some years, many juvenile steelhead (and Chinook salmon) from Lower Stony Creek are believed to primarily represent non-natal rearing by juveniles spawned elsewhere in the Sacramento River system. Maslin and McKinney (1994) collected fall-run Chinook salmon, spring-run Chinook salmon and steelhead juveniles in the lower three miles of Stony Creek. Corwin and Grant (2004) linked capture of steelhead (and spring-run Chinook salmon) in Lower Stony Creek to specific hatchery releases upstream in the Sacramento River or at Coleman National Fish Hatchery (H.T. Harvey and Associates 2007a).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Numerous seasonally created agricultural diversions in Thomes Creek reduce instream flows, impede fish passage, and entrain small fish. Most of these diversions are unscreened. Restoration actions for anadromous salmonids in Thomes Creek should be directed at minimizing the adverse effects of agricultural diversions and improving fish passage to the upper watershed. Much of Thomes Creek can be characterized as boulder filled canyons, which likely present challenging conditions for spring-run Chinook salmon and steelhead on their upstream migration to holding and spawning habitats in the headwaters.

Viability potential

CV spring-run Chinook salmon - **Low**

CV steelhead - **Moderate**

Thomes Creek is characterized as having a **low** potential to support a spring-run Chinook salmon population. This characterization is based on the following factors: (1) very few spring-run Chinook salmon have been observed in Thomes Creek in recent years, although consistent monitoring has not occurred; (2) the watershed has limited area at higher elevation and is highly dependent on rainfall, rather than having a large snowpack to provide inputs of cool snowmelt during the spring (Lindley et al. 2004); (3) natural fish passage impediments likely preclude spring-run Chinook salmon adults from reaching high elevation holding habitats, and there are few large, deep pools at those elevations for spring-run Chinook salmon to hold in over the summer; (4) water diversions limit instream flows and also affect fish passage; and (5) water temperatures under the current climate may already be beyond the thermal requirements of coldwater species such as spring-run Chinook salmon, particularly during the summer holding life stage, and climate change is expected to increase water temperatures in the Central Valley (Lindley et al. 2007).

Thomes Creek is characterized as having a **moderate** potential to support a steelhead population. Adult steelhead have a higher leaping ability than spring-run Chinook salmon and typically migrate upstream during high flow conditions occurring in winter. For these reasons steelhead have a higher probability of reaching higher elevation holding and spawning habitats and thus are better suited to deal with the upstream migration challenges affecting spring-run Chinook salmon. Additionally, unlike spring-run Chinook salmon, adult steelhead do not hold over the summer and are not exposed to warm water temperatures prior to spawning.

Although Thomes Creek presents less challenges for steelhead than for spring-run Chinook salmon, a “high” characterization for the potential of the creek to support a spawning steelhead population is not warranted because of the limited area of habitat at higher elevation, the potential effects of climate change, the watershed’s dependence on rainfall instead of snow melt, and the effects of diversions.

Key Threats and Stressors

Key stressors to Central Valley spring-run Chinook salmon and steelhead in the Thomes Creek watershed as identified in the Recovery Plan, include but are not limited to the following:

- ❖ Passage impediments/barriers by agricultural diversion dams, braiding and natural channel gradients affecting adult immigration and holding
- ❖ Water temperature changes affecting adult immigration and holding, spawning, and embryo incubation
- ❖ Agricultural diversions limiting instream flows

Key Actions

- ❖ Conduct a feasibility study on potential channel modifications that would improve upstream migration conditions in Thomes Creek.
- ❖ Enhance watershed resiliency in Thomes Creek by identifying and implementing projects that would reduce the potential for, and magnitude of a catastrophic wildfire, restore meadows to potentially increase summer flows and reduce local water temperatures, or increase riparian shade.
- ❖ Develop and implement a spawning gravel augmentation plan in Thomes Creek.
- ❖ Implement projects to increase floodplain habitat availability in Thomes Creek to improve juvenile rearing habitat
- ❖ Re-establish natural channel morphology in Thomes Creek by: (1) applying NMFS gravel mining criteria to all gravel mining projects; (2) integrating natural morphological features and functions into bank protection and other stream side development projects; and (3) implementing non-native plant (e.g. Arundo) eradication plan.

Watershed Description

As reported by TCRCD (2006), Thomes Creek originates in the western portion of the Tehama West Watershed and flows eastward for approximately 70 miles before

entering the Sacramento River four miles north of the town of Corning, California. The Thomes Creek Watershed extends from the Yolla Bolly-Middle Eel Wilderness Area, south to Anthony Peak.

Geology

The Tehama West Watershed encompasses an area of diverse geologic features critical to Tehama County's agricultural and mining industries (TCRCD 2006). The Thomes Creek watershed includes portions of the eastern Coast Range and western Great Valley Geologic Provinces (TCRCD 2006). The Coast Range Province is characterized by northwest-trending mountain ranges composed of thick Mesozoic and Cenozoic strata, commonly characterized by zones of extensive shearing and the presence of ophiolite/serpentinite mélanges (TCRCD 2006). The Great Valley Province is a sedimentary basin, characterized by a thick deposit of moderately deformed Jurassic and Cretaceous marine sedimentary layers that consist of detrital materials derived from uplifted basement rocks of the Klamath Mountain and Coast Range Provinces (TCRCD 2006). Great Valley rocks consist primarily of mudstone, shale, and sandstone (TCRCD 2006). These units yield an abundance of suspended sediment but relatively little gravel to the watershed (TCRCD 2006). An analysis by the USGS showed that the annual suspended sediment yield of Thomes Creek is nearly three times higher than other streams of comparable size (TCRCD 2006). Thomes Creek continuously transports and deposits eroded sediments along floodplains of the Sacramento River (TCRCD 2006).

For further information on the geology of the Thomes Creek Watershed, refer to the Tehama West Watershed Assessment (TCRCD 2006).

Hydrology

Thomes Creek drains a watershed of approximately 188 square miles and contributes a mean annual run-off of about 200,000 acre-feet (TCRCD 2006). Although there are two seasonal diversion dams located near Paskenta and Henleyville, Thomes Creek does not have any major dams (TCRCD 2006).

Headwaters of the streams in the Tehama West Watershed, including Thomes Creek, have relatively little, if any, drainage area with significant snowpack (TCRCD 2006). However, the upper-most elevation of Thomes Creek exceeds 5,000 feet and during some years may have significant snowpack. In the lower portion of the drainage, snowfall is infrequent and does not significantly contribute to streamflow in Thomes Creek (TCRCD 2006). Thomes Creek is usually dry or intermittent below the USGS

stream gauge near Paskenta until the initial heavy Fall rains occur (DWR 2009). Hence, Thomes Creek exhibits rapid responses to storms, and flow levels fluctuate greatly between storm-periods and intervening dry spells (TCRCD 2006). Peak flows in Thomes Creek generally occur during the month of February (**Table 19**).

Due to the hydrology of the Tehama West Watershed, including Thomes Creek, groundwater is the primary water supply, and because surface water supplies are unpredictable and limited, future growth in the region and water demand during drought conditions will depend on the continued availability of groundwater (TCRCD 2006).

Table 19. Thomes Creek monthly stream flow

Month	Thomes Creek (1921 – 1996)		
	Mean	Minimum	Maximum

December	395	6.93	2,879
Average	295	-	-

Source: TCRCD 2006

Land Use

The Thomes Creek Watershed is largely rural, with isolated pockets of human inhabitants, primarily concentrated along Interstate 5 (TCRCD 2006). Land use in this watershed largely depends on ownership (TCRCD 2006). While most of the low- and mid-elevation lands are held by private individuals who use these areas primarily for agriculture (i.e., ranching and farming) and residential uses, the upper elevations are held by commercial timber companies and the U.S. Forest Service or the Bureau of Land Management (TCRCD 2006).

Fisheries and Aquatic Habitat

The physical and hydrologic characteristics of the Thomes Creek watershed determine the habitat availability to fishery resources. Flows tend to rise quickly following storm events, drop equally promptly following storms, and carry very large quantities of sediment (TCRCD 2006). The snowpack in this watershed results in relatively light warm-season runoff, resulting in perennial Coast Range stream reaches; mid-reach sections that may be dry in mid-summer; and lower reaches near the Sacramento River that may contain small amounts of water from irrigation run-off (TCRCD 2006). Thomes Creek has an unimpaired hydrologic pattern of flashy winter and spring flows and very low summer and fall flows, creating an environment of fairly inconsistent habitat (CALFED 2000a). Thomes Creek is usually dry or intermittent below the USGS stream gage near Paskenta until the first heavy fall rains occur (DWR Website 2007). Therefore, spring-run Chinook salmon utilization of Thomes Creek would likely only occur during wet years. Inconsistent flows, particularly during the fall and early winter months, promote an increased potential for redd dewatering.

There are no significant dams on Thomes Creek other than two seasonal diversion dams, one near Paskenta and the other near Henleyville. Several small pump diversions are seasonally operated in the stream (DWR Website 2007). These dams would be in place during the time when spring-run Chinook salmon would be immigrating to upstream areas and likely present obstacles to upstream immigration. Additionally, gravel mining downstream of the Tehama-Colusa Canal siphon crossing has reportedly resulted in a partial barrier to salmonids returning to Thomes Creek to spawn (Vestra Resources, Inc. 2006).

Thomes Creek has been evaluated in recent years with regards to its upper reach accessibility to anadromous fish. In May 2004 the California Department of Fish and Game determined that an impassible barrier to Chinook salmon and steelhead exists at the point immediately above the confluence of the stream with Horse Trough Creek (Barron, F. Personal communications, as cited in TCRCD 2006). This location is approximately 9 miles upstream from Paskenta and at an elevation of approximately 1,500 feet (TCRCD 2006).

During most years, water temperatures during the summer months are likely too warm to support adult spring-run Chinook salmon holding. Chinook salmon utilizing Thomes Creek for spawning likely hold in the mainstem Sacramento River.

The lower reach of Thomes Creek has been significantly altered by the construction of flood control levees and bank protection measures (i.e., riprapping) (CALFED 2000a), resulting in reduced habitat availability for juvenile salmonids.

Spring-Run Chinook Salmon

GrandTab escapement data for Thomes Creek spring-run Chinook salmon is generally unavailable. However, in 1998 and 2002, spring-run Chinook salmon escapement was reported to be 1 and 2, respectively (CDFG 2009; D. Killam, pers. comm., 2009).

As reported in the Tehama West Watershed Assessment (TCRCD 2006), California Department of Fish and Game files provide anecdotal information regarding Chinook salmon usage of Thomes Creek. In one memo, spring-run Chinook were reported in the stream in 1946 and 1961; however, the locations of the observations were not noted. In 1958 a rancher observed 30–40 spring-run Chinook salmon near Henleyville (TCRCD 2006).

Steelhead

As reported by TCRCD (2006), in 1982, 22 species of fish were recorded within various portions of Thomes Creek (Brown *et. al.* 1983 as cited in CALFED 2000). Steelhead were reported to be the most abundant fish species above the “Gorge”, however, these fish were likely rainbow trout, as there is an anadromous fish barrier a short distance above the “Gorge” (TCRCD 2006).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Cottonwood Creek itself does not contain suitable spawning habitat to support a spring-run Chinook salmon population. However, Beegum Creek, a tributary of Cottonwood Creek, does currently support a small persistent population (since 1998). Lindley *et al.* (2004) considers the Beegum Creek population to be dependant upon input of migrants from populations such as Deer, Mill and Butte creeks (thereby classified as a “dependent” population). Another possibility is that the group of streams in the Northwestern California Diversity Group operate as a metapopulation (Hanski and Gilpin, 1991), i.e., individual populations may not be viable on their own, but migration among members of the group maintains persistence of the whole group. Either way, the small area of available habitat argues against the existence of an independent population historically. The classification of these populations as dependent does not mean that they have no role to play in the persistence or recovery of the Central Valley spring-run Chinook salmon ESU. If these populations are adapted to their unusual spawning and rearing habitats, they may contain a valuable genetic resource (perhaps being more tolerant of high temperatures than other spring-run Chinook salmon). These habitats and populations may also serve to link other populations in ways that increase ESU viability over longer time scales (Lindley et al. 2004).

The prospects for spring-run Chinook salmon in Beegum Creek are dampened by global warming. Spring-run Chinook salmon in Beegum Creek are limited to low elevation habitat that is thermally marginal now, and will become intolerable within decades if the climate warms as expected (Williams 2006).

Viability potential

CV spring-run Chinook salmon: **low**

CV steelhead: **moderate**

The Cottonwood Creek Watershed is characterized as having a *low* potential to support a viable independent population of spring-run Chinook salmon. However, the Beegum Creek spring-run Chinook salmon population is considered an important persistent

component of the Northwestern California Diversity Group. With successful restoration efforts to improve spawning habitat and flows, the dependent population of spring-run will be supported. Because the numbers of spring-run in this system vary from numbers well below 50 to over 100 fish, the extinction risk for this dependent population is high. Implementation of key recovery actions could improve conditions to reduce the risk of extinction; however, even with restoration efforts, a population size greater than of 50 to 500 holding adults may never be achieved.

Cottonwood Creek Watershed, including Beegum Creek has a *moderate* potential to support a viable population of CV steelhead. Although comprehensive population abundance data are not available, there is a widespread presence of *O. mykiss* throughout the watershed, and it is currently designated as critical habitat for steelhead. Sections of the Cottonwood Creek watershed, such as the middle fork, south fork, and Beegum contain more suitable habitat than other areas within the watershed. With some restoration efforts (described below), much of the watershed could become important steelhead habitat for the diversity group.

Key Threats and Stressors

Key stressors to Central Valley spring-run Chinook salmon and steelhead in the Cottonwood/Beegum watershed include, but are not limited to the following:

- ❖ Loss of floodplain and riparian habitat and instream cover from gravel mining affecting juvenile rearing and outmigration\]
- ❖ Loss of natural river morphology from gravel mining (e.g., channel braiding) affecting adult immigration, juvenile rearing and outmigration
- ❖ Low flow conditions (i.e., low flows and flow fluctuations) associated with attraction and migratory cues in Cottonwood Creek affecting adult immigration, spawning and embryo incubation
- ❖ Natural elevated water temperatures and poor water quality affecting adult immigration and holding, spawning and embryo incubation
- ❖ Natural Spawning habitat availability affecting adult spawning

Key Actions that would help support persistent dependent populations

- ❖ Re- establish natural channel morphology in Cottonwood Creek by: (1) applying NMFS gravel mining criteria to all gravel mining projects; (2) integrating natural morphological features and functions into bank protection and other stream side development projects; and (3) implementing non-native plant (e.g. Arundo) eradication plan.

- ❖ Integrate riparian habitat restoration into bank protection and other stream side development projects in Beegum Creek and the greater Cottonwood watershed.
- ❖ Develop cooperative water use agreements (e.g., groundwater exchange agreements) with local water users to provide flows in Cottonwood Creek during the immigration life stage.
- ❖ Enhance watershed resiliency in Beegum Creek by identifying and implementing projects that would reduce the potential for, and magnitude of, a catastrophic wildfire, and restore forested areas within the watershed including riparian areas.

Watershed Description

Cottonwood Creek is the third largest watershed tributary west of the Sacramento River and the largest undammed tributary in the upper Sacramento River basin (CALFED 1997). The watershed is located within Shasta and Tehama counties on the north-west side of northern California's Central Valley, with a peak elevation of approximately 7,860 feet (CH2MHILL 2002, 2007) (Table 20). The lower two-thirds of the drainage lies in the Central Valley uplands, while the upstream portion includes the east slope of the North Coast Mountain Range and Klamath Mountains, and the southern slopes of the Trinity Mountains (CH2MHILL 2002). Cottonwood Creek is fed by three major branches (i.e., North, Middle, and South forks).

Table 20. Cottonwood Creek watershed characteristics

Characteristic	Value
Watershed Area	938 square miles
Cottonwood Creek Stream Length	68 miles
Headwater Elevation	7,680 feet
Mean Discharge	860 cubic feet per second (cfs)
10-year Flood	50,000 cfs
100-year Flood	93,000 cfs
Mean precipitation	36 inches

Source: CH2MHILL 2007

Beegum Creek is a major tributary to the Middle Fork Cottonwood Creek. The North, Middle, and South forks of Beegum Creek originate in the easternmost portion of the Shasta-Trinity National Forests and converge to form the mainstem of Beegum Creek before entering a remote, steep-sided canyon known as Beegum Gorge (CH2MHILL 2002).

Geology

The three principal geological provinces in the Cottonwood Creek watershed are the Great Valley Province, the Coast Range Province, and the Klamath Mountain Province. The Great Valley Province is a 400-mile-long by 60-mile-wide sedimentary basin that comprises the majority of the watershed (CH2MHILL 2002). The Coast Range Province and the Klamath Mountains Province consist of various highly erosive formations including South Fork Mountain Schist, Rattlesnake Creek terrain, and North Fork terrain, in addition to the decomposed granitic soils of the Shasta Bally Batholith (CH2MHILL 2002).

The Coast Range fault, Stoney Creek fault, Cold Fork fault, Sulfur Spring fault, Oak Flat fault, Battle Creek fault, and numerous cross faults and thrust faults occur in the Cottonwood Creek watershed. Fault traces located east of South Fork are likely obscured by stream activity and agricultural practices (USGS 1988; WET 1991; Dupras 1997 *as cited in* CH2MHILL 2002). The most recent fault movement is believed to have occurred more than 125,000 years ago (DWR 1993 *as cited in* CH2MHILL 2002).

Large, active landslides that contribute to the sediment discharge are abundant in the South Fork Mountain Schist of the South Fork of Cottonwood Creek (DWR 1992 *as cited in* CH2MHILL 2002) and the Rattlesnake Creek terrain of Beegum Creek (USFS 1997 *as cited in* CH2MHILL 2002). A notable slide is located on Slide Creek, tributary to the South Fork of Cottonwood Creek; in 1995 this slide contributed a large amount of sediment to South Fork Cottonwood Creek. Cottonwood Creek is a major contributor of spawning gravel to the Sacramento River (P. Bratcher, pers. comm., 2009).

Hydrology

The entire Cottonwood Creek watershed is essentially unregulated, although a small reservoir, Rainbow Lake (capacity 4,800 acre-feet), is located on the NF Cottonwood Creek (Graham Matthews and Associates 2003). The hydrology of Cottonwood Creek is typical of watersheds found along the west side of the Sacramento Valley (CH2MHILL 2002). The relatively low elevation of the watershed limits the amount of snowpack that can accumulate in any given year, which results in a hydrologic regime closely correlated to storm events (CH2MHILL 2002). Mean annual runoff in Cottonwood Creek from 1941-2000 is approximately 645,000 acre-feet (Graham Matthews and Associates 2003). Cottonwood Creek is a source of flood flow in the Sacramento River between Shasta Dam and Ord Ferry. Groundwater development is largely limited to the alluvial area near the confluence with the Sacramento River (CH2MHILL 2002).

Land Use

Human impacts on Cottonwood Creek watershed began in the 1850's with gold mining operations. The gold mining in placer deposits commonly used dredge, hydraulic, and ground-sluicing techniques, resulting in the discharge of sediment to the watershed. Effects resulting from historical mining operations have generally dissipated, with the possible exception of the presence of residual mercury wastes in the tailings of historical mining sites (CH2MHILL 2007).

The Cottonwood Creek Watershed remains relatively undeveloped, and is generally characterized by tracts of harvestable timber in the upper reaches, irrigated pastureland in the middle reaches, and ranches, residential housing, and gravel mining operations in the lower reaches. Approximately 70 percent of land within the watershed is privately owned (CH2M HILL 2002). The Beegum Creek watershed is generally forest-covered and has not been significantly modified (D. Killam, CDFG, pers. comm. 2009).

Fisheries and Aquatic Habitat

The Cottonwood Creek watershed continues to provide habitat for anadromous fish, including spring-run Chinook salmon and steelhead. Within the Cottonwood Creek Watershed, spring-run Chinook salmon and steelhead are known to utilize the mainstem, North Fork, Middle Fork and South Fork of Cottonwood Creek, in addition to Beegum Creek (CH2MHILL 2002). However, Beegum Creek is the principal location for spring-run Chinook salmon holding and spawning in the Cottonwood Creek watershed. Refer to Table 21 for habitat characteristics of Cottonwood and Beegum Creeks. Environmental factors including hydrology, stream temperature, channel morphology, and gravel recruitment allow Cottonwood Creek to support significant fish populations on a seasonal and year-round basis (RMI 1987 *as cited in* CH2MHILL 2002).

Spring-Run Chinook Salmon

Historically, approximately 500 adult spring-run Chinook salmon may have spawned in Cottonwood and Beegum Creeks annually (CH2MHILL 2002). Recent Beegum Creek spring-run Chinook salmon escapement estimates are displayed in **Table 22**. The highest known spring-run Chinook salmon escapement in Beegum Creek is 477, occurring in 1998. Spring-run Chinook salmon escapement has generally exhibited a downward trend from 2001 through 2008.

Table 2.1. Habitat characteristics of Cottonwood and Beegum Creeks

Creek	Total Length (miles)	Anadromous Access (miles)	Maximum Elevation (feet)	Suitable Spawning Habitat (sq. ft.)

Steelhead

Cottonwood Creek is one of the major tributaries to the Sacramento River system that supports steelhead spawning (CH2MHILL 2002). Because they migrate during high flows, and it is difficult to distinguish juvenile steelhead from resident rainbow trout, few steelhead population estimates have been recorded in Cottonwood Creek

(CH2MHILL 2002). The USFS and CDFG have observed populations of juvenile steelhead in the upper South Fork Cottonwood Creek Yolla Bolly Middle Eel Wilderness Area in the summer of 1976 (CH2MHILL 2002). Small runs of adult steelhead have been observed to migrate in the mainstem and lower reaches of the North, Middle, and South Fork Cottonwood Creek.

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

Clear Creek historically was not known to support a large Central Valley spring-run population. Records from historical data sets are sparse, so the abundance that is seen in Clear Creek today for spring-run salmon and for steelhead does not have an adequate baseline to determine what the original carrying capacity was for this watershed. Since 1998, spring-run Chinook salmon have shown an increasing trend in abundance. In 2000 a small dam was removed which opened up 12 miles of prime spawning habitat for spring-run and steelhead. Increasing abundance is due in part to the reliable cool water source diverted from the Trinity River water, released at Whiskeytown Reservoir (Reclamation 2008). In addition, spring-run Chinook salmon and steelhead populations in Clear Creek have also responded to extensive restoration efforts by joint agency partnerships through such programs as CVPIA and CALFED.

Viability potential

CV spring-run Chinook salmon: **High**

CV Steelhead: **High**

The Clear Creek spring-run Chinook salmon and steelhead populations are currently considered persistent, dependent upon input of migrants from populations such as Deer, Mill and Butte creeks (thereby classified as a “dependent” population). Indications that the Clear Creek populations have a *high* potential to become viable independent populations with a low risk of extinction include: low stray rates from hatchery produced salmonids, and a recent increase in the annual number of spring-run Chinook salmon and steelhead migrating into Clear Creek, anticipated to reach an effective population size greater than 500, or a census population size of greater than 2500, as described by Lindley *et al.* (2007) as criteria for assessing the level of extinction risk for Pacific salmonids (see Table 4-1 in the Recovery Plan). A recent review of habitat potential on Clear Creek indicated carrying capacity estimates of 3,122 spring-run Chinook salmon and 7,292 steelhead (Matt Brown, USFWS, pers. com.). Efforts towards this end include: implementation of a long-term gravel augmentation plan, managed releases of optimal flows; maintaining water temperatures below 65°F year round; and recent extensive riparian, instream channel and floodplain restoration.

Key Threats and Stressors

Key threats and stressors to spring-run Chinook salmon and steelhead in Clear Creek include, but are not limited to the following:

- ❖ Passage impediments/barriers at Redd Bluff Diversion Dam and Whiskeytown Dam affecting adult immigration, and consequently holding, spawning, redd superimposition, competition for habitat, hybridization and genetic integrity
- ❖ Water temperatures and water quality affecting adult immigration and holding, spawning and embryo incubation
- ❖ Physical habitat alteration (particularly associated with limited supplies of instream gravel), affecting adult spawning habitat suitability
- ❖ Flow conditions (i.e., low flows) affecting juvenile rearing and outmigration
- ❖ Sedimentation affecting embryo incubation
- ❖ Loss of floodplain habitat and natural river morphology affecting juvenile rearing and outmigration

Key Restoration Actions

- ❖ Develop a spawning gravel budget and implement a long term augmentation plan in Clear Creek, and use flow management to optimize spawning weighted usable area in consideration of hydrologic limitations and life stage requirements.
- ❖ Increase stream flows in Clear Creek as needed to reduce water temperatures (NMFS 2007b)
- ❖ Develop a real time water temperature model to track the coldwater pool in Whiskeytown Reservoir and budget releases to Clear Creek to meet daily water temperature of 60°F at the Igo gauge from June 1 to September 15 and 56°F from September 15 to October 31.
- ❖ Develop and implement flow ramping protocols in Clear Creek to protect all life stages of spring-run Chinook salmon.
- ❖ Develop and implement optimal pulse flow schedules and increase flow allocation for Clear Creek in years with low water availability.

Watershed Description

Clear Creek is the first major tributary to the Sacramento River below Shasta Dam. Clear Creek originates in the mountains east of Clair Engle Reservoir and flows approximately 35 miles to its confluence with the Sacramento River at RM 289 near the south Redding city limits in Shasta County, California. Clear Creek drains approximately 238 square miles (USFWS 1995).

Whiskeytown Dam, constructed in 1963 near RM 18.1, stores and regulates run-off from the Clear Creek watershed and diversions from the Trinity River (USFWS 1995). The former McCormick-Saeltzer Dam was located approximately 12 miles downstream from Whiskeytown Dam at RM 6.4, and diverted water for irrigation use (USFWS 1995), but was removed in 2000.

The stream channel below Whiskeytown Dam can be divided into two predominant types at Clear Creek Road Bridge (RM 8.5) (USFWS 1995). Upstream, the creek is mainly confined by steep canyon walls and is characterized by falls, high gradient riffles, and deep pools (USFWS 1995). The substrate is mainly bedrock, large boulders, and fine sand. Downstream from RM 8.5 is the alluvial reach with a much lower gradient and a much wider valley relatively unconstrained by bedrock (USFWS 1995). Substrate is mainly a mixture of cobble, gravel, and sand (USFWS 1995).

The climate in the Clear Creek watershed is Mediterranean, with most precipitation occurring in the winter months (i.e., November through April), and dry summers with temperatures exceeding 100°F (McBain and Trush et al. 2000). Average annual precipitation in the Clear Creek watershed varies from 20 inches near the confluence with the Sacramento River to over 60 inches in the upper watershed (McBain and Trush et al. 2000). Precipitation is primarily rainfall, with snow occurring at the highest elevations of the watershed (McBain and Trush 2000).

Geology

Lower Clear Creek flows over Pleistocene age stream gravel that has been extensively mined. The historical pre-dam transport of gravel into lower Clear Creek is not known, and the present transport and recruitment of gravel in lower Clear Creek also is unknown. Lower Clear Creek, below Whiskeytown Dam can be grouped into two reaches. The upper canyon-bound reach of Clear Creek has stream slopes in the range of 0.6 to 2.0 percent, as measured from USGS 1:24,000 scale topographic quadrangles. The lower reach has an average stream gradient of 0.3 percent (Castro 1996 in Sacramento River Watershed Program 2008). Upstream tributaries to the canyon bound reach typically have stream slopes greater than 4 percent (Sacramento River Watershed Program 2008). The lower reach has lost its natural meander pattern. In places, the stream runs in straight highly entrenched channel dug to facilitate gravel mining. Steep bluffs, composed of the Pleistocene epoch Riverbank and Red Bluff formations (Helly and Harwood 1985) occur where Clear Creek has cut into these formations and where hydraulic placer mining historically occurred (Sacramento River Watershed Program 2008).

The impoundment-induced coarse sediment deficit and concomitant reduction in habitat quality

in Clear Creek below Whiskeytown Dam has been well documented by various investigators (Coots 1971 as cited in McBain and Trush 2001, GMA 2003). Effects of reduced coarse sediment supply include: riffle coarsening, fossilization of alluvial features, loss of fine sediments available for overbank deposition and riparian regeneration, and a reduction in the amount and quality of spawning gravels available for anadromous salmonids.

Below Whiskeytown Dam to Clear Creek Road, the channel exhibits typical inner-gorge, bedrock dominated, morphology with a high degree of confinement and little alluvial storage. However, exhibits remnant alluvial features and hence, demonstrates potential for alluvial processes to develop. Tributary sources of coarse sediment for the first 1.8 miles below the dam are extremely limited and contribute coarse sediment only

during highly infrequent stochastic events (Rasmussen 2006; Steensen 1997). Colluvial sources (canyon walls) contribute very little within practical management timeframes and such material is of limited ecological value until it is transported and rounded over some distance. Gravel bars, coarse-cobble riffles and (post-dam) abandoned floodplains alternate with deep scour pools and bedrock-constricted chutes. Most spawning riffles in the reach have coarsened and appear relatively immobile as intermittent high flows from dam-spills and releases winnow, but lacking sediment input, do not replace finer material.

Below Clear Creek Road, the combination of over-extraction and reduced coarse sediment supply led to channel down-cutting and a loss of floodplain connectivity (McBain and Trush 2001). Many of these effects are exacerbated in the lower parts of the watershed by the legacy of dredging and gravel extraction overlain by the increase in fine sediment production from impacted tributaries and by the removal of a relic dam (Saeltzer Dam).

Hydrology

The median historical unimpaired run-off in Clear Creek is 69 thousand acre-feet (TAF), with a range of 0-421 TAF (USFWS 1995). Construction of Whiskeytown Dam greatly reduced the volume and magnitude of historic flows (McBain and Trush et al. 2000).

Since 1964, a portion of the flow from the Trinity River Basin has been exported to the Sacramento River Basin through Whiskeytown Reservoir (Reclamation 2008). Water is diverted from the Trinity River at Lewiston Dam via the Clear Creek Tunnel and passes through the Judge Francis Carr Powerhouse as it is discharged into Whiskeytown Lake on Clear Creek (Reclamation 2008). From Whiskeytown Lake, water is released through the Spring Creek Power Conduit to the Spring Creek Powerplant and into Keswick Reservoir. All of the water diverted from the Trinity River, in addition to a portion of Clear Creek flows, is diverted through the Spring Creek tunnel into Keswick Reservoir (Reclamation 2008). A larger volume of water from the Trinity River goes to the Sacramento River through the Spring Creek Power Conduit than goes to Clear Creek (Reclamation 2008). On average, 1.2 MAF (up to 2,000 cfs) of water from the Trinity River is diverted each year into Keswick Reservoir compared to 200 cfs released to Clear Creek for fishery needs (NMFS 2008) between the Fall and Spring. Flows provided to Clear Creek below Whiskeytown Dam are consistently at least 200 cfs from October through June. During the summer months, flows are maintained to provide adequate water temperatures for holding adult spring-run Chinook salmon and water temperatures for rearing steelhead per the 2004 OCAP Biological Opinion (NMFS 2008). The Spring Creek Power Conduit water is used primarily to deliver agricultural,

municipal and industrial water, and generate power. This water helps cool the Sacramento River during the summer during winter-run Chinook salmon spawning and embryo incubation (Reclamation 2008).

Land Use

As reported in the Lower Clear Creek Floodway Rehabilitation Project Design Document (McBain and Trush *et al.* 2000), lower Clear Creek has undergone significant changes due to land use beginning with the discovery of gold at Reading Bar in 1848. Various forms of gold mining transformed the natural landscape into piles of placer, hydraulic, and dredger tailings. In most locations, the entire lower Clear Creek floodway was “turned upside down” in the search for gold. Gold mining also brought secondary impacts to the creek, including road building, deforestation, and urban development. Dredger tailings adjacent to the creek between the former Saeltzer Dam and Clear Creek Road Bridge are the most pronounced relics of historic gold mining activity, with the tailings confining the river and providing very little value as floodplain or riparian habitat (McBain and Trush *et al.* 2000).

The most recent significant land use impact to lower Clear Creek was instream and off-channel gravel mining, occurring from 1950 to 1978 (McBain and Trush *et al.* 2000). Impacts to channel morphology and salmonid habitat were significant; the bankfull channel was destroyed and floodplains removed, leaving wide shallow channels and interspersed deep pits (McBain and Trush *et al.* 2000).

Fisheries and Aquatic Habitat

Historically, there were approximately 25 river miles of Chinook salmon habitat available for use in Clear Creek of which only 18.1 are currently accessible (NMFS Website 2005) because of the construction of a dam to create power and water for the Redding area. Whiskeytown Dam is a complete barrier to fish passage and is the uppermost boundary of habitat available to anadromous salmon and steelhead.

Other negative effects to the spring-run and the steelhead fishery resulted from Whiskeytown being “stretched” across this wild river. The construction of Whiskeytown Dam, gold mining, and gravel mining in the Clear Creek watershed has diminished suitable spawning gravel substrate and reduced riparian habitat along the lower sections of Clear Creek (CDFG 2004). Excessive gravel removal exposed a clay hardpan over much of the channel bottom, directly removing salmonid spawning and fry rearing habitat (McBain and Trush *et al.* 2000). Gravel mining also resulted in lost channel confinement, allowing both adult and juvenile salmonids to stray into adjacent

pits and become stranded (McBain and Trush et al. 2000). Construction of Whiskeytown Dam reduced the magnitude and frequency of high flow events responsible for creating and maintaining lower Clear Creek, which allowed fine sediment to accumulate in the channel and allowed riparian vegetation to establish and mature along the low flow channel (McBain and Trush et al. 2000). As the vegetation matured, the combined root strength of the riparian band “fossilized” gravel deposits and reduced the quantity and quality of aquatic habitat in some areas (McBain and Trush et al. 2000).

One of the keys to success for recovery of both populations of salmonids includes a good supply of cold water from Whiskeytown Reservoir. Water temperatures in Clear Creek at the USGS Igo gaging station (RM 10.85) are maintained below 65°F year-round due to releases of cool Whiskeytown Reservoir water diverted from the Trinity River (Reclamation 2008). The spring-run Chinook salmon population in Clear Creek does not appear to be currently habitat-limited as long as water temperatures are suitable (Reclamation 2008).

In recent years, a multi-phase restoration project on lower Clear Creek (i.e., The Lower Clear Creek Floodway Rehabilitation Project) *recreated a defined channel and floodplain, and included construction of a natural bar (plug) to reduce stranding of juvenile salmon and improve passage conditions for adult salmon migrating upstream* (California Association of Resource Conservation Districts 2005). In addition, aggregate extraction pits within the stream channel and floodplain were filled, and active rehabilitation was conducted including improving floodplain connectivity, and re-vegetation of natural riparian communities (California Association of Resource Conservation Districts 2005).

Success in increasing population abundance has occurred in part because of the numerous gravel augmentation projects that have been implemented in lower Clear Creek, resulting in the addition of over 100,000 tons of gravel (Table 23). Spawning gravel is routinely added every year at various sites to compensate for channel down-cutting. Spawning gravel augmentation *has greatly improved suitable habitat for spring-run Chinook salmon and steelhead* (NMFS 2009). Additional gravel augmentation at 11 sites along lower Clear Creek is being proposed by the National Park Service and the Bureau of Land Management (NPS and BLM 2008). Up to 25,000 tons of gravel would be placed system-wide annually for ten years (NPS and BLM 2008).

Table 23. Past gravel augmentation totals in Clear Creek (as of April 2007)

Placement Site	Total Quantity (Tons)	Jurisdiction
Whiskeytown Dam	23,258	BOR
Below NEED Camp	3,602	NPS
Placer Road Bridge	19,802	Non-Federal
Clear Creek Road	3,003	BLM
Reading Bar	999	BLM
Saeltzer Gorge	36,953	BLM
Above Phase 3A	1,730	BLM
Floodway	11,721	BLM
Phase 2B Exchange	1,404	BLM
TOTAL	102,470

Spring-run Chinook Salmon

Historically, Clear Creek supported spring-run Chinook salmon (Reclamation 2008). However, historical accounts of spring-run Chinook in Clear Creek are sparse and population estimates are nonexistent (Reclamation 2008). Since 1998, spring-run Chinook salmon have shown an increasing trend in abundance from 50 (in 1998) to about 200 adults (highest number on record) in 2008 (Figure 14). From 2005 through 2008, Clear Creek spring-run Chinook salmon escapement was estimated at 69, 77, 194 and 200 adults, respectively (CDFG 2009).

Some spring-run Chinook salmon in Clear Creek may be descendants of Chinook salmon from the Feather River Hatchery (FRH), which were stocked into Clear Creek in the early 1990's (Newton and Brown 2004). In order to re-establish spring-run Chinook salmon in Clear Creek, approximately 200,000 juveniles from the FRH were planted in Clear Creek annually in 1991, 1992 and 1993 (Brown 1996, as cited in Newton and Brown 2004). Contribution by the stocked FRH fish to the current spring-run Chinook salmon population may be limited due to: 1) a lack of suitable water temperatures during their holding and early spawning periods; and 2) probable hybridization with fall-run Chinook salmon (Newton and Brown 2004).

Figure 14. Clear Creek Spring-run Chinook Salmon Escapement (Source: NMFS 2008)

Since 2003, the USFWS has separated fall-run Chinook salmon adults from spring-run Chinook salmon adults holding in the upper reaches of Clear Creek with the use of a picket weir located at either RM 8.1 or 7.4 (S. Giovannetti, USFWS, pers. comm., 2009). The weir is operated from approximately August 23 to November 1 to prevent fall-run Chinook from spawning in spring-run Chinook spawning areas to reduce hybridization, superimposition and competition. After November 1, fall-run Chinook salmon have access to the entire river for spawning, but rarely move upstream into spring-run Chinook salmon spawning areas.

Under dry and warm climate conditions, water temperatures above 60° F occur in Clear Creek. Lindley et al. (2004) suggested that Clear Creek appears to offer habitat of marginal suitability to spring-run, having limited area at higher elevations and being highly dependent on rainfall.

Steelhead

Historically, steelhead probably ascended Clear Creek past the French Gulch area, but access to the upper basin was blocked by Whiskeytown Dam in 1964 (Yoshiyama *et al.* 1996). Operation of Whiskeytown Dam can produce suitable coldwater habitat downstream to Placer Road Bridge depending on flow releases (DFG 1998, as cited in (Reclamation 2008)). Removal of the McCormick-Saeltzer Dam in 2000 has provided steelhead access to an additional 12 miles of habitat (NMFS 2009). Steelhead have recolonized this area and taken advantage of newly added spawning gravels.

Recent redd surveys conducted since 2001 indicate a small but increasing population resides in Clear Creek (Figure 15), with the highest density in the first mile below Whiskeytown Dam (USFWS 2007, as cited in NMFS 2009). Spawning distribution has recently expanded from the upper 4 miles to throughout the 18 miles of Clear Creek, although it appears to be concentrated in areas of newly added spawning gravels (NMFS 2009).

Figure 15. Abundance of steelhead in Clear Creek based on annual redd counts 2003-2009. Spawning population based on average 1.23 males per female on the American River (Hannon and Deason 2007). 2009 estimate is preliminary based on 4 surveys (USFWS 2008, Brown 2009)

Source: NMFS 2009.

In addition to the anadromous form of *O. mykiss*, many resident trout reside in Clear Creek, making it difficult to identify CV steelhead except when they are spawning (*i.e.*, resident trout spawn in the spring and have smaller size redds). Large riverine *O. mykiss* that reside in the Sacramento River can migrate up Clear Creek to spawn with either the anadromous or resident forms. No hatchery steelhead (*i.e.*, presence of adipose fin-clip) were observed during the 2003-2007 kayak and snorkel surveys in Figure 15, indicating that straying of hatchery steelhead is probably low in Clear Creek (USFWS 2008).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

A small, apparently self-sustaining population of steelhead exists in the Calaveras River (NMFS 2008). Steelhead opportunistically use the watershed when sufficient rainfall produces passage flows in the system (Fishbio 2008). Surveys on the Calaveras River over the past several years indicate that small numbers of steelhead continue to run up the river with the first fall rains and during the winter (USFWS 2003). Flow is reported to be a principal factor currently limiting salmonids in the Calaveras River (CALFED Bay-Delta Program 2000, as cited in Marsh 2006). As far as hatchery influences, information on hatchery steelhead was collected below Bellota Weir, however, the carcasses were too deteriorated to determine if the adipose fins were clipped (USFWS 2003).

Although the importance of the Calaveras River for steelhead production is currently unknown, restoration opportunities exist to improve fish passage and aquatic habitat for anadromous salmonids. Several have been identified at several locations, including the Mormon Slough flood control channel, the Old Calaveras River channel, and at the SEWD and the CCWD facilities (Fishbio 2008). SEWD and CCWD are working cooperatively with NMFS to improve the conditions for salmonids in the Calaveras River by including appropriate conservation measures and an adaptive management

plan as part of this Calaveras River Habitat Conservation Plan. SEWD also is continuing to implement interim fish passage improvements until long-term fish passage and screening solutions are identified and put into operation (Fishbio 2008).

With continued fish passage improvements and flow augmentation, the lower Calaveras is considered a suitable system for steelhead to increase in numbers.

Viability potential in the lower watershed

Central Valley Steelhead: *Moderate*

The lower Calaveras River is characterized as having a *moderate* potential to support a viable independent or persistent population of steelhead. This potential is based upon the improvement of fish passage and the timing of flow releases from New Hogan Reservoir. As well, improvements in habitat conditions that are ongoing, are anticipated to increase production.

Opportunities to improve fish passage and aquatic habitat for anadromous salmonids have been identified at several locations, including the Mormon Slough flood control channel, the Old Calaveras River channel, and at the SEWD and the CCWD facilities (Fishbio 2008). SEWD and CCWD are working cooperatively with NMFS to improve the conditions for salmonids in the Calaveras River by including appropriate conservation measures and an adaptive management plan as part of this Calaveras River Habitat Conservation Plan. SEWD also is continuing to implement interim fish passage improvements until long-term fish passage and screening solutions are identified and put into operation (Fishbio 2008).

The lower watershed below New Hogan dam could also support a stronger steelhead population with further instream and riparian habitat improvements. These improvements include increase in shade and channel complexity, which over time could support better rearing.

Potential for Historic Habitats to Support Spawning Populations

Above New Hogan Dam

CV Steelhead – **Low**

It is likely that the upper watershed, above the dam system would not support a population of steelhead, so the potential to support anadromous steelhead is *low*. *Trout*

habitat above the dam is not suitable because of the lack of cold water. Even with the creation of volitional passage, the habitat carrying capacity for steelhead is not high in the upper watershed. Predicted historical distribution of summer rearing habitat for anadromous *O. mykiss* by Lindley et. Al. above New Hogan dam shows that there is a low percentage of upper watershed stream reaches suitable for summer rearing habitat indicating that the steelhead run for the Calaveras River was probably never one of the stronger systems for steelhead production.

Key Threats and Stressors

Key threats and stressors (i.e., identified as “Very High”) to Central Valley steelhead in the Calaveras River include, but are not limited to the following:

- ❖ Fish passage impediments/barriers at Mormon Slough, the Old Calaveras River channel, Camanche Dam, Pardee Reservoir Dam, Bellota Weir and other locations affecting adult immigration and holding, and juvenile rearing and outmigration
- ❖ Flow conditions (i.e., low flows, flood flows) affecting attraction and migratory cues for adult immigration and holding
- ❖ Water quality conditions (i.e., urban and agricultural runoff) in the Calaveras River affecting adult immigration and holding
- ❖ Physical habitat alternation associated with limited supplies of instream gravel affecting spawning
- ❖ Flow fluctuations affecting spawning and embryo incubation
- ❖ Water temperatures affecting spawning and embryo incubation, and juvenile rearing and outmigration
- ❖ Hatchery effects related to redd superimposition, competition for spawning habitat, and genetic integrity
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Hatchery effects related to juvenile rearing and outmigration

Key Restoration Actions

- ❖ Develop long-term instream flow schedules and requirements based on physical habitat modeling and critical riffle analysis
- ❖ Establish a minimum carryover storage level at New Hogan Reservoir that meets the instream flow and water temperature requirements in the lower Calaveras River
- ❖ Remove or modify all fish passage impediments in the lower river to meet NMFS fish passage criteria

- ❖ Screen water diversions to meet NMFS fish screen criteria

Watershed Description

In the San Joaquin River system, the Calaveras River is a relatively small Sierra watershed between the Mokelumne and Stanislaus rivers, and encompasses parts of Calaveras, Stanislaus, and San Joaquin counties (USFWS 2003). The Calaveras River watershed (**Figure 16**) is approximately 600 square miles with an average historic unimpaired runoff of 150,000 acre-feet per year and a minimum of about 12,000 acre-feet per year. The North Fork begins at Pine Ridge at an elevation of about 4,000 feet. The headwaters of the South Fork, San Antonio Creek, begins at Summit Level Ridge at an elevation of 6,000 feet (USFWS 2003).

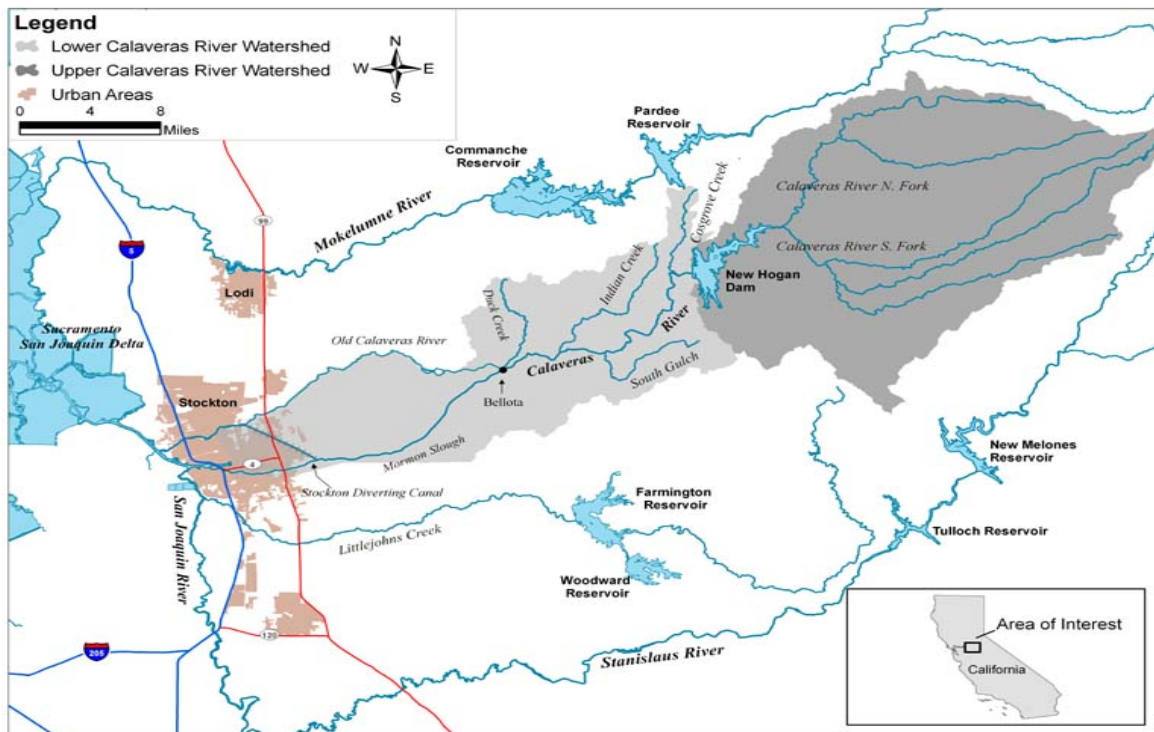

Figure 16. Calaveras River Watershed (Source: Calaveras River Watershed Stewardship Group 2007)

Geology

The Eastern San Joaquin Subbasin underlies a large portion of the eastern area of San Joaquin County. This basin is drained from the San Joaquin River and several of its tributaries including the Stanislaus, Calaveras and Mokelumne Rivers (California Department of Water Resources 2006a in San Joaquin Council of Governments 2007).

Water bearing formations in this subbasin consists of the Alluvium and Modesto/Riverbank Formations, Flood Basin Deposits, Laguna Formation, and the Mehrten Formation (San Joaquin Council of Governments 2007). In the northern portion of Calaveras County, soils are reportedly coarse, very acidic, and nutrient-poor, mostly derived from the Eocene Ione formation (Holland 1986 in Calaveras County 2008).

Hydrology

Average precipitation is ranges from about 20 inches a year in the western region to 60 inches in the northeast, and the rainy season extends from October 1 through May 1 (Calaveras Country 2008).

The most prominent manmade facility in the watershed is New Hogan Dam and Reservoir at river mile (RM) 42 (measured via the Mormon Slough route) which controls flows on the lower Calaveras River. Streamflow in the lower watershed is controlled by releases from New Hogan Reservoir, a 317,000 acre-foot U.S. Army Corps of Engineers (Corps) flood control and water supply reservoir formed by New Hogan Dam, which was constructed in 1964 and is located 38 miles upstream from the mouth of the river (USFWS 2003). Prior to construction of New Hogan Dam, the hydrology of the Calaveras River exhibited higher flow during the winter and spring, as well as periods of low-to-no flow during the late summer and fall. After New Hogan Reservoir was constructed in 1964, winter and spring flow peaks have been reduced and water now flows year round between New Hogan Dam and Bellota Weir (Marsh 2006). Because of the paucity of high elevation habitat capable of holding snowpack, the Calaveras watershed is a rain-driven system unlike other surrounding watershed. Thus, New Hogan Reservoir captures most of the rainfall into the watershed, and local runoff in the lower Mokelumne River below New Hogan Dam seeps quickly into the groundwater table (USFWS 2003).

The four main tributaries below New Hogan Dam are Cosgrove Creek, South Gulch, Indian Creek, and Duck Creek. Cosgrove Creek provides the largest contribution of runoff to the Calaveras River, as much as 8,500 acre-feet in some years (Calaveras River Watershed Stewardship Group 2007). The lower Calaveras River Mormon Slough area below New Hogan Dam encompasses approximately 115,000 acres and receives up to 90,000 acre-feet of surface water supply from the lower Calaveras River.

Releases from the New Hogan Reservoir provide year-round flows downstream to Bellota (USFWS 2003). Releases from the spring through early fall irrigation season generally range from 150 to 250 cfs. Non-irrigation season releases in non-drought years

range from 20 to 50 cfs to meet downstream municipal water supply demands. In drought years, non-irrigation season releases are less. Water diversions from New Hogan Dam downstream to Bellota, including those of Stockton East Water District (SEWD) and the Calaveras County Water District (CCWD), remove most of the river flow, except during the rainy season. A small amount of water is released into the Old River channel and Mormon Slough at Bellota during the irrigation season for downstream users including groundwater recharge; however, the lower channels near Stockton are usually dry except during the rainy season. The two main water diversions are the CCWD diversion just below New Hogan Dam, which diverts water via a Rainy Well system, and the SEWD Bellota Intake diversion that feeds the Dr. Joe Waidhofer Water Treatment Plant via the Bellota Pipeline. In addition there are 29 operating agricultural water diversions between New Hogan Dam and Bellota Weir, and several more in each channel below the Bellota Weir (USFWS 2003).

Most of the water entering the lower Calaveras system at Bellota is diverted to Mormon Slough for irrigation and flood control purposes (USFWS 2003). Only during flood flows does water pass over the weir into the Old Calaveras River channel. Some water is diverted into the Old River channel through gated culverts during the irrigation season. Near Stockton, Mormon Slough flows are diverted to the Stockton Diverting Canal back to the Old Calaveras River channel, where water flows down to the San Joaquin River. Below the Bellota Weir, the Calaveras River system has been reconfigured as a flood control and storm drainage system with Mormon Slough and the Diverting Canal being the principle water conveyance channels. During the dry season, both Mormon Slough and the Old River Channel serve as conveyance for local irrigation supplies (USFWS 2003).

The river reach above the Bellota Weir upstream to New Hogan Dam is a natural stream channel confined in most places by a foothill canyon. The lower section of the river immediately above Bellota has a lower gradient and its floodplain has been altered for agriculture. The channels below Bellota are essential ditches designed to carry irrigation water during the irrigation season and flood flows in winter and spring (USFWS 2003).

Land Use

Near its confluence with the San Joaquin River, the Calaveras River is bordered on both banks by the City of Stockton, passing through housing subdivisions, the University of the Pacific campus, and parks (USFWS 1998, as cited in Marsh 2006). The Calaveras River serves as an important source of water for agricultural and municipal uses in Calaveras and San Joaquin counties. Levees along Mormon Slough and the Stockton

Diverting Canal are covered with sparse grass or shrubs, and adjacent to the old Calaveras River channel are orchards or light industry (Marsh 2006). Additionally, local stakeholder groups have expressed concerns regarding potential effects to water quality and aquatic habitats resulting from storm water runoff, agriculture, recreation, mining, unscreened diversion operations, and other land uses in the basin (The Calaveras River Watershed Stewardship Group 2007).

Fisheries and Aquatic Habitat

While very few studies of the fishery resources in the Calaveras River have been conducted to date, recent monitoring indicates that steelhead opportunistically use the watershed when sufficient rainfall produces passage flows in the system (Fishbio 2008). As reported by Marsh (2006), anadromous fish have access to 36 miles of the Calaveras River between New Hogan Dam and the San Joaquin River, when flows permit. Downstream of New Hogan Dam there is a dense riparian corridor bordering the river along the 18 miles down to Bellota Weir (USFWS 1998, as cited in Marsh 2006). Eighteen river miles upstream from the mouth, Bellota Weir splits the Calaveras River into two channels, Mormon Slough and the Old Calaveras River channel. Mormon Slough and the Stockton Diverting canal downstream are the primary channels used by migrating anadromous fish to access upstream spawning areas in the mainstem Calaveras River upstream of Bellota Weir (Figure 17). Fall flows in Mormon Slough, following the end of the irrigation season, frequently are reduced to levels less than 20 to 30 cubic feet per second (cfs) and may prevent spawning migration (FFC 2004, as cited in Marsh 2006). Mormon Slough, the primary salmonid migration channel, still experiences dry periods during summer and early fall as it did under the pre-1964 unregulated hydrologic regime (Marsh 2006).

Figure 17. Primary barriers and features of the Calaveras River Watershed (Source: Marsh 2006).

Historically, salmon and steelhead production in the Calaveras River was limited by low, intermittent flows during summer and fall. Chinook salmon have not been observed in the Calaveras River since 1984 (USFWS 1995). Although the duration and magnitude of peak winter/spring flows have been reduced due to reservoir operations, salmonids are able to opportunistically access the reach between the Bellota Weir and New Hogan Dam for spawning whenever adequate naturally occurring migration flows are available and no structural barriers are installed (i.e., flashboard dams). Upstream and downstream migration opportunities are currently limited to occasions between November and early April when passage conditions are created by substantial precipitation events that result in flood control releases and/or run-off events below the dam. In many years, precipitation events resulting in passage conditions do not begin until December because rainfall from initial storm events is generally absorbed into the ground through infiltration and run-off does not occur until the ground becomes saturated.

Currently, little data has been collected regarding the abundance, life-history preferences, and migration success of *O. mykiss* in the Calaveras River (Fishbio 2008). As reported by Marsh (2006), the Calaveras River does have the potential to support anadromous fish based on habitat qualities such as geomorphology (i.e., 22 feet per mile gradient, numerous riffles and pools), adequate spawning gravels, and a dense riparian

canopy (USFWS 1993, CALFED Bay-Delta Program 2000, as cited in Marsh 2006). Spawning gravels occur in the lower Calaveras River in the first mile of river below New Hogan Dam and further downstream in the canyon and Jenny Lind reaches. In addition there are small areas of gravel riffles in Mormon Slough below Bellota Weir. Spawning gravels in the first mile below New Hogan Dam suffer from low permeability, but are adequate for several hundred pairs of salmon (USFWS 2003). Spawning gravels are similar in the middle reach between New Hogan Dam and the Bellota Weir. Below Bellota Weir the spawning gravels are limited and have poor permeability, but have produced some fry salmon in recent years. Several steelhead redds in this area in the spring of 2002 were likely unsuccessful as water temperatures reached lethal levels for trout eggs in the redds during the spring (USFWS 2003).

Adult steelhead entering the Calaveras River system are likely to move up the mainstem San Joaquin River channel before branching off into the channels of their natal rivers (NMFS 2008). Adult salmonid upstream passage problems include blockage at structural barriers and adequacy of stream flows for upstream adult migration (USFWS 2003). Juvenile salmonid downstream passage problems include structural barriers, lack of streamflow, and unscreened water diversions. Habitat concerns include: (1) instream flows for spawning and rearing; (2) adequacy of gravel spawning habitat; (3) adequacy of cool water rearing habitat; and (4) competition and predation by non-native warm-water fishes (USFWS 2003). There are many barriers to salmonid passage in the lower Calaveras River channels including several each in the Old Calaveras channel, the Diversion Canal, and Mormon Slough. Weirs at Bellota including one at the head of Mormon Slough, and one at the head of the Old River Channel are virtually impassable at many flows (USFWS 2003). However, two fish ladders have been placed at the Bellota Dam to assist with fish movement along the Calaveras River, and a hydraulic analyses of both ladders was conducted in 2005 (Fishery Foundation of California 2005).

Artificial structures (e.g., low-flow road crossings with culverts, low-flow road crossings without culverts, bridges, permanent dams and weirs, and flashboard dams with the flashboards removed) play a major role in reducing the Calaveras River's fisheries productivity (DWR 2007). Although the importance of the Calaveras River for steelhead production is currently unknown, opportunities to improve fish passage and aquatic habitat for anadromous salmonids have been identified at several locations, including the Mormon Slough flood control channel, the Old Calaveras River channel, and at the SEWD and the CCWD facilities (Fishbio 2008). SEWD and CCWD are working cooperatively with NMFS to improve the conditions for salmonids in the Calaveras River by including appropriate conservation measures and an adaptive management plan as part of this Calaveras River Habitat Conservation Plan. SEWD

also is continuing to implement interim fish passage improvements until long-term fish passage and screening solutions are identified and put into operation (Fishbio 2008).

Steelhead

Although it is likely that steelhead once inhabited most of the San Joaquin River Basin streams used by Chinook salmon for spawning, they probably traveled farther upstream into smaller tributaries (Moyle et al. 1996). These passages are now blocked by dams. There is also little or no historic record of escapement available. Current annual escapements of steelhead in the San Joaquin River Basin, including the Calaveras River, are limited due to the long-term scarcity or absence of steelhead in the basin (Reclamation 2001). The conclusions of Lindley et al. (2006) that several Calaveras River tributaries upstream of New Hogan Dam historically supported summer rearing habitat for steelhead and had an historical independent population of steelhead are supported by the collected anecdotal and documented information presented by Marsh (2006).

Flow is reported to be a principal factor currently limiting salmonids in the Calaveras River (CALFED Bay-Delta Program 2000, as cited in Marsh 2006). However, a small, apparently self-sustaining population of steelhead exists in the Calaveras River (NMFS 2008). Surveys on the Calaveras River over the past several years indicate that small numbers of steelhead continue to run up the river with the first fall rains and during the winter (USFWS 2003). Although no Chinook salmon have been observed in live collections or carcass count surveys have been adipose clipped hatchery fish, too few have been collected to discount the possibility that many are hatchery strays given the low percentage of salmon clipped and code wire tagged at Central Valley hatcheries (USFWS 2003). Carcasses of several steelhead collected below Bellota Weir were too deteriorated to determine if the adipose fins were clipped (USFWS 2003).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

The habitat currently available to salmonids on the Stanislaus River has been severely limited and impacted as a result of human activities over the past hundred years. Because of the significant impacts to habitat on the Stanislaus River, spring-run Chinook and viable populations of steelhead have been extirpated from the watershed. Steelhead are present but only in low numbers. Installation of the Goodwin, Tulloch, and New Melones Dams has been the primary cause of depleted, degraded habitat. The dams are physical barriers between migrating adult salmonids and their historic spawning habitat as well as a physical barrier that impedes the natural downstream transport of spawning gravel. The operation of the dams has resulted in decreased and more uniform flow. This has resulted in many negative effects including degraded water quality, channel incision and a loss in habitat diversity due to inhibiting geomorphic processes, and a lack in connectivity to floodplain rearing habitat.

In addition to the installation and operation of the dams, other human impacts have an effect of the river. This would include gravel mining activities. Although this does not occur as frequently today in the watershed, remnant gravel mining pits provide warm-water refugia for non-native predators. This activity has also depleted gravel abundance needed to replenish spawning habitat downstream. In addition, gravel and gold mining activities have contributed to the Lower Stanislaus River's listing as an impaired water body for mercury (2006 Clean Water Act section 303(d) list). Agricultural and urban landscape runoff contribute pesticide, herbicide, and fertilizer pollutants into the watershed.

Some restoration has been occurring to address the dearth in good flow and good gravels. In the spring, the Vernalis Adaptive Management Program (VAMP) flows are designed to stimulate outmigration for juvenile fall-run Chinook salmon, and consequently steelhead, into the Delta. CVPIA funding has provided funding for gravel augmentation to the river; however, more gravel is needed to replenish past losses as well as maintain current annual losses (NMFS 2009). Restoration actions that would restore viability: release of more flow to lower water temperature, dilute pollutants, and carry juveniles downstream to more suitable rearing habitat, and vary flow rates to provide more geomorphic function and increase habitat diversity. Restoration of riparian habitat in the lower river would also increase good habitat for steelhead and provide much needed refugia that is missing because of the off channel opportunities that are denied because of the lack of access to upper habitats.

Viability Potential for Existing Populations

Central Valley steelhead: **Low to moderate**

The Stanislaus River Watershed below New Melones dam can be characterized as having a **low to moderate** potential to support population of steelhead. Recent monitoring has detected small, self-sustaining populations of steelhead in the Stanislaus, Mokelumne, Calaveras, and other streams previously thought to be void of steelhead (McEwan 2001). In 2004, a total of 12 steelhead smolts were collected at Mossdale (CDFG unpublished data). In the 2006-7 season 12 steelhead were observed passing through a Stanislaus River counting weir (Anderson et al. 2007). Even with gravel augmentation and flow augmentation, the lack of off channel and small tributary habitat typical of steelhead systems, may make it unlikely for steelhead to recover a viable population, although many improvements in flow conditions and spawning gravels may give them a fighting chance.

In the Stanislaus River, nearly 90 percent of *O. mykiss* sampled were offspring of resident adults (Zimmerman et al. 2008). The uncertain participation of Merced and Tuolumne River water operations in spring pulse flows in the future can affect the diversity and continued existence of the Stanislaus River population and of the Southern Sierra diversity Group. As described in Lindley *et al.* 2007, there are almost no data with which to assess the status of any of the extant steelhead populations in the Central Valley, so these assessments need to be undertaken.

Potential for Historic Habitats to Support Spawning Populations

Above New Melones Dam:

Central Valley steelhead – **Moderate**

Central Valley Spring-run Chinook salmon - **Moderate**

The potential to support a viable population of spring-run salmon above New Melones dam in the upper Stanislaus River is **moderate**. This area above New Melones lies within the Stanislaus National Forest and the north fork Stanislaus is designated as Wild and Scenic, which offers further protection if volitional passage was achieved above the dam.

The potential to support a viable population of steelhead above New Melones dam in the upper Stanislaus is **moderate**. The habitat above the dam has the North, Middle and South Forks is reported to be suitable for steelhead. Much of the flow is however

through steep rocky canyons before joining to form the main stem of the Stanislaus River in the headwaters of the New Melones Reservoir. Therefore, the extent of steelhead habitat quantity is unknown and needs further investigation.

Key Threats and Stressors

Key threats and stressors to steelhead in the Stanislaus River include but are not limited to the following:

- ❖ Passage impediments/barriers at Goodwin, New Melones and Tulloch dams affecting adult immigration and holding
- ❖ Flow conditions (i.e., low flows) associated with attraction and migratory cues into the Stanislaus River affecting adult immigration
- ❖ Physical habitat alteration associated with limited supplies of instream gravel, habitat suitability and spawning habitat availability affecting adult spawning
- ❖ Flow conditions (i.e., flow fluctuations), particularly during flood releases, affecting spawning and embryo incubation
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Current summer water temperature objectives encouraging residency (J.D. Wikert, pers. comm., 2009)
- ❖ Changes in hydrology and channel morphology (e.g., reduced instream gravel recruitment, reduced channel complexity, increased predator habitats) affecting juvenile rearing and outmigration
- ❖ Loss of riparian habitat, floodplain and side-channel habitat, and instream cover affecting juvenile rearing and outmigration

Key Restoration Actions

- ❖ Manage releases from New Melones Reservoir in consideration of all steelhead life stages
- ❖ Implement the Spawning Gravel Augmentation Program (Reclamation); augment spawning gravel in suitable locations upstream of Oakdale (AFRP website 2005)
- ❖ Conduct feasibility studies for allowing steelhead access to habitat above New Melones Dam, including assessing habitat suitability and passage logistics (i.e., getting immigrating adults above the dam and emigrating juveniles below it)
- ❖ If the feasibility studies suggest that fish passage can be successful, then design and conduct an experimental fish passage program evaluating adult distribution, survival, spawning, and production in habitats above New Melones Dam

- ❖ If the experimental fish passage program demonstrates that passage above New Melones Dam can substantively contribute to the long-term viability of the DPS, then develop and implement long-term fish passage programs
- ❖ Evaluate pulse flow benefits for steelhead attraction and passage in the Stanislaus River; if pulse flows are determined to be effective for attracting steelhead, implement the most beneficial pulse flow regime
- ❖ Work with State and Federal water acquisition programs to dedicate instream water in the Stanislaus River

Watershed Description

The Stanislaus River originates in the western slopes of the Sierra Nevada and is one of the largest tributaries of the San Joaquin River. The Stanislaus River is approximately 113 miles long and covers an area of approximately 1,075 square miles (USFWS 2008) (Figure 18).

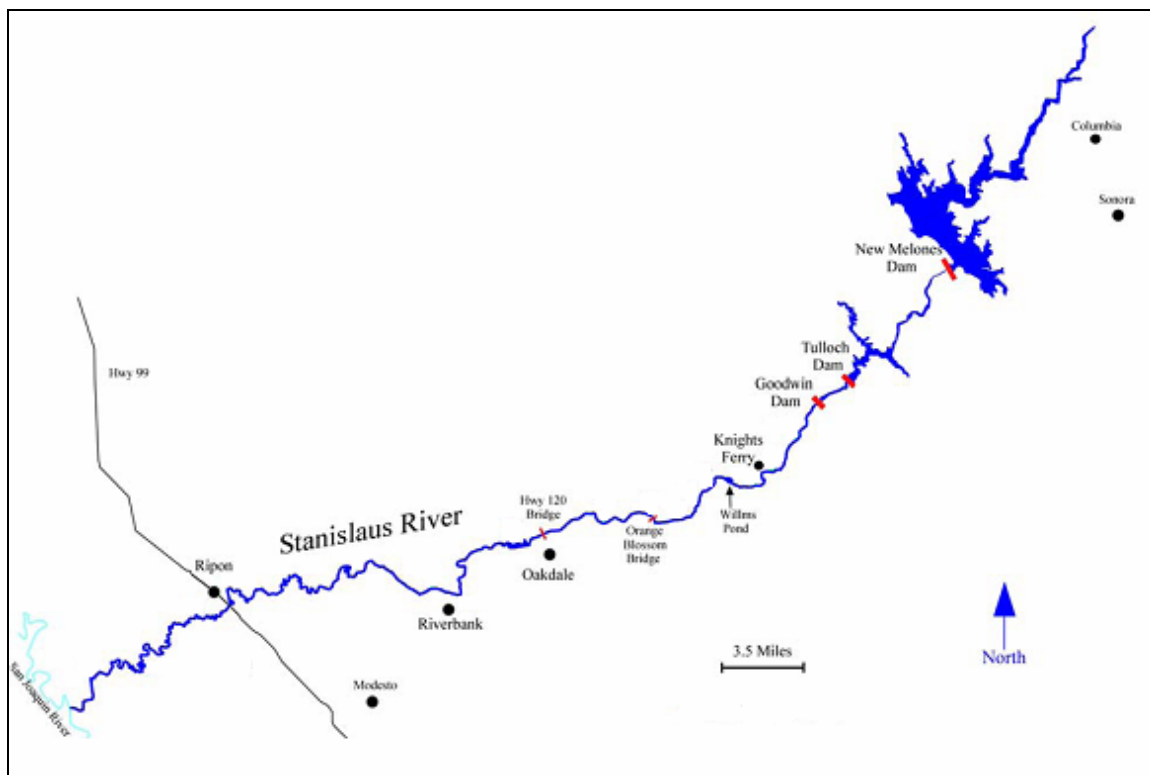

Figure 18. The Lower Stanislaus River between New Melones Reservoir and the San Joaquin confluence (Source: Modified from SRFG 2003)

The Stanislaus River is extensively dammed and diverted. Donnell's Dam on the middle fork forms Donnell Lake, high in the Sierra Nevada. Downstream is Beardsley Dam, which forms Beardsley Lake. McKays' Point Diversion Dam diverts water on the north

fork for hydroelectricity production and domestic use. The New Melones Dam blocks the river after the confluence of all three forks. Downstream from New Melones Lake, there is Tulloch Dam, which forms Tulloch Reservoir, and Goodwin Dam (RM 58), which is the first major barrier for anadromous fish on the Stanislaus River.

Geology

In the upper Stanislaus River watershed, the geology is primarily glaciated granite with mid-river reaches of metamorphic rock. Between Goodwin Dam and Knights Ferry, the rock is predominately volcanic. Below Knights Ferry, the river flows through Holocene alluvial deposits adjacent to late Pleistocene fill terraces.

Hydrology

The average unimpaired runoff in the watershed is about 1.2 million acre-feet (maf) (Reclamation 2008). The median historical unimpaired runoff is 1.1 maf per year, with a range of between 0.2 and 3.0 maf (USFWS 1995). Snowmelt contributes the largest portion of the flows in the Stanislaus River, with the highest runoff occurring in the months of April, May, and June (Reclamation 2008). Agricultural water supply development in the Stanislaus River watershed began in the 1850s and has significantly altered the basin's hydrologic conditions. The 32 dams within the Stanislaus River watershed large enough to be regulated by the Division of Safety of Dams have a total capacity of about 2.85 maf, or 237 percent of the average unimpaired runoff (SRFG 2003). The current hydrograph differs greatly from unimpaired flow conditions. Spring and summer flows are capped at 1,500 cfs (barring flood releases), while summer flows are increased to maintain downstream water quality.

Currently, New Melones Dam and Reservoir, completed by the Corps in 1979, is now the largest storage reservoir in the basin with a storage capacity of 2.4 maf, and was designed to control floods up to the 100-year-flood (Kondolf *et al.* 2001). New Melones Dam and Reservoir is located approximately 60 miles upstream from the confluence of the Stanislaus River and the San Joaquin River.

Another major water storage project in the Stanislaus River watershed is the Tri-Dam Project, a power generation project that consists of Donnell's and Beardsley Dams, located upstream of New Melones Reservoir on the middle fork Stanislaus River, and Tulloch Dam and Powerplant, located approximately 6 miles downstream of New Melones Dam on the mainstem Stanislaus River (Reclamation 2008). New Spicer Reservoir on the north fork of the Stanislaus River has a storage capacity of 189,000 af and is used for power generation. Releases from Donnell's and Beardsley Dams affect

inflows to New Melones Reservoir. Under contractual agreements between Reclamation, the Oakdale Irrigation District (OID), and South San Joaquin Irrigation District (SSJID), Tulloch Reservoir provides afterbay storage to reregulate power releases from New Melones Powerplant (Reclamation 2008).

The main water diversion point on the Stanislaus River is Goodwin Dam, located approximately 1.9 miles downstream of Tulloch Dam. Goodwin Dam, constructed by OID and SSJID in 1912, creates a re-regulating reservoir for releases from Tulloch Powerplant and provides for diversions to canals north and south of the Stanislaus River for delivery to OID and SSJID. Water impounded behind Goodwin Dam may be pumped into the Goodwin Tunnel for deliveries to the Central San Joaquin Water Conservation District and the Stockton East Water District (Reclamation 2008).

Twenty unengaged tributaries contribute flow to the lower portion of the Stanislaus River, below Goodwin Dam (Reclamation 2008). These streams provide intermittent flows, occurring primarily during the months of November through April. Agricultural return flows, as well as operational spills from irrigation canals receiving water from both the Stanislaus and Tuolumne Rivers, enter the lower portion of the Stanislaus River. In addition, a portion of the flow in the lower reach of the Stanislaus River originates from groundwater accretions (Reclamation 2008).

The New Melones Reservoir flood control operation is coordinated with the operation of Tulloch Reservoir. The flood control objective is to maintain flood flows at the Orange Blossom Bridge at less than 8,000 cfs. When possible, however, releases from Tulloch Dam are maintained at levels that would not result in downstream flows in excess of 1,250 cfs to 1,500 cfs because of seepage problems in agricultural lands adjoining the river associated with flows above this level (Reclamation 2008).

As part of the East Side Division of the Central Valley Project (CVP), New Melones Dam and Reservoir are operated by the Bureau of Reclamation (Reclamation). Flows in the lower Stanislaus River serve multiple purposes concurrently. The purposes include water supply for riparian water right holders, fishery management objectives, and dissolved oxygen (DO) requirements per State Water Resources Control Board Decision (D)-1422. Issued in 1973, SWRCB D-1422 provided the primary operational criteria for New Melones Reservoir and permitted Reclamation to appropriate water from the Stanislaus River for irrigation and M&I uses. Under D-1422, Reclamation was required to release up to 98 thousand acre-feet (taf) of water per year from New Melones Reservoir to the Stanislaus River on a distribution pattern to be specified each year by CDFG for fish and wildlife purposes (SRFG 2003). In addition, water from the Stanislaus River enters the San Joaquin River where it contributes to flow and helps

improve water quality conditions at Vernalis. D-1422 requires the operation of New Melones Reservoir include releases for existing water rights, fish and wildlife enhancement, and the maintenance of water quality conditions on the Stanislaus and San Joaquin rivers (Reclamation 2008).

More recently, CVP operations on the Stanislaus River have been guided by the New Melones Interim Plan of Operation (NMIPO) (Reclamation 2008). The NMIPO was developed as a joint effort between Reclamation and USFWS, in conjunction with the Stanislaus River Basin Stakeholders over a period of several years (SRFG 2003). The process of developing the plan began in 1995 with a goal to develop a management plan with clear operating criteria, given a fundamental recognition by all parties that New Melones Reservoir water supplies are overcommitted on a long-term basis, and consequently, unable to meet all the potential beneficial uses designated as purposes (Reclamation 2008). Although meant to be a short-term plan, it continues to be in effect and defines categories of water supply and operations criteria for the annual planning to meet beneficial uses from New Melones Reservoir storage (Reclamation 2008).

Instream fishery management flow volumes on the Stanislaus River, as part of the NMIPO, are based on a combination of fishery flows pursuant to the 1987 CDFG Agreement and the USFWS AFRP in-stream flow goals (Reclamation 2008). Dedication of (b)(2) water on the Stanislaus River also provides actual in-stream flows below Goodwin Dam greater than the fish and wildlife requirements previously identified for the East Side Division, and in the past has been generally consistent with the NMIPO (Reclamation 2008). Actual in-stream fishery management flows below Goodwin Dam will be determined in accordance with the Decision on Implementation of Section 3406 (b)(2) of the CVPIA. Reclamation has begun a process to develop a long-term operations plan for New Melones Reservoir, which will be coordinated with B2IT members, along with the stakeholders and the public before it is finalized (Reclamation 2008).

The operating criteria for New Melones Reservoir are affected by (1) water rights; (2) in-stream fish and wildlife flow requirements; (3) SWRCB D-1641 Vernalis water quality requirements; (4) dissolved oxygen (DO) requirements on the Stanislaus River; (5) SWRCB D-1641 Vernalis flow requirements; (6) CVP contracts; and (7) flood control considerations. Water released from New Melones Dam and Powerplant is re-regulated at Tulloch Reservoir and is either diverted at Goodwin Dam or released from Goodwin Dam to the lower Stanislaus River (Reclamation 2008).

Land Use

The lower Stanislaus River has been extensively developed to provide water, hydroelectric power, gravel, and conversion of floodplain habitat for agricultural and residential uses (SRFG 2003). While the upper reaches of the lower Stanislaus River (below Goodwin Canyon) remain relatively undeveloped, the river floodplain below Knights Ferry (with the exception of a narrow riparian border) has been converted to urban and rural development or used for agriculture (Wikert pers. comm. 2009). By 1994, it was estimated that approximately 50 percent of the riparian corridor along the lower Stanislaus River had been converted for agricultural, mining, and urban uses (USFWS 1995, as cited in KDH Environmental Services 2008).

Fisheries and Aquatic Habitat

The Stanislaus River historically had 113 miles of anadromous fish habitat (USFWS 2008), but currently only the lower 58 river-miles are accessible to anadromous fish, with access terminating at Goodwin Dam (KDH Environmental Services 2008). Historically, spring-run Chinook salmon were believed to be the primary salmon run in the Stanislaus River, but the fall-run population became dominant following construction of Goodwin Dam, which blocked upstream migration between 1913 and 1929 (in Yoshiyama *et al.* 1996; NMFS 2009). It is likely that hydraulic mining caused the initial decline of the salmon and steelhead runs in the Stanislaus River, because the early dams were too small to substantially affect flows and they did not completely block the salmon's upstream migration until Old Melones Dam was constructed in 1926 (SRFG 2003).

Although records on anadromous salmonids in the San Joaquin tributaries are sparse (Yoshiyama *et al.* 1998), the Stanislaus River still provides valuable spawning and rearing habitat for fall-run Chinook salmon and steelhead (NMFS 2004). Spawning is focused on the extensive gravel beds located from the town of Riverbank to Knights Ferry, with 95 percent of fall-run Chinook salmon spawning occurring from Orange Blossom Road to Knights Ferry (NMFS 2008). One mile upstream of Knights Ferry, spawning is concentrated at Two-Mile Bar (NMFS 2008).

Compared to historic conditions, the area of suitable salmonid spawning and rearing habitats has been substantially reduced due to anthropogenic influences including dam construction, in-river aggregate mining, and the conversion of floodplain habitat for agricultural uses (KDH Environmental Services 2008). A series of dams in the Stanislaus River has blocked access to spawning habitat in the upper river, and has blocked the transport of gravel to downstream reaches (KDH Environmental Services 2008). Gravel

recruitment was reduced by 92 percent following construction of Goodwin Dam in 1912 (KDH Environmental Services 2008). Mobilization of gravel and fines below Goodwin Dam was further reduced in 1981 when the expansion of New Melones Dam reduced the frequency and magnitude of flooding in the lower reaches (Kondolf *et al.* 2001, as cited in KDH Environmental Services 2008), inhibiting the flushing of fine particles from coarser bed materials (CDWR 1994, as cited in KDH Environmental Services 2008). Along most of the lower Stanislaus River, agricultural and urban encroachment has separated the river from its floodplain. As a result, the channel is incised, which prevents the river from developing and maintaining shallow spawning and rearing habitats necessary for salmonids.

Gold and aggregate mining also have had a detrimental effect on spawning and rearing habitats in the Stanislaus River (KDH Environmental Services 2008). Approximately 40 percent of historic gravel beds were excavated from the 13.6-mile reach between Goodwin Dam and Orange Blossom Bridge between the years 1939 and 1980 for gold and aggregate mining purposes (Mesick 2003, as cited in KDH Environmental Services 2008). Mining activities left instream pits and long, uniform ditches 5 to 10 feet deep and 100 to 165 feet wide in the active channel near Lover's Leap from RM 53.4 downstream to RM 51.8. Gravels entering the river from tributaries below Goodwin Dam, or mobilized in high flow events become trapped in these pits rather than replenishing downstream riffles (SRFG 2003). Furthermore, these ditches sustain large populations of predatory fish, but provide little habitat for salmonids (KDH Environmental Services 2008).

Isolation of floodplain and riparian habitats from the Stanislaus River by dikes also has had a negative impact on salmonid spawning and rearing habitats (KDH Environmental Services 2008). Dikes confine flood flows to the river channel, increasing the rate of scouring of gravel from spawning and rearing habitat (KDH Environmental Services 2008).

Reduced gravel recruitment, in-river gravel mining, and the loss of functional floodplain, have severely reduced the quality and quantity of the spawning and rearing habitat for anadromous salmonids in the lower Stanislaus River (KDH Environmental Services 2008). The limited riffle habitat that remains has become armored and shortened due to erosion and the blockage of gravel recruitment (Mesick 2001, as cited in KDH Environmental Services 2008).

Restoration actions conducted to date have been limited to spawning gravel augmentation and providing additional water to supplement Stanislaus River flows in accordance with Section 3406(b)(2) and 3406(b)(3) provisions of the Central Valley

Project Improvement Act (CVPIA)⁸. Additional restoration work is needed to replace gravel lost to mining and dams, and to provide additional floodplain habitat to replace that which has been lost due to the flattening of the hydrograph (USFWS 2008).

In September 2007, the Lover's Leap Restoration Project was implemented in the lower Stanislaus River near Lover's Leap, and was intended to replenish spawning gravel at existing and new restoration sites and to restore riverbed topography (KDH Environmental Services 2008). The overall objective was to increase and improve steelhead (and Chinook salmon) spawning and rearing habitat by adding approximately 18,000 tons of cleaned spawning-sized gravels and roughly 7,000 tons of larger cobble to degraded areas within the 25.5 mile salmonid spawning reach. (KDH Environmental Services 2008) Increasing the area of suitable spawning habitat should increase the abundance and condition of Chinook salmon and steelhead by reducing the effect of density dependent factors such as redd superimposition and by decreasing the area of habitat available for predatory fish (KDH Environmental Services 2008).

Steelhead

Central Valley steelhead were thought to be extirpated from the San Joaquin River system. However, monitoring has detected small self-sustaining (i.e., non-hatchery origin) populations of steelhead in the Stanislaus River and other streams previously thought to be devoid of steelhead (McEwan 2001).

A fish counting weir operated in the river near the town of Riverbank has documented the passage of large *Oncorhynchus mykiss* upstream. However, surveys have not been conducted to determine where steelhead spawn in the Stanislaus River, but it is presumed that a majority of spawning occurs between Goodwin Dam and the Orange Blossom Bridge (SRFG 2003). The potential spawning sites with holding and feeding habitat, and spawning-sized gravel where large adults are frequently caught with hook-and-line include the four gravel addition sites in Goodwin Canyon, eight of the Knights Ferry Gravel Replenishment sites near Lovers Leap, Horseshoe Road, and Honolulu Bar, and four riffles adjacent to deep mine pits near Frymire Ranch, "Willms Pond", and Button Bush Park. Although the abundance of steelhead is not surveyed in the

⁸ Section 3406(b)(2) of the CVPIA directs the Secretary of the Interior to dedicate and manage annually eight hundred thousand acre-feet of Central Valley Project yield for the primary purpose of implementing the fish, wildlife, and habitat restoration purposes and measures authorized by the CVPIA. The 800,000 acre-feet of water dedicated by the CVPIA is referred to as "(b)(2) water."

Stanislaus River, the catch of adult steelhead using hook-and-line began to increase in 1997 and again in 1999 (SRFG 2003).

Juvenile salmonid monitoring has been conducted at Oakdale and/or Caswell on the Stanislaus River since 1995, and is used to estimate abundance of out-migrating fall-run juvenile Chinook salmon (*O. tshawytscha*) and Central Valley steelhead/rainbow trout (*O. mykiss*) to the San Joaquin River as part of the U.S. Fish and Wildlife Service's Anadromous Fish Restoration Program (AFRP) (USFWS 2008; USFWS 2008a). Steelhead smolts also have been captured in the rotary screw traps at Caswell State Park and Oakdale each year since 1995 (Cramer and Associates Inc. 2000; 2001). Studies by CDFG also have documented juvenile *O. mykiss* in the river with maternal anadromy using SR:Ca ratios. More recently, Zimmerman *et al.* (2008) has documented steelhead in the Stanislaus River based on otolith microchemistry.

Based on surveys conducted during 2000 and 2001, Fisheries Foundation (2002 in SRFG 2003) reports that young steelhead began to emerge from the gravel in the upper spawning reaches by April, and they were abundant from May through September. Juvenile fish were most abundant at the upper Goodwin Canyon site and Two-Mile Bar and least abundant at Oakdale (the lowermost study site). Trout parr were observed downstream to Honolulu Bar by June, where they remained common throughout the summer and fall. Few juvenile fish were observed at Oakdale where water temperature was the highest, ranging between 64.4 and 68°F (Fisheries Foundation 2002 in SRFG 2003). Yearling and post-yearling trout were concentrated in the upper river for most of the 2000 and 2001 surveys at the upper Goodwin Canyon site and Two-Mile Bar (Fisheries Foundation 2002 in SRFG 2003). A few fish were observed in lower reaches whereas some were abundant at the experimental sites (Knight's Ferry, Lovers Leap, and Orange Blossom). Water temperatures rarely exceeded 59°F in the upper reaches, whereas downstream temperatures were near or at stressful levels of 64.4 and 68°F during most of the summer. Yearling trout were slightly more abundant in 2001 than in 2000 in downstream reaches as water temperatures were slightly lower with higher flows in 2001. Abundance at the upper Goodwin Canyon site and Two-Mile Bar appeared to increase over the summer, which may indicate a positive upstream movement of yearling trout to the cooler water below Goodwin Dam (Fisheries Foundation 2002 in SRFG 2003).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration Potential

Prior to the arrival of European pioneers and explorers, steelhead trout and spring-run salmon occurred throughout the Tuolumne River drainage. Currently, steelhead populations in the Stanislaus, Tuolumne, Merced, and Calaveras rivers are the *only remaining representatives* of the Southern Sierra Nevada diversity group of the Central Valley steelhead (NMFS 2009). However, none of these populations are considered to be viable at this time (Lindley *et al.* 2007), although they are considered persistent. New research is showing what contribution hatcheries and native trout are contributing to this persistence and anadromy. Spring-run salmon have been extirpated from the Tuolumne River due to human developments such as dams, diversions, mining and urbanization.

It is reported that the remaining accessible prime spawning reach of the lower Tuolumne River (which has the largest naturally reproducing population of Chinook in the San Joaquin Valley) suffers from lack of native riparian vegetation, fine sediment overloading, high stranding, and a floodplain disconnected from its channel (Tuolumne River Preservation Trust 2002).

Over the past several years, the Anadromous Fish Restoration Program (AFRP) has been working with the Tuolumne River Technical Advisory Committee (TRTAC) and the FERC Settlement Agreement framework to develop restoration and monitoring strategies (USFWS 2008). These strategies include utilizing an integrative approach to reestablish critical ecological functions, processes and characteristics that, under regulated flow and sediment conditions, promote recovery and maintenance of a resilient, naturally reproducing salmon population and the river's natural animal and

plant communities (USFWS 2008). Initial priorities include: (1) continue to develop and fund the remaining two segments within the 6-mile Mining Reach; (2) complete restoration of two large in-channel pits; (3) develop a sediment management plan that will protect and restore critical spawning and rearing areas in the upper Tuolumne River; (4) work with agriculture and municipal interests in the lower river to establish and restore a riparian corridor for river function; and (5) continue to work with local interests and the U. S. Army Corps of Engineers (Corps) on a flood protection strategy (USFWS 2008). The AFRP also is working with the TRTAC to finalize river-wide and project-specific monitoring strategies that will guide adaptive management and allow the TRTAC to evaluate efficacy of FERC Settlement Agreement actions (USFWS 2008).

Viability Potential for Existing Populations:

Central Valley Steelhead – Low to Moderate

The lower Tuolumne River is characterized as having a *Low to Moderate* potential to support a viable independent or persistent population of steelhead. Extensive habitat restoration has already occurred in the lower watershed through AFRP programs and other agreements. Lower Tuolumne restoration is limited by low flows, so it is unclear the current restoration could increase production of steelhead unless flows were improved. Projects already funded by CALFED have helped with riparian areas. These improvements include increases in shade and channel complexity, which over time could support better rearing. Despite these improvements, the lower Tuolumne River does not have the channel complexity, off channel rearing habitats and the tributary habitats to support a thriving population of steelhead, thus the chances for this lower system to support a viable population are tenuous until further flow and gravel augmentation measures are implemented.

Potential for Historic Habitats to Support Spawning Populations

Above La Grange and Don Pedro:

Central Valley steelhead –**Moderate**

Central Valley spring-run Chinook salmon –**Moderate**

The upper Tuolumne River is characterized as having a *moderate* potential to support a spawning population of spring-run salmon and steelhead. Habitat quality above the Don Pedro and La Grange system historically was good and supported a population of spring-run salmon. Because of its historic importance the upper Tuolumne River should be considered a **candidate** area for recovery. Upper Tuolumne habitats are also

protected because they go through an area of Wild and Designation downstream of the Yosemite National Park.

Key Threats and Stressors

Key threats and stressors to Central Valley steelhead in the Tuolumne River include, but are not limited to, the following:

- ❖ Passage impediments/barriers in the Tuolumne River at La Grange and Don Pedro dams affecting adult immigration and holding
- ❖ Flow conditions (i.e., flow fluctuations, low flows) affecting attraction and migratory cues for adult immigration and holding, spawning and embryo incubation, and flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Physical habitat alternation associated with limited supplies of instream gravel, and suitability of available habitat affecting adult spawning
- ❖ Water temperature and water quality effects on adult immigration and holding, spawning, and juvenile rearing and outmigration

Key Actions

- ❖ Continue with research to determine the distribution of steelhead and assess the relationship between resident and anadromous forms of *O. mykiss*
- ❖ Improve production of native Steelhead trout by improving adequate temperature and flow regimes, especially for juvenile rearing
- ❖ Improve project operations, outlet modifications, and establishment of minimum pools for reservoirs so that cool water temperatures could be provided in late-summer and fall Install fishways on presently impassable dams to allow access to tail water habitat

Watershed Description

Draining an area of about 1,900 square miles, the Tuolumne River originates in Yosemite National Park and flows southwest through Yosemite, Stanislaus National Forest and private lands to its confluence with the San Joaquin River, approximately 10 miles west of Modesto, California (SFPUC 2009; TRTAC 1999). With its headwaters above the 10,000-foot level in Yosemite National Park, the Tuolumne River is one of the largest rivers in California's Sierra Nevada mountain range. The mainstem of the river begins in Tuolumne Meadows at the confluence of streams descending from the slopes of Mt. Lyell (13,100 feet) and Mt. Dana (13,155 feet). From there the river descends

through the steep Yosemite wilderness, including the Tuolumne's own "Grand Canyon," before its flow is impounded by the O'Shaughnessy Dam in Hetch Hetchy Valley (3,500 feet). Similar to most major rivers in the Sierra Nevada, the Tuolumne River is dammed in several locations, principally to provide reliable water supplies for California's farms and cities. La Grange Dam marks the upstream extent of currently accessible anadromous salmonid habitat. From La Grange Dam, the Tuolumne River flows in a westerly direction for approximately 50 miles before entering the San Joaquin River.

Geology

At higher elevations, the watershed is composed primarily of granitic bedrock that was scoured by glaciers during glacial periods down to the location of O'Shaughnessy Dam, resulting in mountainous terrain, patchy forests, and a variety of steep canyons and mountain meadows. The middle portion of the watershed from Don Pedro Reservoir to above Hetch Hetchy Reservoir is characterized by deep canyons and forested terrain. Near the town of La Grange, the river exits the Sierra Nevada foothills and flows through a gently sloping alluvial valley that is incised into Pleistocene alluvial fans (SFPUC 2009).

Hydrology

As reported by USFWS (1995), the median historical unimpaired runoff is 1.8 million acre-feet (maf), with a range of 0.4 maf to 4.6 maf. About 60 percent of the Tuolumne River flow occurs between April and June, when warm weather melts the Sierra snowpack. Similar to most other California rivers, flows in the Tuolumne River vary widely with annual precipitation. In about one out of every four years, the annual flow is less than 1.1 million acre-feet.

The Don Pedro Project is the largest reservoir located above the spawning reach on the Tuolumne River. Don Pedro Reservoir is owned by the Turlock Irrigation District (TID) and the Modesto Irrigation District (MID) and is licensed by the Federal Energy Regulatory Commission (FERC). TID and MID jointly regulate the flow to the lower river downstream of Don Pedro Reservoir, which has a gross storage capacity of 2.0 maf. In addition to providing power and irrigation, water storage in Don Pedro Reservoir is also managed to prevent the Tuolumne River from flooding Modesto and surrounding areas.

The river above Don Pedro Reservoir is regulated by three reservoirs (Cherry Lake, Lake Eleanor, and Hetch Hetchy Reservoir) owned and operated by the City and

County of San Francisco. These reservoirs have a combined storage capacity of 800 thousand acre-feet (taf) or more. During each of the past 10 years, approximately 220 taf of Tuolumne River water has been annually exported to San Francisco. Hetch Hetchy Reservoir, with 360,000 acre-feet of storage capacity, is the largest reservoir in the upper watershed. Other small impoundments in the watershed include Modesto Reservoir (29 taf) and Turlock Lake (45.6 taf). LaGrange Dam, located downstream of Don Pedro Dam, diverts approximately 900 af per year for power, irrigation, and domestic purposes. LaGrange Dam is the upstream barrier to salmon migration (USFWS 1995).

Land Use

Agriculture, ranching, mining, and tourism dominate the region, and many people depend on the river for their sustained livelihoods (TRTAC 1999). The lower Tuolumne River has an extensive history of gold mining, municipal and agricultural water storage, power generation, agriculture, and recreation. Large dredges were used for gold mining and in recent years, the dredger tailings have been mined for gravel.

Fisheries and Aquatic Habitat

The San Joaquin River and its tributaries (e.g., Tuolumne River) once supported populations of both spring and fall-run Chinook salmon (Yoshiyama et al. 1996, 1998, as cited in SFRG 2003). Spring-run Chinook salmon were extirpated from the San Joaquin Drainage by the late 1940's. Since then, fall-run salmon have declined by more than 90 percent and the populations remaining are in jeopardy of further decline (USFWS 2004). In the past, steelhead probably existed in the Tuolumne River. However, in recent years, a few confirmed reports of steelhead in the San Joaquin River drainage have been received, suggesting a viable but very small population (USFWS 2004).

Historically, the Tuolumne River Watershed is reported to have contained about 99 miles of anadromous fish habitat, and currently contains about 47 miles of habitat for fall-run Chinook salmon and steelhead (USFWS 2008). The lower Tuolumne River once hosted an extensive track of this riparian forest much of which has been removed due to growing urban settlement and extensive agriculture in the area (Tuolumne River Trust 2009). Past gravel-mining operations have reduced the low flow and bank-full channel capacity and changed the channel morphology of the Tuolumne River. In 1998, efforts to restore the lower Tuolumne River were initiated to restore the channel to its "pre-mining" condition.

Constructed in 1893, the La Grange Dam (RM 52.2) presents an impassable barrier to upstream migrating anadromous salmonids and marks the upstream extent of currently

accessible steelhead habitat in the Tuolumne River. Dam construction ended the coarse sediment supply from the Tuolumne River Watershed upstream of the town of La Grange, and sediment transported during high flows have come from the bed itself or limited floodplain deposits (USFWS 2008a). Elimination of upstream sediment supply also has caused bed particle coarsening in the spawning reach near La Grange.

The Chinook salmon runs of the Stanislaus, Tuolumne, and Merced Rivers are perhaps the southernmost in the species range, and summer water temperatures appear to be among the primary factors determining the life-history strategies of these population, as well as those of steelhead (Hume 2005). Permanent upstream fish passage impairment dates back to dams constructed in the 19th century, eliminating access to cold-water refugia above the present dams. Unanticipated effects have resulted in the reduction of the timing window available for Chinook salmon and steelhead spawning because: (1) elevated water temperatures in the Delta, the San Joaquin River, and lower reaches of the tributaries usually prevent young salmon from migrating out of the tributaries much after May; (2) elevated water temperatures in the lower and middle reaches of the tributaries limit the effectiveness of life-history strategies which require over-summering by adults or juveniles; and (3) elevated water temperatures in the lower reaches of the tributaries usually prevent adult returns from spawning much before October (Hume 2005).

One of many stressors identified in recent studies on the Tuolumne River that limit salmonid populations are the aggregate extraction pits, which are a byproduct of extensive in-stream and off-channel mining (Turlock Irrigation District 2001). Many of these instream and off-channel pits have negatively impacted salmonid populations by stranding juveniles in ponds and fostering large populations of non-native predator fish (bass). Additionally, spawning and rearing habitats have been negatively impacted by either complete removal during aggregate extraction, degradation by channel encroachment from dikes along mining pits, or fine sediment infiltration. Many of the off-channel pits have only a small berm of undisturbed native material separating them from the river. Common floods (e.g., 1983, 1986, 1995, & 1998) of less than 8,000 cfs regularly breach some of these brims resulting in entrapment of salmon fry and smolts (Turlock Irrigation District 2001).

Given the large potential to make significant improvements in wild salmon production and the success of the TRTAC in promoting river-wide restoration goals, the CALFED – ERP has designated the Tuolumne River as one of three “Demonstration Streams” in the Central Valley. The problems that are the focus of the Tuolumne River restoration program fall into two major categories: (1) impairment of geomorphic and ecosystem processes caused by flow regulation, gold and aggregate mining, and land uses, and (2)

reduction in fall-run Chinook salmon population abundance and resiliency (Turlock Irrigation District 2001).

Steelhead

The California Department of Fish and Game (CDFG) has conducted fall-run Chinook salmon spawning surveys on the Tuolumne River since 1971, as required under the cooperative fish study program for the Don Pedro Project FERC license (TID/MID 2009). The Tuolumne River supports a population of fall-run Chinook salmon, whose numbers have fluctuated from about 40,000 fish in 1985, to a low of 77 fish in 1991, and have subsequently shown a decline from 17,873 fish in 2000 to 7,173 (2002), 1,984 (2004), 719 (2005), 625 (2006), 224 (2007), and 455 (2008) (CDFG 2009). Incidental catches and observations of juvenile steelhead have occurred on the Tuolumne River during fall-run Chinook salmon monitoring activities (Good *et al.* 2005).

Although some steelhead reportedly persist in the Tuolumne River, debate over historical distribution and less emphasis on commercial value have shifted the primary focus of restoration efforts from steelhead to fall-run Chinook salmon in the Tuolumne River Basin (McBain and Trush 2000). However, more recent fisheries monitoring for the Don Pedro Project (FERC Project No. 2299) by the TID and MID has documented the presence of *Oncorhynchus mykiss* in the lower Tuolumne River (TID/MID 2005). Additionally, as part of the April 3, 2008 FERC Order on Ten-Year Summary Report Under Article 58, TID and MID were required to start conducting *O. mykiss* population estimate surveys during the summer (June/July) and winter (February/March) of 2008 to determine population abundance by habitat type. The purpose of the *O. mykiss* population surveys is to provide population size estimates over several sampling seasons of differing environmental conditions to determine habitat use and needs within the lower Tuolumne River. Reportedly, a total of 135 young-of-the-year (YOY)/juvenile (< 150 mm FL) and 45 adult (> 150 mm FL) (180 total) *O. mykiss* were observed from RM 51.8 to RM 41.1 within the study reach extending down to RM 39.6 (TID/MID 2009a). Most juveniles were found in riffles and the upstream end (heads) of run habitat, while adults mainly were found within pool heads and riffles. Using a bounded counts population estimator, approximately 3,096 *O. mykiss* were estimated within the survey reach, with 95% confidence bounds of 1,905–3,047 and 325–914 YOY/juvenile and adult size classes, respectively (TID/MID 2009a).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration Potential

Prior to the arrival of European pioneers and explorers, steelhead trout occurred throughout the upper Merced River drainage, occupying aquatic habitat as far upstream as Yosemite Valley on the mainstem, and probably, as far upstream on the South Fork, beyond Wawona, and most of its lower elevation tributaries (such as Skeleton Creek) as reported by Miller 2008. Currently, steelhead are present in the Merced River and spawn between Crocker Huffman Dam (RM52) and Highway J59 Bridge Crossing (RM42). Steelhead populations in the Stanislaus, Tuolumne, Merced, and Calaveras rivers are the *only remaining representatives* of the Southern Sierra Nevada diversity group of the Central Valley steelhead (NMFS 2009). However, none of these populations are considered to be viable at this time (Lindley *et al.* 2007). The Merced River in particular is considered to be the most impacted of these southern rivers in terms of loss of flow, good gravels for steelhead, as well as poor water quality as a result of development and agriculture, so much habitat and hydrologic restoration is needed to ever see viable populations of steelhead again in the lower Merced River.

At this time, there are three obstructions to migrating fish: Crocker Huffman irrigation diversion near Snelling, Merced Falls Dam, and Exchequer. The direct and cumulative effect of these dams is that access to greater than 96% of the original historically available spawning and rearing habitat on the Merced River for *O. mykiss* (Steelhead trout) and other anadromous fishes (spring-run, fall-run and late fall-run Chinook

salmon, lamprey) has been eliminated by impassable barriers and/or inundation. (Martin 2008, Schick *et al* 2005). Suitable *O. mykiss* and *O. tshawytscha* spawning and juvenile rearing habitat is now restricted to the Merced River reach between Crocker-Huffman Diversion Dam (RM 52) and the Highway J59 Bridge Crossing (RM 42). Reduction and modification of seasonal flow from the operation of the Project dams has adversely impacted the restricted *O. mykiss* accessible spawning and rearing habitat in this reach through interference with spawning gravel replenishment and armoring of gravel beds and instream flow regimes.

It is likely that steelhead numbers could be restored to the lower Merced River in better numbers *if temperature and flow standards are established that would provide for juvenile rearing*. Also, not much is known about steelhead numbers and current habitat uses in the southern sierra diversity group. Lindley *et al.* (2007) recommend that in order to assess the risk of extinction or develop effective recovery actions for steelhead in the Central Valley, determining the distribution of steelhead and assessing the relationship between resident and anadromous forms of *O. mykiss* is a fundamental need. Lindley *et al.* (2007) stress that any quantitative assessment of population viability would be inadequate unless the role resident fish play in population maintenance and persistence of *O. mykiss* in the Central Valley is known.

Viability Potential for Existing Populations

Central Valley Steelhead below Crocker Hoffman– *Low to Moderate*

The lower Merced River is characterized as having a ***Low to Moderate*** potential to support a viable independent or persistent population of steelhead. Extensive habitat restoration has already occurred in the lower Merced. These improvements include increase in shade and channel complexity, which over time could support better rearing. Despite these improvements, the lower Merced River does not have the channel complexity, off channel rearing habitats and the tributary habitats to support a thriving population of steelhead, thus the chances for this lower system to support a viable population are tenuous until further flow and gravel augmentation measures are implemented.

Potential for Historic Habitats to Support Spawning Populations

Above Crocker-Huffman Dam and New Exchequer system:

Central Valley steelhead – ***Low to Moderate***

Central Valley spring-run Chinook salmon – ***Low to Moderate***

The upper Merced River is characterized as having a *low to moderate* potential to support a spawning population of spring-run salmon. Habitat quality above the New Exchequer system *historically was good and supported a population of spring-run salmon*. Because of its historic importance the upper Merced River should be considered a **candidate** area for recovery. A Limitation to the spring-run and steelhead population is the series of dams throughout this system that would need to be made passable or removed. As well, the lack of good off channel and side channel habitat remain a substantial challenge to steelhead recovery.

How will the Merced River help to buffer the negative effects of climate change for salmonids in the Central Valley?

Under the expected climate warming of around 5°C, substantial salmonid habitat would be lost in the Central Valley, with significant amounts of habitat remaining primarily in the upper Feather and Yuba rivers, and remnants of habitat in the upper Sacramento, McCloud, and Pit rivers, Battle and Mill creeks, and the Stanislaus River (Lindley et al. 2007). Under the less likely but still possible scenario of an 8°C warming, spring-run Chinook salmon habitat would be found only in the upper-most reaches of the north fork Feather River, Battle Creek, and Mill Creek (Lindley et al. 2007).

In addition, while warming may pose as a key threat to spring-run Chinook salmon in the Central Valley, suitable water temperature conditions should persist longer in areas where fish can reach higher altitudes (Williams 2006). Some existing or potential habitat should also remain for some time below various dams that currently release cool water through the summer (Williams 2006).

Key Threats and Stressors

Key threats and stressors (i.e., identified as “Very High”) to Central Valley steelhead in the Merced River include, but are not limited to, the following:

- ❖ Passage impediments/barriers at the Crocker Huffman, McSwain, and New Exchequer dams blocking/impeding adult immigration
- ❖ Flow conditions (i.e., low flows) associated with attraction, migratory cues, flood flows and the attraction of non-natal fish into the Merced River affecting adult immigration and holding
- ❖ Physical habitat alteration associated with limited supplies of instream gravel, habitat suitability and spawning habitat availability affecting spawning
- ❖ Water temperatures affecting adult immigration and holding, and spawning
- ❖ Flow fluctuations affecting spawning and embryo incubation

- ❖ Changes in hydrology affecting juvenile rearing and outmigration
- ❖ Flow dependent habitat availability affecting juvenile rearing and outmigration
- ❖ Loss of riparian habitat and instream cover affecting juvenile rearing and outmigration

Key Watershed Restoration and Recovery Actions

- ❖ Improve production of native Steelhead trout by improving adequate temperature and flow regimes, especially for juvenile rearing
- ❖ Improve project operations, outlet modifications, and establishment of minimum pools for reservoirs so that cool water temperatures could be provided in late-summer and fall Install fishways on presently impassable dams to allow access to tail water habitat
- ❖ Improve stock production through hatchery facility supplementation to native steelhead trout populations
- ❖ Maintain, enhance, or restore populations of Steelhead trout in tailwater aquatic habitats caused by project dams and lack of volitional fish bypass
- ❖ Maintain, recover, and restore stream flow regimes sufficient to sustain desired conditions for populations of Steelhead trout, defined as keeping the tailwater fishery in 'good condition' *sensu* California Fish and Game Code 5937
- ❖ Maintain, enhance, or restore populations of native aquatic biota, including fish, benthic macroinvertebrates, and riparian species to be viable with adequate habitat consistent with species' needs
- ❖ Maintain, enhance, or restore all life stages of native aquatic species by ensuring connectivity between project-affected stream reaches, between reaches of mainstem river and their tributaries, and between reservoirs and reaches of mainstem river

Watershed Description

The Merced River is a tributary to the San Joaquin River in the southern portion of California's Central Valley. The Merced River originates in Yosemite National Park and drains an area of 1,276 square miles as it flows down the western slope of the Sierra Nevada range into the Central Valley, eventually joining the San Joaquin River about 87 miles south of Sacramento, California (**Figure 19**). Elevations in the watershed range from 4,000 m at its headwaters to 15 m at the San Joaquin River confluence (USFWS 2007).

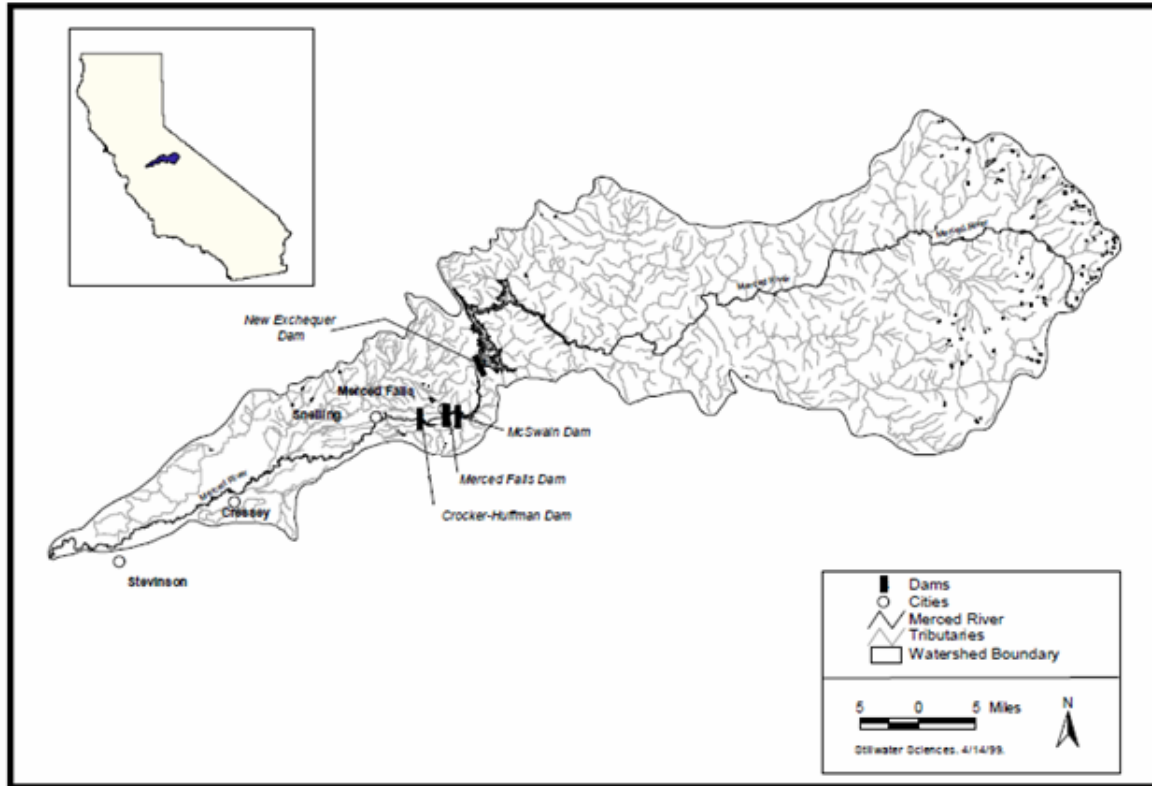

Figure 19. The Merced River Watershed (Source: Modified from Stillwater Sciences 2001)

The upper Merced River watershed encompasses approximately 700,000 acres from the headwaters near Triple Divide Peak to the New Exchequer Dam on Lake McClure, the main storage reservoir on the river (capacity 1 million acre-ft.). A significant part of the Merced River headwaters lies within Yosemite National Park (312,334 acres), while about 272,000 acres lie within the jurisdiction of lands managed by the United States Forest Service and the Bureau of Land Management. Downstream of New Exchequer Dam, the floodplain extent and connectivity in the Merced River have been affected by both flow regulation and levee construction. Flow regulation has reduced flood magnitude and, thus, reduced the extent and frequency of floodplain inundation. In addition, in the reach from Crocker-Huffman Dam to Shaffer Bridge, the river has been converted from a multiple-channel system to a single-channel system, and remnant sloughs have been converted to irrigation canals and drains.

Geology

The following information on geology in the Merced River is taken directly from the *Merced Wild and Scenic Revised Comprehensive Management Plan and Supplemental EIS* (National Park Service 2005).

The Merced River gorge begins at the west end of Yosemite Valley where the gradient of the Merced River abruptly increases and the river enters the gorge. The gorge has remained an incised, V-shaped feature because the most recent glacial events did not extend down the Merced River beyond Yosemite Valley. The transition from the U-shaped, glaciated Yosemite Valley to the steep-gradient, V-shaped, incised Merced River gorge, is identified a feature of the geologic Outstandingly Remarkable Value.

The granitic rocks within the Merced River gorge consist primarily of tonalite; the Bass Lake tonalite is the dominant bedrock feature. Among some of the oldest rocks found in the Sierra Nevada are those just east of El Portal, in the walls of the Merced River gorge. These rocks are metamorphic and remnants of ancient sedimentary and volcanic rocks that were deformed and metamorphosed, in part by granitic intrusions (Huber 1989). This metamorphosed sedimentary rock (which includes banded chert) was once part of the ocean floor that covered the region about 200 million years ago (Huber 1989). The transition from igneous to metasedimentary rocks is identified as a feature of the geologic Outstandingly Remarkable Value in the El Portal segment of the river.

The soils in relatively flat topographic positions in the Merced River gorge and El Portal form from glacial and alluvial sediment deposition processes originating in Yosemite Valley, or by alluvial and colluvial deposition occurring locally within the gorge or near El Portal. Soils that formed in old river channels consist of alluvial boulders, cobbles, river wash, and loamy sands.

Hydrology

The overall climate in the Merced River Basin is temperate, with hot, dry summers and cold, wet winters. The average annual precipitation in Yosemite Valley is 36.5 inches. Annual precipitation decreases to 25 inches in El Portal (2,000 feet) and increases to 70 inches in the red fir forest at 6,000 to 8,000 feet (Eagan 1998, as cited in National Park Service 2005). At elevations above 5,000 feet, 80 percent of the annual precipitation falls as snow.

Similar to other rivers originating from the west side of the Sierra Nevada mountains, flow in the Merced River is typified by late spring and early summer snowmelt, fall and winter rainstorm peaks and low summer base flows (Stillwater Sciences 2001). Snowmelt drives the peak stream flows that occur in May and June, and minimum river flow is observed in September and October (National Park Service 2005). About 85 percent of precipitation falls between November and April, and the highest average precipitation generally occurs during December, January, and February (National Park Service 2005).

Four mainstem dams affect flow conditions in the lower Merced River. The two largest dams are New Exchequer Dam (which impounds Lake McClure) and McSwain Dam (which impounds Lake McSwain) (USFWS 2007; USFWS 1995; Stillwater Sciences 2001). These dams, which are known collectively as the Merced River Development Project, are owned by Merced Irrigation District (Merced ID) and are licensed by the Federal Energy Regulatory Commission. Merced Falls Dam and Crocker-Huffman Dam are low diversion dams which divert flow into the Merced ID Northside Canal and Main Canal, respectively. Merced Falls Dam is owned by Pacific Gas and Electric; Crocker-Huffman Dam is owned by Merced ID. Three additional small dams (i.e., MacMahon, Green Valley, and Metzger) are located on tributaries upstream of the New Exchequer Dam. These dams have a combined reservoir capacity of 835 acre-feet. Also, Kelsey Dam impounds a small (972 acre-feet) reservoir on Dry Creek, the only major tributary to the Merced River downstream of the mainstem dams (Stillwater Sciences 2001).

The New Exchequer Dam (located at RM 62.5) controls runoff from 81 percent of the basin and creates the largest storage reservoir in the system, Lake McClure. The maximum reservoir storage capacity at Lake McClure is 1,024,600 acre-feet, equivalent to 103 percent of the average annual runoff from the basin (as measured below Merced Falls Dam, near Snelling). The New Exchequer Dam provides agricultural water supply, power generation, flood control, recreation, and environmental flows including in-stream fisheries flows and flows to the Merced National Wildlife Refuge (Stillwater Sciences 2001).

McSwain Dam (RM 56) is located 6.5 river miles downstream of the New Exchequer Dam, and is operated as a re-regulation reservoir and hydroelectric facility. Storage capacity in Lake McSwain is 9,730 acre-feet.

The Merced Falls Dam (RM 55) and the Crocker-Huffman Dam (RM 52) are low-head irrigation diversion facilities. The Merced Falls Dam diverts flow into the Merced ID's Northside Canal (capacity = 90 cfs) to the north of the river and generates electricity. The Crocker-Huffman Dam diverts flow into the Merced ID's Main Canal (capacity = 1,900 cfs). In addition to the Merced ID diversions, the Merced River Riparian Water Users maintain seven riparian diversions between Crocker-Huffman Dam and Shaffer Bridge. Between Crocker-Huffman Dam and Shaffer Bridge, Cowell Agreement and riparian water users divert up to approximately 94,000 acre-feet annually and have maintained seven main channel diversions since about the 1850s (Stillwater Sciences and EDAW 2001). These diversions are small wing dams consisting of rock and gravel, which can be transported downstream during high winter river flows. In addition to these diversions, CDFG has identified a large number of diversions, primarily pumps, in the 52 river miles between the Crocker-Huffman Dam and the San Joaquin

confluence. During field surveys, CDFG recorded 244 diversions, which are predominantly used to supply water for agricultural use (206 diversions) (Stillwater Sciences and EDAW 2001).

Land Use

The Merced River Watershed has been significantly modified by dams and flow regulation, flow diversion, gold and aggregate (sand and gravel) mining, levee construction, land use conversion in the floodplain, and clearing of riparian vegetation (Stillwater Sciences 2001). As reported by USFWS (1995), agricultural development began in the 1850s, and significant changes have been made to the hydrologic system since that time. As early as the 1870's, large canal systems were built to divert Merced River water for agricultural uses including, row crops, cattle grazing and orchard crops. Mining for gold and aggregate downstream of the dams has been extensive, leaving tailings and numerous pits within the river corridor (USFWS 2001). Today, the lands within watershed are comprised of rural and privately owned areas, and the primary land use is agricultural and aggregate mining. Many tracts are under active cultivation with orchards and vineyards, and several actively grazed annual grassland pastures abut the river's edge. There is also an expansive gravel mining plant on the north section of the lower Merced River (USFWS 2001).

Fisheries and Aquatic Habitat

Historically, the Merced River supported spring and fall-run Chinook salmon, and occasionally steelhead trout. Over time, the manipulation of the Merced River has led to loss and degradation of native habitat. With the building of dams, access to spawning grounds upstream has been lost and gravel recruitment is greatly reduced in reaches below the dams. The large in-stream ponds left by mining create habitat for introduced predator fish species that prey upon juvenile salmon (USFWS 2005). Despite this loss and degradation of riverine habitat, the Merced River has supported a large population of fall-run Chinook salmon in the San Joaquin Valley. Steelhead have been largely extirpated from the project area, but sporadically use the Merced River for spawning and rearing (USFWS 2000).

Both the Merced Falls Dam and the Crocker-Huffman Dam are equipped with fish ladders, but the ladders were blocked by CDFG in the early 1970s in association with the Merced ID's construction of an artificial salmon spawning channel immediately downstream of Crocker-Huffman Dam. As reported in Stillwater Sciences (2001), anadromous fish generally do not pass upstream of Crocker-Huffman Dam, although some fall Chinook salmon may surmount the dam during high flows. Thus, the

Crocker-Huffman Dam presents an impassable barrier to upstream migration, and demarcates the upstream extent of currently accessible steelhead habitat. Salmon spawn in the 24-mile reach between Crocker-Huffman Dam and the town of Cressy (USFWS 1995), with the primary spawning reach occurring between RM 32 and RM52) (Stillwater Science 2001). Rearing habitat extends downstream of the designated spawning reach, requiring the protection of the entire tributary from Crocker-Huffman Dam to its mouth (USFWS 1995).

Thermographs are used by CDFG to record temperature at several points along the river. Downstream of Crocker-Huffman dam substrate is dominated by gravel and cobble with downstream fining to eventual sand and silt below the lowest spawning area (USFWS 2007.)

Water resource demands and flood control issues on the Merced River will largely determine the extent and types of restoration implemented in the corridor (Stillwater Sciences and EDAW 2001). The Merced River is heavily allocated for agricultural water use. The Merced ID holds pre-1914 appropriative water rights to divert flow from the river. In addition, riparian water users divert flows through seven diversion channels between Crocker-Huffman Dam and Shaffer Bridge and numerous riparian pumps throughout the river. Minimum instream flow requirements in the river are defined under Merced ID's current licenses and agreements and are intended to provide adequate flows for Chinook salmon and for the Merced River Riparian Water Users Association diversions. In addition, under current U.S. Army Corps of Engineers flood control operations rules, the maximum allowable release to the Merced River from New Exchequer Dam is 6,000 cfs. For the above reasons, restoration projects developed within the Merced River Corridor Restoration Plan must, therefore, be designed to function within the current minimum flow requirements and this 6,000 cfs flood control limitation (Stillwater Sciences and EDAW 2001).

There are many opportunities for improving geomorphic and riparian ecosystem conditions in the Merced River. As reported in the Geomorphic and Riparian Vegetation Investigations Report for the Merced River Corridor Restoration Plan (Stillwater Sciences 2001), the major constraints to restoring geomorphic and riparian ecological processes and attributes in the Merced River include: (1) drastic reduction in the flood magnitude, frequency, and duration and the resulting reduction in bedload transport under current dam operations; (2) elimination of floods exceeding 6,000 cfs that will likely continue due to the Corps of Engineers limit to flood releases; (3) the presence of vulnerable structures (such as the City of Livingston sewage treatment plant) and vulnerable land uses in the floodplain; (4) lack of coarse sediment supply due interception of bedload by the large dams; (5) limits to channel migration caused by

reduced flows, bank revetment, and development in the floodplain; (6) the extent of bedload impedance reaches throughout the Gravel Mining 1 and Gravel Mining 2 reaches; and (7) chronic fragmentation and clearing of riparian vegetation for floodplain development. To date, numerous projects to restore and protect floodplain function, as well as channel and riparian habitat have been initiated or completed on the Merced River as a result of the CVPIA and the Merced River Corridor Restoration Plan; however, consistent monitoring of juvenile Chinook salmon and steelhead emigration has been lacking (Stillwater Sciences 2001; USFWS 2007).

Steelhead

Steelhead populations in the Stanislaus, Tuolumne, Merced, and Calaveras rivers are the only remaining representatives of the Southern Sierra Nevada diversity group of the Central Valley steelhead (NMFS 2009). However, none of these populations are considered to be viable at this time (Lindley *et al.* 2007).

The Merced River Fish Hatchery (RM 52), operated by CDFG, is located immediately downstream of Crocker-Huffman dam. Crocker-Huffman Dam is the upstream terminus of fish migration on the Merced River. (USFWS 2007).

Prior to 2007, incidental catches and observations of steelhead juveniles have occurred on the Merced (and Tuolumne) rivers during fall-run Chinook salmon monitoring activities (Good *et al.* 2005). Zimmerman *et al.* (2008) also has documented Central Valley steelhead in the Merced River based on otolith microchemistry.

During 2007, Cramer Fish Sciences began juvenile Chinook salmon and *O. mykiss* population monitoring on the Merced River at George Hatfield State Park (RM 2) under contract with Anadromous Fish Restoration Program. The monitoring effort continues previous work by CDFG at Hagaman State Park (RM 12), and uses rotary screw traps, an established method for measuring juvenile out-migration abundance, to capture juvenile salmonid species while monitoring environmental variables (USFWS 2007). The new site was established to obtain a more accurate estimate of fish contribution to the San Joaquin River. Result from surveys conducted during 2007 indicate that out-migration timing of natural fish strongly coincided with hatchery releases upstream, and weaker associations were observed with temperature and lunar cycle (USFWS 2007). Observations during the 2007 appear to indicate poor natural production of Chinook salmon, however subsequent monitoring of population trends over several seasons is required before conclusions or management decisions can be made (USFWS 2007). No *O. mykiss* were captured during the 2007 sampling season. A more thorough

understanding of *O. mykiss* populations on the Merced River may be necessary to explain the lack of out-migration observed during the 2007 season (USFWS 2007).

Watershed Restoration and Potential to Support a Viable Population

Watershed/Ecosystem Restoration

CV spring-run Chinook salmon and CV steelhead no longer occur in the San Joaquin River south the of the Merced River. According to DFG (1998), the San Joaquin River once supported a very large population. Clark (1929) wrote that in the late 1800s, salmon were very numerous, and Fry (1961) estimated a run of 56,000 spring-run in 1945. The extent of steelhead presence in the San Joaquin River is not well known.

The upper San Joaquin River, a 153-mile stretch of river from the Merced confluence upstream to Friant Dam, has been significantly altered over the past century due to changes in land and water use. The historical populations of Central valley spring-run salmon were extirpated due to several changes caused by development including the building of Friant dam that blocked fish passage to upper San Joaquin River habitats. As well, major agricultural water diversions were built in the last 150 years which lowered the water quality and quantity and caused areas of entrainment, further reducing the population of spring-run salmon and steelhead to the level of extirpation.

Because of these developments, which caused the extinction of the San Joaquin spring-run salmon population, several legal actions were taken which resulted in a Settlement in October of 2006 that was reached in the case of *NRDC et al. v. Kirk Rodgers et al.*, and was termed: the San Joaquin River Restoration Program (SJRRP). The following restoration goals were produced from this settlement:

Restoration Goal – To restore and maintain fish populations in “good condition” in the mainstem San Joaquin River below Friant Dam to the confluence with the Merced River, including naturally reproducing and self-sustaining populations of salmon and other fish.

Water Management Goal – To reduce or avoid adverse water supply impacts to all of the Friant Division long-term contractors that may result from the Interim Flows and Restoration Flows provided for in the Settlement.

The Settlement establishes a framework for accomplishing the Restoration and Water Management goals that will require environmental review, design, and construction of projects over a multiple-year period. To achieve the Restoration Goal, the Settlement calls for a combination of channel and structural modifications along the San Joaquin River below Friant Dam, releases of water from Friant Dam to the confluence of the Merced River, and the reintroduction of Chinook salmon. With these actions, the prognosis for spring-run populations to returns is high. However, for steelhead, since the main channel San Joaquin does not have suitable habitats that fulfill life history requirements for steelhead such as good off channel and side channel habitats as well as smaller spawning gravels, more restoration will need to be focused on these life history requirements before steelhead would reoccur.

Viability Potential for Populations Below Friant Dam

CV spring-run Chinook salmon (Reintroduced): **High**

CV steelhead: **Low**

The San Joaquin River Watershed below Friant dam can be characterized as having a **high** potential to support a spawning population of reintroduced spring-run Chinook salmon and a **low** potential to support a viable population of steelhead. The high potential to support a viable population of spring-run is based upon successful re-introduction through the SJRRP program. This population will be an experimental population using Sacramento River basin stock while implementing various habitat improvements throughout the restoration area between Friant Dam and the Merced River confluence. The important factor that increases the chances of a successful reintroduction of Central Valley spring-run salmon into the system is the availability of cold water releases from Friant dam. Without the agreement and extensive commitment by the SJRRP to restore the function and habitat suitability to the river below Friant dam fish reintroductions and viability, potential viability could not be discussed.

The **low** potential to support a viable population of steelhead is primarily based upon the low presence of steelhead in the major tributaries of the San Joaquin River (the Tuolumne, Stanislaus, and Merced rivers) as well as the lack of floodplain rearing habitat in the San Joaquin River in general. Since 1992, the Hills Ferry Barrier has been seasonally operated by CDFG and is designed to redirect fall-run Chinook salmon and, incidentally, CV steelhead to the Merced River and prevent migration into the upper mainstem of the San Joaquin River, where conditions are currently unsuitable for Chinook salmon. Once the San Joaquin River is restored below Friant Dam, steelhead will likely utilize the habitat, however, without the extensive side channel and small tributary habitat availability, the steelhead population viability potential remains low.

Potential for Historic Habitats (above Friant Dam) to Support Spawning Populations

Above Friant Dam:

Central Valley spring-run Chinook salmon – **Low to moderate**

Central Valley steelhead – **Low to moderate**

The San Joaquin River Watershed above Friant dam can be characterized as having a **low to moderate** potential to support a spawning population of reintroduced spring-run Chinook salmon and a **low to moderate** potential to support a viable population of steelhead

The San Joaquin River above Friant Dam proceeds for approximately 24 miles before the a natural barrier (Mammoth Pool Reservoir), this section however, would be impassable because it is segmented by Temperance Flat, Kerckhoff, Redinger small hydro reservoirs before Mammoth Pool which would be the upper extent. The habitat above Friant Dam besides the segmented areas, has good quality habitat for spring-run, and fair to good quality habitat for steelhead.

Appendix B

**Threats Assessment for the
Evolutionarily Significant Units of
Winter-run Chinook Salmon (*Oncorhynchus
tshawytscha*) and Central Valley Spring-run Chinook
Salmon
(*O. tshawytscha*), and the Distinct Population Segment
of Central Valley Steelhead (*O. mykiss*)**

Table of Contents

1.0	INTRODUCTION.....	1-1
2.0	SACRAMENTO RIVER WINTER-RUN CHINOOK SALMON.....	2-1
2.1	Background	2-1
2.1.1	Listing History	2-1
2.1.2	Critical Habitat.....	2-1
2.1.3	Unique Species Characteristics.....	2-2
2.1.3.1	Life History Strategy	2-2
2.1.3.2	Historic Spawning Habitat Utilization	2-5
2.1.4	Status of Winter-run Chinook Salmon.....	2-5
2.1.4.1	Historic Population Trends.....	2-5
2.1.4.2	Current Status	2-6
2.1.4.3	Extinction Risk Assessment	2-8
2.2	Life History and Biological Requirements	2-8
2.2.1	Adult Immigration and Holding	2-8
2.2.1.1	Geographic and Temporal Distribution.....	2-8
2.2.1.2	Biological Requirements	2-8
2.2.2	Adult Spawning	2-10
2.2.2.1	Geographic and Temporal Distribution.....	2-10
2.2.2.2	Biological Requirements	2-10
2.2.3	Embryo Incubation	2-10
2.2.3.1	Geographic and Temporal Distribution.....	2-10
2.2.3.2	Biological Requirements	2-10
2.2.4	Juvenile Rearing and Outmigration	2-11
2.2.4.1	Geographic and Temporal Distribution.....	2-11
2.2.4.2	Biological Requirements	2-11
2.2.5	Sub-adult and Adult Ocean Residence	2-12
2.2.5.1	Geographic and Temporal Distribution.....	2-12
2.2.5.2	Biological Requirements	2-12
2.3	Threats and Stressors	2-12
2.3.1	Summary of ESA Listing Factors	2-12
2.3.1.1	Destruction, Modification, or Curtailment of Habitat or Range.....	2-12
2.3.1.2	Overutilization for Commercial, Recreational, Scientific, or Educational Purposes.....	2-14
2.3.1.3	Disease or Predation	2-14
2.3.1.4	Inadequacy of Existing Regulatory Mechanisms	2-14
2.3.1.5	Other Natural and Manmade Factors Affecting the Species’ Continued Existence	2-16
2.3.2	Non-Life Stage-Specific Threats and Stressors	2-16
2.3.2.1	Artificial Propagation Program	2-16
2.3.2.2	Small Population Size Composed of a Single Extant Population.....	2-19
2.3.2.3	Genetic Integrity	2-20
2.3.2.4	Long-term Climate Change	2-21

2.3.3	San Francisco, San Pablo, and Suisun Bays	2-22
2.3.3.1	Adult Immigration and Holding	2-22
2.3.3.2	Juvenile Rearing and Outmigration	2-25
2.3.4	Sacramento-San Joaquin Delta	2-27
2.3.4.1	Adult Immigration and Holding	2-27
2.3.4.2	Juvenile Rearing and Outmigration	2-29
2.3.5	Lower Sacramento River (Princeton [RM 163] to the Delta)	2-36
2.3.5.1	Adult Immigration and Holding	2-36
2.3.5.2	Juvenile Rearing and Outmigration	2-38
2.3.6	Middle Sacramento River (Red Bluff Diversion Dam [RM 243] to Princeton [RM 163])	2-40
2.3.6.1	Adult Immigration and Holding	2-40
2.3.6.2	Juvenile Rearing and Outmigration	2-41
2.3.7	Upper Sacramento River (Keswick Dam [~RM 302] to Red Bluff Diversion Dam)	2-43
2.3.7.1	Adult Immigration and Holding	2-43
2.3.7.2	Spawning	2-44
2.3.7.3	Embryo Incubation	2-47
2.3.7.4	Juvenile Rearing and Outmigration	2-49

List of Acronyms

ACID	Anderson-Cottonwood Irrigation District
AFRP	Anadromous Fish Restoration Program
AMP	Ambient Monitoring Program
Bay-Delta	San Francisco Bay/Sacramento-San Joaquin Delta
Bays	San Francisco, San Pablo, and Suisun bays
BML	Bodega Marine Laboratory
BO	biological opinion
BRT	Biological Review Team
CDFG	California Department Fish and Game
CEQA	California Environmental Quality Act
CESA	California Endangered Species Act
cfs	cubic feet per second
cm	centimeter
cm/sec	centimeters per second
CMP	Sacramento Coordinated Monitoring Program
CNFH	Coleman National Fish Hatchery
CRR	Cohort Replacement Rate
CVI	Central Valley Index
CVP	Central Valley Project
CVPIA	Central Valley Project Improvement Act
CWA	Clean Water Act
CWT	coded wire tag
DDT	Dichloro-Diphenyl-Trichloroethane
Delta	Sacramento-San Joaquin Delta
DPS	Distinct Population Segment
DWR	California Department of Water Resources
EEZ	U.S. Exclusive Economic Zone
ENSO	El Niño-Southern Oscillation
EPA	U.S. Environmental Protection Agency
ERP	Ecosystem Restoration Program
ESA	Endangered Species Act
ESU	Evolutionarily Significant Unit
FERC	Federal Energy Regulatory Commission
FL	Fork Length
FMP	Salmon Fishery Management Plan
FRFH	Feather River Fish Hatchery
ft/sec	feet per second
GCID	Glenn-Colusa Irrigation District
GCMs	General Circulation Models
HCP	habitat conservation plan
HCPP	Hamilton City Pumping Plant
km	kilometers
LSNFH	Livingston Stone National Fish Hatchery
mm	millimeter
MSA	Magnuson-Stevens Fishery Conservation and Management Act

NCCP	Natural Communities Conservation Plan
NEPA	National Environmental Policy Act
NMFS	National Marine Fisheries Service
MRFH	Mokelumne River Fish Hatchery
MRH	Merced River Hatchery
NAHB	National Association of Home Builders
NOAA	National Oceanic and Atmospheric Administration
OCAP	Operations Criteria and Plan
PBDEs	Polybrominated diphenyl ethers
PCBs	polychlorinated biphenyls
PFMC	Pacific Fishery Management Council
PDO	Pacific Decadal Oscillation
PG&E	Pacific Gas and Electric Company
ppt	parts per thousand
PSMFC	Pacific States Marine Fisheries Commission
RBDD	Red Bluff Diversion Dam
RCRA	Resource Conservation and Recovery Act
Reclamation	Bureau of Reclamation
RM	River Mile
RMIS	Regional Mark Information System
RWQCB	Regional Water Quality Control Board
SDWSC	Sacramento Deep Water Ship Channel
SMSCS	Suisun Marsh Salinity Control Structure
SRA	shaded riverine aquatic
SSIDD	South Sutter Irrigation District Dam
SVRIC	Stanford Vina Ranch Irrigation Company
SWP	State Water Project
SWRCB	State Water Resources Control Board
TCC	Tehama-Colusa Canal
TCD	temperature control device
TMDL	Total Maximum Daily Load
USACE	U.S. Army Corps of Engineers
USFWS	U.S. Fish and Wildlife Service
USGS	U.S. Geological Survey
VAMP	Vernalis Adaptive Management Plan

1.0 INTRODUCTION

Past recovery plans generally have focused on the abundance, productivity, habitat and other life history characteristics of a species. While knowledge of these characteristics is certainly important for making sound conservation management decisions, the long-term sustainability of a species in need of recovery can only be ensured by alleviating the threats that are contributing to the status of the species as threatened or endangered. Therefore, the identification of the threats to the species should be a key component of any recovery plan and program (NMFS 2006a).

To be most useful for recovery planning, a threats assessment should be used to determine the relative importance of various threats to a species. A threats assessment includes (1) identifying threats and their sources, (2) evaluating the effects of threats, and (3) ranking each threat based on relative effects. The Interim Endangered and Threatened Species Recovery Planning Guidance (NMFS 2006a) recommends “...using a threats assessment for species with multiple threats to help identify the relative importance of each threat to the species’ status, and, therefore, to prioritize recovery actions in a manner most likely to be effective for the species’ recovery.”

Applying this recommended approach for the National Oceanic and Atmospheric Administration (NOAA) National Marine Fisheries Services’ (NMFS) recovery planning process in the Central Valley, threats assessments were conducted for the Sacramento River winter-run Chinook salmon Evolutionarily Significant Unit (ESU), the Central Valley spring-run Chinook salmon ESU, and the Central Valley steelhead Distinct Population Segment (DPS). The threats assessments identified, evaluated, and ranked factors affecting these two ESUs and DPS in the ocean, in the San Francisco Bay/Sacramento-San Joaquin Delta (Bay-Delta) (**Figure 1-1**), and in Central Valley rivers and tributaries that currently support populations of winter-run Chinook salmon, spring-run Chinook salmon, and/or steelhead.

Threats to winter-run Chinook salmon, spring-run Chinook salmon, and steelhead in the Bay-Delta were geographically distinguished between the Bay and the Delta using the legal definition of the Delta described in Section 12220 of the California Water Code. This places the Delta’s western boundary approximately four miles west of the confluence of the Sacramento and San Joaquin Rivers. The legal Delta extends northward to the I Street Bridge near Sacramento and southward to near Vernalis.

Threats in the mainstem Sacramento River were geographically distinguished among the lower, middle, and upper part of the river (**Figure 1-2**). The lower section extends from the I Street Bridge upstream to Princeton (River Mile [RM] 163), the middle section extends from Princeton to Red Bluff Diversion Dam (RBDD) (RM 243), and the upper section extends from RBDD up to Keswick Dam (RM 302).

In-river threats to winter-run Chinook salmon were assessed in the mainstem Sacramento River, which represents the only extant population in the ESU. Similarly, the threats assessments for the Central Valley spring-run Chinook salmon ESU included rivers that both historically

supported, and currently support spring-run Chinook salmon populations¹. Lindley *et al.* (2004), which describes the population structure of threatened and endangered Chinook salmon ESU's in California's Central Valley Basin was used to identify 12 individual rivers that historically supported and currently support spring-run Chinook salmon populations. These 12 spring-run Chinook salmon populations were categorized into three diversity groups as described by Lindley *et al.* (2007) (**Table 1-1**).

¹ Although the San Joaquin River system historically supported spring-run Chinook salmon, this river system was not included in the threats assessment because: (1) the current absence of spring-run Chinook salmon from the system prevents direct data collection of stressors; and (2) the system is not included in the ESU listing.

For the Central Valley steelhead threats assessment, 26 individual rivers/watersheds² in the Sacramento and San Joaquin (**Figure 1-3**) river systems that historically supported and currently support populations of steelhead were identified using literature describing the historical population structure of steelhead in the Central Valley (Lindley *et al.* 2006) and by using the best professional knowledge of Central Valley salmonid biologists regarding the current distribution of steelhead. These 26 steelhead populations were categorized into four diversity groups based on the geographical structure described in Lindley *et al.* (2007) **Table 1-2**.

This appendix is comprised of three major sections – one for the Sacramento River winter-run Chinook salmon ESU, one for the Central Valley spring-run Chinook salmon ESU, and one for the Central Valley steelhead DPS. Narrative descriptions of the threats affecting each ESU/DPS (Sections 2.3, 3.3, and 4.3, respectively) are organized hierarchically going from location/population to life stage to threats. In addition to narrative descriptions, matrices were developed in order to structure the life stage, population, and threats information so that the threats affecting each ESU/DPS could be ranked, sorted, and prioritized.

² It is recognized that more than 26 rivers/watersheds that historically supported and currently support steelhead exist in the Central Valley, however it is assumed that recovery of the Central Valley steelhead DPS is primarily dependent on the 26 populations included in the threats assessment.

³ Includes steelhead utilizing small tributaries in the Redding area including Stillwater, Churn, Sulphur, Salt, Olney, and Paynes creeks.

Figure 1-3. San Joaquin River and Tributaries

The prioritization of threats was identified as an integral piece in the recovery planning process in NMFS' recovery planning guidance document titled, "*Interim Endangered and Threatened Species Recovery Planning Guidance*" (NMFS 2006a).

The prioritized ranking of threats provides a recovery planning tool to help guide the identification of diversity group- and/or population- specific actions to recover each ESU/DPS. Detailed descriptions of how the stressor matrices were developed for each ESU/DPS are presented in Sections 2.4, 3.4, and 4.4, while the diversity group- and population-specific prioritized lists of stressors are displayed in Attachments A through C, respectively.

2.0 SACRAMENTO RIVER WINTER-RUN CHINOOK SALMON

2.1 BACKGROUND

2.1.1 LISTING HISTORY

NMFS listed the Sacramento River winter-run Chinook salmon ESU as a threatened species under emergency provisions of the Endangered Species Act (ESA) in August 1989 (54 FR 32085 (August 4, 1989)) and formally listed it as a threatened species in November 1990 (55 FR 46515 (November 5, 1990)). In June 1992, NMFS proposed that winter-run Chinook salmon be reclassified as an “endangered”⁴ species (57 FR 27416 (June 19, 1992)). NMFS finalized its proposed rule to re-classify winter-run Chinook salmon as an endangered species on January 4, 1994 (59 FR 440 (January 4, 1994)). NMFS concluded that winter-run Chinook salmon in the Sacramento River warranted listing as an endangered species due to several factors, including: (1) the continued decline and increased variability of run sizes since its first listing as a threatened species in 1989; (2) the expectation of weak adult returns resulting from two small year classes in 1991 and 1993; and (3) continued “take”⁵ of winter-run Chinook salmon (65 FR 42421 (July 10, 2000)). On June 14, 2004, NMFS issued a proposed rule to downgrade the listing status of winter-run Chinook salmon from endangered to threatened (69 FR 33102 (June 14, 2004)). To prevent further decline of the ESU, NMFS proposed to apply the ESA Section 9(a) take prohibitions as the Section 4(d) limits to winter-run Chinook salmon (69 FR 33102 (June 14, 2004)) after this proposed downgrade. Following a series of extensions to the public comment period on the proposed listing determinations, the public comment period closed in November 2004 (69 FR 61348 (October 18, 2004)). On June 28, 2005 NMFS issued a final listing determination for the Sacramento River winter-run Chinook salmon ESU, which concluded that the Sacramento River winter-run Chinook salmon ESU is “in danger of extinction” due to risks to the diversity and spatial structure of the ESU, and therefore, continues to warrant listing as an endangered species under the ESA (70 FR 37160 (June 28, 2005)).

The Sacramento River winter-run Chinook salmon ESU includes winter-run Chinook salmon spawning naturally in the Sacramento River and its tributaries as well as winter-run Chinook salmon that are part of the artificial propagation program at the Livingston Stone National Fish Hatchery (LSNFH) (70 FR 37160 (June 28, 2005)).

2.1.2 CRITICAL HABITAT

Critical habitat for listed salmonids is comprised of physical and biological features essential to the conservation of the species including: (1) space for the individual and population growth and for normal behavior; (2) cover; (3) sites for breeding, reproduction, and rearing of offspring; and (4) habitats protected from disturbance or are representative of the historical geographical and

⁴ Under the ESA, an “endangered species” is “...any species which is in danger of extinction throughout all or a significant portion of its range...” (16 USC § 1533(20)).

⁵ Section 9 of the ESA makes it illegal to “take” (harass, harm, pursue, shoot, wound, kill, trap, capture, or collect or attempt to engage in any such conduct) any endangered species of fish or wildlife with similar provisions for most threatened species of fish and wildlife (16 USC 1538).

ecological distribution of the species. The primary constituent elements considered essential for the conservation of listed Central Valley salmonids are: (1) freshwater spawning sites; (2) freshwater rearing sites; (3) freshwater migration corridors; (4) estuarine areas; (5) nearshore marine areas; and (6) offshore marine areas.

On August 14, 1992, NMFS published a proposed critical habitat designation for winter-run Chinook salmon (57 FR 36626 (August 13, 1992)). The habitat proposed for designation included: (1) the Sacramento River from Keswick Dam, Shasta County (RM 302) to Chipps Island (RM 0) at the westward margin of the Delta; (2) all waters from Chipps Island westward to Carquinez Bridge, including Honker Bay, Grizzly Bay, Suisun Bay, and Carquinez Strait; (3) all waters of San Pablo Bay westward of the Carquinez Bridge; and (4) all waters of San Francisco Bay to the Golden Gate Bridge (NMFS 1997).

On June 16, 1993, NMFS issued the final rule designating critical habitat for winter-run Chinook salmon (58 FR 33212 (June 16, 1993)). The habitat identified in the final designation is identical to that in the proposed ruling except that critical habitat in San Francisco Bay is limited to those waters north of the San Francisco-Oakland Bay Bridge.

2.1.3 UNIQUE SPECIES CHARACTERISTICS

2.1.3.1 LIFE HISTORY STRATEGY

Chinook salmon life history strategies are divided into two basic types: stream-type Chinook salmon and ocean type Chinook salmon. Stream-type Chinook salmon adults migrate to freshwater streams before they reach full maturity, in spring or summer, and juveniles spend a relatively long time (usually more than one year) rearing in fresh water. Ocean-type Chinook salmon adults spawn soon after entering fresh water, in late-summer and fall, and juveniles spend a relatively short time (3 to 12 months) rearing in freshwater (Moyle 2002).

Winter-run Chinook salmon are unique to the Sacramento River and exhibit behaviors characteristic of both stream- and ocean-type Chinook salmon (Healey 1991). They typically migrate upstream as immature silvery fish during winter and spring and then spawn several months later in early summer. Specifically, adult winter-run Chinook salmon enter freshwater in winter or early spring, (December through July with peak upstream migration occurring during March) and delay spawning until spring or early summer (a stream-type trait); whereas, juvenile winter-run Chinook salmon exhibit more ocean-type Chinook salmon behavior by migrating to the ocean after spending as few as five months up to nine months of river life (NMFS 1997). They tend to be smaller than the rest of the runs of Chinook salmon and have low fecundity, mainly because most winter-run Chinook salmon return to spawn as three-year olds.

In the Sacramento River reach between Keswick Dam and RBDD, spawning occurs from mid-April to mid-August, peaking in June and July (Killam 2206). Chinook salmon spawn in clean, loose gravel in swift, relatively shallow riffles; or along the margins of deeper river reaches where suitable water temperatures, depths, and velocities favor redd construction and oxygenation of incubating eggs. Winter-run Chinook salmon are adapted for spawning and rearing in the clear, spring-fed rivers of the upper Sacramento River Basin, where summer water temperatures are typically between 50°F to 59°F. Historically, these conditions were created by

glacial and snowmelt water percolating through porous volcanic formations that surround Mt. Shasta and Mt. Lassen and that cover much of northeastern California. Today, Shasta Dam denies access to winter-run Chinook salmon historical habitats and they persist mainly because water released from Shasta Reservoir during the summer is for the most part cold.

Sacramento River winter-run Chinook salmon migration corridors begin downstream of the spawning area and extend through the lower Sacramento River and the Delta. Fry emergence generally occurs at night. Upon emergence from the gravel, fry swim or are displaced downstream (Healey 1991). Fry seek habitats containing beneficial aspects such as riparian vegetation and associated substrates that provide aquatic and terrestrial invertebrates for food, cover for predator avoidance, and slower water velocities for resting (NMFS 1996b). These shallow water habitats have been described as more productive juvenile salmon rearing habitat than deeper main river channels. Higher juvenile salmon growth rates, partially due to greater prey consumption rates, as well as favorable environmental temperatures have been associated with shallow water habitats (Sommer *et al.* 2001c). Juvenile Chinook salmon migration rates vary considerably presumably depending on the physiological stage of the juvenile and hydrologic conditions. Kjelson (1982) found Chinook salmon fry traveled as fast as 30 kilometers (km) per day in the Sacramento River. Sommer *et al.* (2001a) found rates ranging from approximately 0.5 mile up to more than 6 miles per day in the Yolo Bypass.

As juvenile Chinook salmon grow they move into deeper water with higher current velocities, but still seek shelter and velocity refugia to minimize energy expenditures (Healey 1991). Catches of juvenile salmon in the Sacramento River near West Sacramento by the U.S. Fish and Wildlife Service (USFWS) exhibited larger juvenile captures in the main channel and smaller sized fry along the margins (USFWS 1997). Where the river channel is greater than 9 to 10 feet in depth, juvenile salmon tend to inhabit the surface waters (Healey 1980). Stream flow and/or turbidity increases in the upper Sacramento River basin are thought to stimulate emigration (Poytress 2007).

Similar to adult salmon upstream movement, juvenile salmon downstream movement is primarily crepuscular. Once downstream movement has commenced, salmon fry might continue this movement until reaching the Delta or they might reside in the stream for a time period that varies from weeks to a year (Healey 1991). The residence time of juveniles in streams is typically 5 to 10 months, followed by an indeterminate time in the Delta.

Emigration of juvenile Sacramento River winter-run Chinook salmon past RBDD may begin as early as mid-July, typically peaks in September, and can continue through March in dry years (NMFS 1997; Vogel and Marine 1991). From 1995 to 1999, Sacramento River winter-run Chinook salmon outmigrating as fry passed RBDD by October, and outmigrating pre-smolts and smolts passed RBDD by March (Martin *et al.* 2001).

As Chinook salmon begin the smoltification stage, they are found rearing further downstream where ambient salinity reaches 1.5 to 2.5 parts per thousand (ppt) (Healey 1980; Levy and Northcote 1981). Emigration to the ocean begins as early as November and continues through May (Fisher 1994; Myers *et al.* 1998). The importance of the Delta in the life history of Sacramento River winter-run Chinook salmon is not well understood. However, juvenile

Sacramento River winter-run Chinook salmon are believed to occur in the Delta primarily from November through early May based on data collected from trawls in the Sacramento River at West Sacramento (RM 57) (USFWS 2001). The timing of migration varies somewhat due to changes in river flows, dam operations, and water year type. Winter-run Chinook salmon juveniles remain in the Delta until they reach a fork length (FL) of approximately 118 millimeters (mm) (NMFS 1997).

Within the Delta, juvenile Chinook salmon forage in shallow areas with protective cover, such as tidally influenced sandy beaches and vegetated zones (Healey 1980; Meyer 1979). Cladocerans, copepods, amphipods, and larvae of diptera, as well as small arachnids and ants are common prey items (Kjelson *et al.* 1982; MacFarlane and Norton 2002; Sommer *et al.* 2001b).

Juvenile Chinook salmon movements within the estuarine habitat are dictated by the interaction between tidally driven salt water intrusions through the San Francisco Bay and fresh water outflow from the Sacramento and San Joaquin rivers. Juvenile Chinook salmon follow rising tides into shallow water habitats from the deeper main channels, and return to the main channels when the tides recede (Levy and Northcote 1981). Kjelson (1982) reported that juvenile Chinook salmon demonstrated a diel migration pattern, orienting themselves to nearshore cover and structure during the day, but moving into more open, offshore waters at night. The fish also distributed themselves vertically in relation to ambient light. During the night, juveniles were distributed randomly in the water column, but would school up during the day into the upper three meters of the water column. Juvenile Chinook salmon were found to spend about 40 days migrating from the confluence of the Sacramento and San Joaquin rivers through the San Francisco Estuary and grew little in length or weight until they reached the Gulf of the Farallones Islands (MacFarlane and Norton 2002).

Central Valley Chinook salmon begin their ocean life in the Gulf of the Farallones from where they distribute north and south along the continental shelf primarily between Point Conception and Washington State. Upon reaching the ocean, juvenile Chinook salmon feed voraciously on larval and juvenile fishes, plankton, and terrestrial insects (Healey 1991; MacFarlane and Norton 2002). Chinook salmon grow rapidly in the ocean environment with growth rates dependent on water temperatures and food availability (Healey 1991). The first year of ocean life is considered a critical period of high mortality for Chinook salmon that largely determines survival to harvest or spawning (Beamish and Mahnken 2001; Quinn 2005).

Data from the Pacific States Marine Fisheries Commission (PSMFC) Regional Mark Information System (RMIS) database indicate that Sacramento River winter-run Chinook salmon adults are not as broadly distributed along the Pacific Coast as other Central Valley Chinook salmon and tend to concentrate between San Francisco and Monterey. This localized distribution may indicate a unique life history strategy related to the observation that Sacramento River winter-run Chinook salmon also mature at a relatively young age (two to three years old) (Myers *et al.* 1998). Sacramento River winter-run Chinook salmon remain in the ocean environment for two to four years and tend to enter freshwater as immature fish.

2.1.3.2 HISTORIC SPAWNING HABITAT UTILIZATION

Distribution of winter-run Chinook salmon historically was limited to the upper Sacramento River and its tributaries where cool spring-fed streams supported successful salmon spawning, egg incubation, and juvenile rearing (Slater 1963 and Yoshiyama *et al.* 1998 *in* NMFS 2007). The historical distribution of winter-run Chinook salmon prior to construction of Shasta Dam included the headwaters of the McCloud, Pit, and Little Sacramento rivers and tributaries (e.g., Hat Creek and Fall River) (Myers *et al.* 1998). Since completion of Shasta Dam, the Sacramento River, Battle Creek and the Calaveras River are the only habitats where winter-run Chinook salmon have been reported to occur (USFWS 1987). Primary spawning and rearing habitat in the Sacramento River for winter-run Chinook salmon is now limited to the coldwater areas between Keswick Dam and RBDD. Fish still have access to Battle Creek through the Coleman National Fish Hatchery (CNFH) weir from a fish ladder that is opened during the peak of the winter-run Chinook salmon migration period (Ward and Kier 1999a). Currently, if a winter-run Chinook salmon population exists in Battle Creek; its population size is unknown and is likely very small. In addition, a winter-run Chinook salmon migration to the upper Calaveras River may have occurred between 1972 and 1984, but this information has not been confirmed. Nevertheless, the population seems to have been extirpated by drought, irrigation diversions, and blocked access by the New Hogan Dam (NMFS 1997).

2.1.4 STATUS OF WINTER-RUN CHINOOK SALMON

2.1.4.1 HISTORIC POPULATION TRENDS

Estimates of the Sacramento River winter-run Chinook salmon population (including both male and female salmon) reached nearly 100,000 fish in the 1960s before declining to under 200 fish in the 1990s (**Figure 2-1**) (Good *et al.* 2005 *in* NMFS 2007).

Figure 2-1. Annual Estimate of Sacramento River Winter-run Chinook Salmon Spawning Escapement from 1967-2006

Source: (CDFG 2007)

2.1.4.2 CURRENT STATUS

Shasta Dam blocks access to the entire historical spawning habitat of winter-run Chinook salmon. It was not expected that winter-run Chinook salmon would survive this habitat alteration (Moffett 1949). However, coldwater releases from Shasta Dam create conditions suitable for winter-run Chinook salmon for roughly 100 km downstream from the dam.

Although the Sacramento River winter-run Chinook population has shown improvement in recent years from levels observed in the 1990s, existing population abundance (exhibited by spawning escapement estimates) is far below historic numbers. The five-year moving average of the cohort replacement rate (CRR) has been greater than one since 1995, which is an indication of population growth (**Figure 2-2**). The CRR is a measure of population growth rate, and is generally defined as the ratio of naturally-produced returning adult spawners, to adult spawners that naturally-spawned in the river during the previous generation or brood year.

The population declined from an escapement of near 100,000 in the late 1960s to fewer than 200 in the early 1990s (Good et al. 2005). More recent population estimates of 8,218 (2004), 15,730 (2005), and 17,153 (2006) show a three-year average of 13,700 returning winter-run Chinook salmon (CDFG Website 2007). However, the run size decreased to 2,542 in 2007 and 2,850 in 2008 (**Figure 2-3**).

Figure 2-2. Five-year Moving Average of the Winter-run Chinook Salmon Cohort Replacement Rate

Figure 2-3. Estimated Sacramento River Winter-run Chinook Salmon Run Size (1970-2008). Total estimate includes mainstem in-river, tributaries, hatcheries, and angler harvest. Prior to 2001, mainstem in-river estimates upstream of RBDD were based on RBDD counts; subsequent estimates were based on carcass survey data.

Sacramento River winter-run Chinook salmon may be responding to a number of factors, including wetter than normal winters, changes in ocean harvest regulations since 1995 that have significantly reduced harvests, changes in RBDD operation, improved temperature management on the upper Sacramento River (including installation of a coldwater release device on Shasta Dam), water quality improvements due to remediation of Iron Mountain Mine discharges, changes in operations of the State Water Project (SWP) and federal Central Valley Project (CVP), and a variety of other habitat improvements.

2.1.4.3 EXTINCTION RISK ASSESSMENT

Although the status of the Sacramento River winter-run Chinook salmon population numbers has shown improvement over the last six years, there is still only one naturally-spawned component of the ESU, and this single population depends on coldwater releases from Shasta Dam on the Sacramento River. Lindley *et al.* (2007) considers the Sacramento River winter-run Chinook salmon population at a moderate risk of extinction primarily due to the risks associated with only one existing population. The viability of an ESU that is represented by a single population is vulnerable to changes in the environment through a lack of spatial geographic diversity and genetic diversity that result from having only one population. A single catastrophe with effects persisting for four or more years could extirpate the entire Sacramento River winter-run Chinook salmon ESU (Lindley *et al.* 2007). Such potential catastrophes include volcanic eruption of Mt. Lassen, prolonged drought which depletes the coldwater pool in Shasta Reservoir or some related failure to manage coldwater storage, a spill of toxic materials with effects that persist for four or more years, or a disease outbreak. Moreover, an ESU that is represented by a single population is vulnerable to the limitation in life history and genetic diversity that would otherwise increase the ability of individuals in the population to withstand environmental variation.

2.2 LIFE HISTORY AND BIOLOGICAL REQUIREMENTS

2.2.1 ADULT IMMIGRATION AND HOLDING

2.2.1.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Adult winter-run Chinook salmon on their upstream migration enter San Francisco Bay from November through June and migrate past the RBDD from mid-December through early August (Hallock and Fisher 1985) (**Figure 2-4**). The majority of the winter-run Chinook salmon adults pass RBDD between January and May (Hallock and Fisher 1985), with the peak typically occurring during March and April (Snider *et al.* 2001).

2.2.1.2 BIOLOGICAL REQUIREMENTS

Suitable water temperatures for adult winter-run Chinook salmon migrating upstream to spawning grounds were reported to range from 57°F to 67°F (NMFS 1997). There is evidence suggesting that water temperatures above 70°F may present a thermal barrier to Chinook salmon

upstream migration (Boles *et al.* 1988; USFWS 1995c). Water temperature requirements for adult Chinook salmon holding while eggs are developing are more restrictive with maximum temperatures reported at 59°F to 60°F (NMFS 1997). However, adults holding at 55°F to 56°F have substantially better egg viability (Boles *et al.* 1988; NMFS 1997).

Adult Chinook salmon require water deeper than 0.8 feet and water velocities less than 8 feet per second (ft/sec) for successful upstream migration (Thompson 1972). Adult Chinook salmon are less capable of negotiating fish ladders, culverts, and waterfalls during upstream migration than steelhead, due in part to slower swimming speeds and inferior jumping ability (Bell 1986; Reiser *et al.* 2006).

Adult winter-run Chinook salmon hold in deep, cool, well-oxygenated pools to escape warm water temperatures during the early summer months prior to spawning (DWR and Reclamation 2000). Pools utilized by Chinook salmon for holding are generally greater than 5 feet in depth that contain cover from overhanging vegetation, undercut banks, boulders or large woody debris (Lindsay 1985). Water velocities through these pools range from 0.5 to 2.0 ft/sec (Moyle 2002).

Figure 2-4. Geographic and Temporal Distribution of Sacramento River Winter-run Chinook Salmon

2.2.2 ADULT SPAWNING

2.2.2.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

The primary spawning area for winter-run Chinook salmon extends 31 miles from Keswick Dam (RM 302) downstream to Battle Creek (RM 271) (Snider *et al.* 2001). Within this 31-mile reach, the majority of spawning occurs in the upper 14 miles from Keswick Dam to the Redding Water Treatment Plant (WTP) (Snider *et al.* 2001). Winter-run Chinook salmon primarily spawn from late-April through mid-August, with peak spawning activity in May and June (NMFS 1997).

2.2.2.2 BIOLOGICAL REQUIREMENTS

Generally, successful spawning for Chinook salmon occurs at water temperatures below 60°F (NMFS 1997). Both Chambers (1956), and Reiser and Bjornn (1979) report that upper preferred water temperatures for spawning Chinook salmon range from about 55°F to 57°F. The biological opinion (BO) on the Long-Term CVP and SWP Operations Criteria and Plan (OCAP) requires water temperatures to be maintained below 56°F in the upper Sacramento River above the RBDD (NMFS 2004a). The 56°F temperature criterion is measured as the average daily water temperature and as such, the criterion may allow water temperatures to exceed 56°F for some periods during a day. Chinook salmon spawn in riffles or runs with water velocities ranging from 0.5 to 6.2 ft/sec (DWR and Reclamation 2000; Healey 1991; Moyle 2002; Vogel and Marine 1991).

Spawning depths can range from as little as a few inches to several feet (Moyle 2002). Preferred water depths appear to range from 0.8 to 3.3 feet (Allen and Hassler 1986; Moyle 2002). Substrate is an important component of Chinook salmon spawning habitat, and generally includes a mixture of gravel and small cobbles (Moyle 2002). NMFS (1997) reports that preferred spawning substrate is composed mostly of gravels from 0.75 to 4.0 inches in diameter.

2.2.3 EMBRYO INCUBATION

2.2.3.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

The winter-run Chinook salmon embryo incubation life stage primarily occurs between Keswick Dam and Battle Creek from April through October (NMFS 2004a; Vogel and Marine 1991).

2.2.3.2 BIOLOGICAL REQUIREMENTS

Water temperature, dissolved oxygen concentration, and inter-gravel flow are all important factors in successful embryo incubation of Chinook salmon. Within the appropriate water temperature range, eggs normally hatch in 40 to 60 days. Newly hatched fish (alevins) normally remain in the gravel for an additional four to six weeks until the yolk sac has been absorbed (NMFS 1997). Maximum embryo survival is reported at water temperatures ranging from 41°F to 56°F (Moyle 2002; USFWS 1995b). Yoshiyama *et al.* (2001) report good embryo survival at water temperatures up to 58°F. The USFWS reports decreased embryo survival occurs at water temperatures above 56°F, and no survival of eggs was observed at water temperatures above 62°F (USFWS 1995a).

Successful embryo incubation has been observed within a wide range of water depths and velocities, provided that intra-gravel flow is adequate for delivering sufficient oxygen to developing eggs and alevins (Healey 1991). The minimum intra-gravel percolation rate to ensure good survival of incubating eggs and alevins will vary, depending on flow rate, water depth, and water quality. Under controlled conditions, survival rates of 97 percent and greater have been observed with a percolation rate of 0.001 ft/sec (0.03 centimeters per second [cm/sec]), whereas 60 percent survival was observed at a 0.0001 ft/sec (0.0042 cm/sec) percolation rate (Gangmark and Bakkala 1960; Shelton 1955). Raleigh *et al.* (1986) report optimal embryo survival at dissolved oxygen concentration of 10.5 milligrams per liter.

2.2.4 JUVENILE REARING AND OUTMIGRATION

2.2.4.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Winter-run Chinook salmon fry emerge from the spawning gravels from mid-June through mid-October (NMFS 1997). The downstream migration of juvenile winter-run Chinook salmon past RBDD may begin in late-July, peak in September, and can continue until mid-March (Vogel and Marine 1991). Winter-run Chinook salmon juveniles occur between the RBDD and the confluence of Deer Creek (RM 220) from July through September. Their distribution slowly spreads downstream to Princeton (RM 164) between October and March (Johnson *et al.* 1992; NMFS 1997). Winter-run Chinook salmon juveniles move downstream past Glenn-Colusa Irrigation District's (GCID) Hamilton City Pumping Plant (HCPP) from July through March, with peak movement occurring in October and November (CUWA and SWC 2004). The presence of juvenile winter-run Chinook salmon in the Delta may extend from as early as September to as late as June, with a peak from January through April (NMFS 1997). The timing of emigration from the Delta to the Bays and ocean is not well known, but winter-run Chinook salmon juveniles reportedly reside in fresh and estuarine waters for five to nine months before migrating to the ocean from January (possibly late-December) through June (NMFS 1997). Data collected from the Chipps Island trawl show a winter-run sized Chinook salmon emigration peak in March and April (USFWS 2001).

2.2.4.2 BIOLOGICAL REQUIREMENTS

Optimal water temperatures for juvenile Chinook salmon are reported to range from 53.6°F to 57.2°F (NMFS 1997). A daily average water temperature of 60°F is considered the upper temperature limit for juvenile Chinook salmon growth and rearing (NMFS 1997). Inhibition of Chinook salmon smolt development in the Sacramento River reportedly may occur at water temperatures above 63°F (Marine 1997; Marine and Cech 2004).

Riparian vegetation, including shaded riverine aquatic (SRA) cover, provides juvenile salmon cover from predators, habitat complexity, a source of insect prey, and shade for maintaining water temperatures within suitable ranges for all life stages. Juvenile Chinook salmon prefer riverine habitat with abundant instream and overhead cover (e.g., undercut banks, submerged and emergent vegetation, logs, roots, other woody debris, and dense overhead vegetation) to provide refuge from predators, and a sustained, abundant supply of invertebrate and larval fish prey. On the Sacramento River, juvenile Chinook salmon are more commonly found in association with natural (as opposed to riprapped) riverbanks, and SRA cover (CDFG 1983).

Upon arrival in the Delta, it is likely that winter-run Chinook salmon will tend to rear in the more upstream freshwater portions of the Delta for about two months (Kjelson *et al.* 1981). Within the Delta, juvenile Chinook salmon forage in shallow areas with protective cover, such as intertidal and subtidal mudflats, marshes, channels, and sloughs. Maturing Chinook salmon fry and fingerlings prefer to rear further downstream where ambient salinity is up to 1.5 to 2.5 ppt (Levings and Bouillon 2005). In Suisun Marsh, Moyle *et al.* (1995) reported that Chinook salmon fry tend to remain close to the banks and vegetation, near protective cover, and in dead-end tidal channels. Winter-run Chinook salmon fry remain in the Delta until they reach a FL of about 118 mm (i.e., 5 to 10 months of age) and then begin emigrating to the ocean maybe as early as November and continue through May (Fisher 1994; Myers *et al.* 1998).

2.2.5 SUB-ADULT AND ADULT OCEAN RESIDENCE

2.2.5.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Winter-run Chinook salmon ocean residence normally lasts from one to three years. About one-fourth of the population returns to freshwater as two-year olds, two-thirds as three-year olds and the remainder as four-year olds (NMFS 1997). This age-of-return distribution varies - there are years when overwhelmingly two-year old males return to the upper Sacramento, and years such as 2007 when a substantial component of the returning population are four-year olds. The distribution of sub-adult and adult Sacramento River winter-run Chinook salmon in the ocean is believed to primarily extend from Monterey to Fort Bragg (NMFS 1997).

2.2.5.2 BIOLOGICAL REQUIREMENTS

The availability of food resources and cold water are likely the most important factors controlling the survival of sub-adult and adult Chinook salmon in the ocean. Food resource availability for these fish is largely dependent on the spatial distribution and abundance of plankton, which has been shown to be associated with coastal upwelling in the Pacific Northwest (Nickelson 1986; Pearcy 1997). Coastal upwelling occurs when offshore moving surface water is replaced by water which upwells along the coast from depths of 50 to 100 meters and more (NMFS 1996a). This upwelled water is cooler than the original surface water and typically has much higher concentrations of nutrients such as nitrate, phosphate and silicate that are key to sustaining biological production (NMFS 1996a). Generally, strong upwelling events lasting several months or more bring an abundance of plankton and cold water to the near shore surface waters of the ocean and have been associated with salmon abundance.

2.3 THREATS AND STRESSORS

2.3.1 SUMMARY OF ESA LISTING FACTORS

2.3.1.1 DESTRUCTION, MODIFICATION, OR CURTAILMENT OF HABITAT OR RANGE

The primary threats to the Sacramento River winter-run Chinook salmon ESU have remained the same as when the ESU was first listed in an emergency interim rule in 1989 and final rule in 1990. Dams in the Central Valley have blocked access to the entire historical spawning grounds, altered water temperatures, and reduced habitat complexity, thus resulting in severe risks to the

abundance, productivity, and especially to the spatial structure and genetic diversity of the winter-run Chinook salmon ESU. These four components of abundance, productivity, spatial structure, and diversity are the basis of how NMFS determines population and ESU/DPS viability for salmonids, as defined in (McElhany *et al.* 2000). The construction and operation of Shasta Dam alone immediately reduced the winter-run Chinook salmon ESU from four independent populations to just one. The remaining available habitat for natural spawners is currently maintained artificially with cool water releases from Shasta and Keswick dams, thereby significantly limiting spatial distribution of this ESU.

RBDD, constructed in 1964, presents an impediment to upstream migrants. The construction and operation of the dam were considered one of the primary reasons for the decline of winter-run Chinook salmon in listing the ESU. The RBDD gates are now lowered on May 15, allowing for free passage of upstream migrants to access spawning habitats. An estimated 85% of the run has passed RBDD at that time. Red Bluff Diversion Dam is still partly passable when the gates are down, but the dam does delay migration and forces some fish to spawn below it where the river temperatures are warmer, and the habitat less suitable.

As described in the final listing determination for the ESU, prior to 2001, the flashboard gates at the Anderson-Cottonwood Irrigation District (ACID) Diversion Dam and the inadequate fish ladders blocked passage for upstream migrant fish. The seasonal operation of the dam created unsuitable habitat upstream of the dam by reducing flow over the eggs, which has led to reduced egg survival. In 2001, a new fish screen was placed at the diversion and a state-of-the-art fish ladder was installed to address the threats caused by the diversion dam. The new fish ladder appears to be effective for successful fish passage. For example, during the period 1987 through 2000 an average of 2.35% of winter-run spawning occurred above the ACID dam, and with post-ladder improvements an average of 42.13% of winter-run spawning has occurred above the ACID dam (Killam 2006).

In the first listing determination of the ESU, pollution from Iron Mountain Mine was considered one of the main threats to the ESU. Acid mine drainage produced from the abandoned mine degraded spawning habitat of winter-run Chinook salmon and resulted in high salmon and steelhead mortality. Remediation of Iron Mountain Mine and restoration efforts as outlined in the 2002 Restoration Plan (that was developed by the Iron Mountain Mine Trustee Council composed of several federal and state agencies) are considered to adequately mitigate the threats posed to the ESU. Pollution from Iron Mountain Mine is no longer considered a main factor threatening the ESU. Pollution from agricultural runoff carrying pesticides and fertilizers, however, is still a threat to winter-run Chinook salmon.

Bank stabilization structures to prevent bank erosion may affect the quality of rearing and migration habitat along the river. Juvenile salmon prefer natural streambanks as opposed to riprapped, leveed, or channelized sections of the Sacramento River. Bank stabilization projects in the Sacramento River are beginning to incorporate conservation measures in some areas to provide more suitable seasonal habitat for juvenile salmon as well as reduce predation in the artificially created habitat.

Additionally, the sediment balance of the Sacramento River is highly disrupted, resulting in reduced inputs of gravel due to dams and regulated flows, as well as gravel mining (The Nature Conservancy 2006).

2.3.1.2 OVERUTILIZATION FOR COMMERCIAL, RECREATIONAL, SCIENTIFIC, OR EDUCATIONAL PURPOSES

Overutilization for commercial, recreational, scientific, or educational purposes no longer appears to have a significant impact on winter-run Chinook salmon populations, but warrants continued assessment. Commercial fishing for salmon is managed by the Pacific Fishery Management Council (PFMC) and is constrained by time and area to meet the Sacramento River winter-run ESA consultation standard, and restrictions requiring minimum size limits and use of circle hooks for anglers. Ocean harvest restrictions since 1995 have led to reduced ocean harvest of winter-run Chinook salmon (i.e., Central Valley Chinook salmon ocean harvest index, or Central Valley Index (CVI), ranged from 0.55 to nearly 0.80 from 1970 to 1995, and was reduced to 0.27 in 2001). While overutilization does not seem to be a significant factor under current ocean and terrestrial climate conditions, this could change due to global climate change implications.

Scientific and educational projects permitted under Sections 4(d) and 10(a)(1)(A) of the ESA stipulate specific conditions to minimize take of winter-run Chinook salmon individuals during permitted activities. There are currently four active permits in the Central Valley that may affect winter-run Chinook salmon. These permitted studies provide information about winter-run Chinook salmon that is useful to the management and conservation of the ESU.

2.3.1.3 DISEASE OR PREDATION

Naturally occurring pathogens may pose a threat to winter-run Chinook salmon, and artificially propagated winter-run Chinook salmon are susceptible to disease outbreaks such as the Infectious Hematopoietic Necrosis Virus (IHNV) and Bacterial Kidney Disease.

Predation is a threat to winter-run Chinook salmon, especially in the Delta where there are high densities of non-native fish (e.g., small and large mouth bass, striped bass, catfish, and sculpin) that prey on outmigrating salmon. The presence of man-made structures in the environment that alter natural conditions likely also contributes to increased predation by altering the predator-prey dynamics often favoring predatory species. In the upper Sacramento River, rising of the gates at the RBDD reduces potential predation at the dam by pikeminnow. In the ocean, and even the Delta environment, salmon are common prey for harbor seals and sea lions.

2.3.1.4 INADEQUACY OF EXISTING REGULATORY MECHANISMS

Over the past 10 to 15 years, many protective measures have been implemented to help increase the abundance and productivity of winter-run Chinook salmon.

FEDERAL EFFORTS

There have been several federal actions to reduce threats to the winter-run Chinook salmon ESU. Actions undertaken pursuant to Section 7 BOs have helped to increase the abundance and productivity of winter-run Chinook salmon. The BO for the CVP and SWP has led to increased freshwater survival, and the BOs for ocean harvest have led to increased ocean survival and adult

escapement. There have also been several habitat restoration efforts implemented under the Central Valley Project Impact Act (CVPIA) and CALFED programs that have led to increased abundance and productivity. There has been successful implementation of the artificial propagation program at LSNFH to supplement the abundance of naturally spawning winter-run Chinook salmon and preserve the ESU's genetic resources. Section 10(a)(1)(B) of the ESA authorizes habitat conservation plans (HCP) for non-federal actions. However, many private parties are hesitant to engage in the HCP process because it can be costly and time-consuming. Developing an HCP is usually a voluntary process, thus, there are no guarantees that large-scale, long-term planning efforts will occur.

However, despite federal actions to reduce threats to the winter-run Chinook salmon ESU through conservation efforts, there is still a lack of diversity within the ESU and there still remains only one single extant population. Although there has been a marked increase in abundance of winter-run Chinook salmon over the last several years, the expansion of spatial distribution of winter-run Chinook salmon spawners has not been possible, as winter-run Chinook currently spawn within the only existing suitable habitat. It is uncertain whether ongoing efforts to restore habitat and passage to Battle Creek through the CALFED Ecosystem Restoration Program (ERP) will lead to successful establishment of a second independent population. The funding and implementation of that program remains uncertain. As noted in Lindley *et al.* (2006), at least two additional populations need to be successfully established to attain ESU viability for winter-run Chinook salmon, but there has not been an active push to establish additional populations. NMFS does not believe that current protective efforts being implemented for the winter-run Chinook salmon ESU provide sufficient certainty that the ESU will not be in danger of extinction in the foreseeable future.

NON-FEDERAL EFFORTS

A wide range of restoration and conservation actions have been implemented or are in the planning stages of development to aid in the recovery of the winter-run Chinook salmon ESU. Most of these actions are pursuant to implementation of conservation and restoration actions in the CALFED Bay-Delta Program, which is composed of 25 state and federal agencies, and has aided to increase abundance and productivity of winter-run Chinook salmon. The state of California listed winter-run Chinook salmon as endangered in 1989 under the California Endangered Species Act (CESA). The state's Natural Communities Conservation Plan (NCCP) involves long-term planning with several stakeholders. The state has also implemented freshwater harvest management conservation measures, and increased monitoring and evaluation efforts in support of conserving this ESU. Local governments, such as the City of Redding, and grassroots organizations, such as the Battle Creek Watershed Conservancy, are engaged in the development and implementation of conservation and recovery measures to improve conditions for winter-run Chinook salmon.

Despite federal and non-federal efforts and partnerships, the winter-run Chinook salmon ESU remains at risk of extinction because the existing regulatory mechanisms do not provide sufficient certainty that efforts to reduce threats to the ESU will be fully funded or implemented. The effectiveness of regulations depends on compliance, and tracking and enforcement of compliance has not occurred consistently within this ESU.

2.3.1.5 OTHER NATURAL AND MANMADE FACTORS AFFECTING THE SPECIES' CONTINUED EXISTENCE

Artificial propagation programs for winter-run Chinook salmon conservation purposes were developed to increase abundance and diversity of winter-run Chinook salmon, but it is still unclear what the effects of the program are to the productivity and spatial structure of the ESU (i.e., fitness and productivity). Global and localized climate changes, such as El Niño ocean conditions and prolonged drought conditions, may play a significant role in the decline of salmon, with unstable Chinook salmon populations potentially reaching lower levels. The ESU is highly vulnerable to drought conditions. During dry years, less cold water is available for release from Shasta Dam, which is the sole provider of cold water on which the fish are dependent. The resulting increased water temperature reduces availability of suitable spawning and rearing conditions.

Unscreened water diversions entrain outmigration juvenile salmon and fry. Unscreened water diversions and CVP and SWP pumping plants entrain juvenile salmon, leading to fish mortality. The cumulative effect of entrainment at these diversions and delays in outmigration of smolts caused by reduced flows may affect winter-run Chinook salmon survival.

Although the status of winter-run Chinook salmon is improving, there is only one population, and it depends on cold water releases from Shasta Dam, which would be vulnerable to a prolonged drought. Increasing the number of independent populations has yet to occur. With only one extant population of winter-run Chinook salmon, there is a need to ensure more diversity within this ESU, because it is more susceptible to catastrophic events arising from natural and/or anthropogenic processes. The need for a second naturally spawning population has been recognized and plans have been proposed to establish a second population in Battle Creek, but implementation of restoration in this watershed continues to be delayed. However, there is no guarantee that this planned protective effort will provide enough certainty to reduce the risk to the population of becoming extinct. Additional opportunities exist to provide further protection to the species, but actions to minimize threats will require close collaboration with many agencies, stakeholders, and special interest groups.

2.3.2 NON-LIFE STAGE-SPECIFIC THREATS AND STRESSORS

Potential threats to the California Central Valley winter-run Chinook salmon population that are not specific to a particular life stage include the potential negative impacts of the current artificial propagation program utilizing the LSNFH; the small wild population size; the genetic integrity of the population due to both hatchery influence and small population size; and the potential effects of long-term climate change. Each of these potential threats is discussed in the following sections.

2.3.2.1 ARTIFICIAL PROPAGATION PROGRAM

A conservation hatchery program for winter-run Chinook salmon was initiated in 1989 at the CNFH on Battle Creek; a tributary of the upper Sacramento River above the RBDD. The purpose of the program is to reduce the risk of extinction by conservation of the winter-run Chinook salmon genome and supplementation of the wild winter-run Chinook salmon spawning population in the upper Sacramento River. Potential winter-run Chinook salmon broodstock

have been collected in fish traps at Keswick Dam and RBDD, and were originally spawned at CNFH. As additional insurance, captive broodstock programs also were adopted to provide gametes for artificial propagation as needed, by rearing program winter-run juveniles to maturity in captivity. A captive rearing program was initiated in 1991 at the University of California Bodega Marine Laboratory (BML), where it played a role in winter-run research studies; and at Steinhart Aquarium, which provided a forum to educate the public to the status of the endangered Sacramento River winter-run Chinook salmon. All conservation hatchery winter-run Chinook salmon have been protected under the ESA and have been part of the Sacramento River winter-run Chinook salmon ESU.

The first release of hatchery-raised winter-run fry occurred in 1990, with an average annual release of 30,600 juveniles from CNFH between brood years 1991 and 1995. Although the intent of the program is to contribute winter-run adults to the spawning population in the upper Sacramento River, the CNFH winter-run juveniles imprinted on Battle Creek water and returned instead to Battle Creek as mature adults. In addition, genetic analyses indicated that 8 of the 129 Chinook salmon used for hatchery propagation in 1993, 1994 and 1995 were likely spring-run (NMFS 1997b). Hybrid fish inadvertently were included in program winter-run releases in 1993 and 1994, but were held back in 1995 (NMFS 1997b). At the time, the microsatellite locus, *Ots-2*, was being used exclusively to determine run assignment on captured fish; however, most of the major alleles at this locus are shared by both winter-run and spring-run Chinook salmon (Hedgecock *et al.* 1996). In response to the need to identify fish to run before being used as program broodstock, the genetics team at BML (Banks 1996) identified a number of highly polymorphic microsatellite loci in winter-run which have since been refined with multi-allelic gene markers. While these issues were being addressed, BML operations provided program fish from 1996 through 1998 while a conservation hatchery facility on the upper Sacramento River was being planned. The winter-run conservation program was moved to the LSNFH in 1998 and a third captive rearing program was established at LSNFH. Winter-run production fish are marked with coded wire tags (CWT) and adipose fin-clipped, and released in the upper Sacramento River as pre-smolts each winter in late January or early February. In the CALFED Science Conference of 2003 (Brown and Nichols 2003) it was reported that winter-run conservation program has contributed to the abundance of returning adult winter-run Chinook salmon. **Table 2-1** shows the annual number of winter-run Chinook salmon released from the facility from 1999 through 2005. The table also provides information based on data acquired during mark-recapture studies on the amount of time required by the smolts to migrate through the Delta.

Table 2-1. Winter-run Chinook Salmon Juvenile Releases from LSNFH (Broodyears 1998-2008) and Date of Initial Recapture at Chipps Island.

Brood Year	Upper Sacramento River Release Date	Number of Pre-Smolts Released ¹	Initial Date ² of Recapture at Chipps Island
1998	1/28/1999	153,908	3/15/1999
1999	1/27/2000	30,840	3/18/2000
2000	2/01/2001	166,206	3/09/2001
2001	1/30/2002	252,684	3/20/2002
2002	1/30/2003	233,613	2/14/2003

2003	2/05/2004	218,617	2/20/2004
2004	2/03/2005	168,261	2/22/2005
2005	2/02/2006	173,344	2/17/2006
2006	2/08/2007	196,288	2/17/2007
2007	1/31/2008	71,883	3/12/2008
2008	1/29/2009	146,211	
Source: (¹ USFWS Red Bluff; ² Paul Cadrett, USFWS, personal com.)			

There is evidence that hatchery fish may negatively affect the genetic constitution of wild fish (Allendorf *et al.* 1997; Hindar *et al.* 1991; Waples 1991). One indication of this is the observation of a reduction in wild fish populations following the initiation of a hatchery release program (Hilborn 1992; Washington and Koziol 1993). An explanation offered for this observation is that hatchery fish are adapted to the hatchery environment; therefore, natural spawning with wild fish reduces the fitness of the natural population to the natural environment. The winter-run conservation program has a broodstock collection target limit of 15 percent of the estimated upriver winter-run escapement, up to a maximum of 120 natural-origin winter-run but no fewer than 20 fish. The number of hatchery-origin winter-run Chinook salmon that may be incorporated as broodstock cannot exceed 10 percent of the total number of winter-run Chinook salmon being spawned. Broodstock collection is based on the historic migration timing of winter-run past RBDD. Collected adults are assessed for phenotypic indicators of winter-run classification and may be selected for the program only after tissue samples are genetically confirmed. The majority of winter-run hatchery releases have been F1 generation (progeny of wild fish crosses spawned at LSNFH). The annual production goal is a maximum of 250,000 pre-smolt winter-run Chinook salmon sub-yearlings for release, which was met in 2001 (Table 2-1). There may be a trade-off over time between reducing the demographic risks and increasing the genetic risks to the wild population with hatchery supplementation; conservation hatchery programs are intended to be phased out as the natural population recovers. USFWS has begun this process with the phase out of the winter-run captive rearing programs at BML and LSNFH in 2005 and 2006, respectively (Steinhart Aquarium discontinued as a captive broodstock site in 2001). Recently, NMFS reports that the rising proportion of hatchery fish among returning adults may threaten to shift the population from a low to moderate risk of extinction. Lindley *et al.* (2007) recommend that in order to maintain a low risk of genetic introgression with hatchery fish, no more than five percent of the naturally spawning population should be composed of hatchery fish. LSNFH provides a higher level of survival to winter-run at the egg, alevin and early juvenile salmon life stages than what is found in nature. Since 2001, hatchery origin winter-run Chinook salmon have made up more than five percent of the run and in 2005, the contribution of hatchery fish exceeded 18 percent (Lindley *et al.* 2007).

However, Since LSNFH is a Conservation Hatchery (using Best Management Practices), a more appropriate tool to determine associated genetic risk may be the Proportionate Natural Influence (PNI). PNI can be calculated as an approximate index by using the following formula:

$$PNI \text{ Approx} = pNOB / (pNOB + pHOS)$$

Where pNOB is defined as the Proportion of Natural Origin Brood Stock, and pHOS as the Proportion of Hatchery Origin In-River Spawners.

The Hatchery Scientific Review Group (HSRG), an independent scientific review panel for the Pacific Northwest Hatchery Reform Project, developed guidelines as minimal requirements for minimizing genetic risks of hatchery programs to naturally spawning populations, and are as follows: PNI must exceed 0.5 in order for the natural environment to have a greater influence than the hatchery environment on the genetic constitution of a naturally-spawning population. In addition, maintaining PNI greater than 0.67 for natural populations considered essential for the recovery or viability of an ESU/DPS.

LSNFH has a calculated PNI average over the last six years (2003-2008) of 0.91, due to following strict management practices, which satisfies the guidelines (Bob Null, personal communication).

In summary, LSNFH is one of the most important reasons that Sacramento River winter-run Chinook salmon still persist, and the hatchery is beneficial to the ESU over the short term. However, if the continued existence of the ESU depends on LSNFH, it by any reasonable definition cannot be characterized as having a low risk of extinction, and therefore the ESU should not be delisted on that basis. The winter-run Chinook salmon ESU cannot be delisted until there are at least two viable populations (e.g., Battle Creek and Sacramento River above Shasta Dam). If the ESU has a high likelihood of persistence without LSNFH, the LSNFH winter-run Chinook program should be phased out and eventually terminated. To obtain long-term sustainability, ESUs need to have some low-risk populations with essentially no hatchery influence in the long run; they could have additional populations with some small hatchery influence, but there needs to be a core of populations that are not dependent on hatchery production.

2.3.2.2 SMALL POPULATION SIZE COMPOSED OF A SINGLE EXTANT POPULATION

One of the main threats to the Central Valley winter-run Chinook salmon population is the small population size. The Biological Review Team (BRT) (Good *et al.* 2005) suggests that one of the chief threats to the winter-run Chinook salmon population in the Sacramento River is small population size. The population declined from an escapement of near 100,000 in the late 1960s to less than 200 in the early 1990s (Good *et al.* 2005). The California Department of Fish and Game (CDFG) estimated that 191 winter-run Chinook salmon returned in 1991 and that 189 returned in 1994 (Arkush *et al.* 1997). Runs increased to 1,361 in 1995 and 1,296 in 1996 (Arkush *et al.* 1997). Escapements increased to 8,120, 7,360 and 8,133 in 2001, 2002 and 2003 respectively (CDFG 2004b). However, a significant portion of these fish are likely returns from the winter-run Chinook salmon propagation program at the LSNFH.

A small population is particularly vulnerable to changes in environmental conditions such as droughts, El Niño events, and hazardous material spills, any of which could result in a year class failure. Magnifying the problem of a small population size of winter-run Chinook salmon in the Central Valley is that virtually all spawning activity occurs in the upper Sacramento River between the RBDD and Keswick Dam. A problem in this reach of the river could potentially destroy an entire year class. Historically, winter-run Chinook salmon spawned in several different tributaries of the upper Sacramento River including the McCloud, Pit and Little

Sacramento rivers (NMFS 1997). Small population sizes are also vulnerable to adverse genetic effects as discussed in Section 2.3.2.3 below.

Botsford and Brittnacher (1998) propose a delisting criterion of >10,000 spawning females over any 13 consecutive years. Furthermore, due to the limited accuracy in measuring spawner abundance and the finite number of samples used to estimate population growth rate, estimates must be based on at least 13 years of data (Botsford and Brittnacher 1998).

2.3.2.3 GENETIC INTEGRITY

Available literature suggests several concerns with hatchery stocks reproducing with wild stocks. For example, Fleming and Gross (1992) documented the competitive inferiority of hatchery coho when attempting to spawn with wild stocks. Hatchery males were less aggressive, more submissive, and were denied access to spawning females; hatchery females spawned smaller portions of their eggs than did wild females and lost more eggs to redd destruction by other females. Busack and Currens (1995) report that raising fish in an artificial environment for all or part of their lives imposes different selection pressures on them than does the natural environment. Fish in hatchery environments may be exposed to higher densities, different food, flow regimes, substrate, protective cover, etc. These changes allow more fish to survive in the hatchery than in the wild but they also create an opportunity for genetic change in the overall population (Busack and Currens 1995). Doyle *et al.* (1995) report that the presence of a hatchery rearing stage in the life cycle of a fish will inevitably select for improved hatchery performance even when the hatchery broodstock is collected every generation from the wild. Because the correlation of hatchery fitness and fitness in nature is usually negative, this has created a problem in many enhancement programs. Lindley *et al.* (2007) recommend that in order to maintain a low risk of genetic introgression with hatchery fish, no more than five percent of the naturally spawning population should be composed of hatchery fish. Since 2001, hatchery-origin winter-run Chinook salmon have made up more than five percent of the run and in 2005, the contribution of hatchery fish exceeded 18 percent (Lindley *et al.* 2007).

In contrast to the concerns expressed above, Campton (1995) reviewed the literature on genetic effects of hatchery fish and wild stocks of Pacific salmon and steelhead and concluded that most genetic effects detected to date appear to be caused by hatchery or fishery management practices and not biological factors intrinsic to hatcheries or hatchery fish. Additionally, Olson *et al.* (1995) reported that based on data gathered on wild and hatchery spring-run Chinook salmon and summer steelhead in an Oregon stream, hatchery production is providing increased contribution to tribal and sport fisheries while not adversely affecting wild stock production.

Another potential problem of a small natural population is the potential for artificial propagation to reduce the effective size of the naturally spawning wild population. Ryman and Laikre (1991) suggest that supplementation may, under certain circumstances, decrease the overall effective population size and that the greatest danger of such a reduction occurs when the effective population of the natural proportion of the population is small. Small population sizes also reduce genetic variation in the population. Arkush *et al.* (2007) suggest that pathogen susceptibility in winter-run Chinook salmon will increase if further genetic variation is lost. These are the very circumstances that might occur in the case of an endangered or threatened salmonid species (NMFS 1997).

The winter-run captive broodstock program maintained representation of winter-run family groups and maximized genetic variation in spawning matrices. The artificial propagation program collects broodstock on the basis of historic run-timing and abundance of winter-run past RBDD. Collected adults are assessed for phenotypic indicators of winter-run classification and may be selected for the program only after tissue samples are genetically confirmed through molecular and statistical methods.

Adult hatchery winter-run returns are intended to contribute to the effective spawning population (N_e) by supplementing the abundance of the natural population. N_e is a measure of the rate of genetic drift within a population, and is directly related to the rate of loss of genetic diversity and the rate of increase in inbreeding within a population (Riemann and Allendorf 2001). USFWS conducts an annual analysis on the likelihood of loss of genetic variation in the winter-run effective population as a consequence of releases of hatchery-origin winter Chinook salmon. Two estimates of N_e are calculated for the winter-run population: one assumes genetic contribution by 10 percent of the run size estimate (Bartley *et al.* 1992) and one assumes genetic contribution by 33 percent of the run size estimate (R. Waples, NMFS Northwest Fisheries Science Center, pers. comm. to USFWS).

2.3.2.4 LONG-TERM CLIMATE CHANGE

California's Central Valley is located at the extreme southern limit of Chinook salmon distribution. The southern limit of Chinook salmon distribution is likely a function of climate. In California, observations reveal trends in the last 50 years toward warmer winter and spring temperatures, a smaller fraction of precipitation falling as snow, a decrease in the amount of spring snow accumulation in lower and middle elevation mountain zones and an advance in snowmelt of 5 to 30 days earlier in the spring (Knowles *et al.* 2006). Given this trend, it is likely that most species currently at the southern extent of their range, including Chinook salmon, will experience less desirable environmental conditions in the future.

Although current models are broadly consistent in predicting increases in global air temperatures, there are considerable uncertainties about precipitation estimates. For example, many regional modeling analyses conducted for the western United States indicate that overall precipitation will increase, but uncertainties remain due to differences among larger scale General Circulation Models (GCMs) (Kiparsky and Gleick 2003). Some researchers believe that climate warming might push the storm track on the West Coast further north, which would result in drier conditions in California. At the same time, relatively newer GCMs, including those used in the National Weather Assessment, predict increases in California precipitation (Roos 2003). Similarly, two popular models, including HadCM2 developed by the U.K. Hadley Center and PCM developed by the U.S. National Center for Atmospheric Research, also predict very different future scenarios. The HadCM2 predicts wetter conditions while the PCM predicts drier conditions (Brekke *et al.* 2004).

While much variation exists in projections related to future precipitation patterns, all available climate models predict a warming trend resulting from the influence of rising levels of greenhouse gasses in the atmosphere (Barnett *et al.* 2005). The potential effects of a warmer climate on the seasonality of runoff from snowmelt in California's Central Valley have been

well-studied and results suggest that melt runoff would likely shift from spring and summer to earlier periods in the water year (Vanrheenen *et al.* 2004). Currently, snow accumulation in the Sierra Nevada acts as a natural reservoir for California by delaying runoff from winter months when precipitation is high (Kiparsky and Gleick 2003). Despite the uncertainties about future change in precipitation rates, it is generally believed that higher temperatures will lead to changes in snowfall and snowmelt dynamics. Higher atmospheric temperatures will likely increase the ratio of rain to snow, shorten and delay the onset of the snowfall season, and accelerate the rate of spring snowmelt, which would lead to more rapid and earlier seasonal runoff relative to current conditions (Kiparsky and Gleick 2003). Studies suggest that the spring streamflow maximum could occur about one month earlier by 2050 (Barnett *et al.* 2005).

If air temperatures in California rise significantly, it will become increasingly difficult to maintain appropriate water temperatures in order to manage coldwater fisheries, including winter-run Chinook salmon. A reduction in snowmelt and increased evaporation could lead to decreases in reservoir levels and, perhaps more importantly, coldwater pool reserves (California Energy Commission 2003). As a result, water temperatures in rivers supporting anadromous salmonids, including winter-run Chinook salmon, could potentially rise and no longer be able to support over-summering life stages (i.e., winter-run Chinook salmon embryo incubation, fry emergence, and juvenile emigration). The California Department of Water Resources (DWR) (2006) suggests that under a warmer climate scenario, water temperature standards in the upper Sacramento River likely could not be maintained.

2.3.3 SAN FRANCISCO, SAN PABLO, AND SUISUN BAYS

Adult winter-run Chinook salmon on their upstream migration enter San Francisco Bay from November through June (Hallock and Fisher 1985). Migration through the Delta and into the lower Sacramento River occurs from December through July, with a peak during the period extending from January through April (USFWS 1995a). The majority of the winter-run Chinook salmon adults pass the RBDD between January and May (Hallock and Fisher 1985), with the peak typically occurring during March and April (Snider *et al.* 2001). See Section 2.2.1 for a more complete description of the biological requirements and description of this life stage. Factors that may adversely affect winter-run Chinook salmon adult immigration and holding are similar in each of the three river reaches described below although the magnitude of the effects may differ.

2.3.3.1 ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Suisun Marsh is one of the largest contiguous brackish water tidal marshes in the United States and is situated west of the Delta and north of Suisun Bay. In 1978, water salinity standards for Suisun Marsh were established by the State Water Resources Control Board's (SWRCB) Decision 1485 (D-1485) to improve waterfowl food plant production and to preserve the Suisun Marsh as a brackish water tidal marsh. In response to D-1485, DWR initiated a "Plan of Protection for the Suisun Marsh," which proposed actions to improve the water quality of the inner marsh. The Suisun Marsh Salinity Control Structure (SMSCS), which spans the entire 465-foot width of Montezuma Slough, includes permanent barriers adjacent to the levee on each side of the slough, gates with flashboards, and a boat lock. The SMSCS was installed in 1989 to

control salinity levels in the marsh. The gates are operated from September through May, by closing on flood tides and opening on ebb tides (NMFS 2004a).

The SMSCS may delay and block immigration of adult Chinook salmon attempting to return to their natal spawning areas. Operation of the SMSCS reverses the net tidal flow within Montezuma Slough from a net eastward to a net westward flow. In addition, water flowing out of Montezuma Slough contains water from the Sacramento River. These hydrologic conditions may increase the attraction of adult Chinook salmon into the slough. Adult Chinook salmon that have entered the lower end of Montezuma Slough from the Delta cannot access spawning areas in the upper Sacramento River watershed and may be blocked or hindered by the SMSCS when they attempt to return to the Delta (NMFS 1997).

Several studies conducted to assess the effects of the SMSCS on adult salmon passage have confirmed that Chinook salmon may be attracted into Montezuma Slough and subsequently delayed or blocked from reaching spawning habitats in the Sacramento or San Joaquin rivers (CDFG 1996a; DWR and CDFG 2002). In an attempt to minimize passage problems associated with the SMSCS, the flashboards on the gates were modified by incorporating slots for fish to pass through. A SMSCS Steering Group analyzed data collected during salmon passage studies conducted in 1998 and 1999 and concluded that the modified flashboards were not improving salmon passage at the SMSCS (DWR Website 2007a). Results from ultrasonic telemetry studies conducted each year from 2001 through 2004 indicated that Chinook salmon were able to effectively pass upstream and downstream of the SMSCS when the boat lock was open. Subsequently, the OCAP BO included a term and condition stating that the boat lock will be held open when the flashboards are installed (NMFS 2004a). In addition, the OCAP BO states that the Bureau of Reclamation (Reclamation) and DWR should remove the flashboards on the SMSCS in a timely and efficient manner between September and May during periods when the operation of the SMSCS is not required to meet water quality standards in Suisun Marsh. In response to the OCAP BO, DWR and Reclamation developed a proposal describing the operational strategy for minimizing adverse effects of the SMSCS on Chinook salmon migration (DWR and Reclamation 2005).

HARVEST/ANGLING IMPACTS

Most fishery impacts on winter-run Chinook salmon occur in the recreational and commercial hook-and-line fisheries off the coast of California (NMFS 1997). Presumably, some harvest of winter-run Chinook salmon adults occurs within the Bays, but the effect of this harvest is likely negligible relative to the ocean harvest.

WATER TEMPERATURE

Water temperature at the U.S. Geological Survey (USGS) gage near Carquinez, which is located just east of San Pablo Bay, fluctuates annually between about 46°F and 73°F (USGS Website 2000). Because winter-run Chinook salmon reportedly immigrate through the Bay-Delta from November through June (Hallock and Fisher 1985), when water temperatures are seasonally cool, these fish are not expected to experience thermal stress migrating through this location. Although water temperatures at Carquinez during May and June may reach up to 68°F, a water temperature that reportedly has been stressful to Chinook salmon (Marine 1992; Ordal and Pacha 1963), the majority of winter-run Chinook salmon have already migrated through the Bay-Delta by this time (Yoshiyama *et al.* 1998).

WATER QUALITY⁶

Water quality in the Bay-Delta has improved because of regulations that followed the passage of the Clean Water Act (CWA) in 1972. Those regulations have largely alleviated problems with organic waste and nutrients to lead to algae blooms. However, Bay-Delta faces problems with industrial toxins and urban and agricultural runoff. According to the San Francisco Estuary Institute, mercury (total mercury and methylmercury), polychlorinated biphenyls (PCBs), and dioxins are believed to have the most severe impacts on San Francisco Bay water quality because they are distributed throughout the entire bay at concentrations well above established thresholds. Selenium, legacy pesticides (i.e., Dichloro-Diphenyl-Trichloroethane (DDT), Dieldrin, and Chlordane), and polycyclic aromatic hydrocarbons (PAHs) are also of concern because, either the entire bay or several bay locations are included on the 303(d) list and concentrations are above established thresholds of concern. The 303(d) list refers to Section 303(d) of the CWA, which requires states to identify water bodies that do not meet water quality standards (SFEI 2007).

The SFEI classifies Polybrominated diphenyl ethers (PBDEs), pyrethroids, sediment toxicity, and pollutant mixtures as rising concerns because although water quality objectives have not yet been established for these pollutants in order to place them on the 303(d) list of impaired waters, there is a significant amount of concern about their impacts on the bay. These concerns are growing, either because of increasing rates of input into the bay or advances in understanding of their hazards (SFEI 2007).

Managers have recently shifted their attention toward implementing provisions originally included in the CWA that have not previously enforced. The CWA calls for the development of cleanup plans known as Total Maximum Daily Loads (TMDLs) for pollutants on the 303(d) List. A TMDL recently adopted for mercury and TMDLs in development for PCBs, dioxins, selenium, and legacy pesticides will address some of the most serious current threats to water quality. Implementation of the mercury TMDL is now beginning, with a major focus on the remaining challenge of reducing loads from urban runoff and other pathways that were not an emphasis in the first wave of implementation of the CWA (SFEI 2007).

Poor water quality has been demonstrated to affect many aquatic organisms in the Bay-Delta, and particularly has adversely affected organisms at lower trophic levels (e.g., benthic snails) (Thompson *et al.* 2006). The extent of contaminant effects on fish in the Bay-Delta is not well understood due to the lack of information on the effects of long-term, low-level exposures of fish to contaminants. However, some fairly recent studies (Bacey *et al.* 2005; Bennett *et al.* 1995; Kuivla and Moon 2004; Teh *et al.* 2005; Weston *et al.* 2004) have shown that contaminants are having some effects on Bay-Delta fish species, although the consequences for fish populations are uncertain (Thompson *et al.* 2007). Specific to salmonids, Clifford (2005) reported that juvenile Chinook salmon exposed to 100 ng/g of the pyrethroid pesticide esfenvalerate in sediment had reduced time to death compared to the controls after being exposed to the hemapoetic viral necrosis virus. Considering the water quality problems in the Bay-Delta resulting from industrial toxins and urban and agricultural runoff, and the associated effects that

⁶ The San Francisco Estuary Institute conducts a Regional Monitoring Program for Water Quality in San Francisco Bay and publishes an associated annual report title, *The Pulse of the Estuary*. Much of the information in this section was directly derived from the 2007 annual report, which is available at the following website: http://www.sfei.org/rmp/pulse/2007/Pulse2007_full_report_web2.pdf.

have been demonstrated to occur in the aquatic community, water quality is believed to be an important stressor to juvenile winter-run Chinook salmon. However, the adult immigration and holding life stage of winter-run Chinook salmon is likely not substantially affected by water quality problems in the Bay-Delta.

2.3.3.2 JUVENILE REARING AND OUTMIGRATION

WATER QUALITY

Poor water quality in the Bay-Delta, which results from both point- and non-point sources of pollution, introduces the risk of acute toxicity and mortality or long-term toxicity and associated detrimental physiological responses, such as reduced growth or reproductive impairment to Chinook salmon and other organisms utilizing the Bay-Delta (CALFED 2000a). Point source pollution in the Bay-Delta includes the discharge of selenium and contaminants from various municipal and industrial discharges. Non-point source pollution affecting the Bay-Delta includes high levels of suspended sediments and contaminants from stormwater runoff, and agricultural drainage containing high levels of nutrients, herbicides, and pesticides (NMFS 1997). Between both point- and non-point sources, an estimated 5,000 to 40,000 tons of contaminants enter the Bay-Delta annually (CALFED 2000a).

The major sources of selenium entering the Bay-Delta include (1) agricultural drainage via direct discharge to the Bay-Delta; (2) effluents from the North Bay oil refineries; (3) San Joaquin River inflows which include agricultural drainage; and (4) Sacramento River inflows (USGS Website 2007). Selenium dissolves in water as selenite and selenate. Effluents from North Bay oil refineries contain concentrations of selenite, while selenium from agricultural drainages is principally in the form of selenate (NMFS 1997). Several laboratory studies have documented the adverse effects of the bioaccumulation of selenium in Chinook salmon (Hamilton 2003). None of these studies were designed to mimic selenium concentrations found in the Bay-Delta, but the results indicate the potential for reduced growth and survival of Chinook salmon in the Bay-Delta.

Another factor which may contribute to reduced growth and survival of fish in the Bay-Delta is the effect that inputs of ammonium (NH_4) have on the food web. Dugdale *et al.* (2007) concluded that low annual primary production in San Francisco Bay is partially controlled by high concentrations of NH_4 that can prohibit phytoplankton from accessing nitrate (NO_3), effectively reducing the occurrence of phytoplankton blooms in the spring. Secondary production by higher trophic levels is adversely affected by this reduced spring phytoplankton production, which results from relatively high (i.e., $> 4 \mu\text{mol L}^{-1}$) NH_4 concentrations (Dugdale *et al.* 2007). Reducing anthropogenic inputs of NH_4 to help achieve target concentrations below $4 \mu\text{mol L}^{-1}$ may be a viable management action to promote increased primary and secondary production in the Bay-Delta.

LOSS OF TIDAL MARSH HABITAT

Reclamation of land at the edge of the Bay-Delta filled in or altered 85 to 95 percent of the wetlands in the Bay-Delta (SFEP 1999). In San Francisco Bay, remaining tidal marshes are located in isolated pockets or in linear strips along sloughs or bay-front dikes. The largest marshes in the Bay-Delta are in Suisun Bay, along the Petaluma, Sonoma, and Napa rivers, and along the northern shore of San Pablo Bay (NMFS 1997).

The importance of marsh habitat to juvenile Chinook salmon in the Bay-Delta is unclear. Some Chinook salmon have been collected in tidal marsh areas near Liberty Island and Little Holland Tract (NMFS 1997), but data supporting that juvenile Chinook salmon extensively rely on tidal marsh habitat in the Bay-Delta for rearing do not exist or at least have not been published. However, research in the Pacific Northwest has demonstrated that tidal marsh habitat is important to the growth and survival of juvenile Chinook salmon (Bottom *et al.* 2005; Levy and Northcote 1981). The benefits of tidal marshes to juvenile Chinook salmon include the availability of rich feeding habitat, refugia from predators, and increasing the overall productivity of tidal habitats. The lack of tidal marsh habitat in the Bay-Delta, relative to estuaries in the Pacific Northwest, may partially explain why juvenile Chinook salmon produced in the Central Valley spend little time rearing in the Bays and Delta, and exhibit slow growth and decreased condition while there (MacFarlane and Norton 2002).

The need to restore tidal marsh habitats in the Bay-Delta has been recognized. The first attempt to prescribe restoration needs for the entire Bay-Delta was in 1993, when the Governor and the U.S. Environmental Protection Agency (EPA) approved the Comprehensive Conservation and Management Plan for the Bay-Delta (San Francisco Estuary Project Website). Three North American Wetland Conservation Act grants totaling nearly \$3 million have been allocated for wetland conservation actions in Suisun Marsh and in the Yolo and Delta basins. For a comprehensive list of wetland restoration projects that have been implemented around the San Francisco Bay, see the database and maps available at the Wetlands and Water Resources web site, www.swampthing.org (SFEP and CALFED 2006).

INVASIVE SPECIES/FOOD WEB CHANGES

Although there is a dearth of information on the feeding and growth of juvenile Chinook salmon as they migrate through the Delta and bays, the available data suggest that these fish may be food limited (Kjelson *et al.* 1982; MacFarlane and Norton 2002). MacFarlane and Norton (2002) examined the migration timing, diet, and growth of juvenile fall-run Chinook salmon collected at locations spanning from the confluence of the Sacramento and San Joaquin rivers to the Golden Gate Bridge and in the coastal waters of the Gulf of the Farallones. These fish migrated from the confluence to the Golden Gate Bridge in about 40 days and grew little compared to juvenile Chinook salmon in most estuaries to the north. Further evidence that residence in the Bays may not be beneficial to juvenile salmon is that their condition (K-factor) declined while migrating through the San Francisco Estuary. The authors argued that the decline in condition occurred because the quantity and/or quality of prey available to juvenile Chinook salmon was limited, not because of stomach fullness or metabolic state (e.g., smoltification). Once juvenile Chinook salmon reached the Gulf of the Farallones they began to grow rapidly and improve in condition (MacFarlane and Norton 2002).

Substantial food web alterations in the Bays and Delta that have occurred over the last few decades may have reduced the availability of preferred prey for juvenile Chinook salmon (and steelhead) rearing and migrating through those locations. These food web changes, which were primarily caused by unintentional introductions of non-native species (Carlton *et al.* 1990; Kimmerer *et al.* 1994), are one of several factors identified by the Interagency Ecological Program's Pelagic Organism Decline Team as causing the recent decline in the abundance of pelagic fish (i.e., longfin smelt, threadfin shad, juvenile striped bass, and delta smelt) in Suisun

Bay and the Delta. Because the trophic feeding level of juvenile Chinook salmon overlaps with that of the pelagic fish species that are declining in abundance, at least partially due to food limitation, it is reasonable to assume that juvenile salmon in the San Francisco Estuary may also be food limited.

ENTRAINMENT

Entrainment of winter-run Chinook salmon in San Francisco, San Pablo, and Suisun bays (Bays) is not considered to be a major factor controlling this species' abundance. Although some level of entrainment may occur at pumping facilities in the Bays, the Delta is the region where entrainment is a serious threat that must be minimized or alleviated. Nevertheless, opportunities to decrease entrainment in the Bays should be identified and implemented.

PREDATION

Little is known regarding the level of predation on juvenile salmonids occurring in the Bays. Known predators of salmon occurring in abundance in the Bays include striped bass, water birds such as cormorants and terns, and pinnipeds. Further study is needed in order to develop quantitative information on the effect that these predators may be having on Chinook salmon in the Bays.

HATCHERY EFFECTS

Hatchery fish are assumed to utilize the Bay-Delta similar to wild salmonids, for some amount of time to complete acclimation to the marine environment. It does not appear that there is much opportunity for feeding within the habitat. Hatchery fish may aggressively compete with natural juveniles over limited available prey during their residency. Salmonid residence time in the Bays may be very short, which would limit the effects of hatchery winter-run on the natural population. Larger hatchery salmonids occupying the Bays such as juvenile or adult steelhead may predate on smaller-sized winter-run juveniles.

2.3.4 SACRAMENTO-SAN JOAQUIN DELTA

2.3.4.1 ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The Sacramento Deep Water Ship Channel (SDWSC) branches off Cache Slough near Ryer Island and extends 25 miles to West Sacramento. At the upstream end of the SDWSC is an 86-foot wide, 640-foot long navigation lock. Adult salmon have been caught close to the lock at the upstream end of the channel and also have been observed to be blocked from migrating upstream by the lock (NMFS 1997). DWR conducted a study in 2003 to provide fish passage information to the Delta Cross Channel/Through Delta Facilities Team and CALFED. During this study, 35 Chinook salmon adults, categorized as winter-run based on month of capture (i.e., November through June) and size, were sampled at the upstream end of the SDWSC, indicating that the SDWSC is a threat to adult winter-run Chinook salmon migrating through the Delta.

Additionally, any adult winter-run Chinook salmon that migrate upstream through the central Delta rather than directly up the Sacramento River are blocked from entering the Sacramento River by the Delta Cross Channel gates, which are closed from December to May. These fish must turn around and migrate downstream through the San Joaquin River in order to locate the

mouth of the Sacramento River. Thus, the Delta Cross Channel can be a passage barrier that delays winter-run Chinook salmon from reaching their spawning areas.

HARVEST/ANGLING IMPACTS

There is no commercial fishery for salmon in the Delta. Little information is available on the magnitude of harvest of winter-run Chinook salmon in the Delta, but it should be insignificant largely due to sportfishing regulations designed to protect winter-run Chinook salmon. If current fishing regulations are adhered to, freshwater harvest of winter-run Chinook salmon should be near zero. The extent of poaching of winter-run Chinook salmon in the Delta is unknown, although the potential for poaching is considered high as adult Chinook salmon do become concentrated behind ineffective passage facilities intended to allow fish that migrate up the Yolo and Sutter to pass back into the mainstem Sacramento River.

WATER TEMPERATURE

Water temperatures in the Delta are generally suitable throughout the winter-run Chinook salmon adult immigration and holding life stage period (i.e., December through July), except for during June and July (**Figure 2-5**). Water temperatures in the Delta during June and July are frequently warmer than 67°F, which is reported to be the upper limit of the range acceptable for adult Chinook salmon immigration (NMFS 1997). For example, mean daily water temperatures in the Sacramento River at Hood were warmer than 67°F for all of June and July in 2001, 2002, and 2004, and were warmer than 67°F for 46 days in 2003, 32 days in 2005, and 42 days in 2006. However, most winter-run Chinook salmon adults are expected to have migrated to cooler areas upstream of the Delta before warm water temperatures occur in the Delta.

Figure 2-5. Mean Daily Water Temperatures in the Sacramento River at Hood during December Through July from 2000 to 2006. Source: <http://cdec.water.ca.gov/>

WATER QUALITY

Like in the San Francisco, San Pablo, and Suisun bays, water quality is considered an important stressor to the aquatic community, but likely does not substantially affect adult winter-run Chinook salmon migrating through the Delta.

2.3.4.2 JUVENILE REARING AND OUTMIGRATION

Juvenile winter-run Chinook salmon depend on the Delta for rearing and smoltification and may be present there from as early as September to as late as June (NMFS 1997). The highest numbers of juvenile winter-run Chinook salmon in the Delta occurs from January through April (NMFS 1997). The timing of emigration from the Delta to the San Francisco Bay and ocean is not well known but is believed to occur from late-December through June (NMFS 1997).

WATER TEMPERATURE

Water temperatures in the Delta likely do not adversely affect winter-run Chinook salmon juveniles until the spring (April through June) (NMFS 1997).

WATER QUALITY

An estimated 5,000 to 40,000 tons of contaminants enter the Bay-Delta system annually (CALFED 2000c). Contaminants entering the system are distributed by complex flow patterns influenced by inflow from the rivers and the amount of water being pumped from the Delta. Contaminants include inorganic substances such as heavy metals, nitrates and phosphates, organic contaminants such as PCBs, pesticides, plastics, detergents and fertilizers, and biological pathogens such as bacteria, viruses and protozoans (CALFED 2000c). The origin of these contaminants is from both point and non-point sources.

Currently there are several sources of point-source pollution in the Delta. The State Lands Commission identified two oil terminals, three paper processors, four oil production facilities, and several manufacturing facilities, all of which discharge into the Delta (NMFS 1997). Studies examining the uptake of contaminants by juvenile Chinook salmon indicate elevated levels of PCBs and other chlorinated pesticides. The source of these contaminants is not known but likely stem from non-point sources such as stormwater and urban runoff as well as agricultural drainage. The effects of these contaminants include the suppression of immune competence and reduced growth (NMFS 1997).

Increased regulation on organophosphate insecticide use has led to increased use of pyrethroid insecticides for both urban and agricultural uses. Pyrethroid use in the Central Valley in 2000-2003 was nearly double that in 1991-1995. Pyrethroid insecticides are hydrophobic compounds with a strong tendency to adsorb to sediments instead of dissolving in the water column. As such, pyrethroid transport likely occurs with mass transport of sediment and particulates during storm and irrigation runoff events. In addition, pyrethroids are most likely to cause toxicity to benthic organisms. Pyrethroids are very toxic to both fish and invertebrates. However, environmental pyrethroid concentration (exposure) data is needed to determine the risk to aquatic organisms in the Delta system. Although pyrethroids are relative insoluble in water, all are sufficiently soluble to cause adverse biological effects. Amphipods and copepods are among the most sensitive to pyrethroids insecticides. Pyrethroid insecticides have been detected in sediments from Central Valley agricultural and urban drainage dominated water bodies at

concentrations high enough to contribute to toxicity to sensitive aquatic species. In agricultural drainage dominated water bodies the highest concentrations are detected shortly after their peak use in July (Oros and Werner 2005).

As described in Section 2.3.3.2, one factor that may contribute to reduced growth and survival of fish in the Bay-Delta is the effect that inputs of ammonium (NH_4) have on the food web. Dugdale *et al.* (2007) concluded that low annual primary production in San Francisco Bay is partially controlled by high concentrations of NH_4 that can prohibit phytoplankton from accessing nitrate (NO_3), effectively reducing the occurrence of phytoplankton blooms in the spring. Secondary production by higher trophic levels is adversely affected by this reduced spring phytoplankton production, which results from relatively high (i.e., $> 4 \mu\text{mol L}^{-1}$) NH_4 concentrations (Dugdale *et al.* 2007). Reducing anthropogenic inputs of NH_4 to help achieve target concentrations below $4 \mu\text{mol L}^{-1}$ may be a viable management action to promote increased primary and secondary production in the Bay-Delta.

Mercury contamination in the Bay/Delta and its tributaries has long been recognized as a serious problem. Water column mercury concentrations in the Bay/Delta often exceed the California state standard of 12 ng Hg L^{-1} (Choe *et al.* 2003). Although mercury exists in many forms in the aquatic environment, Methylmercury is the form of primary concern because it is readily accumulated in the food web and poses a toxicological threat to highly exposed species. A statewide review of fish monitoring data from the past 30 years concluded that methylmercury contamination is common in California aquatic food webs, with long-term trends indicating little change over the past few decades (SFEI 2007). Little research has been conducted exploring the effects of methylmercury accumulation on fish survival or behavior during any life stage.

FLOW CONDITIONS

CVP and SWP operations have changed the seasonal flow regimes in the Delta from historic conditions. Generally, the natural variability in flows has been reduced with flows in late spring and summer less than historic conditions and increased flows in the late summer and fall. Peak flows to the Delta generally occur in the winter and early spring when juvenile winter-run Chinook salmon are present.

During the winter and early spring, when both the Sacramento and San Joaquin rivers are at peak discharge, net flows in the Delta move downstream towards the west. During the year, as the quantity of water exported from the Delta increases relative to Sacramento River outflow, water can be drawn upstream through the lower channels of the San Joaquin River creating reverse flow conditions. Additionally, flow patterns are altered when the Delta Cross Channel is opened (generally June through November) and a proportion of the Sacramento River flow is diverted through the Delta Cross Channel. This water is conveyed in a southerly direction towards the CVP and SWP pumping plants. Historically, juvenile Chinook salmon migrated from the Sacramento River into the central Delta via Georgiana and Three Mile sloughs, in proportion to the amount of water transporting them, which was estimated to be about 20 percent (NMFS 1997). Now, with the Delta Cross Channel in operation, as much as 70 percent of Sacramento River flow may be diverted into the central Delta (NMFS 1997). Mark recapture studies with fall-run Chinook salmon have suggested that salmon smolts entering the central Delta via the Delta Cross Channel and Georgiana Slough have a much lower survival index than those remaining in the mainstem Sacramento River (NMFS 1997). Currently, the Delta Cross Channel

gates are closed from the beginning of February through May and may be closed an additional 45 days at the discretion of the resource agencies from the beginning of October through January in order to protect juvenile salmonids (Brown and Nichols 2003). However, with the gates closed, large numbers of emigrating salmonids can be entrained into Georgiana Slough. Taking this route through the interior Delta as compared to remaining in the mainstem Sacramento River has been shown to increase mortality (Brown and Nichols 2003).

The primary factors causing mortality of winter-run Chinook salmon in the Delta are considered to be the diversion of juveniles from the mainstem Sacramento River into the central and southern Delta where environmental conditions are poor and reverse flow conditions exist which may move them into the lower San Joaquin River and into the south Delta waterways (NMFS 1997). Survival through central Delta migratory routes is substantially lower than through northern routes. The numbers of juveniles arriving at the export pumps is lower as river flows increase, pumping decreases, and the Delta Cross Channel gates are closed (Cramer *et al.* 2003). CVP and SWP operations have profoundly affected flow patterns in the Delta. These changes have resulted in a longer migration route to the ocean. The channel complexity and reverse flow conditions in the central Delta likely delay migration to the ocean thereby increasing the length of time that fish may be exposed to adverse conditions. Historically, the central Delta probably provided beneficial habitat for rearing juvenile Chinook salmon due to the extensive acreage of tidal marsh habitat and associated nutritional and cover benefits. However, degradation of the central Delta waterways have resulted in adverse conditions for the rearing and migration of juvenile Chinook salmon (NMFS 1997).

Potential temporary passage impediments also occur when levees protecting Delta islands breach in very wet years as a result of land subsidence and levee failures. A levee breach essentially creates a large-scale diversion that can draw several thousand acre-feet of water onto Delta islands. Levees are generally repaired while or after the islands are emptied. During drainage, fish can be stranded or are potentially harmed passing through the pumps. The magnitude of this potential problem has not been quantified, however, accounts of extensive fish stranding during the 1996 draining of Prospect Island following a levee breach suggest that mortality can be substantial (CALFED 2000c). In June of 2005, the Jones Tract levee broke causing fish to become trapped inside the tract. Although this break occurred at a time that juvenile winter-run were not present, the probability for more Delta levee breaching and associated fish stranding is high. Mount and Twiss (2005) state that there is a two-in-three chance that a 100-year recurrence interval floods or earthquakes will cause catastrophic flooding and significant change in the Delta by 2050.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Much of the historic riparian habitat in the Delta has been lost because of urban and agricultural development as well as levee construction for flood control and water delivery operations.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Prior to European colonization, the Delta was a vast marshland complex of multiple channels, natural levees, and frequently inundated islands composed largely of organic rich sediments (CALFED 2000b). Water delivery operations of the CVP and SWP, levee construction, agricultural and urban development have all served to change natural conditions in the Delta.

LOSS OF FLOODPLAIN HABITAT

Most of the historic flood plain habitat in the Delta has been converted to agriculture and urban uses. Agricultural and urban areas that were once part of the historic flood plain are now protected by levees.

LOSS OF TIDAL MARSH HABITAT

Few empirical studies on the importance of tidal marsh habitat have been conducted in the Delta. Some monitoring in the Delta has verified the use of this habitat by juvenile Chinook salmon (NMFS 1997). Research conducted in the Pacific Northwest has found that tidal marsh habitat is important to juvenile salmonids (NMFS 1997). Of all the salmonid species, juvenile Chinook salmon show the highest tendency to utilize this habitat type. The benefits of tidal marshes to juvenile Chinook salmon include: (1) the contribution of nutrients to the detritus-based food chain, (2) the availability of rich feeding habitat, (3) refugia from predators, and (4) the provision of suitable habitat for juveniles to undergo smoltification.

Historically, tidal marsh was one of the most common habitat types in the Delta. At present, only two percent of historical tidal marsh habitat remains in the Delta (NMFS 1997). In the Delta, tidal marsh habitat is now restricted to remnant patches mainly in channels where the area between levees is wide enough or where substrate has been deposited high enough for tules and reeds to survive.

The relative importance of tidal marsh habitat to juvenile winter-run Chinook salmon likely depends on water year type. This habitat may be more important in wetter years or in storm events during dry years when fry may be flushed into the Delta with early storms and require more time for rearing prior to undergoing the smoltification process.

INVASIVE SPECIES/FOOD WEB CHANGES

Historically, the San Joaquin River has been an important source of nutrients to the Delta. Most of the San Joaquin River is now being diverted from the south Delta by CVP/SWP operations. The resultant loss in nutrients has likely contributed to an overall decrease in fertility of the Delta, limiting its ability to produce food (NMFS 1997). Additionally, pumping operations may result in a loss of zooplankton reducing their abundance in the Delta. Poor food supply may limit the rearing success of winter-run Chinook salmon.

Extensive areas of the Delta are below mean high tide, but because of levees and flapgates installed throughout the Delta, these areas are no longer subject to tidal action. This effectively reduces the volume of water subject to tidal mixing and the size of the Delta floodplain. Reduced residence time of Delta water and associated nutrients restricts the development of foodweb organisms (CALFED 2000c).

Invasive species include both plants and animals, most of which have been introduced to the Delta unintentionally through ship ballast. However, some species have been introduced intentionally by resource agencies for sportfishing or forage.

Invasive aquatic plants have become established in many areas of the Delta. Establishment of invasive aquatic plants can harm or kill native aquatic species because they form dense mats that block sunlight and deplete oxygen supplies. Most of these aquatic weeds were introduced to the

Delta unintentionally and include water hyacinth (*Eichhornia crassipes*), hydrilla (*Hydrilla verticillata*) and egeria (*Egeria densa*). Within the Delta, the construction of levees and the conversion of adjacent riparian communities to other land uses have substantially changed the ecosystem. These changes have stressed native aquatic flora and fauna allowing infestation of invasive aquatic weeds. Invasive weeds flourish in the disturbed environment and may reduce foodweb productivity potentially harming fish and wildlife (CALFED 2000c).

The majority of clams, worms and bottom dwelling invertebrates currently inhabiting the Delta are non-native species. Non-native species also comprise an increasing proportion of the zooplankton and fish communities in the Bay-Delta system. It is estimated that a new non-native species is identified in the Bay-Delta every 15 weeks (CALFED 2000c). Many fish known to prey on juvenile anadromous salmonids were introduced by resource agencies to provide sportfishing. These fish include striped bass, American shad and largemouth bass.

Although introductions have increased diversity in the Bay-Delta system, this increase in diversity has been at the expense of native species, many of which have declined precipitously or become extinct through predation and competition for resources (CALFED 2000c). At the same time, many non-native species are performing vital ecological functions such as serving as primary consumers of organic matter or as a food source for native fish and other wildlife populations (CALFED 2000c).

ENTRAINMENT

Fish in the Delta are vulnerable to entrainment in flows leading to export facilities in the southern Delta. Although facilities associated with the export facilities are designed to salvage fish from the water and return them to the Delta, the process is not very efficient (Kimmerer 2006). The efficiency of the fish salvage facilities varies from 14 to 80 percent depending on the size of the fish. For salmonids, unknown losses occur due to predation and cleaning operations, when fish screens are lifted out of the water. Mortality of fish associated with export pumping has been blamed in part for declines of numerous fish species including delta smelt and Chinook salmon. Additionally, many fish are lost to predation in waterways leading to the fish facilities (Kimmerer 2006).

According to NMFS (1997), entrainment of juvenile winter-run Chinook salmon is one of the most ubiquitous causes of mortality in the Sacramento River and Delta. A primary source of entrainment is unscreened or inadequately screened diversions. Diversion facilities in the Delta range from small siphons diverting 20 cubic feet per second (cfs) or less to the large export facilities operated by Reclamation and DWR in the southern Delta with a combined capacity of up to 12,000 cfs. A survey by CDFG indicated that a minimum of 2,050 unscreened diversions are present in the Delta (NMFS 1997). Some of these diversions include the Jones Pumping Plant, Banks Pumping Plant, Contra Costa Water District's unscreened Rock Slough, West Stanislaus Water District's unscreened diversion, Barker Slough (which is screened but not monitored), as well as numerous agricultural diversions. However, the magnitude of these diversions and the extent to which these diversions cause juvenile losses has not been adequately studied (NMFS 1997). There have been some extensive screening program efforts in the past ten years, however, there are still currently over 2,000 unscreened diversions within the Delta (Calfish Website).

Under current CVP/SWP operations, many juvenile salmon are entrained in the Clifton Court Forebay. The Clifton Court Forebay serves as a regulating reservoir providing a reliable water supply for pumping operations at the Banks Pumping Plant (DWR and Reclamation 1996). The forebay has a maximum capacity of 31,000 acre-feet. Five radial gates are opened at high tide to allow the forebay reservoir to fill and closed at low tide to retain water that supplies the pumps. Fish that enter the forebay may take up residence, be eaten by other fish, taken by anglers, further entrained at the Banks Pumping Plant, impinged on fish screens at the Skinner Fish Protection Facility or bypassed and salvaged at the fish protection facility.

Two large fossil fuel power plants are operated in the Bay-Delta, one is located in Antioch and the other in Pittsburg. Each of these plants utilizes large screened intake systems for cooling. The screens utilize 1950s technology and do not effectively screen juvenile fish. Although the water is returned to the Delta, many entrained juvenile fish are killed by mechanical damage or heat stress (CALFED 2000c).

PREDATION

Most of the predation on juvenile Chinook salmon in the Delta likely occurs from introduced species such as striped bass, black crappie, white catfish, largemouth bass and bluegill. Native Sacramento pikeminnow and steelhead also occur in the Delta and are known to prey on juvenile salmonids. Of these non-native predatory species, striped bass are likely the most important predators because: (1) the estimated abundance of striped bass in the Sacramento-San Joaquin system greater than 18 inches in length has ranged from about 600,000 to about 1,900,000 during the period between 1969 to 2005; (2) the total number of striped bass preying upon juvenile Chinook salmon in the system is greater than these estimated population sizes because striped bass smaller than 18 inches in length feed on juvenile Chinook salmon; (3) anecdotal information indicates that striped bass movements up the Sacramento River coincide with juvenile Chinook salmon emigration, resulting in a co-occupancy of habitat; and (4) striped bass are opportunistic feeders, and almost any fish or invertebrate occupying the same habitat eventually appears in their diet (Moyle 2002).

Figure 2-6. Striped Bass Population Estimates from 1969 to 2005 for Fish Greater than 18 Inches in Length in the Sacramento-San Joaquin River System. Data were obtained from Marty Gingras (CDFG)

Early studies in the Delta indicate that Chinook salmon comprise one to six percent of striped bass diet (NMFS 1997). However, predation at fish salvage release sites is particularly heavy. For example, Orsi (1967) found that predation occurred on approximately 10 percent of the fish released and that 80 percent of that predation was by striped bass. Similarly, Pickard *et al.* (1982 cited in NMFS 1997) conducted predator studies at salvage release sites and found high densities of striped bass and Sacramento pikeminnow. Additionally, predation rates for salmon smolts entering the Clifton Court Forebay have been estimated to range from 68 to 99 percent. In mark recapture studies, mortality rates for juvenile salmon were estimated at 91.3 percent per mile compared to 2.7 percent in the central Delta. This difference in mortality rates was thought to be due to the higher number of predators, primarily striped bass, as well as hydraulic conditions and the operational characteristics of the Clifton Court Forebay (NMFS 1997).

HATCHERY EFFECTS

Winter-run hatchery production is released in the upper Sacramento River in late-January or early-February, and has been documented as reaching the Delta pumps within 14 days of release (B. Oppenheim, NMFS, pers. comm.). Up to 250,000 pre-smolt winter-run are released on average at 85 mm FL and may reach 100 mm FL in size by the time they reach the Delta pumps (B. Oppenheim, NMFS, pers. comm.). Natural-produced winter-run begin to appear at the Delta pumps in December through March at 100 to 150 mm FL, peaking in early March. There is likely some competition between hatchery- and naturally-produced winter-run over prey sources and refugia; it is unclear if there are behavioral differences between hatchery and wild winter-run during residency in the Delta. The Delta serves primarily as a migration corridor for winter-run,

and in general, it is thought that salmonids do not remain in the Delta for any significant length of time. The USFWS is currently providing fish tissue, scale and otolith samples for a study that has the potential to determine residency time of salmon in the Delta (K. Niemela, USFWS, pers. comm.).

2.3.5 LOWER SACRAMENTO RIVER (PRINCETON [RM 163] TO THE DELTA)

2.3.5.1 ADULT IMMIGRATION AND HOLDING

In the lower section of the Sacramento River, the potential threats to the adult immigration and holding life stage of winter-run Chinook salmon include passage impediments, harvest in the sportfishery and poaching, adverse water temperatures, poor water quality, and adverse flow conditions.

PASSAGE IMPEDIMENTS/BARRIERS

The SDWSC branches off Cache Slough near Ryer Island and extends 25 miles to West Sacramento. At the upstream end of the SDWSC is an 86-foot wide, 640-foot long navigation lock. Adult salmon have been caught close to the lock at the upstream end of the channel and also have been observed to be blocked from migrating upstream by the lock (NMFS 1997). DWR conducted a study in 2003 to provide fish passage information to the Delta Cross Channel/Through Delta Facilities Team and CALFED. During this study, 35 Chinook salmon adults, categorized as winter-run based on month of capture (i.e., November through June) and size, were sampled at the upstream end of the SDWSC, indicating that the SDWSC presents a potential passage barrier and may delay upstream migration of winter-run Chinook salmon (NMFS 1997).

HARVEST/ANGLING IMPACTS

There is no commercial fishery for salmon in the Sacramento River. The in-river sportfishery allows for the taking of salmon generally from mid-July through January 1. Little information is available on the magnitude of in-river harvest of winter-run Chinook salmon. Hallock and Fisher (1985) report that the freshwater sport fisheries caught an average of 10 percent of the winter-run Chinook salmon run for the 1968 to 1975 period. More recently, the PFMC's Sacramento River Winter- and Spring Chinook Salmon Workgroup calculated a harvest rate of 24 percent based on the 1998 cohort reconstruction (PFMC 2003). Currently, sportfishing regulations in the Sacramento River are designed to prevent the taking of salmon during the time periods that adult winter-run Chinook salmon are present. However, Sacramento River regulations allow for the taking of salmon up to January 1 and some early migrating winter-run Chinook salmon are likely taken. For example, CDFG's Central Valley Salmon and Steelhead Harvest Monitoring Project indicated that a relatively high inland sport harvest of winter-run Chinook salmon may have occurred in late December 2000 and early January 2001. Winter-run Chinook salmon were identified by CWT hatchery-origin fish (CDFG 2004c). However, since the no-retention of salmon regulation was changed from January 15 to January 1 in 2003, no additional CWT winter-run Chinook salmon have been observed in the inland sport harvest.

The extent of poaching of winter-run Chinook salmon in this reach of the river is unknown. There are no terminal barriers that would unnaturally increase densities allowing for easy

poaching. However, some level of poaching likely occurs at the Fremont, Colusa, and Tisdale weirs.

WATER TEMPERATURE

Suitable water temperatures for adult winter-run Chinook salmon migrating upstream to spawning grounds range from 57°F to 67°F (NMFS 1997). However, winter-run Chinook salmon are immature when upstream migration begins and need to hold in suitable habitat for several months prior to spawning. The maximum suitable water temperature for holding is 59°F to 60°F (NMFS 1997). Because water temperatures in the lower Sacramento River generally begin exceeding 60°F in April, it is likely that little if any suitable holding habitat exists in this reach and that it is only used by adults as a migration corridor. Adult Chinook salmon migrating into the lower Sacramento River after April may experience water temperatures exceeding 65°F which may result in reduced energy supplies needed for spawning, pre-spawning mortality, and reduced gamete viability (NMFS 1997). The potential for diseases in adults also increases as water temperatures increase.

NMFS (1997) reports that water temperatures in the lower Sacramento River may have risen by as much as 4°F to 7°F since the late 1970s. The cumulative losses of riparian habitats and associated shade along the river may have influenced water temperatures in this reach.

WATER QUALITY

Agricultural runoff and low water velocities in the lower Sacramento River can lead to poor water quality conditions, especially during late spring and summer. Because adult winter-run Chinook salmon use the lower Sacramento River strictly as a migration corridor on their way to upstream holding and spawning habitats, they likely are not substantially affected by water quality in the lower river. Furthermore, most winter-run adults have migrated upstream to the middle and upper sections of the Sacramento River before the worst water quality conditions set in during the summer months.

FLOW CONDITIONS

During high flow or flood events, water is diverted into the Sutter and Yolo bypasses upstream of the City of Sacramento. Adult winter-run Chinook salmon migrating upstream may enter these bypasses, where their migration may be delayed or blocked by control structures. To date, there have not been any measures implemented to protect adult winter-run Chinook salmon from entrainment into the flood control bypasses (NMFS 1997).

The lower Sacramento River flows through both agricultural land and a large and growing metropolitan region. This area often is affected by in-water or near-river construction projects. These construction activities have the potential to adversely affect fisheries and aquatic resources through the inadvertent discharge of toxic substances, increased sedimentation, aquatic habitat modification, and vibration and hydrostatic pressure waves generated by blasting activities. Because of the number of construction projects that take place in the area, there is potential for adverse impacts on fish species occurring in the area, including winter-run Chinook salmon. However, this potential is minimized by key environmental regulations governing environmental degradation, species protection, water pollution, hazardous wastes, and reporting requirements including the ESA, CEQA, NEPA, CESA, the CWA, the Porter-Cologne Act, RCRA, the Hazardous Control Law, the Comprehensive Environmental Response, Compensation, and

Liability Act, the Hazardous Substances Account Act, and the Toxic Substances Control Act. As such, short-term in-water construction in the area is not considered to be a major threat to the adult immigration and holding life stage of winter-run Chinook salmon.

2.3.5.2 JUVENILE REARING AND OUTMIGRATION

Factors that may adversely affect the juvenile rearing and outmigration of winter-run Chinook salmon in this reach of the river include fluctuating flow regimes; physical habitat alteration; water quality parameters including temperature and both point and non-point source pollution; predation; and entrainment into water diversions. Each of these factors is described below.

WATER TEMPERATURE

Optimal water temperatures for juvenile Chinook salmon range from 53.6°F to 57.2°F (NMFS 1997). A daily average water temperature of 60°F is considered the upper temperature limit for juvenile Chinook salmon growth and rearing (NMFS 1997). Winter-run Chinook salmon juveniles are most abundant in the lower Sacramento River during winter months when average water temperatures are normally less than 60°F. It is possible that early or late outmigrating juveniles are exposed to water temperatures above 60°F. Additionally, late outmigrating winter-run Chinook salmon may be exposed to warmwater releases from the Colusa Drain at Knights Landing. Warm water is released from the drain to the river mainly from April through June. Releases from the drain can exceed 2,000 cfs and 80°F.

WATER QUALITY

The major point source threat of pollution in the Sacramento River is the Iron Mountain Mine as described below in Section 2.3.7.3. However, because the Iron Mountain Mine is located many miles north of the lower Sacramento River section, most heavy metal contaminants from the mine have likely either settled out or have been diluted to acceptable EPA standards by the time water reaches this reach of the river. Another point source is the NH₄ in the discharge from the Sacramento regional waste treatment facilities.

The main non-point sources of pollution in the lower Sacramento River are urban runoff and agricultural drainage. Stormwater runoff from the city of Sacramento has been shown to be acutely toxic to aquatic invertebrates (NMFS 1997). Significant urban runoff also occurs during the dry season and is created from domestic/commercial landscape irrigation, groundwater infiltration, pumped groundwater discharges and construction projects (NMFS 1997). The Colusa Basin Drain is the largest source of agricultural return flow in the Sacramento River. It drains agricultural areas serviced by the Tehama-Colusa and Glenn-Colusa Irrigation districts and discharges to the Sacramento River below Knights Landing. The drain has been identified as a major source of warm water, pesticides, turbidity, suspended sediments, dissolved solids, nutrients and trace metals (NMFS 1997).

FLOW CONDITIONS

Flood control structures in the lower Sacramento River are designed to divert water from the river during a major flood event into the Butte Creek basin and the Sutter and Yolo bypasses. The diversions can be significant. For example, the flood control system can divert as much as four to five times more flow down the bypasses than remains in the river (NMFS 1997). Juvenile winter-run Chinook salmon migrating down the river may enter the diversions during

storm events. Studies conducted on the Sutter Bypass show that the highest proportion of flows are diverted from December through March with a peak occurring in February, corresponding to the range and peak outmigration patterns for juvenile winter-run Chinook salmon (NMFS 1997). Juveniles diverted into the bypasses may experience migration delays, potential stranding as flood flows recede and increased rates of predation. However, both the Sutter and Yolo bypasses provide high quality rearing habitat for juveniles, potentially resulting in greater survival relative to fish that stay in the Mainstem (Sommer *et al.* 2001).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The lower Sacramento River has been channelized for flood control measures. Channelization of the lower river has involved rip-rapping the banks in many areas. Rip-rapping the river bank involves removing vegetation along the bank and upper levees which removes most instream and overhead cover in nearshore areas. Woody debris and overhanging vegetation within SRA habitat provide escape cover for juvenile salmonids from predators. Aquatic and terrestrial insects are an important component of juvenile salmon diet. These insects are dependent on a healthy riparian habitat.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Flood control measures, regulated flow regimes and river bank protection measures have all had a profound effect on riparian and instream habitat in the lower Sacramento River. Levees constructed in this reach are built close to the river in order to increase streamflow, channelize the river to prevent natural meandering, and maximize the sediment carrying capacity of the river (NMFS 1997). Additionally, nearshore aquatic areas have been deepened and sloped to a uniform gradient, such that variations in water depth, velocity and direction of flow are replaced by consistent moderate to high velocities. Juvenile Chinook salmon prefer slow and slack water velocities for rearing and the channelization of the river has removed most of this habitat type.

LOSS OF FLOODPLAIN HABITAT

The process of channelizing the lower Sacramento River has resulted in a loss of connectivity with the floodplains which serves as an important source of woody debris and gravels that aid in establishing a diverse riverine habitat, as well as providing juvenile salmon rearing habitat.

ENTRAINMENT

Entrainment is defined as the redirection of fish from their natural migratory pathway into areas or pathways not normally used. Entrainment also includes the take, or removal, of juvenile fish from their habitat through the operation of water diversion devices and structures such as siphons, pumps and gravity diversions (NMFS 1997). A primary source of entrainment is unscreened or inadequately screened diversions. A survey by CDFG identified 350 unscreened diversions along the Sacramento River downstream of Hamilton City.

Entrainment of juvenile winter-run Chinook salmon has been identified as one of the most significant causes of mortality in the Sacramento River and Delta (NMFS 1997). In addition, a program to flood rice field stubble during the winter has been implemented extending the period for potential entrainment (NMFS 1997). Outmigrating juvenile winter-run Chinook salmon also may be diverted into the Yolo or Sutter bypasses during high flow or flood events and stranded as flood waters recede. Additionally, Sacramento River water is diverted into the SDWSC, and

outmigrating juvenile Chinook salmon may enter the channel where water quality, flow levels and rearing conditions are extremely poor (NMFS 1997).

PREDATION

Only limited information on predation of winter-run Chinook salmon juveniles is available. Native species that are known to prey on juvenile salmon include Sacramento pikeminnow and steelhead. Predation by pikeminnow can be significant when juvenile salmon occur in high densities such as below dams or near diversions. Although Sacramento pikeminnow are a native species and predation on juvenile winter-run Chinook salmon is a natural phenomenon, loss of SRA habitat and artificial instream structures tend to favor predators and may change the natural predator-prey dynamics in the system favoring predatory species (CALFED 2000c). Non-native striped bass may also be a significant predator on juvenile salmon. Although no recent studies of striped bass predation on juvenile salmon have been completed, Thomas (1967 *in* NMFS 1997) found that in the lower Sacramento River, salmon accounted for 22 percent of striped bass diet. Lindley and Mohr (Lindley and Mohr 2003) estimate that the current striped bass population consumes about nine percent of juvenile winter-run Chinook salmon outmigrants.

HATCHERY EFFECTS

In the lower Sacramento River, hatchery steelhead from the Feather River Fish Hatchery (FRFH) are planted in the Feather River below Yuba City at a large enough size and at a time when they could intercept outmigrating winter-run Chinook salmon juveniles (NMFS 1997).

SRA habitat along this river reach is severely limited and would be competed over by salmonids for rearing and outmigrating refugia. Hatchery fish are more aggressive and typically larger than their wild counterparts, and have a greater chance to displace them from SRA habitat, forcing smaller juveniles into fast-moving flows and leaving them vulnerable to predation and detrimental environmental variables.

2.3.6 MIDDLE SACRAMENTO RIVER (RED BLUFF DIVERSION DAM [RM 243] TO PRINCETON [RM 163])

2.3.6.1 ADULT IMMIGRATION AND HOLDING

In the middle section of the Sacramento River, the potential threats to the adult immigration and holding life stage of winter-run Chinook salmon include passage impediments, harvest in the sportfishery and poaching, adverse water temperatures, poor water quality, and adverse flow conditions.

PASSAGE IMPEDIMENTS/BARRIERS

There are no known passage impediments or barriers in the middle section of the Sacramento River. Although the GCID HCPP (~RM 205) and associated water diversions may present problems for emigrating juvenile salmonids, adults are likely not affected.

HARVEST/ANGLING IMPACTS

Adverse effects due to harvest and poaching in this reach of the river are likely similar to those occurring in the lower Sacramento River as described above in Section 2.3.5.1.

WATER TEMPERATURE

Water temperatures in the middle section of the Sacramento River are similar to, and sometimes slightly cooler than those occurring in the lower Sacramento River. However, some holding of adult winter-run Chinook salmon may occur downstream of the RBDD in deep coldwater pools. With the installation of the temperature control device at Shasta Dam in 1997, water temperatures have cooled slightly and suitable water temperatures for adult holding likely extend downstream of the RBDD for a short distance.

WATER QUALITY

Water quality in the middle reach of the Sacramento River is not at a level to cause adverse effects on immigrating adult salmonids.

FLOW CONDITIONS

Flows in the middle Sacramento River are sufficient to support upstream migration of adult winter-run Chinook salmon.

2.3.6.2 JUVENILE REARING AND OUTMIGRATION

Factors that may adversely affect juvenile winter-run Chinook salmon in the middle Sacramento River are similar to those that occur in the lower river as described above. However, in addition to those factors there is a potential downstream passage impediment at the GCID HCPP at RM 205.

WATER TEMPERATURE

Water temperatures in the middle Sacramento River are similar to those described above in the lower Sacramento River. Water temperatures normally exceed 60°F from July through September and in dry years can often exceed 66°F (NMFS 1997).

WATER QUALITY

The only point source pollution that has been identified and may potentially affect this reach of the river is the Iron Mountain Mine described in Section 2.3.7.3. Non-point source pollution sources include both urban and agricultural runoff similar to that described above for the lower Sacramento River. Urban runoff is likely not as great in this reach of the river as that occurring in the lower Sacramento River but agricultural runoff is likely similar or greater.

FLOW CONDITIONS

Historically, the GCID HCPP at RM 205 has created downstream migration problems for winter-run juvenile Chinook salmon. The GCID pumping plant may divert up to 20 percent of the Sacramento River. Rotary drum fish screens were installed in 1972 to help protect juvenile salmon but they were largely ineffective and never met NMFS or CDFG screen design criteria. Flat plate screens were installed in front of the rotary screens in 1993 to help alleviate the problem until a more permanent solution could be found. Juvenile winter-run Chinook salmon are exposed to the GCID pumping plant facilities as early as mid-July extending through their peak downstream movement during August and September, and into late-November when the diversion season ends.

The interim flat-plate screens are an improvement over the rotary drum screens but are still likely to subject juvenile salmon to impingement due to high approach velocities along the screens,

inadequate sweeping to approach velocities, and long exposure time at the screen (USFWS 1995 *in* NMFS 1997). Construction of a new screening facility was completed in 2001 and the testing and monitoring program for the facility are now underway (Reclamation 2007). The testing and monitoring of the new facility has indicated that the screen is functioning to protect juvenile entrainment and impingement, but predation rates in the project area remain high. The TAC is studying predation effects and developing designs to reduce these effects (Howard Brown, personal communication).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Loss of riparian habitat and instream cover in the middle reach of the Sacramento River is similar to that described above for the lower reach.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Physical habitat alteration that has occurred in the middle Sacramento River is similar to that described above for the lower Sacramento River. The river is not quite as confined in this reach as levees are constructed further from the channel than those occurring in the lower river.

LOSS OF FLOODPLAIN HABITAT

Similar to the lower Sacramento River, the channelization and construction of levees along the middle reach of the Sacramento River has caused the river to become disconnected from the floodplain.

ENTRAINMENT

The exact number of unscreened diversions in this reach of the river is not known. A study by the California Advisory Committee on Salmon and Steelhead Trout completed in 1987 reported that over 300 unscreened irrigation, industrial, and municipal water supply diversions occur on the Sacramento River between Redding and Sacramento (NMFS 1997). Although most of these diversions are small, cumulatively they likely entrain a large number of outmigrating juvenile salmonids.

Studies are currently underway to determine the effectiveness of new fish screens at the GCID HCPP to determine the effectiveness of new fish screen installed in 2001 (Reclamation 2007). Historically, of the four Sacramento River Chinook salmon races, winter-run Chinook salmon have probably been the most vulnerable to entrainment because newly emerged fry occur in the vicinity of the pumping plant's intake facility during the July through August time periods of high diversion (NMFS 1997). However, juvenile emigration data suggest that peak winter-run Chinook salmon movement past the GCID facility occurs in October and November, when pumping volume is low or has ceased for the season (CUWA and SWC 2004).

PREDATION

Predation on juvenile winter-run Chinook salmon in the middle Sacramento River is likely occurring from native Sacramento pikeminnow, native and hatchery-reared steelhead and striped bass. Although the extent of predation is unknown, predation from Sacramento Pikeminnow and striped bass is likely similar to that occurring in the lower Sacramento River as described above.

Opportunities for high predation rates also may be present at the GCID HCPP. The plant is described above as a passage impediment. Studies have indicated that Sacramento pikeminnow

are the primary predator at the pumping plant, although striped bass were also found with Chinook salmon in their stomachs (CALFED 2000c). Vogel and Marine (1995) report that predation is likely in the vicinity of the fish screens associated with the diversion.

HATCHERY EFFECTS

Predation from hatchery steelhead is likely somewhat less than that occurring in the lower Sacramento River because the Feather River hatchery-reared steelhead enter the Sacramento River downstream of this reach. Additionally, steelhead released from the CNFH are likely more evenly distributed throughout the river by the time they reach this section.

SRA habitat is not as limiting along this stretch of the river, and competition between hatchery and natural fish for SRA may not be as intense in years other than dry years when river flow may be limiting and temperatures higher than normal. In those cases, the effects would be the same as previously described for the lower stretch.

2.3.7 UPPER SACRAMENTO RIVER (KESWICK DAM [~RM 302] TO RED BLUFF DIVERSION DAM)

2.3.7.1 ADULT IMMIGRATION AND HOLDING

In the upper section of the Sacramento River, the primary threats to the adult immigration and holding life stage of winter-run Chinook salmon include potential passage impediments at the RBDD, harvest in the sportfishery and poaching. Keswick Dam, at the upstream terminus of this reach of the river presents an impassable barrier to upstream migration.

PASSAGE IMPEDIMENTS/BARRIERS

Keswick Dam (~RM 302) presents an impassable barrier to the upstream migration of all winter-run Chinook salmon in the Sacramento River. The ACID Dam (RM 298.5) was constructed in 1917 about three river miles downstream of the current Keswick Dam. Originally the dam was a barrier to upstream fish migration until 1927 when a poorly designed fish ladder was installed (NMFS 1997). The dam is a 450-foot long flashboard structure which has the capability of raising the backwater level 10 feet. The dam is only installed during the irrigation season which typically runs from early April to October or early November. As mentioned above, the fish ladder providing passage around the dam was poorly designed and although winter-run Chinook salmon were able to negotiate the ladder, it did present a partial impediment to upstream migration. In 2001, a new fish ladder was installed. Post-project monitoring indicates that the new fish ladder is operating effectively (CDFG 2004c). Another potential problem associated with the facility is that high volume releases from the ACID's canal downstream of the dam may create false attraction flows for migrating adult salmon where they could be stranded (NMFS 1997).

The proportion of the spawning run that is affected by ACID Dam is uncertain. Although data on the spatial distribution of winter-run Chinook salmon spawning indicate that since the ladder improvements in 2001, an average of 42.13% spawn between Keswick Dam and ACID Dam (CDFG 2004), data on the temporal distribution of winter-run Chinook salmon upstream migration suggest that in wet years about 50 percent of the run has passed the RBDD by March,

and in dry years, migration is typically earlier, with about 72 percent of the run having passed the RBDD by March (CUWA and SWC 2004).

The RBDD at RM 243 is a concrete structure 52 feet high and 740 feet long. The dam has 11 gates which are raised or lowered to control the level of Lake Red Bluff enabling gravity diversion into the Tehama Colusa Canal (TCC). Permanent fish ladders are located on each abutment of the dam. The fish ladders are inefficient in allowing upstream migration of adult salmonids (NMFS 1997). In several radio tagging studies of adult winter-run Chinook salmon, 43 to 44 percent of tagged fish were blocked by the dam (Vogel *et al.* 1988, Hallock *et al.* 1982 *in* NMFS 1997). Tagged winter-run Chinook salmon that eventually passed the dam were delayed by an average of 125 hours in one study (Vogel *et al.* 1988 *in* NMFS 1997) and 437 hours in a previous study (Hallock *et al.* 1982 *in* NMFS 1997). At present, the dam gates are kept in the raised position from September 15 through May 14 allowing free passage for about 85 percent of the run (NMFS 1997). However, there are intermittent closures during this time period of up to 10 days. The remaining portion of the run (migrating upstream past May 15) is likely to be delayed or blocked from passing the dam.

HARVEST/ANGLING IMPACTS

Although California sportfishing regulations are designed to protect winter-run Chinook salmon from recreational harvest, early arriving fish may still be harvested prior to January 1. Additionally, higher densities of fish in this portion of the river may lead to higher early harvest rates. Higher densities of fish, particularly below dams, likely create opportunities for both illegal poaching of salmon and the inadvertent or intentional snagging of fish. In addition, the upper Sacramento River supports substantial angling pressure for rainbow trout. Rainbow trout fishers tend to concentrate in locations and at times where winter-run Chinook are actively spawning (and therefore concentrated and more susceptible to impacts). By law, any winter-run Chinook inadvertently hooked in this section of river must be released without removing it from the water, however, winter-run Chinook are impacted as a result of disturbance and the process of hook-and-release.

WATER TEMPERATURE

Following the installation of the Temperature Control Device (TCD) at Shasta Dam in 1997, water temperatures in this reach of the river seldom exceed 60°F and are suitable for adult immigration and holding.

WATER QUALITY

Water quality in this reach of the Sacramento River is not at a level to cause adverse effects on immigrating adult salmonids.

FLOW CONDITIONS

Flow conditions in the upper Sacramento River are not likely to adversely affect the upstream adult immigration period for winter-run Chinook salmon.

2.3.7.2 SPAWNING

Spawning escapements of winter-run Chinook salmon in the Sacramento River have declined from near 100,000 in the late 1960s to less than 200 in the early 1990s (Good *et al.* 2005). The CDFG estimated that 191 winter-run Chinook salmon returned in 1991 and that 189 returned in

1994 (Arkush *et al.* 1997). Runs increased to 1,361 in 1995 and 1,296 in 1996 (Arkush *et al.* 1997). Escapements increased to 8,120, 7,360 and 8,133 in 2001, 2002 and 2003 respectively (CDFG 2004c). It should be noted that, some proportion of the escapement is made up of winter-run Chinook salmon propagated at the LSNFH. In 2005, over 18 percent of the run was composed of fish from LSNFH (Lindley *et al.* 2007).

In the Sacramento River, winter-run Chinook salmon spawn from late-April through mid-August with peak spawning activity in May and June (NMFS 1997). See Section 2.2.2 for a more complete description of the biological requirements and description of this life stage. Factors that may adversely affect winter-run Chinook salmon spawning are similar in both river reaches described below although the magnitude of the effects may differ.

Spawning in this reach of the Sacramento River may be affected by adverse flow conditions, physical habitat alteration, recreational sportfishing and poaching, and poor water quality (water temperature). Each of these potential effects is described below.

Although lower water temperatures in this reach of the Sacramento River make spawning habitat more suitable, the adverse effects of changing flow regimes, physical habitat alteration, sportfishing harvest and poaching are likely magnified in this reach due to higher densities of winter-run Chinook salmon spawning.

PASSAGE IMPEDIMENTS/BARRIERS

Keswick Dam presents an impassable barrier to upstream salmonid migration and, therefore, marks the upstream extent of currently accessible spawning habitat in this reach of the Sacramento River.

HARVEST/ANGLING IMPACTS

Sport fishing regulations in the Sacramento River are designed to minimize the legal take of winter-run Chinook salmon. However, because the taking of salmon is permitted after August 1, some late spawning winter-run Chinook salmon may be taken. Additionally, the Sacramento River is a popular year-round fishery and some salmon may be inadvertently caught or incorrectly identified by anglers fishing for rainbow trout.

Unnaturally high densities of salmon may occur below the RBDD during certain flow conditions when dam passage is difficult. This may lead to the inadvertent or deliberate snagging of salmon and may create increased poaching opportunities.

WATER TEMPERATURE

Because of suitable water temperatures in this reach of the river and only marginal water temperature conditions downstream of the RBDD, almost all spawning activity occurs in the upper Sacramento River. Other factors affecting winter-run Chinook salmon spawning in the upper Sacramento River are similar to those affecting spawning in the middle Sacramento River described above. Water temperatures in this reach of the river are slightly lower than those found in the middle Sacramento reach making spawning habitat more suitable.

Generally, successful spawning for Chinook salmon occurs at water temperatures below 60°F (NMFS 1997). The NMFS OCAP BO requires water temperatures to be maintained below 56°F.

The 56°F temperature criterion is measured as the average daily water temperature and as such, the criteria may allow water temperatures to exceed 56°F for some periods during a day. However, water temperatures are not likely to exceed 56°F for more than a few hours. Prior to 1997, during some years, water temperatures began exceeding 60°F in May and during July and August, water temperatures were frequently above 60°F (NMFS 1997). In 1997, a TCD was installed at Shasta Dam allowing better management of water temperatures in the Sacramento River. CDFG (2004c) reports that the TCD is working well and that very low egg loss occurred due to adverse water temperatures in 2002 and 2003. Currently the 56°F compliance point is at Bend Bridge near the town of Red Bluff. Downstream of this point, water temperatures likely increase rather quickly during the summer months because of the warm weather and warmwater agricultural return flows.

WATER QUALITY

Water quality in the upper Sacramento River is similar to that described in the idle reach described above. Because of the proximity of the Iron Mountain Mine, point source pollutants may be more concentrated in this reach of the river but effects on spawning are likely negligible.

FLOW CONDITIONS

Large flow fluctuations are the main concern regarding adverse flow conditions in the middle and upper Sacramento River. The largest and most frequent flow reductions have occurred in the late summer and early fall when flashboards at the ACID Dam require adjustment. However, because the largest flow reductions normally occur after spawning has taken place, it is not likely that adverse flow conditions in this reach of the river have a significant negative effect on winter-run Chinook salmon spawning.

SPAWNING HABITAT AVAILABILITY

It is generally thought that available spawning habitat in the upper Sacramento River is sufficient to support the winter-run Chinook salmon population at its currently low level (NMFS 1997). However, as the population recovers, spawning gravel availability could become a limiting factor (NMFS 1997).

PHYSICAL HABITAT ALTERATION

Chinook salmon require clean loose gravel from 0.75 to 4.0 inches in diameter for successful spawning (NMFS 1997). The construction of dams in the upper Sacramento River has eliminated the major source of suitable gravel recruitment to reaches of the river below Keswick Dam. Gravel sources from the banks of the river and floodplain have also been substantially reduced by levee and bank protection measures. Levee and bank protection measures restrict the meandering of the river which would normally release gravel into the river through natural erosion and deposition processes.

HATCHERY EFFECTS

Hatchery effects that are not specific to a particular life stage are discussed above in Section 2.3.2.1. Potential negative effects specific to spawning are discussed below.

The first release of hatchery-raised winter-run Chinook salmon fry from the CNFH occurred in 1990. Use of the CNFH for the propagation program was unsuccessful primarily because fish imprinted on Battle Creek and adults returned to Battle Creek where instream conditions are too warm to allow successful spawning and embryo incubation. Additionally, genetic analyses

showed that some spring-run Chinook salmon were misidentified as winter-run and used for hatchery propagation in 1993, 1994 and 1995 (NMFS 1997). Subsequently, hybrids were released in 1993 and 1994.

The LSNFH has been producing and releasing winter-run Chinook salmon since 1998. The fish are marked with CWTs, adipose fin clipped and released as pre-smolts each winter in late-January or early-February.

Broodstock for the winter-run conservation program is collected from fish traps at Keswick Dam and RBDD, decreasing the number of potentially spawning adults in the natural population. The overall strategy of the program is to increase the abundance of the natural population and bring it closer to recovery status. Fish are trapped throughout migration run-timing at Keswick Dam; however, many fish do not reach the upper Sacramento River but hold in the reach above RBDD and therefore, some representation of winter-run may not be always adequately represented. Not all components of the run can be collected at RBDD because the gates remain open for the bulk of the run. There have also been some instances of predation on trapped fish before their collection, which has precipitated changes in trapping protocols. The greatest potential effect on spawning may be dominance of hatchery influence on the natural population. High survival is afforded to hatchery juveniles. Artificial propagation of winter-run preferentially spawns natural adults, but with the limitations of current collection methods, there may be skewing of genetic representation of the population not par with natural selection. Preferential survival of hatchery fish over time may disrupt gene complexes of the natural population with those inherited through artificial selection. Taylor (1991) reports that because hatchery fish are adapted to the hatchery environment, natural spawning with wild fish reduces the fitness of the natural population. Recently, NMFS (2007a) reported that the rising proportion of hatchery fish among returning adults threatens to shift the population from a low to moderate risk of extinction. Additionally, Lindley *et al.* (2007) recommend that in order to maintain a low risk of genetic introgression with hatchery fish, no more than five percent of the naturally spawning population should be composed of hatchery fish.

Since 2001, hatchery-origin winter-run Chinook salmon have made up more than five percent of the run and in 2005, the contribution of hatchery fish exceeded 18 percent (Lindley *et al.* 2007).

2.3.7.3 EMBRYO INCUBATION

In the Sacramento River, winter-run Chinook salmon spawning occurs from late-April through mid-August. Fry emergence occurs from mid-June through mid-October (NMFS 1997). Therefore, embryo incubation is believed to occur from mid-April through mid-October. Nearly all spawning of winter-run Chinook salmon occurs in the upper Sacramento River upstream of the RBDD. In 2002, one redd was observed downstream of RBDD, while in 2003, three redds were observed below this point (CDFG 2004). Embryo incubation is defined as the time span from fertilized egg deposition until fry emergence from the gravel. Within the appropriate water temperature range, eggs normally hatch in 40 to 60 days. Newly hatched fish (alevins) normally remain in the gravel for an additional four to six weeks until the yolk sac has been absorbed (NMFS 1997). See Section 2.2.3 for a more complete description of the biological requirements and description of this life stage. Factors that may affect winter-run Chinook salmon embryo

incubation are similar in both river reaches and are described below; however, the magnitude of the effects may differ.

Factors affecting winter-run Chinook salmon embryo incubation in the upper Sacramento River are similar to those affecting embryo incubation in the middle Sacramento River described above. Water temperatures in this reach of the river are lower than those found in the middle Sacramento River reach making embryo incubation habitat more suitable and warm water temperatures are seldom a problem for developing embryos in this reach of the river.

The adverse effects of fluctuating flow regimes and water pollution from both point and non-point sources are likely magnified in this reach of the river because of the higher densities of embryo development.

HARVEST/ANGLING IMPACTS

Because recreational fishing in the Sacramento River is permitted year-round, it is possible that incubating embryos in redds could be disturbed by wading anglers.

WATER TEMPERATURE

The embryo incubation life stage of winter-run Chinook salmon is the most sensitive to elevated water temperatures. Preferred water temperatures for Chinook salmon egg incubation and embryo development range from 46°F to 56°F (NMFS 1997). A significant reduction in egg viability occurs at water temperatures above 57.5°F and total mortality may occur at 62°F (NMFS 1997). Additionally, several diseases that can adversely affect developing embryos become more virulent as water temperatures increase. For example, Saprolegnia is a common fungal disease, which spreads rapidly and suffocates developing eggs in a redd. The rate of fungal growth rises exponentially as water temperatures increase from the mid-50s to the low-60s (NMFS 1997). Historically, water temperatures in the middle Sacramento River typically exceeded 60°F from July through September and in drier years may have exceeded 66°F (NMFS 1997). Winter-run Chinook salmon that spawned downstream of the RBDD normally did not produce viable offspring because of lethal water temperatures (Hallock and Fisher 1985). However, with implementation of the TCD at Shasta Dam in 1997 suitable water temperatures for embryo incubation may extend downstream of Bend Bridge. Currently, river water temperatures just below the RBDD only marginally exceed the incipient lethal level for incubating eggs during June through September, by reaching 57°F to 58°F. These water temperatures are in the range that would typically cause mortality for 10 to 20 percent of eggs (Cramer *et al.* 2003).

WATER QUALITY

Water quality issues that may produce adverse effects on winter-run Chinook salmon include both point source and non-point source pollution. Non-point source pollution consists of sediments from storm events, stormwater runoff in urban and developing areas and agricultural runoff. Sediments constitute nearly half of the material introduced to the river from non-point sources (NMFS 1997). Excess silt and other suspended solids are mobilized during storm events from plowed fields, construction and logging sites and mines. High sediment loading can interfere with eggs developing in redds by reducing the ability of oxygenated water to percolate down to eggs in the gravel. Stormwater runoff in urban areas can transport oil, trash, heavy

metals and toxic organics all of which are potentially harmful to incubating eggs. Agricultural runoff can contain excess nutrients, pesticides and trace metals.

The inactive Iron Mountain Mine in the Spring Creek watershed near Keswick Dam creates the largest point source discharge of toxic material into the Sacramento River. The three metals of particular concern are copper, cadmium and zinc. The early life stages of salmon are the most sensitive to these metals (NMFS 1997). The acid mine drainage from Iron Mountain Mine is among the most acidic and metal laden anywhere in the world (NMFS 1997). Historically, discharge from the mine has produced massive fish kills.

In 1983, the Iron Mountain Mine site was declared a superfund site. Since that time various mitigation measures have been implemented including a neutralization plant that has improved the ability to control metal loadings to the river. (NMFS 1997) reported that although significant improvements have been made, basin plan objectives were not yet achieved by 1997. Since that time, other mitigation measures have been implemented resulting in a 95 percent reduction in historic copper, cadmium and zinc discharges (EPA 2006). At present, acid mine waste still escapes untreated from waste piles and seepage on the north side of Iron Mountain and flows into Boulder Creek, which eventually flows into the Sacramento River (EPA 2006). However, there were no significant exceedances of dissolved metal concentrations in the Sacramento River in 2002 and 2003 (CDFG 2004c). Another point source of pollution in the upper Sacramento River is the Simpson Mill near Redding, which discharges PCBs into the river (NMFS 1997).

FLOW CONDITIONS

Flow fluctuations are a serious concern related to potential adverse effects on the embryo incubation life stage of winter-run Chinook salmon. For example, if spawning salmon construct redds during periods of high flow, those redds could become dewatered during subsequent periods of low flow. Historically, the largest and most rapid flow reductions have occurred during the irrigation season when adjustments are required at the ACID Dam. To accommodate these adjustments, Sacramento River flows at times have been decreased by one-half or greater, over the course of a few hours (NMFS 1997). Flow fluctuations adversely affecting winter-run Chinook salmon embryo and pre-emergent fry incubation occur every year and could only be controlled by significant changes in dam operations. Specifically, releases from Keswick Dam typically drop from summer high flows of 13,000 to 15,000 cfs to fall flows of 3,250 to 5,500 cfs in September, prior to the emergence of fry from the tail end of the winter-run spawning distribution. Dropping flows from 13,000 cfs to 5,500 cfs would result in dewatering 20.7% of winter-run redds (USFWS 2006). Adherence to NMFS ramping criteria and the use of CVPIA B2 water serve to reduce the adverse effects of flow fluctuation.

2.3.7.4 JUVENILE REARING AND OUTMIGRATION

Winter-run Chinook salmon juveniles rearing in the upper Sacramento River exhibit peak abundance during September, with outmigration past the RBDD occurring from July through March (Reclamation 1992; Vogel and Marine 1991). NMFS (1997) reports juvenile rearing and outmigration extending from June through April. Outmigration of juveniles past Knights Landing, approximately 155 river miles downstream of the RBDD, reportedly occurs between November and March peaking in December (Snider and Titus 2000). See Section 2.2.4 for a more complete description of the biological requirements and description of this life stage.

Factors that may adversely affect winter-run Chinook salmon juvenile rearing and outmigration are similar in each of the three river reaches described below although the magnitude of the effects may differ.

Factors that may adversely affect juvenile winter-run Chinook salmon in the upper Sacramento River are similar to those described above in the middle Sacramento River and include passage impediments, physical habitat alteration, water quality, predation, and entrainment. In addition to those factors described above, adverse flow conditions in this reach of the river likely have a greater impact on juveniles as described below.

WATER TEMPERATURE

Following the installation of the TCD at Shasta Dam in 1997, water temperatures in this reach of the river seldom exceed 60°F and are suitable for juvenile salmon rearing year-round.

WATER QUALITY

Point source pollution may occur from both the Iron Mountain Mine and the Simpson Mill as described above. Because the juvenile life stage of Chinook salmon is the most susceptible to adverse effects from pollution and the proximity of these two potential sources of pollution, potential adverse effects are likely more profound in the upper Sacramento River compared to the lower reaches. Effects of non-point source pollution from urban runoff and agricultural drainage are similar to those described above for the middle Sacramento River. However, pollution associated with urban runoff is likely higher due to the proximity of the cities of Redding and Red Bluff.

FLOW CONDITIONS

Almost all spawning and embryo incubation of winter-run Chinook salmon occurs in the upper Sacramento River upstream of the RBDD. Therefore, there is a high density of newly emerged fry in this section of the river. The emergence of fry from the gravel coincides with the irrigation season when flashboard adjustments at the ACID Dam are required and cause reductions in flow. Winter-run Chinook salmon fry prefer shallow nearshore areas with slow current and cover during the late summer and fall. Sudden flow reductions associated with flashboard adjustments at the ACID Dam may strand fry in shallow pools or sidechannels where they may be dewatered or subjected to high water temperatures.

Keswick Dam at RM 302 presents an impassable barrier to upstream migrating adult Chinook salmon, and hence represents the upstream extent of winter-run Chinook salmon habitat. The ACID Dam, located about three miles below Keswick Dam, represents the furthest upstream impediment, due to injury, to juvenile outmigration. The dam is only in place during the irrigation season which typically extends from April through November. During the rest of the year neither upstream adult migration nor downstream juvenile outmigration is hindered. However, peak juvenile outmigration occurs in September and October while the dam is in place. Juveniles migrate past the dam by either dropping as much as ten feet over the dam to the river below or moving through the bypass facility. In either case, juveniles may become disoriented and more susceptible to predation.

The RBDD, at the downstream extent of the upper Sacramento River, creates the final passage impediment to downstream outmigration in this reach of the river. The dam is described in

Section 2.3.7.1. When the dam gates are lowered, Lake Red Bluff is formed slowing flows and delaying juvenile outmigration allowing more opportunities for predation as described below under Predation. Historically there was a high level of mortality associated with fish using an ineffective juvenile fish bypass facility at the dam. A “Downstream Migrant Fish Facility” was installed in 1992, which appears to have reduced mortality associated with use of the bypass facility.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Physical habitat alteration in the upper Sacramento River is similar to that described above for the middle Sacramento River. However, the adverse effects of loss of riparian habitat on juvenile Chinook salmon rearing in the upper Sacramento River may be more profound because of the higher densities of juveniles in this river reach. Whereas the lower reaches of the river serve more as a migration corridor, the upper Sacramento River is where initial juvenile rearing occurs.

Levee building, bank protection measures and the disconnection of the river from its historic floodplain have all had negative effects on riparian habitat. Woody debris and SRA habitat provide important escape cover for juvenile salmon. Aquatic and terrestrial insects, a major component of juvenile salmon diet, are dependent on riparian habitat. Aquatic invertebrates are dependent on the organic material provided by a healthy riparian habitat and many terrestrial invertebrates also depend on this habitat. Studies by the CDFG as reported in NMFS (NMFS 1997) demonstrated that a significant portion of juvenile Chinook salmon diet is composed of terrestrial insects, particularly aphids, which are dependent on riparian habitat.

ENTRAINMENT

Adverse effects due to entrainment of outmigrating juvenile winter-run Chinook salmon at unscreened diversions are similar to those described above for the middle Sacramento River. The new downstream migrant fish facility at the RBDD may have reduced entrainment problems at the RBDD.

PREDATION

Significant predators of juvenile winter-run Chinook salmon in the upper Sacramento River include Sacramento pikeminnow and both hatchery and wild steelhead. Striped bass, a significant predator in lower reaches of the river typically do not utilize the upper Sacramento River; however, they are present immediately below the RBDD.

The most serious adverse effect due to predation occurs in the vicinity of the RBDD. Passage through Lake Red Bluff can delay outmigrating juvenile winter-run Chinook salmon and increases the opportunities for predation by both fish and birds (Vogel and Smith 1986 as cited in NMFS 1997). Winter-run Chinook salmon juveniles passing under the gates at the RBDD are heavily preyed upon by both striped bass and Sacramento pikeminnow (NMFS 1997). Large concentrations of Sacramento pikeminnow have been observed accumulating immediately below the RBDD when juvenile winter-run Chinook salmon begin outmigration in late summer and early fall (Garcia 1989 in NMFS 1997).

The extent of predation on juvenile Chinook salmon by hatchery reared steelhead is not known. However, steelhead releases by the CNFH may have a high potential for inducing high levels of

predation on naturally produced Chinook salmon (CALFED 2000b). The CNFH has a current production target of releasing approximately 600,000 steelhead in January at a size of four fish per pound, approximately 195 mm (USFWS 2001). There is also evidence of residualization of CNFH steelhead in the upper Sacramento River, which would compound the effects of annual CNFH steelhead releases.

HATCHERY EFFECTS

The extent of predation on juvenile Chinook salmon by hatchery-reared steelhead is not known. However, steelhead releases by the CNFH may have a high potential for inducing high levels of predation on naturally produced Chinook salmon (CALFED 2000c). The CNFH has a current production target of releasing approximately 600,000 steelhead in January and February at sizes of 125 to 275 mm (CALFED 2000c).

LSNFH releases up to 250,000 pre-smolt winter-run at 85 to 90 mm FL, a larger size than their wild counterparts. LSNFH winter-run appear to leave the upper Sacramento River enmass, and may precipitate the outmigration of remaining wild winter-run they encounter through a “pied-piper effect.” The net effect of this phenomenon is two-fold: a smaller wild fish may leave before its development triggers an outmigration response and compete poorly for refugia and prey, but it may be afforded some protection by traveling amid a large number of fish.

2.3.8 SUB-ADULT AND ADULT OCEAN RESIDENCE

2.3.8.1 HARVEST

The recent increase in abundance of winter-run Chinook salmon is attributed to the harvest management measures developed by the PFMC in accordance with the NMFS 1996 and 1997 supplemental BOs on the FMP restricting recreational and commercial fisheries south of Point Arena, California (NMFS 2000). The harvest index (CVI) ranged from 0.55 to about 0.80 from 1970 to 1995, when harvest rates were restricted to protect winter-run Chinook salmon. In 2001, the CVI fell to 0.27.

The recent release of a significant number of adipose fin-clipped juvenile winter-run Chinook salmon has provided new information on the harvest rates of winter-run Chinook salmon in coastal recreational and troll fisheries. The PFMC’s Sacramento River Winter and Spring Chinook Salmon Workgroup performed a cohort reconstruction of the 1998 brood year (NMFS 2003). Winter-run Chinook salmon are mainly vulnerable to ocean fisheries at age 3. The workgroup estimated that the ocean fishery impact rate on 3-year olds was 0.23, and the in-river sportfishery impact rate was 0.24. These impacts combine to reduce escapement by 59 percent of what it would have been in the absence of fisheries mortalities, assuming no natural mortality during the fishing season. The high estimated rate of harvest from the in-river sportfishery is a consequence of the recovery of eight coded-wire tags, and was not anticipated due to fishery closures from January 15 to July 31 to reduce impacts on winter-run Chinook salmon. Currently (2007), the in-river sportfishery is closed from December 31 through July 16 to avoid harvest of winter-run Chinook salmon during the tail end of the late-fall Chinook salmon run.

While ocean sport fishing regulations prevent the retention of winter-run Chinook salmon, there are mortalities associated with the capture and subsequent release of fish. The hook-and-release

mortality rate for Chinook salmon of all sizes released from recreational ocean fisheries was estimated to be 14 percent by the Salmon Technical Team (PFMC 2000). In addition, the Salmon Technical Team recommended using a *drop-off-mortality-rate* (i.e., the proportion of fish encountered by fishing gear that are killed without being brought into the vessel) of 5 percent.

Pacific coast salmon management is based largely on the analysis of CWT recoveries from hatchery fish. The CWT contains information on the fish's origin, brood year, year of release and other information. The recent recoveries of CWT fish in the ocean and river have provided data to re-examine the impact of ocean harvest on winter-run Chinook salmon. The CWT data indicate that the harvest fraction on winter-run Chinook salmon was 0.54 for the brood year 1992 (NMFS 1996c). The NMFS Biological Assessment indicates that this harvest fraction was estimated based on relatively limited data due to the small size of juveniles tagged. However, the recovery of tagged winter-run Chinook salmon verifies the incidence of harvest and provides a rough approximation of present ocean impacts.

It was determined that the 0.54 harvest rate was acceptable because it was below levels sustained by other Chinook salmon stocks. However, the winter-run Chinook salmon population has shown low spawning abundances and therefore, it may be that a harvest fraction of 0.50 is too high to sustain the winter-run Chinook salmon population.

A biological opinion on the winter-run Chinook salmon ocean harvest suggests that for brood years 1998, 1999, and 2000, the spawner reduction rates associated with winter-run ocean harvest were 0.26, 0.23, and 0.24, respectively. The spawner reduction rate is the observed fishery mortality in terms of adult-equivalents (fish that are expected to survive natural mortality and spawn) divided by the predicted number of spawners that would survive natural mortality in the absence of fishery mortality (NMFS 2004b).

Figure 2-6. Historical Upper Sacramento River Winter-run Chinook Salmon Spawning Escapement Estimates

2.3.8.2 OCEAN CONDITIONS

In recent years scientific evidence supports hypotheses about the direct and indirect effects of climate change on the ocean production of salmon. Most of this research has focused on the effects of oceanic climate change on the growth and abundance of salmonids (Hollowed *et al.* 2001; Kruse 1998; Myers *et al.* 2000; Percy 1997). Two of the most researched phenomena are the El Niño-Southern-Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO). ENSO is a short-term (8 to 15 months) climate change event that occurs at irregular intervals (approximately every 3 to 7 years) and alternates between two phases, the El Niño (warm) and the La Nina (cool).

The PDO is a multi-decadal (20 to 30 year) ENSO-like pattern of North Pacific climate change. The PDO seems to be associated with an inverse relationship between salmon abundance in the Alaska and the U.S. Pacific Coast regions. During a positive PDO phase, the abundance of Alaska salmon is high, and the abundance of U.S. West Coast salmon is low.

ENSO has been shown to produce dramatic effects on marine communities. Alterations in the physical oceanographic properties of the marine environment can be observed as far north as Alaska. Less known is the phenomenon of La Nina, the cool phase of ENSO events that follows El Niño. During the 1982-1983 El Niño event there were observable alternations in oceanic plankton distributions, fish community structure, and reduced ocean catches off the coastal waters of southern California. Along central California coast, the 1992-1993 El Niño corresponded to delayed phytoplankton blooms, changes in the abundance and distribution of invertebrates, an increase in the productivity of southern fish species; however there was a dramatic decline in the northerly rockfish species. More recently, the largest decline in

macrozooplankton abundance off central southern California occurred during the 1997-1998 El Niño (Brodeur and Pearcy 1992a).

Brodeur *et al.* (1992b) found that juvenile Chinook and coho salmon have the potential to easily exhaust prey resources during years when ocean productivity is low (e.g., El Niño), but during most years they consume less than 1 percent of the total prey production.

2.4 STRESSOR PRIORITIZATION

2.4.1 STRESSOR MATRIX DEVELOPMENT

2.4.1.1 STRESSOR MATRIX OVERVIEW

A stressor matrix⁷, in the form of a single Microsoft Excel worksheet, was developed to structure the winter-run Chinook salmon population, life stage, and stressor information into hierarchically related tiers so that stressors to the ESU could be prioritized. The individual tiers within the matrix, from highest to lowest, are: (1) population; (2) life stage; (3) primary stressor category; and (4) specific stressor. These individual tiers were related hierarchically so that each variable within a tier had several associated variables at the next lower tier, except at the lowest (i.e. fourth) tier.

The general steps required to develop and utilize the winter-run stressor matrix are described as follows:

1. Each life stage within the population was weighted so that all life stage weights in the population summed to one;
2. Each primary stressor category within a life stage was weighted so that all primary stressor category weights in a life stage summed to one;
3. Each specific stressor within a primary stressor category was weighted so that all specific stressor weights in a primary stressor category summed to one;
4. A composite weight for each specific stressor was obtained by multiplying the product of the population weight, the life stage weight, the primary stressor weight, and the specific stressor weight by 100;
5. A normalized weight for each specific stressor was obtained by multiplying the composite weight by the number of specific stressors within a particular primary stressor group; and
6. The stressor matrix was sorted by the normalized weight of the specific stressors in descending order.

The completed stressor matrix sorted by normalized weight is a prioritized list of the life stage-specific stressors affecting the ESU. Specific information explaining the individual steps taken to generate this prioritized list is provided in the following sections.

⁷ For winter-run Chinook salmon, a single stressor matrix was developed corresponding to the mainstem upper Sacramento River population, whereas for spring-run Chinook salmon and steelhead, multiple individual stressor matrices were developed corresponding to each of the extant populations for these species.

2.4.1.2 POPULATION IDENTIFICATION AND RANKING

The winter-run Chinook salmon threats assessment was limited to the Sacramento River population, which represents the only extant⁸ population in the ESU. Thus, this population received a weight of one in the stressor matrix.

2.4.1.3 LIFE STAGE IDENTIFICATION AND RANKING

For the purpose of developing the stressor matrices, the freshwater life cycle for winter-run Chinook salmon was broken up into four commonly acknowledged life stages: (1) adult immigration and holding; (2) spawning; (3) embryo incubation; and (4) juvenile rearing and outmigration. When weighting stressors in the juvenile rearing and outmigration life stage, the temporal and spatial distribution of post-emergent fry, young-of-year, and yearling/smolts was considered along with the factors affecting each of these juvenile age/size classes.

The individual life stages of winter-run Chinook salmon were weighted in relative importance according to: (1) the relative importance of each life stage in establishing initial year class strength; and (2) relative vulnerability of each life stage to current stressors. It is recognized that each life stage is important to the production the subsequent year class and, as such, life stages were ranked unequally only when differences were clearly warranted. For example, for winter-run Chinook salmon, the adult immigration and staging life stage was given a lower (i.e., 0.1) ranking relative to the three other life stages because flows are generally high and water temperatures are generally cool during this life stage making the life stage relatively less vulnerable to current stressors. The other three winter-run Chinook salmon life stages were ranked relatively equal (i.e., 0.25-0.35) to one another. The life stage weightings for each spring-run Chinook salmon and steelhead population are presented in Appendices B and C, respectively.

2.4.1.4 STRESSOR IDENTIFICATION AND RANKING

The primary stressors affecting winter-run Chinook salmon throughout its life cycle were identified by: (1) conducting three public workshops; (2) reviewing published literature, including the proposed Sacramento winter-run Chinook salmon recovery plan published in 1997 (NMFS 1997), Chinook salmon status review documents (Myers *et al.* 1998), and numerous other technical sources related to Central Valley salmon; and (3) utilizing the technical expertise of several Central Valley salmonid biologists. The threats lists generated from the public workshops were used as a starting point for identifying and categorizing threats. The following is a list of the primary stressor categories ultimately considered for the stressor matrix development.

1. Passage Impediments/Barriers
2. Harvest/Angling Impacts
3. Water Temperature
4. Water Quality
5. Flow Conditions
6. Loss of Riparian Habitat and Instream Cover
7. Loss of Natural River Morphology and Function

⁸ Historically, winter-run Chinook salmon inhabited the Little Sacramento River, Pit-Fall-Hat Creeks, the McCloud River, and Battle Creek.

8. Loss of Floodplain Habitat
9. Loss of Tidal Marsh Habitat
10. Spawning Habitat Availability
12. Physical Habitat Alteration (e.g., lack of instream gravel supply, watershed disturbance)
13. Invasive Species/Food Web Changes
14. Entrainment
15. Predation
17. Hatchery Effects

The primary stressor categories presented were not necessarily considered to be an exhaustive list of stressors. However, the list contains the major threats and stressors to the Sacramento River population that can potentially be alleviated through recovery actions. Threats to the Sacramento River winter-run Chinook salmon population not on this list include low abundance as well as changes in ocean conditions that may adversely affect the ocean food web (i.e., altered ocean currents that limit upwelling). The threat of low abundance should be reduced if the primary stressors considered in the stressor matrix are minimized or eliminated. The threat of an altered oceanic food distribution adversely affecting the population is an impossible threat to alleviate through recovery actions.

Some of the primary stressor categories are self explanatory, while others require some elucidation to fully understand their context and how they were considered in the stressor matrix. “Passage Impediments/Barriers” were considered to be threats affecting both the adult immigration and staging, and the spawning life stages, because the impediments/barriers may physically block access to historic staging and spawning habitats. As a consequence, they also eliminate the spatial segregation of spawning habitat that historically existed for spring-run and fall-run Chinook salmon. “Harvest/Angling Impacts” include recreational and commercial harvest in the ocean⁹, Bay-Delta, and river systems, as well as incidental impacts of anglers physically disturbing incubating embryos while wading through the river. “Flow Conditions” includes flow dependent habitat availability in-river systems and the anthropogenically altered hydrology in the Delta. For example, the CVP and SWP have resulted in changing the Delta from a tidally driven saline-estuarine-freshwater system to one that is primarily fresh water. Additionally, the C.W. Jones (formerly Tracy) and the Harvey O. Banks pumping plants affect Delta flow conditions in several ways including: (1) by creating reverse flow conditions in Old and Middle Rivers; (2) by effectively pulling Sacramento River water down into the central Delta. “Loss of Natural River Morphology and Function” is the result of river channelization and confinement, which leads to a decrease in riverine habitat complexity, and thus, a decrease in the quantity and quality of juvenile rearing habitat. Additionally, this primary stressor category includes the effect that dams have on the aquatic invertebrate species composition and distribution, which may have an effect on the quality and quantity of food resources available to juvenile salmonids. For example, in a natural river system without one or more large dams, there is an upstream source of lotic aquatic invertebrate species available to juvenile salmonids, whereas on a river with a large terminal dam, the upstream drift of food resources to juvenile salmonids is drastically altered. The “Spawning Habitat Availability” category was considered to include the quantity and quality of spawning habitat currently accessible to the fish, whereas,

⁹ For ease of application to the stressor matrix, the impact of ocean harvest was considered in the adult immigration and holding/staging life stage.

as previously mentioned, the loss of access to historic spawning habitat was considered in the “Passage Impediments/Barriers” category. The “Invasive Species/Food Web Changes” category included the potential effects of native (i.e., microsystem) and non-native (e.g., Asian clam, *A. aspera*) species on the quantity and quality of food available to juvenile salmonids in the Bay-Delta system. The “Hatchery Effects” primary stressor category was considered a threat to the spawning and the juvenile rearing and outmigration life stages. The spawning life stage is affected due to the potential for hatchery-origin salmon to compete with naturally-origin for spawning habitat, and due to the potential for reduced genetic integrity when hatchery-origin salmon spawn with natural-origin salmon. The juvenile rearing and outmigration life stage is affected due to competition between hatchery- and natural-origin for habitat and food, and due to predation by yearling-sized or larger steelhead released from hatcheries on young-of-year Chinook salmon.

Specific stressors are the individual physical structures or locations at which the primary stressor category is affecting the species. As shown in **Table 2-2**, four river sections of the Sacramento River system (i.e., the Delta, and the lower, middle, and upper Sacramento River) are identified as specific stressors within the water temperature primary stressor category.

Table 2-2. Excerpt from the Winter-run Chinook Salmon Stressor Matrix

Life Stage	Life Stage Weight (0-1) Sum to 1	Primary Stressor Category	Primary Stressor Weight (0-1) Sum to 1	Specific Stressor	Specific Stressor Weight (0-1) Sum to 1	Composite Weight (X100)	Number of Specific Stressors	Normalized Weight (Composite * # of specific stressors)	Overall Stressor Category
Juvenile Rearing and Outmigration	0.325	Water Temperature	0.050	Delta	0.200	0.325	4	1.30	M
Juvenile Rearing and Outmigration	0.325	Water Temperature	0.050	Lower Sacramento River	0.300	0.488	4	1.95	H
Juvenile Rearing and Outmigration	0.325	Water Temperature	0.050	Middle Sacramento River	0.400	0.650	4	2.60	H
Juvenile Rearing and Outmigration	0.325	Water Temperature	0.050	Upper Sacramento River	0.100	0.163	4	0.65	L

The criteria considered when evaluating and weighting primary stressor categories and specific stressors were adapted from the Interim Endangered and Threatened Species Recovery Planning Guidance (NMFS 2006):

- ❑ Scope – The geographic scope of the threat to the species. Impacts can be widespread or localized.
- ❑ Severity – A measure of the level of damage to the species or system that can reasonably be expected within 10 years under current circumstances. Ranges from total destruction, serious or moderate degradation or slight impairment.

- ❑ Magnitude – The severity plus scope.
- ❑ Frequency – A temporal measure of the threat.
- ❑ Immediacy – There are varying degrees of immediacy, including , a species is intrinsically vulnerable to threats, or identifiable threats can be “mapped” and seen as increasing or decreasing, or the threats are reasonably predictable.
- ❑ Persistence – To identify a persistent threat, the active and historical sources of the stress are evaluated.

In order to account for variation in the number of specific stressors within primary stressor categories, it was necessary to normalize the composite weight. Without this normalization, a given set of specific stressors that have an equal affect on the species may inappropriately receive an unequal weighting if some specific stressors in the set are within a primary stressor category containing only a few specific stressors while the other specific stressors in the set are within a primary stressor category containing several specific stressors. Normalizing the composite weight was accomplished by multiplying the composite weight by the number of specific stressors within a particular primary stressor group.

After all of the variables in the matrix were identified and weighted, and all of the normalized weights were calculated, the matrix was sorted by normalized weight in descending order. This sort put the highest weighted stressors – those with the largest biological impact – at the top of the matrix and the lowest weighted stressors at the bottom. After this initial sort, the matrix was reviewed for stressors that appeared to be inappropriately weighted, slight adjustments were then made until the sorted matrix reasonably represented a prioritized list of stressors.

It is important to discuss and understand the application of the stressor matrix results. Although the matrix provides a pseudo-quantitative means of comparatively ranking individual stressors, we want to avoid attributing unwarranted specificity to the prioritized stressor list. As such, the prioritized stressor list was distributed into four separate quartiles which represent four tiers of stressor importance. The stressors in the quartile with the highest normalized weights were identified as having “Very High” importance. The stressors in the other three quartiles were identified as having either a “High”, “Medium”, or “Low” importance depending on the magnitude and distribution of the normalized weights. For example, a population with 100 individual stressors with distinct (i.e., unequal) normalized weights would have 25 stressors that were considered of “Very High” importance, 25 with “High” importance, 25 with “Medium” importance, and 25 with “Low” importance. However, if the calculated normalized weight of some of the stressors were equal, then the distribution could be altered such that not all importance categories received the same number of stressors. Staying with this example, if the 25th and 26th ranked stressors in the sorted list of 100 stressors were equal, then the “Very High” importance stressor category would contain 26 stressors. The “High” importance category would receive 25 or more stressors depending on whether the normalized weights for the stressors at the quartile cutoff were equal or not, and so on.

2.4.2 STRESSOR MATRIX RESULTS

Each life stage of winter-run Chinook salmon is affected by stressors of “Very High” importance. These stressors include:

- ❑ The barriers of Keswick and Shasta dams, which block access to historic staging and spawning habitat;
- ❑ Ocean harvest;
- ❑ Flow fluctuations, water pollution, water temperatures in the upper Sacramento River during embryo incubation;
- ❑ Loss of juvenile rearing habitat in the form of lost natural river morphology and function, and lost riparian habitat and instream cover;
- ❑ Predation during juvenile rearing and outmigration; and
- ❑ Changes in Delta hydrology, diversion into the central Delta, and entrainment of juveniles at the C.W. Jones and Harvey O. Banks pumping plants.

The complete prioritized list of life stage-specific stressors to the Sacramento River winter-run Chinook salmon ESU is presented in Attachment A.

3.0 CENTRAL VALLEY SPRING-RUN CHINOOK SALMON

3.1 BACKGROUND

3.1.1 LISTING HISTORY

Central Valley spring-run Chinook salmon was proposed as “endangered” by NMFS on March 9, 1998 (63 FR 11482 (March 9, 1998)). NMFS concluded that the Central Valley spring-run Chinook salmon ESU was in danger of extinction because native spring-run Chinook salmon have been extirpated from all tributaries in the San Joaquin River Basin, which represented a large portion of the historic range and abundance of the ESU as a whole. Moreover, the only streams considered to have wild spring-run Chinook salmon at that time were Mill and Deer Creeks, and possibly Butte Creek (tributaries to the Sacramento River). These populations were considered relatively small with sharply declining trends. Hence, demographic and genetic risks due to small population sizes were considered to be high. NMFS also determined that habitat problems were the most important source of ongoing risk to this ESU. Spring-run Chinook salmon cannot access most of their historical spawning and rearing habitat in the Sacramento and San Joaquin River basins (which is now above impassable dams), and current spawning is restricted to the mainstem and a few river tributaries in the Sacramento River (63 FR 11482 (March 9, 1998)). NMFS reported that the remaining spawning habitat accessible to fish is severely degraded. Important juvenile rearing habitat and migration corridor also were degraded. General degradation conditions to rearing and migrating habitat included elevated water temperatures, agricultural and municipal diversions and returns, restricted and regulated flows, entrainment of migrating fish into unscreened or poorly screened diversions, and the poor quality and quantity of remaining habitat. In addition, serious concern existed for threats to genetic integrity posed by hatchery programs in the Central Valley. Most of the spring-run Chinook salmon production in the Central Valley is of hatchery-origin, and naturally spawning populations could be interbreeding with both fall/late fall- and spring-run hatchery fish. NMFS reported that this problem was exacerbated by the increasing production of spring-run Chinook salmon from the Feather River Hatchery. Hatchery strays also were considered to be an increasing problem due to the management practice of releasing a larger proportion of fish off station (into the Delta and San Francisco Bay) (NMFS 2007b).

On September 16, 1999, NMFS listed the Central Valley ESU of spring-run Chinook salmon as a “threatened” species (64 FR 50394 (September 16, 1999)). Although in the original Chinook salmon status review and proposed listing it was concluded that the Central Valley spring-run Chinook salmon ESU was in danger of extinction (Myers *et al.* 1998), in the status review update, the BRT majority shifted to the view that this ESU was not in danger of extinction, but was likely to become endangered in the foreseeable future. A major reason for this shift was data indicating that a large run of spring-run Chinook salmon on Butte Creek in 1998 was naturally produced, rather than strays from Feather River Hatchery (NMFS 2007b).

On March 11, 2002, pursuant to a January 9, 2002 rule issued by NMFS under Section 4(d) of the ESA (15 USC § 1533(d)), the take restrictions that apply statutorily to endangered species

began to apply to the Central Valley ESU of spring-run Chinook salmon (67 FR 1116 (January 9, 2002)).

On June 14 2004, NMFS proposed that the Central Valley spring-run Chinook salmon remain a “threatened” species based on the BRT strong majority opinion that the Central Valley spring-run Chinook ESU is “*likely to become endangered within the foreseeable future.*” The BRT based its conclusions on the greatly reduced distribution of Central Valley spring Chinook ESU and hatchery influences on natural population. In addition, the BRT noted moderately high risk for the abundance, spatial structure, and diversity Viable Salmonid Population criteria, and a lower risk for the productivity criterion reflecting positive trends. On June 28, 2005, NMFS reaffirmed the threatened status of the Central Valley spring-run Chinook salmon ESU (70 FR 37160 (June 28, 2005)). All naturally spawned populations of spring-run Chinook salmon in the Sacramento River and its tributaries in California, and the Feather River Hatchery spring-run Chinook salmon population are included as part of the Central Valley spring-run Chinook salmon ESU.

3.1.2 CRITICAL HABITAT DESIGNATION

On March 9, 1998, NMFS designated critical habitat for Central Valley spring-run Chinook salmon to include all river reaches accessible to Chinook salmon in the Sacramento River and its tributaries in California. Also included were river reaches and estuarine areas of the Delta, all waters from Chipps Island westward to Carquinez Bridge, including Honker Bay, Grizzly Bay, Suisun Bay, and Carquinez Strait, all waters of San Pablo Bay westward of the Carquinez Bridge, and all waters of San Francisco Bay (north of the San Francisco/Oakland Bay Bridge) from San Pablo Bay to the Golden Gate Bridge.

In response to litigation brought by National Association of Homebuilders (NAHB) on the grounds that the agency did not adequately consider economic impacts of the critical habitat designations (NAHB v. Evans, 2002 WL 1205743 No. 00–Central Valley–2799 (D.D.C.)), NMFS sought judicial approval of a consent decree withdrawing critical habitat designations for 19 Pacific salmon and *O. mykiss* ESUs. The District Court in Washington DC approved the consent decree and vacated the critical habitat designations by Court order on April 30, 2002 (NAHB v. Evans, 2002 WL 1205743 (D.D.C. 2002)).

NMFS proposed new critical habitat for Central Valley spring-run Chinook salmon on December 10, 2004, and published a final rule designating critical habitat for this species on September 2, 2005. The critical habitat encompasses 1,158 miles of stream habitat in the Sacramento River Basin and 254 square miles of estuary habitat in the San Francisco-San Pablo-Suisun Bay complex (70 FR 52488 (September 2, 2005)). For a list of designated critical habitat units, see the September 2, 2005 Federal Register Notice (70 FR 52488 (September 2, 2005)).

3.1.3 UNIQUE SPECIES CHARACTERISTICS

Spring-run Chinook salmon enter rivers as immature fish in spring and early summer and exhibit a classic stream type life history pattern, although the stay of some juveniles in fresh water may be less than a year (Moyle 2002). Spring-run Chinook salmon require freshwater streams with cold temperatures over the summer and suitable gravel for reproduction (CALFED 2000a).

Adult Central Valley spring-run Chinook salmon leave the ocean to begin their upstream migration in late January and early February (CDFG 1998) and enter the Sacramento River between mid February and September, primarily in May and June (Yoshiyama *et al.* 1998, Moyle 2002). While maturing, adults typically hold in large, deep (usually > 2 meters) and cold pools, typically with bedrock bottoms and moderate velocities. These fish can reach higher elevations before the onset of elevated water temperatures and low flows that inhibit access to these areas in the fall (Myers *et al.* 1998).

Central Valley spring-run Chinook salmon spawn on the mainstem Sacramento River between RBDD and Keswick Dam and in tributaries such as Mill, Deer, and Butte Creeks. Spawning occurs at the tails of holding pools between late-August and early-October, peaking in September (Moyle 2002; NMFS 2007b). Redd sites are apparently chosen in part by the presence of subsurface flow. Chinook salmon usually seek a mixture of gravel and small cobbles with low silt content to build their redds. Females deposit their eggs in nests in gravel-bottom areas of relatively swift water. Each female produces 2,000 to 17,000 eggs (Moyle 2002).

Adult Pacific Chinook salmon usually die after spawning (Allen and Hassler 1986; Moyle 2002). However, mature 1-year-old males that have never gone to sea are assumed to spawn by sneaking into the nest of large adults, and may actually survive to spawn a second time. These precocious yearlings have enormous testes – about 21 percent of the body weight. In addition, behavior includes the presence of small jack males that also spawn as streakers. The combination of regular and irregular males endures a high degree of fertilization of eggs – more than 90 percent (Moyle 2002).

The length of time for eggs to develop depends largely on water temperatures. In Butte and Big Chico creeks, emergence occurs from November through January and in the colder waters of Mill and Deer creeks, emergence typically occurs from January through as late as May (Moyle 2002). For maximum embryo survival, water temperatures reportedly must be between 41°F and 55.4°F and oxygen levels must be close to saturation (Moyle 2002). Under those conditions, embryos hatch in 40 to 60 days and remain in the gravel as alevins for another 4 to 6 weeks, usually after the yolk sac is fully absorbed. After emerging, Chinook salmon fry tend to seek shallow, nearshore habitat with slow water velocities and move to progressively deeper, faster water as they grow. However, fry may disperse downstream, especially if high-flow events correspond with emergence (Moyle 2002). Movement occurs mostly at night and tends to cease after a couple of weeks, when fry settle down into rearing habitat in streams or estuaries.

Emigration timing is highly variable, as they may migrate downstream as young-of-the year, juveniles, or yearling juveniles. The average size of fry migrants (approximately 40 mm between December and April in Mill, Butte, and Deer Creeks) reflects a prolonged emergence of fry from the gravel (Lindley *et al.* 2004). Studies in Butte Creek (Ward *et al.* 2003a; Ward and McReynolds 2001) found the majority of Central Valley spring-run Chinook salmon migrants to be fry moving downstream primarily during December, January and February; and that these movements appeared to be influenced by flow. Small numbers of Central Valley spring-run Chinook salmon remained in Butte Creek to rear and migrated as yearlings later in the spring. Juvenile emigration patterns in Mill and Deer Creeks are very similar to patterns observed in

Butte Creek, with the exception that Mill and Deer Creek juveniles typically exhibit a later young-of-the year migration and an earlier yearling migration (Lindley *et al.* 2004).

Spring-run Chinook salmon juveniles may reside in freshwater habitat for 12 to 16 months, but many juveniles migrate to the ocean as young-of-the-year in the winter or spring within eight months after hatching (CALFED 2000a). The social behavior of juveniles varies from schooling to territoriality. Spring-run Chinook salmon emigration tends to peak in the Sacramento River during winter (January and February) and spring (April) (Moyle 2002).

Central Valley spring-run Chinook salmon migration corridors begin downstream of the spawning area and extend through the lower Sacramento River and the Delta. Spring-run Chinook salmon in Butte Creek move out as both fry and smolts. Downstream movements of juveniles of all runs serve not only to disperse and move them toward the ocean, but also to provide access to temporary habitats in which slightly warmer water temperatures and abundant food may encourage rapid growth. The tendency of juveniles in rivers to move toward shallow edges, especially during the day, puts them in heavy cover or among emergent vegetation, where invertebrates are abundant and where many predators have a hard time finding them.

Riverine and estuarine habitats of the Bay-Delta are important rearing areas for these migrants. Maslin *et al.* (1999) also have found that substantial numbers of spring-run juveniles use tributaries for non-natal rearing. While small tributaries generally have insufficient flow for spawning adults, juveniles can move upstream to rear, depending on the size, gradient, and quality of the tributary. In the Delta, terrestrial insects are by far the most important food, but crustaceans are also eaten. Juvenile Chinook salmon feed mostly during the day, with peak feeding occurring at dawn and during the afternoon.

Chinook salmon spend two to four years maturing in the ocean before returning to their natal streams to spawn. In the ocean, juvenile Chinook salmon become voracious predators on small fish and crustaceans.

Recovery of CWT Chinook salmon from the Feather River Hatchery in the ocean recreational and commercial fisheries (PSMFC RMIS Database) indicates that Central Valley spring-run Chinook salmon adults are broadly distributed along the Pacific Coast from Northern Oregon to Monterey. Like other stream-type Chinook salmon, Central Valley spring-run Chinook salmon are found far from the coast in the central North Pacific (Healey 1983; Myers *et al.* 1984).

Central Valley spring-run Chinook salmon remain in the ocean for two to four years and then home to their natal region over great distances (NMFS 2007). Once they reach the region of the stream mouth, many “landmarks” are available to guide them further, including geomagnetic anomalies, visual cues and distinctive odors of their home stream. Upstream migration takes place mainly during the day, with fish apparently tracking stream odors on which they imprinted when small. Some Chinook salmon stray to other streams. Straying is presumably also an adaptive mechanism, allowing Chinook salmon to colonize newly opened areas and to mix genetically with other runs, especially those in other streams close to the natal streams (Moyle 2002).

3.1.4 STATUS OF SPRING-RUN CHINOOK SALMON

Historically, spring-run Chinook salmon were predominant throughout the Central Valley occupying the upper and middle reaches (1,000 to 6,000 feet) of the San Joaquin, American, Yuba, Feather, Sacramento, McCloud and Pit rivers, with smaller populations in most tributaries with sufficient habitat for adult salmon holding over the summer months (Stone 1874, Rutter 1904, Clark 1929 *in* NMFS 2007). Clark (1929) estimated that there were historically 6,000 stream miles of salmonid habitat in the Sacramento-San Joaquin River Basin, but only 510 miles remained by 1928. Completion of Friant Dam extirpated the native population from the San Joaquin River and its tributaries (NMFS 2007b).

Central Valley spring-run Chinook salmon were once the most abundant run of salmon in the Central Valley (Campbell and Moyle 1992). The Central Valley drainage as a whole is estimated to have supported spring-run Chinook salmon runs as large as 600,000 fish between the late 1880s and 1940s (CDFG 1998). More than 500,000 Central Valley spring-run Chinook salmon were caught in the Sacramento-San Joaquin commercial fishery in 1883 (CDFG 1998; Yoshiyama *et al.* 1998). Before construction of Friant Dam, nearly 50,000 adults were counted in the San Joaquin River (Fry 1961). The San Joaquin populations essentially were extirpated by the 1940s, with only small remnants of the run persisting through the 1950s in the Merced River (Yoshiyama *et al.* 1998). Populations in the upper Sacramento, Feather, and Yuba rivers were virtually eliminated with the construction of major dams during the 1950s and 1960s (NMFS 2007b). On the American River, the completion of Nimbus Dam in 1955 extirpated the spring-run Chinook salmon population, which was already greatly diminished by the effects of smaller dams (e.g., Old Folsom Dam and the North Fork Ditch Company Dam) and mining activities (Yoshiyama *et al.* 1996).

The Central Valley spring-run Chinook salmon ESU has displayed broad fluctuations in adult abundance between 1967 and 2006 (**Figure 3-1**). Sacramento River tributary populations in Mill, Deer, and Butte Creeks are probably the best trend indicators for the Central Valley spring-run Chinook ESU as a whole because these streams contain the primary independent populations with the ESU. Generally, these streams have shown a positive escapement trend since 1992, which is when consistent escapement methodologies started being used on tributary spring-run surveys, making data comparable between years (**Figure 3-2**). Escapement numbers are dominated by Butte Creek returns, which have averaged over 7,000 fish since 1995 (NMFS 2007b).

During this period (1992-2006), there have been significant habitat improvements (including the removal of several small dams and increases in summer flows) in these watersheds, as well as reduced ocean fisheries and a favorable terrestrial and marine climate (NMFS 2007b).

On the Feather River, significant numbers of spring-run Chinook salmon, as identified by run timing, return to the Feather River Hatchery. Coded-wire tag, information from these hatchery returns, however, indicates that substantial introgression has occurred between fall-run and spring-run Chinook salmon populations within the Feather River system due to hatchery practices. This introgression has compromised the genetic integrity of the spring-run Chinook salmon stock. For this reason, the Feather River spring-run Chinook population numbers are not included in the discussion of ESU abundance (NMFS 2007b). In addition, the Central Valley

hatchery practice of trucking fall-run production for out-of-basin release, and the use of large numbers of hatchery fall-run juveniles for monitoring studies, has resulted in high straying rates of returning adults, and threatening the genetic integrity of all extant spring-run populations as well as natural fall-run populations (Williamson and May 2003).

Figure 3-1. Annual Estimated Central Valley Spring-run Chinook Salmon Escapement from 1967 to 2006

Source: (CDFG 2007)

Figure 3-2. Spring-run Chinook Salmon Combined Population Estimates for Mill, Deer and Butte Creeks from 1992 to 2006

Source: (CDFG 2007)

Although recent Central Valley spring-run Chinook salmon population trends are positive, annual abundance estimates display a high level of fluctuation, and the overall number of Central Valley spring-run Chinook salmon remains well below estimates of historic abundance.

The viability of the Central Valley spring-run Chinook salmon, essentially represented by three populations located within the same ecoregion is vulnerable to changes in the environment through a lack of spatial geographic diversity. The current geographic distribution of viable populations makes the Central Valley spring-run Chinook salmon ESU vulnerable to catastrophic disturbance (Lindley *et al.* 2007). Such potential catastrophes include volcanic eruption of Lassen Peak, prolonged drought conditions reducing coldwater pool adult holding habitat, and a large wildfire (approximately 30 kilometer maximum diameter) encompassing the Deer, Mill and Butte creek watersheds. Because the Central Valley spring-run Chinook salmon ESU is spatially confined to relatively few remaining streams, continues to display broad fluctuations in abundance, and a large proportion of the population (i.e., in Butte Creek) faces the risk of high mortality rates due to elevated water temperatures during the adult holding period, the population remains at a moderate to high risk of extinction (NMFS 2007b).

3.2 LIFE HISTORY AND BIOLOGICAL REQUIREMENTS

3.2.1 ADULT IMMIGRATION AND HOLDING

3.2.1.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Adult Central Valley spring-run Chinook salmon leave the ocean to begin their upstream migration in late-January and early February (CDFG 1998), and enter the Sacramento River between mid February and September, primarily in May and June (Moyle 2002; Yoshiyama *et al.* 1998). Figures 3-3, 3-4, and 3-5 show the timings of this life stage by diversity group.

3.2.1.2 BIOLOGICAL REQUIREMENTS

Similar to the winter-run, spring-run Chinook salmon generally enter rivers as sexually immature fish and must hold in freshwater for up to several months before spawning (Moyle 2002). Spring-run Chinook salmon spawn in areas with water velocities ranging from 0.06 to 3.80 ft/sec (USFWS 2003b). Spawning depths can range from as little as 0.3 feet to 3.3 feet (USFWS 2003b). Preferred water depths (defined as a suitability greater than 0.5) range from 0.5 to 3.0 feet (USFWS 2003b). Substrate is an important component of Chinook salmon spawning habitat, and generally includes a mixture of gravel and small cobbles (Moyle 2002). USFWS (2003b) reports that preferred spring-run Chinook salmon spawning substrate (defined as a suitability greater than 0.5) is composed mostly of large gravel and small cobbles from 1-3 inches to 3-5 inches in diameter.

3.2.2 ADULT SPAWNING

3.2.2.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Spawning of Central Valley spring-run Chinook salmon generally takes place from about mid-August through October but may vary somewhat among individual streams within each diversity group as shown in Figures 3-3, 3-4 and 3-5.

3.2.2.2 BIOLOGICAL REQUIREMENTS

Spawning of Central Valley spring-run Chinook salmon normally occurs between mid-August and early October, peaking in September (Moyle 2002). Habitat requirements to support the biological needs of spring-run Chinook salmon spawning are similar to those for winter-run described above in Section 2.2.3.2.

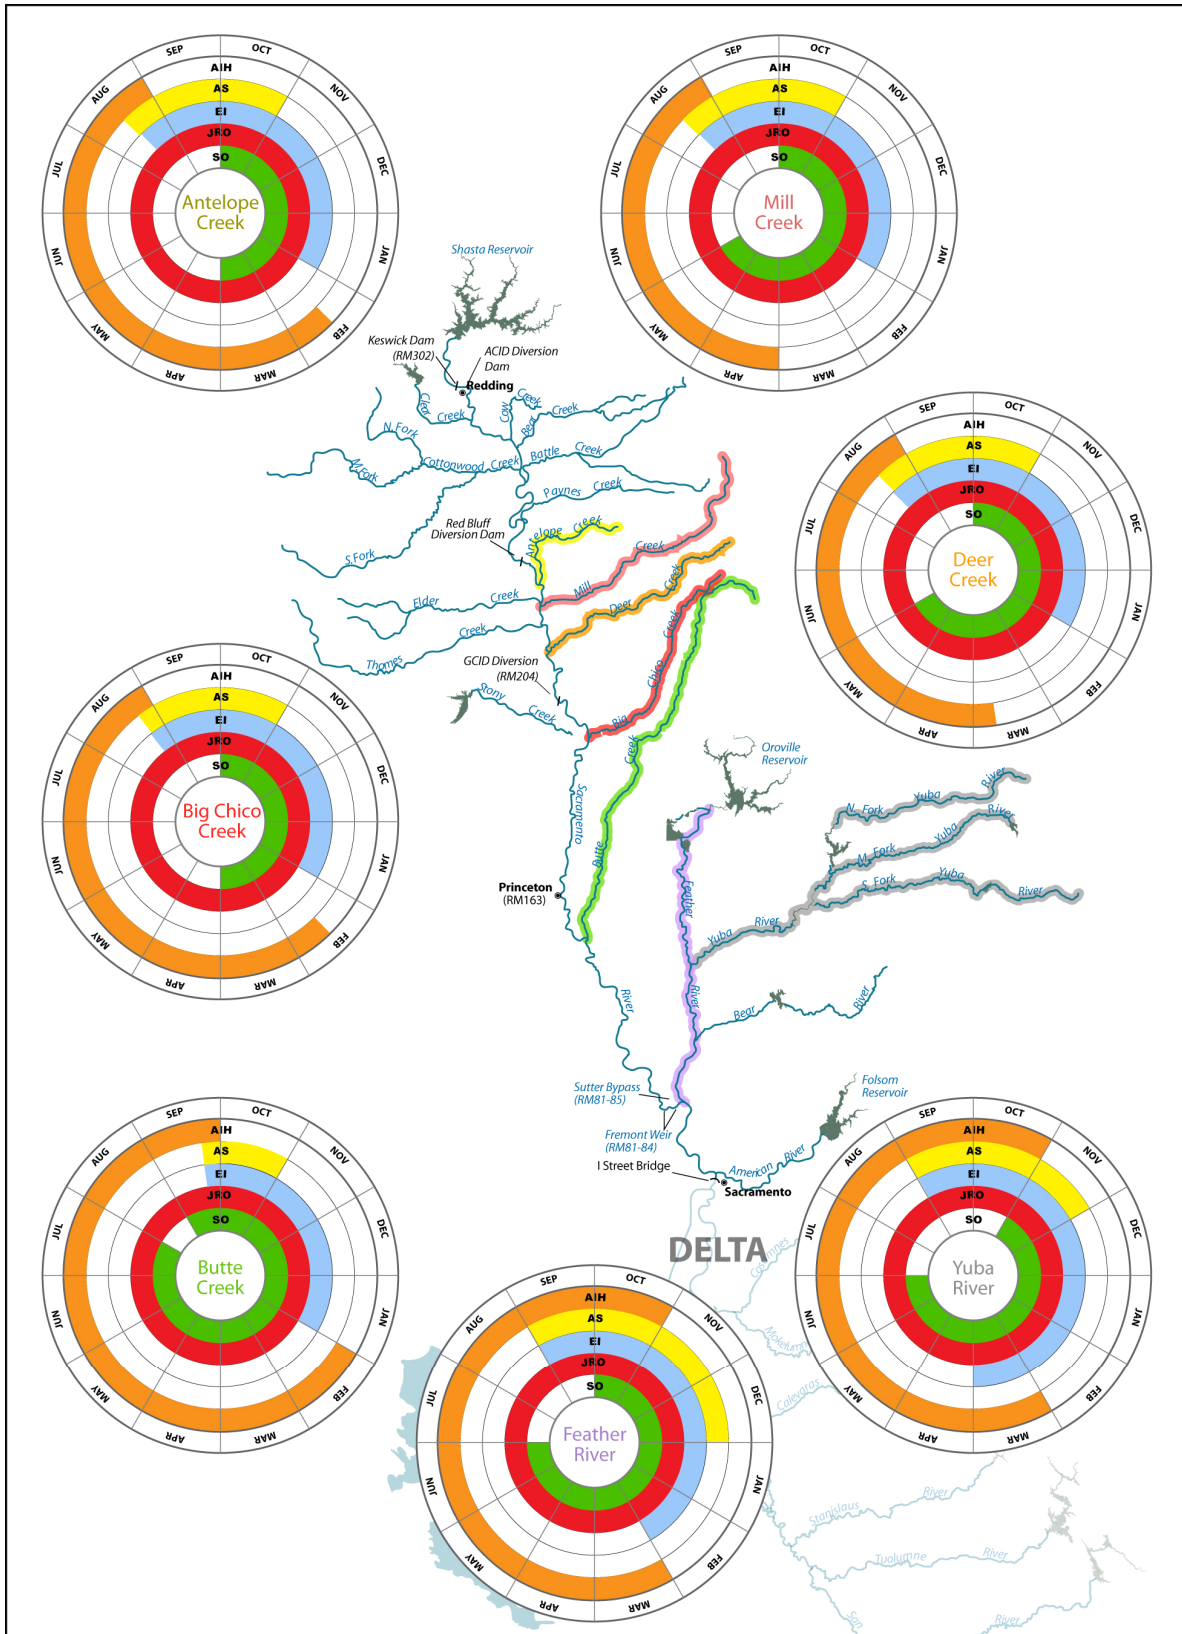

Figure 3-3. Life Stage Timing for Spring-run Chinook Salmon Populations in the Northern Sierra Nevada Diversity Group

Figure 3-4. Life Stage Timing for Spring-run Chinook Salmon Populations in the Basalt and Porous Lava Diversity Group

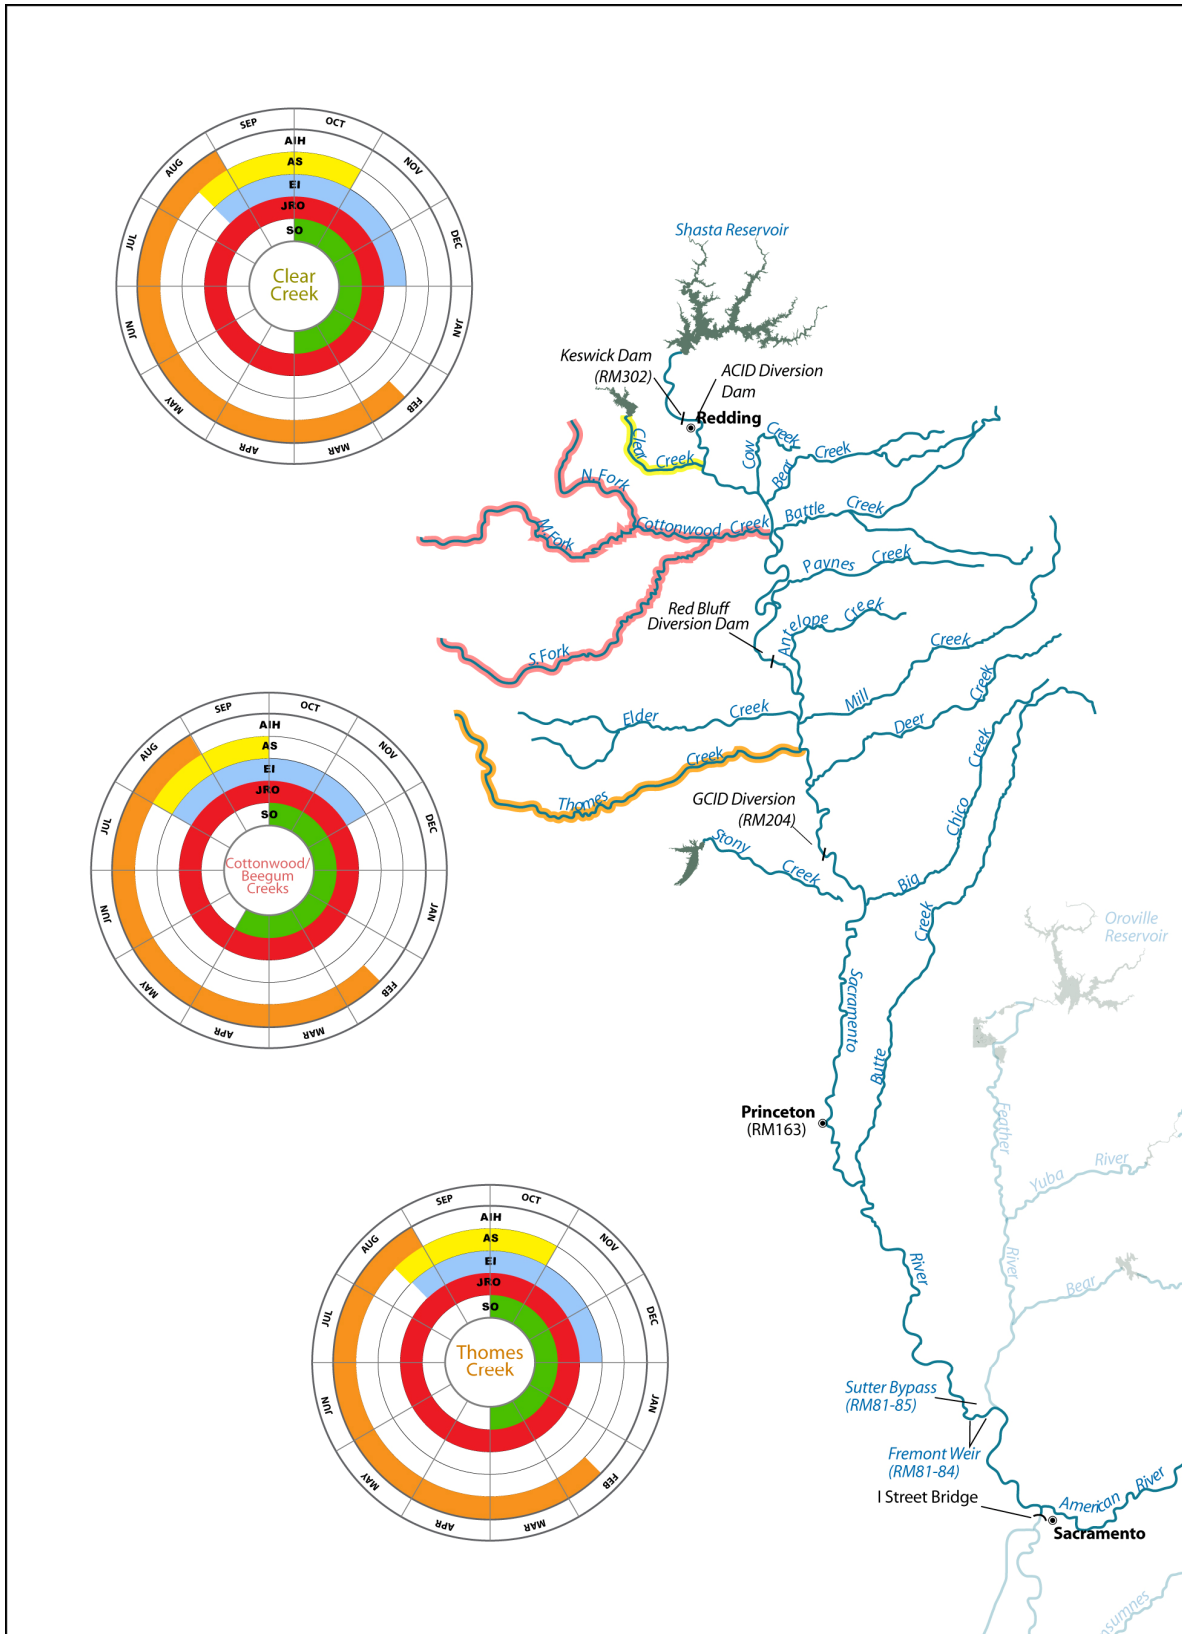

Figure 3-5. Life Stage Timing for Spring-run Chinook Salmon Populations in the Northwestern California Diversity Group

3.2.3 EMBRYO INCUBATION

3.2.3.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

In the Sacramento River, putative spring-run Chinook salmon spawning occurs from August through October. Embryo incubation is defined as the time span from fertilized egg deposition until fry emergence from the gravel. Within the appropriate water temperature range, eggs normally hatch in 40 to 60 days. Newly hatched fish (alevins) normally remain in the gravel for an additional four to six weeks until the yolk sac has been absorbed (NMFS 1997). Therefore; embryo incubation is expected to last from August potentially through January as shown in Figures 3-3, 3-4 and 3-5.

3.2.3.2 BIOLOGICAL REQUIREMENTS

The length of time required for embryo incubation and emergence from the gravel is dependant on water temperature. For maximum embryo survival, water temperatures reportedly must be between 41°F and 55.4°F and oxygen saturation levels must be close to maximum (Moyle 2002). Under those conditions, embryos hatch in 40 to 60 days and remain in the gravel as alevins (the life stage between hatching and egg sack absorption) for another 4 to 6 weeks before emerging as fry (Moyle 2002). Spring-run Chinook salmon fry emerge from the gravel from November to March (Moyle 2002). Habitat requirements to support the biological needs of spring-run Chinook salmon embryo incubation are similar to those for winter-run Chinook salmon described above in Section 2.2.3.2.

3.2.4 JUVENILE REARING AND OUTMIGRATION

3.2.4.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Juvenile rearing and outmigration varies by stream within each diversity group as shown in Figures 3-3, 3-4 and 3-5.

3.2.4.2 BIOLOGICAL REQUIREMENTS

Upon emergence from the gravel, juvenile spring-run Chinook salmon may reside in freshwater for 12 to 16 months, but some migrate to the ocean as young-of-the-year in the winter or spring months within eight months of hatching (CALFED 2000e). The average size of fry migrants (approximately 40 mm between December and April in Mill, Butte and Deer creeks) reflects a prolonged emergence of fry from the gravel (Lindley *et al.* 2004). Studies in Butte Creek (Ward *et al.* 2003a) found the majority of spring-run migrants to be fry moving downstream primarily during December, January and February; and that these movements appeared to be influenced by flow. Small numbers of spring-run juveniles remained in Butte Creek to rear and migrate as yearlings later in the spring. Juvenile emigration patterns in Mill and Deer creeks are very similar to patterns observed in Butte Creek, with the exception that Mill and Deer creek juveniles typically exhibit a later young-of-the-year migration and an earlier yearling migration (Lindley *et al.* 2004). In contrast, data collected on the Feather River suggests that the bulk of juvenile emigration occurs during November and December (DWR and Reclamation 1999; Painter *et al.* 1977). Seesholtz *et al.* (2003) speculate that because juvenile rearing habitat in the Low Flow Channel of the Feather River is limited, juveniles may be forced to emigrate from the area early due to competition for resources. Other habitat requirements to support the biological needs of

spring-run Chinook salmon juvenile rearing and outmigration are similar to those for winter-run described above in Section 2.2.4.2.

3.2.5 SMOLT OUTMIGRATION

3.2.5.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Generally smolt outmigration occurs from late fall through early spring. However, the timing of smolt outmigration may differ by stream of origin within each diversity group as shown in figures 3-3, 3-4 and 3-5.

3.2.5.2 BIOLOGICAL REQUIREMENTS

Little is known about estuarine residence time of spring-run Chinook salmon. MacFarlane and Norton (2002) concluded that unlike populations in the Pacific Northwest, Central Valley Chinook salmon show little estuarine dependence and may benefit from expedited ocean entry. Spring-run Chinook salmon yearlings are larger in size than the other runs of Chinook salmon and are ready to smolt upon entering the Delta; therefore, they probably spend little time rearing in the Delta.

3.2.6 SUB-ADULT AND ADULT OCEAN RESIDENCE

3.2.6.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Central Valley spring-run Chinook salmon generally spend from one to four years in the ocean before returning to spawn in their natal streams. Fisher (1994) reports that 87 percent of returning spring-run Chinook salmon are three year olds as determined by catches at the Red Bluff Diversion Dam. Adults normally leave the ocean and enter the Sacramento River between mid February and July as immature fish and hold in cool water pools until sexually mature.

3.2.6.2 BIOLOGICAL REQUIREMENTS

Habitat requirements to support the biological needs of spring-run Chinook salmon sub-adult and ocean residence are similar to those for winter-run described above in Section 2.2.5.2.

3.3 THREATS AND STRESSORS

3.3.1 SUMMARY OF ESA LISTING FACTORS

Threats to Central Valley spring-run Chinook salmon generally fall into three broad categories: loss of most historical spawning habitat, degradation of remaining habitat, and genetic threats from the Feather River Hatchery spring-run Chinook salmon program.

Native spring-run Chinook salmon have been extirpated from all tributaries in the San Joaquin River Basin, which represents a large portion of the historic range and abundance of the ESU. Yoshiyama *et al.* (2001) estimated that 72 percent of salmon spawning and rearing habitat has been lost in the Central Valley. This figure is for fall- as well as spring-run Chinook salmon; hence NMFS (2005) reported that the amount of spring-run Chinook salmon habitat lost is presumably higher because spring-run Chinook salmon spawn and rear in higher elevations, areas more likely to be behind impassable dams. Naturally-spawning populations of Central

Valley spring-run Chinook salmon currently are restricted to accessible reaches of the upper Sacramento River, Antelope Creek, Battle Creek, Beegum Creek, Big Chico Creek, Butte Creek, Clear Creek, Deer Creek, Feather River, Mill Creek, and Yuba River (CDFG 1998). These populations are likely relatively small. The Feather River population is supplemented by the Feather River Hatchery production, and may be hybridized with fall-run Chinook salmon. Little is known about the status of the spring-run Chinook salmon population on the Yuba River, other than that it appears to be small. The upper Sacramento River supports a small spring-run Chinook salmon population, but population status is poorly documented, and the degree of hybridization with fall-run Chinook salmon is unknown (CDFG 1998).

Habitat problems are one of the most important sources of ongoing risk to the Central Valley spring-run Chinook salmon (NMFS 1998). Like most spring-run Chinook salmon, Central Valley spring-run Chinook salmon require cool freshwater while they mature over the summer. In the Central Valley, summer water temperatures are reportedly suitable for Chinook salmon only above 150 to 500-meter elevations, and most such habitat is now upstream of impassable dams (NMFS 2005). Current spawning is restricted to the mainstem and a few river tributaries in the Sacramento River, where the habitat is severely degraded (NMFS 1998).

General degradation of rearing and migrating habitat includes elevated water temperatures, agricultural and municipal diversions and returns, restricted and regulated flows, entrainment of migrating fish into unscreened or poorly screened diversions, predation by nonnative species, and the poor quality and quantity of remaining habitat (NMFS 1998). Hydropower dams and water diversions in some years have greatly reduced or eliminated instream flows during spring-migration periods (NMFS 1998).

In addition, hatchery programs in the Central Valley may pose threats to spring-run Chinook salmon stock genetic integrity (NMFS 1998). Most of the Central Valley spring-run Chinook salmon production is of hatchery-origin, and naturally spawning populations may be interbreeding with both fall/late fall- and spring-run Chinook salmon hatchery fish. This problem has been exacerbated by the continued production of spring-run Chinook salmon from the Feather River Hatchery, especially in light of reports suggesting a high degree of introgression between spring- and fall/late fall-run broodstock in the hatcheries. In the 1940s, trapping of adult Chinook salmon that originated from areas above Keswick and Shasta dams may have resulted in stock mixing, and further mixing with fall-run Chinook salmon apparently occurred with fish transferred to the CNFH. Deer Creek, one of the locations generally believed most likely to retain essentially native spring-run Chinook salmon, was a target of adult outplants from the 1940s trapping operation, but the success of those transplants is uncertain (NMFS 2005).

Hatchery strays are considered to be an increasing problem due to the management practice of releasing a larger proportion of fish off-site (NMFS 1998). Any activity involving the release of hatchery fish away from their natal stream source will result in the straying of some component of the release, with a direct correlation between distance from stream source and rate of straying (CDFG *et al.* 2001). Since 1967, artificial production has focused on the program at the Feather River Hatchery. The Feather River Hatchery began trucking and releasing half its spring-run Chinook salmon production into San Pablo Bay, causing high rates of straying (CDFG 2001a).

Cramer and Demko (1996) assumed that half of the hatchery-reared spring-run Chinook salmon returning to the Feather River did not return to the hatchery. This assumption was made based on previous data reported in Meyer (1982) as cited in Cramer and Demko (1996), which showed that for one cohort, only about 40 percent of the run entered the hatchery. The number of FRFH spring-run which stray into other Central Valley streams is largely unknown due to the current lack of adequate monitoring. Given the large number of juveniles released off station, the potential contribution of straying adults to rivers throughout the Central Valley is considerable (NMFS 2005).

Protective efforts aimed at the Central Valley spring-run Chinook salmon include: (1) the CVPIA; (2) CALFED Bay-Delta ERP; (3), CDFG's Salmonid Restoration Program for coastal watersheds; (4) NMFS and state-funded multi-county conservation planning efforts in California; (5) the ongoing ESA Section 7 and habitat conservation planning efforts within the range of currently listed species; (6) the state listing of Sacramento River (Central Valley) spring-run Chinook salmon as a threatened species under the CESA; (7) the joint effort of NMFS, DWR and CDFG to address hatchery concerns; incorporating conservation elements into the FRFH spring-run hatchery program; (8) state-implemented freshwater harvest management conservation measures; and (9) increased monitoring and evaluation efforts in support of conservation of this ESU. Specifically, in the Sacramento River Basin, significant efforts are underway to restore habitat in the Battle Creek drainage in the upper Sacramento River. NMFS, USFWS, and CDFG reached agreement with the Pacific Gas and Electric Company (PG&E) to restore access to nearly 42 miles of high quality spawning and rearing habitat. Significant habitat restoration efforts also were conducted in Butte, Deer, Mill and Clear Creeks to remove barriers, improve streamflows, and improve riparian habitat conditions. Major new fish screen projects also were initiated or completed. Additional habitat restoration efforts were funded in the Delta region, which should benefit anadromous salmonids in the Central Valley, San Joaquin River, and the Delta.

Unfortunately, existing protective efforts have proved inadequate to ensure that the Central Valley spring-run Chinook salmon ESU is no longer at risk of becoming endangered. Risks persist to the spatial structure and diversity of the ESU. Only three extant independent populations exist, and they are especially vulnerable to disease or catastrophic events because they are in close proximity. In addition, until there are means to spatially separate the spring-run and fall-run populations in the lower basin of the Feather River, some level of genetic introgression of the races is expected to continue.

3.3.1.1 DESTRUCTION, MODIFICATION, OR CURTAILMENT OF HABITAT OR RANGE

Habitat degradation is the most important source of ongoing risk to spring-run Chinook salmon. The distribution of spring-run Chinook salmon is limited by access to historical spawning habitat above impassable dams and degraded habitat in the Sacramento. Current spawning habitat is restricted to the mainstem and a few tributaries to the Sacramento River. The remaining accessible habitat for spawning or juvenile rearing is severely degraded by elevated water temperatures, agricultural and municipal diversions and returns, restricted and regulated flows, and entrainment of migrating fish into unscreened or poorly screened diversions. Dams and

water diversions for agriculture, flood control, domestic and hydropower purposes have greatly reduced or eliminated historically accessible habitat, and degraded remaining habitat.

3.3.1.2 OVERUTILIZATION FOR COMMERCIAL, RECREATIONAL, SCIENTIFIC, OR EDUCATIONAL PURPOSES

Overutilization for commercial, recreational, scientific or educational purposes does not appear to have a significant impact on spring-run Chinook salmon populations but warrants continued assessment. Commercial fishing for salmon is managed by the PFMC and is constrained by time and area to meet the Central Valley spring-run Chinook salmon ESA consultation standard, and includes restrictions requiring minimum size limits and use of circle hooks for anglers. Ocean harvest restrictions since 1995 have led to reduced ocean harvest of spring-run Chinook salmon (i.e., Central Valley Chinook salmon ocean harvest index, or CVI, ranged from 0.55 to nearly 0.80 from 1970 to 1995, and was reduced to 0.27 in 2001.

The permits NMFS issues for scientific or educational purposes stipulate specific conditions to minimize take of spring-run Chinook salmon individuals during permitted activities. There are currently five active permits in the Central Valley that may affect spring-run Chinook salmon. These permitted studies provide information about spring-run Chinook salmon that is useful to the management and conservation of the ESU.

3.3.1.3 DISEASE OR PREDATION

Chinook salmon are exposed to bacterial, protozoan, viral, and parasitic organisms in spawning and rearing areas, hatcheries, migratory routes, and the marine environment. Naturally spawned fish tend to be less susceptible to pathogens than hatchery-reared fish, which are more susceptible to disease such as IHNV outbreaks that are common in hatcheries.

Predation is a threat to spring-run Chinook salmon, especially in the Delta where there are high densities of non-native fish (e.g., small and large mouth bass, striped bass, catfish, sculpin) that prey on outmigrating salmon. Currently, studies are proposed to evaluate predation rates of juvenile salmonids in riprapped banks in the mainstem Sacramento River and at the oxbow channel near the GCID fish screen. In the ocean environment, salmon are common prey for harbor seals and sea lions.

3.3.1.4 INADEQUACY OF EXISTING REGULATORY MECHANISMS

FEDERAL EFFORTS

There have been several federal actions to try to reduce threats to the spring-run Chinook salmon ESU. Actions undertaken pursuant to Section 7 BOs have helped to increase the abundance of spring-run Chinook salmon. Actions taken under the BO for the CVP and SWP has led to increased freshwater survival, and the BOs for ocean harvest have led to increased ocean survival and adult escapement. There have also been several habitat restoration efforts implemented under CVPIA and CALFED programs that have led to several projects involving fish passage improvements, fish screens, floodplain management, habitat restoration, watershed planning, and other projects that have led to improved fish habitats and increased abundance of spring-run Chinook salmon. There are several important projects that have been initiated or implemented in the Central Valley, such as restoring salmonid habitat in the Battle Creek drainage, improving fish passage, riparian habitat, and streamflows in Butte, Deer, Mill and

Clear creek tributaries in the upper Sacramento River, and installing major new fish screens at large diversions in the Sacramento River.

However, despite federal actions to reduce threats to the spring-run Chinook salmon ESU, the existing protective efforts are inadequate to ensure the ESU is no longer at risk of becoming endangered. There remain risks to the spatial structure and diversity of the ESU. There are only three extant independent populations, and they are especially vulnerable to disease or catastrophic events because they are in close proximity.

NON-FEDERAL EFFORTS

A wide range of restoration and conservation actions have been implemented or are in the planning states of development to help the spring-run Chinook salmon ESU. Most of these actions are pursuant to implementation of conservation and restoration actions in the CALFED Bay-Delta Program, which is composed of 25 state and federal agencies, and has contributed to increased abundance and productivity of the spring-run Chinook salmon ESU. The state of California listed spring-run Chinook salmon as threatened in 1998 under CESA. The state's NCCP involves long-term planning with several stakeholders. CDFG has established specific in-river fishing regulations to protect spring-run Chinook salmon. CDFG and DWR have started a marking/tagging and recovery program to evaluate the contribution of hatchery and natural production in naturally spawning populations in the Feather River, as well as to review and modify hatchery operating criteria to help ensure natural stock integrity. CDFG's 1994 Fish Screen Policy requires screening of all diversions located with the essential habitat of a CESA-listed species. Several spring-run Chinook salmon tributaries have been identified and assigned a high priority for implementing corrective actions and receive restoration funding. Grassroots organizations, such as the Battle Creek Watershed Conservancy, Butte Creek Conservancy, Sutter Bypass water users, Butte Sink Duck Clubs, Mill Creek Conservancy, and Deer Creek Watershed Conservancy, are engaged in the development and implementation of conservation and recovery measures to improve conditions for spring-run Chinook salmon.

However, despite federal and non-federal efforts and joint partnerships, some of the ongoing protective efforts are very recent and few address salmon conservation at a scale that is adequate to protect and conserve the entire ESU.

3.3.1.5 OTHER NATURAL AND MANMADE FACTORS AFFECTING THE SPECIES' CONTINUED EXISTENCE

In the last two decades, the abundance of spring-run Chinook salmon has shown a positive trend in productivity, but the increase in fish numbers does not address the concern for lack of spatial structure and diversity within the ESU. The hatchery stock of spring-run Chinook salmon in the Feather River contributes to the ESU in terms of abundance. In the past three years, CDFG has been restoring and enhancing the spring-run genotype at the Feather River Hatchery, in an effort to isolate fish arriving at the hatchery early in the season from those arriving late. If efforts to isolate the spring-run phenotype in the Feather River are successful, the risks to the ESU's spatial structure and diversity would be reduced.

Changes in climatic events and global climate, such as El Niño ocean conditions and prolonged drought conditions, may be a significant factor in the decline of salmon as unstable Chinook

salmon populations reach particularly low levels. The ESU is highly vulnerable to drought conditions. With the three independent populations located in such close proximity (Deer, Mill and Butte creeks), any regional catastrophic event may have severe impacts to the remaining independent populations.

Unscreened water diversions entrain outmigrating juvenile salmon and fry. Unscreened water diversions and CVP and SWP pumping plants entrain juvenile salmon, leading to fish mortality. The cumulative effect of entrainment at these diversions and delays in outmigration of smolts caused by reduced flow may affect spring-run Chinook salmon fitness.

3.3.2 NON-LIFE STAGE-SPECIFIC THREATS AND STRESSORS FOR THE ESU

Potential threats to the California Central Valley spring-run Chinook salmon population that are not specific to a particular life stage include the potential negative impacts of the current artificial propagation program utilizing the FRFH; the small wild population size; the genetic integrity of the population due to both hatchery influence and small wild population size; and the potential effects of long-term climate change. Each of these potential threats is discussed in the following sections.

3.3.2.1 FEATHER RIVER HATCHERY ARTIFICIAL PROPAGATION PROGRAM

The FRFH is the only hatchery in the Central Valley that currently produces spring-run Chinook salmon. The FRFH was constructed in 1967 to compensate for anadromous salmonid spawning habitat lost with construction of the Oroville Dam. The FRFH has a goal of releasing 2,000,000 spring-run Chinook salmon smolts annually (DWR 2004a). Adverse effects of artificial propagation programs are described in Section 2.3.2.1 for winter-run Chinook salmon produced at the Livingston Stone National Hatchery and many of these potential adverse effects would also apply to the FRFH's production of spring-run. Other effects unique to the FRFH and spring-run Chinook salmon are described below.

Prior to 2004, FRFH hatchery staff differentiated spring-run Chinook salmon from fall-run Chinook salmon by opening the ladder to the hatchery on September 1. Those fish ascending the ladder from September 1 through September 15 were assumed to be spring-run Chinook salmon while those ascending the ladder after September 15 were assumed to be fall-run (Kastner 2003). This practice led to considerable hybridization between spring- and fall-run Chinook salmon (DWR 2004a). Since 2004, the FRFH fish ladder remains open during the spring months, closing on June 30, and those fish ascending the ladder are marked with an external floy tag and returned to the river. This practice allows FRFH staff to identify those previously marked fish as spring-run when they re-enter the ladder in September (DWR 2004a). Only floy-tagged fish are spawned with floy-tagged fish in the month of September. No other fish are spawned during this time as part of an effort to prevent hybridization with fall-run, and introduce a temporal separation between stocks in the hatchery. During the FRFH spring-run spawning season, all heads from adipose fin-clipped fish will be taken and sent to CDFG's laboratory in Santa Rosa for tag extraction and decoding. The tag information will be used to test the hypothesis that early spring-run spawners will produce progeny that maintain that run fidelity.

The FRFH also releases a significant portion of its spring-run production into San Pablo Bay. This practice increases the chances that these fish will stray into other Central Valley streams

when they return as adults to spawn. This straying has the potential to transfer genetic material from hatchery fish to wild naturally spawning fish and is generally viewed as an adverse hatchery impact. Of particular concern would be the straying of hatchery fish into Deer, Mill or Butte creeks, affecting the genetic integrity of the only significantly distinct spring-run Chinook salmon populations in the Central Valley (DWR 2004a).

3.3.2.2 SMALL POPULATION SIZE COMPOSED OF ONLY THREE EXTANT NATURAL POPULATIONS

Streams that currently support wild, persistent populations of spring-run Chinook salmon in the Central Valley include Mill, Deer and Butte creeks (CDFG 1998). Population index counts for these three creeks for the 1995 to 2007 time period are shown in Figure 3-6.

Figure 3-6 . Adult Spring-run Chinook Salmon Population Index for Mill, Deer and Butte Creeks.

Each of these three populations is small and isolated. Additionally, these populations are genetically distinct from other populations classified as spring-run Chinook salmon in the Central Valley (e.g., Feather River) (DWR 2004a). Banks *et al.* (2000) suggest that the spring-run phenotype in the Central Valley is actually shown by two genetically distinct subpopulations- 1) Butte Creek and 2) Deer and Mill creeks spring-run Chinook salmon. Lindley *et al.* (2007) report that the current distribution of viable populations makes the Central Valley spring-run Chinook salmon ESU vulnerable to catastrophic disturbance. All three extant independent populations are in basins whose headwaters lie within the debris and pyroclastic

flow radii of Lassen Peak, an active volcano that USGS views as highly dangerous. Additionally, a fire with a maximum diameter of 30 km, big enough to burn the headwaters of Mill, Deer and Butte creeks simultaneously, has roughly a 10 percent chance of occurring somewhere in the Central Valley each year.

CDFG (1998) reports that there may be other streams supporting spring-run Chinook salmon including Battle, Antelope, Clear, Cottonwood, and Big Chico creeks, and the mainstem Sacramento, Yuba, and Feather rivers. These populations may be hybridized to some degree with both fall-run due to the lack of spatial separation of spawning habitat and with FRFH spring-run. Other potential problems associated with a small population are similar to those associated with the winter-run Chinook salmon population and are further described in Section 2.3.2.2.

3.3.2.3 GENETIC INTEGRITY

Issues concerning the genetic integrity of spring-run Chinook salmon are similar to those described for winter-run Chinook salmon in Section 2.3.2.3 above. Other issues that may be unique to spring-run Chinook salmon in the Central Valley are described below.

Historically, spring-run Chinook salmon acquired and maintained genetic integrity through spatiotemporal isolation with other Central Valley Chinook salmon runs. Spring-run Chinook salmon were temporally isolated from winter-run, and largely isolated in both time and space from the fall-run. With the construction of dams presenting impassable barriers to upstream tributaries of the Sacramento River much of this historical spatiotemporal integrity has been eliminated.

Several sources suggest that putative spawning by spring-run Chinook salmon in the mainstem Sacramento River may actually be by spring-run/fall-run hybrids or early fall-run. For example, in the NMFS OCAP BO, reports that due to the overlap of ESUs and resultant hybridization since the construction of Shasta Dam, Chinook salmon that spawn in the mainstem Sacramento River during September are more likely to be early fall-run rather than spring-run. In the CVP and SWP OCAP BA (Reclamation 2003), it is reported that the increasing overlap in spring-run and fall-run Chinook salmon spawning periods is evidence that genetic introgression is occurring.

3.3.2.4 LONG-TERM CLIMATE CHANGE

The potential effects of long-term climate change on Central Valley spring-run Chinook salmon would be similar to those described above in Section 2.3.2.4 for winter-run Chinook salmon. However, because spring-run Chinook salmon normally spend a longer time in freshwater as juveniles than other Chinook salmon races, and pre-spawning adults typically hold in the river during the warmest summer months, any negative effects of climate change may be more profound on this race of Chinook salmon.

3.3.3 SAN FRANCISCO, SAN PABLO, AND SUISUN BAYS

3.3.3.1 ADULT IMMIGRATION AND HOLDING

Adult spring-run Chinook salmon immigration and holding in California's Central Valley Basin occurs from mid-February through July, and peaks during April and May (CDFG 1998; DWR and Reclamation 1999; Lindley *et al.* 2004). Threats to spring-run Chinook salmon adult immigration and holding that potentially occur in the Bays are similar to those described above in Section 2.3.3.1 for winter-run Chinook salmon.

3.3.3.2 JUVENILE REARING AND OUTMIGRATION

Threats to spring-run Chinook salmon juvenile rearing and outmigration that potentially occur in San Francisco, San Pablo, and Suisun Bay are similar to those described above in Section 2.3.3.2 for winter-run Chinook salmon.

3.3.4 SACRAMENTO-SAN JOAQUIN DELTA

3.3.4.1 ADULT IMMIGRATION AND HOLDING

Threats to spring-run Chinook salmon adult immigration and holding that potentially occur in the Delta are similar to those described above in Section 2.3.4.1 for winter-run Chinook salmon. Because water temperatures in the Delta are normally too warm for this life stage during June and July, it is likely that most spring-run have passed through the Delta into the mainstem Sacramento River and beyond by this time. Water temperatures in the Delta would not be suitable for holding after the end of May.

3.3.4.2 JUVENILE REARING AND OUTMIGRATION

Factors creating threats to the juvenile rearing and outmigration life stage of spring-run Chinook salmon would be similar to those described above in Section 2.3.4.2 for winter-run Chinook salmon. Water temperatures in the Delta begin rising in April and are likely unsuitable after May. Recent recoveries of CWT Butte Creek spring-run Chinook salmon in Delta salvage and trawl data indicate that these fish are present during March, April, and May.

3.3.5 LOWER SACRAMENTO RIVER (PRINCETON [RM 163] TO THE DELTA)

3.3.5.1 ADULT IMMIGRATION AND HOLDING

Adult spring-run Chinook salmon immigration into the Delta and the lower Sacramento River occurs from mid-February through July, and peaks during April-May (Moyle 2002). See Section 3.2.1 for a more complete description of the biological requirements and description of this life stage. Factors that may adversely affect spring-run Chinook salmon adult immigration and holding in the lower Sacramento River include passage impediments, adverse flow conditions, harvest in the sportfishery, poaching, and potential water quality problems, particularly adverse water temperatures.

PASSAGE IMPEDIMENTS/BARRIERS

In the lower portions of the Sacramento River, flows are diverted into the SDWSC. Adult salmon have been caught close to the locks at the upstream end of the channel and have also been observed to be blocked from migrating upstream by the locks (NMFS 1997).

HARVEST/ANGLING IMPACTS

There is no commercial fishery for salmon in the Sacramento River and the in-river sportfishery only allows the taking of salmon from the beginning of August through December 31. Therefore, based on the run timing of spring-run Chinook salmon there is likely no legal harvest in this section of the river.

The extent of poaching of spring-run Chinook salmon in this reach of the river is unknown. There are no man-made structures that would unnaturally increase densities allowing for easy poaching however, some level of poaching likely occurs due to snagging by anglers or inadvertent misidentification of caught fish.

WATER TEMPERATURE

Suitable water temperatures for adult spring-run Chinook salmon migrating upstream to spawning grounds range from 57°F to 67°F (NMFS 1997). However, spring-run Chinook salmon are immature when upstream migration begins and need to hold in suitable habitat for several months prior to spawning. The maximum suitable water temperature for holding is 59°F to 60°F (NMFS 1997). Because water temperatures in this reach of the lower Sacramento River generally begin exceeding 60°F in April, it is likely that little if any suitable holding habitat exists in this reach and that it is only used by adults as a migration corridor.

NMFS (1997) reports that recent research has indicated that water temperatures in the lower Sacramento River may have risen by as much as 4 to 7°F since the late 1970s. Potentially the cumulative losses of shade along the river may have influenced water temperatures in this reach. The loss of shaded habitat and potential effects are described below in Section 3.3.5.2.

WATER QUALITY

Water quality in the lower Sacramento River is not likely to adversely affect adult immigrating spring-run Chinook salmon.

FLOW CONDITIONS

During high flow or flood events, water is diverted into the Sutter and Yolo bypasses upstream of the City of Sacramento. Adult spring-run Chinook salmon migrating upstream may enter these bypasses, where their migration may be delayed or blocked by control structures, particularly during early spring months. To date, there have not been any measures implemented to protect adult spring-run Chinook salmon from entrainment into the flood control bypasses (NMFS 1997).

3.3.5.2 JUVENILE REARING AND OUTMIGRATION

The timing of juvenile spring-run Chinook salmon emigration from the spawning and rearing grounds varies among the tributaries of origin, and can occur during the period extending from October through April (Vogel and Marine 1991).

WATER TEMPERATURE

Optimal water temperatures for juvenile Chinook salmon range from 53.6°F to 57.2°F (NMFS 1997). A daily average water temperature of 60°F is considered the upper temperature limit for

juvenile Chinook salmon growth and rearing (NMFS 1997). Spring-run Chinook salmon juveniles are most abundant in the lower Sacramento River during winter months when average water temperatures are normally less than 60°F. However, because some spring-run Chinook salmon juveniles may be in this reach of the river at any time during the year it is possible that juveniles are exposed to water temperatures above 60°F. Additionally, outmigrating spring-run Chinook salmon may be exposed to warmwater releases from the Colusa Drain at Knights Landing. Warm water is released from the drain to the river mainly from April through June. Releases from the drain can exceed 2,000 cfs and 80°F.

WATER QUALITY

The major point source threat of pollution in the Sacramento River is the Iron Mountain Mine as described for winter-run Chinook salmon above. However, because the Iron Mountain Mine is so far north of the lower Sacramento River, most heavy metal contaminants from the mine have likely either settled out or have been diluted to acceptable EPA standards by the time water reaches this reach of the river. Within the lower Sacramento River and Bay-Delta there are three large municipal water treatment plants which can be an important point source of pollution: the West Sacramento Wastewater Treatment Plant (WWTP), the Sacramento Regional WWTP, and the Stockton Sewage Treatment Plant. Pre-treatment, primary treatment and secondary treatments in place since the 1950s have all reduced pollutant loading to the system however, heavy metal loadings and toxic organic pollutants remain a major concern (NMFS 1997).

The main non-point sources of pollution in the lower Sacramento River are urban runoff and agricultural drainage. Stormwater runoff from the city of Sacramento has been shown to be acutely toxic to aquatic invertebrates (NMFS 1997). Significant urban runoff also occurs during the dry season and is created from domestic/commercial landscape irrigation, groundwater infiltration, pumped groundwater discharges and construction projects (NMFS 1997). The Colusa Basin Drain is the largest source of agricultural return flow in the Sacramento River. It drains agricultural areas serviced by the Tehama-Colusa and Glenn-Colusa Irrigation districts and discharges to the Sacramento River below Knights Landing. The drain has been identified as a major source of warm water, pesticides, turbidity, suspended sediments, dissolved solids, nutrients and trace metals (NMFS 1997).

Because the lower Sacramento River is used only as a migration corridor for spring-run Chinook salmon immigration, water quality is not likely to adversely affect this life stage.

FLOW CONDITIONS

Flood control structures in the lower Sacramento River are designed to divert water from the river during a major flood event into the Butte Creek Basin and the Sutter and Yolo bypasses. The diversions can be significant. For example, the flood control system can divert as much as four to five times more flow down the bypasses than remains in the river (NMFS 1997). Juvenile spring-run Chinook salmon migrating down the river may enter the diversions during storm events. Studies conducted on the Sutter Bypass show that the highest proportion of flows are diverted from December through March with a peak occurring in February (NMFS 1997). Juveniles diverted into the bypasses may experience migration delays, potential stranding as flood flows recede and increased rates of predation. However, the Sutter and Yolo bypasses also provide important rearing habitat to juvenile salmonids. Therefore, stranding likely occurs only during very high flow events followed by a rapid cessation of flow.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Stream bank stabilization in the lower Sacramento River has primarily involved riprapping. Riprapping the river bank involves removing vegetation along the bank and upper levees which removes most instream and overhead cover in nearshore areas. Overhanging vegetation is referred to as SRA habitat. Woody debris and overhanging vegetation within SRA habitat provide escape cover for juvenile salmonids from predators. Aquatic and terrestrial insects are an important component of juvenile salmon diet. These insects are dependent on a healthy riparian habitat. SRA habitat also can provide some degree of local temperature modification and refugia during summer months due to the shading it provides to nearshore habitats (USFWS 1980). The importance of SRA habitat to Chinook salmon was demonstrated in studies conducted by the USFWS (DeHaven 1989). In early summer, juvenile Chinook salmon were found exclusively in areas of SRA habitat, and none were found in nearby riprapped areas (DeHaven 1989).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Flood control measures, regulated flow regimes and river bank protection measures have all had a profound effect on riparian and instream habitat in the lower Sacramento River. Levees constructed in this reach are built close to the river in order to increase streamflow, channelize the river to prevent natural meandering, and maximize the sediment carrying capacity of the river (NMFS 1997). Channelization of the river requires bank protection measures such as riprapping to reduce the effects of streambank erosion. Additionally, nearshore aquatic areas are deepened and sloped to a uniform gradient, such that variations in water depth, velocity and direction of flow are replaced by consistent moderate to high velocities.

LOSS OF FLOODPLAIN HABITAT

The process of channelizing the lower Sacramento River and the construction of levees for flood control has resulted in a loss of connectivity with the floodplain which serves as an important source of woody debris and gravels that aid in establishing a diverse riverine habitat. In addition, floodplains in the Central Valley have been shown to provide quality rearing habitat for salmonids (Sommer *et al.* 2001a).

ENTRAINMENT

Entrainment is defined as the redirection of fish from their natural migratory pathway into areas or pathways not normally used. Entrainment also includes the take, or removal, of juvenile fish from their habitat through the operation of water diversion devices and structures such as siphons, pumps and gravity diversions (NMFS 1997). A primary source of entrainment is unscreened or inadequately screened diversions. A survey by CDFG identified 350 unscreened diversions along the Sacramento River downstream of Hamilton City.

Entrainment of juvenile winter-run Chinook salmon has been identified as one of the most significant causes of mortality in the Sacramento River and Delta (NMFS 1997) and is likely also true for spring-run. In addition, a program to flood rice field stubble during the winter has been implemented extending the period for potential entrainment (NMFS 1997).

Outmigrating juvenile spring-run Chinook salmon may also be diverted into the Yolo or Sutter bypasses during high flow or flood events and stranded as flood waters recede. The entrance to the Yolo Bypass is the Fremont Weir upstream of Sacramento near the confluence with the Feather River. During high flows weir gates are open and because the weir is not screened, juveniles enter the Yolo Bypass, where they may rear and eventually leave through the lower end

upstream of Chipps Island in the Delta, or be trapped in isolated ponds as waters recede. Additionally, Sacramento River water is diverted into the SDWSC, and outmigrating juvenile Chinook salmon may enter the channel where water quality, flow levels and rearing conditions are extremely poor (NMFS 1997).

PREDATION

Only limited information on predation of spring-run Chinook salmon juveniles is available. Native species that are known to prey on juvenile salmon include Sacramento Pikeminnow and steelhead. Predation by pikeminnow can be significant when juvenile salmon occur in high densities such as below dams or near diversions. Although Sacramento pikeminnow are a native species and predation on juvenile spring-run Chinook salmon is a natural phenomenon, loss of SRA habitat and artificial instream structures tend to favor predators and may change the natural predator-prey dynamics in the system favoring predatory species (CALFED 2000c). Hatchery reared steelhead may also prey on juvenile salmon. Non-native striped bass may also be a significant predator on juvenile salmon. Although no recent studies of striped bass predation on juvenile salmon have been completed, Thomas (1967 *in* NMFS 1997) found that in the lower Sacramento River, salmon accounted for 22 percent of striped bass diet.

HATCHERY EFFECTS

In the lower Sacramento River, hatchery steelhead from the FRFH are planted in the Feather River below Yuba City at a large enough size and at a time when they could intercept outmigrating spring-run Chinook salmon juveniles (NMFS 1997).

3.3.6 MIDDLE SACRAMENTO RIVER (RED BLUFF DIVERSION DAM [RM 243] TO PRINCETON [RM 163])

3.3.6.1 ADULT IMMIGRATION AND HOLDING

In this reach of the river, the potential threats to the adult immigration and holding life stage of spring-run Chinook salmon arise from a potential passage impediment at the GCID HCPP, potential water quality problems, particularly adverse water temperatures, harvest in the sportfishery and poaching.

PASSAGE IMPEDIMENTS/BARRIERS

Although the GCID HCPP (~RM 205) and associated water diversions present problems for emigrating juvenile salmonids, adults are likely not affected.

HARVEST/ANGLING IMPACTS

Current sportfishing regulations in the Sacramento River allow for the taking of salmon after August 1. It is possible that some spring-run Chinook salmon could be holding in the mainstem river below the RBDD prior to spawning in mid-August to October. The magnitude of the harvest of spring-run Chinook salmon is not known.

The extent of poaching of spring-run Chinook salmon in this reach of the river is unknown. Some level of poaching likely occurs due to snagging by anglers or inadvertent misidentification

of caught fish. Additionally, when passage at the RBDD is hindered there may be unusually high densities of salmon downstream of the dam that present poaching opportunities.

WATER TEMPERATURE

Water Temperatures in this reach of the river are similar to those occurring in the lower Sacramento River. However, some holding of adult spring-run Chinook salmon may occur downstream of the RBDD in deep coldwater pools. With the installation of the TCD at Shasta Dam in 1997, water temperatures have cooled slightly and suitable water temperatures for adult holding likely extend downstream of the RBDD for a short distance.

WATER QUALITY

Water quality in the middle Sacramento River is not likely to adversely affect adult immigrating spring-run Chinook salmon.

3.3.6.2 JUVENILE REARING AND OUTMIGRATION

Factors that may adversely affect juvenile spring-run Chinook salmon in the middle Sacramento River are similar to those that occur in the lower river as described above. However, in addition to those factors there is a potential downstream passage impediment at the GCID HCPP at RM 205.

PASSAGE IMPEDIMENTS

Historically, the GCID HCPP at RM 205 created downstream migration problems for spring-run juvenile Chinook salmon. The GCID pumping plant may divert up to 20 percent of the Sacramento River flow. Rotary drum fish screens were installed in 1972 to help protect juvenile salmon but they were largely ineffective and never met NMFS or CDFG screen design criteria. Flat plate screens were installed in front of the rotary screens in 1993 to help alleviate the problem until a more permanent solution could be found. Juvenile spring-run Chinook salmon are exposed to the GCID pumping plant facilities as early as mid-July extending into late-November when the diversion season ends.

The interim flat-plate screens were an improvement over the rotary drum screens but were still likely to subject juvenile salmon to impingement due to high approach velocities along the screens, inadequate sweeping to approach velocities, and long exposure time at the screen (USFWS 1995 *in* NMFS 1997). Construction of a new screening facility was completed in 2001 and the testing and monitoring program for the facility are now underway (Reclamation 2007). The testing and monitoring of the new facility is scheduled to be completed in 2007 (Reclamation 2007).

WATER TEMPERATURE

Water temperatures normally exceed 60°F from July through September and in dry years can often exceed 66°F (NMFS 1997). Therefore, the middle Sacramento River likely provides little habitat suitable for juvenile Chinook salmon rearing.

WATER QUALITY

Water quality issues in the middle Sacramento River are similar to those described above in the lower Sacramento River. The only point source pollution that has been identified and may potentially affect this reach of the river is the Iron Mountain Mine described for winter-run

Chinook salmon above. Non-point source pollution sources include both urban and agricultural runoff similar to that described above for the lower Sacramento River. Urban runoff is likely not as great in this reach of the river as that occurring in the lower Sacramento River but agricultural runoff is likely similar or greater.

FLOW CONDITIONS

Flow conditions, under current regulated flow regimes, in the middle Sacramento River likely have little effect on outmigrating juvenile spring-run Chinook salmon.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Loss of riparian habitat that has occurred in the middle Sacramento River is similar to that described above for the lower Sacramento River.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Physical habitat alteration that has occurred in the middle Sacramento River is similar to that described above for the lower Sacramento River. The river is not quite as confined in this reach as levees are constructed further from the channel than those occurring in the lower river.

LOSS OF FLOODPLAIN HABITAT

Although the river is not quite as confined in this reach as levees are constructed further from the channel than those occurring in the lower river, the river is disconnected from its historic floodplain by flood control measures including regulated flows and levees.

ENTRAINMENT

Entrainment is defined for winter-run Chinook salmon above. The exact number of unscreened diversions in this reach of the river is not known. A study by the California Advisory Committee on Salmon and Steelhead Trout completed in 1987 reported that over 300 unscreened irrigation, industrial, and municipal water supply diversions occur on the Sacramento River between Redding and Sacramento (NMFS 1997). Although most of these diversions are small, cumulatively they likely entrain a large number of outmigrating juvenile salmonids.

Studies are currently underway to determine the effectiveness of new fish screens at the GCID HCPP to determine the effectiveness of new fish screen installed in 2001 (Reclamation 2007). However, juvenile emigration data suggest that peak spring-run movement past the GCID facility occurs in fall and winter months, when pumping volume is low or has ceased for the season (CUWA and SWC 2004).

PREDATION

Predation on juvenile spring-run Chinook salmon in the middle Sacramento River is likely occurring from native Sacramento pikeminnow, native and hatchery-reared steelhead and striped bass. Although the extent of predation is unknown, predation from Sacramento pikeminnow and striped bass is likely similar to that occurring in the lower Sacramento River as described above. Predation from hatchery steelhead is likely somewhat less than that occurring in the lower Sacramento River because the Feather River hatchery fish enter the Sacramento River

downstream of this reach. Additionally, steelhead released from the CNFH are likely more evenly distributed throughout the river by the time they reach this section.

Opportunities for high predation rates also may be present at the GCID HCPP. The plant is described below as a passage impediment. Studies have indicated that Sacramento pikeminnow are the primary predator at the pumping plant, although striped bass were also found with Chinook salmon in their stomachs (CALFED 2000c). Vogel and Marine (1995) report that predation is likely in the vicinity of the fish screens associated with the diversion.

HATCHERY EFFECTS

Direct adverse effects of hatchery operations are likely minimal in the middle reach of the Sacramento River primarily because steelhead released from the Feather River Hatchery enter the river downstream and steelhead released by the CNFH are likely more evenly distributed throughout the system by the time they reach the middle reach.

3.3.7 UPPER SACRAMENTO RIVER (KESWICK DAM TO RED BLUFF DIVERSION DAM)

3.3.7.1 ADULT IMMIGRATION AND HOLDING

In this reach of the river, the potential threats to the adult immigration and holding life stage of spring-run Chinook salmon arise from potential passage impediments at the RBDD, harvest in the sportfishery and poaching. Keswick Dam, at the upstream terminus of this reach of the river, presents an impassable barrier to upstream migration.

PASSAGE IMPEDIMENTS/BARRIERS

Keswick Dam (~RM 302) presents an impassable barrier to all upstream migration of spring-run Chinook salmon and represents the upstream extent of anadromous salmonid habitat in the mainstem Sacramento River. The ACID Dam (RM 298.5) was constructed in 1917 about three river miles downstream of the current Keswick Dam site. Originally the dam was a barrier to upstream fish migration until 1927, when a poorly designed fish ladder was installed (NMFS 1997). The dam is a 450-foot long flashboard structure which has the capability of raising the backwater level 10 feet. The dam is only installed during the irrigation season which typically runs from early April to October or early November. As mentioned above, the fish ladder that provides passage around the dam was poorly designed and although spring-run Chinook salmon were able to negotiate the ladder, it did present a partial impediment to upstream migration. In 2001 a new fish ladder was installed. Post-project monitoring indicates that the new fish ladder is operating effectively (Killam 2006). Another potential problem associated with the facility is that high volume releases from the ACID's canal downstream of the dam may create false attraction flows for migrating adult salmon and encourage them to enter the canal where they could be stranded (NMFS 1997).

The reach from the ACID to Keswick Dam is three miles; representing only a small portion of the potential spawning area. Winter-run carcass surveys from 2001 through 2006 (post ladder improvements) indicate that an average of 42.13% of the winter-run spawn above the ACID Dam (Killam 2006) and the same is likely true for spring-run.

The RBDD at RM 243 is a concrete structure 52 feet high and 740 feet long. The dam has 11 gates which are raised or lowered to control the level of Lake Red Bluff enabling gravity diversion into the TCC. Permanent fish ladders are located on each abutment of the dam. The fish ladders are inefficient in allowing upstream migration of adult salmonids (NMFS 1997). In several radio tagging studies of adult winter-run Chinook salmon, 43-44 percent of tagged fish were blocked by the dam (Vogel *et al.* 1988, Hallock *et al.* 1982 in NMFS 1997). Tagged winter-run Chinook salmon that eventually passed the dam were delayed by an average of 125 hours in one study (Vogel *et al.* 1988 in NMFS 1997) and 437 hours in a previous study (Hallock *et al.* 1982 in NMFS 1997). At present, the dam gates are kept in the raised position from September 15 through May 14. Spring-run Chinook salmon arriving at the RBDD before September 15 or after May 14 may experience delays in passing the dam.

HARVEST/ANGLING IMPACTS

Harvest of spring-run Chinook salmon in this reach of the river is likely similar to that in the middle reach. High densities of salmon near Keswick Dam could create poaching opportunities.

WATER TEMPERATURE

Following the installation of the TCD at Shasta Dam in 1997, water temperatures in this reach of the river seldom exceed 60°F and are suitable for spring-run Chinook salmon adult immigration and holding.

WATER QUALITY

Water quality in this reach of the Sacramento River is not at a level to cause adverse effects on immigrating adult salmonids.

FLOW CONDITIONS

Large flow fluctuations are the main concern regarding adverse flow conditions in the middle and upper Sacramento River. Historically, the largest and most frequent flow reductions have occurred in the late summer and early fall when flashboards at the ACID required adjustment. In years of full water deliveries by the CVP, flows had been reduced from levels of 10,000 to 14,000 cfs to a level of 5,000 cfs (NMFS 1997). Currently, under the CVP/SWP BO, flow reduction rates are divided into several intervals to prevent rapid reductions potentially stranding adults. Although these flow reductions may adversely affect other life stages, adult immigration is likely not affected.

3.3.7.2 SPAWNING

The amount of spawning of spring-run Chinook salmon in the mainstem Sacramento River is not certain. CDFG (2004b) reports that they cannot make reliable carcass survey estimates of returning adult spring-run Chinook salmon in the mainstem Sacramento River because of the overlap in spawn timing with fall-run Chinook salmon. In 2002, an estimated 608 salmon displaying spring-run characteristics passed RBDD. Of these, 125 were estimated to have entered Beegum Creek, a tributary to Cottonwood Creek. The remaining fish (485) may have spawned in the mainstem Sacramento River or entered other upstream tributaries such as Clear Creek or Battle Creek. Aerial redd surveys showed no redds downstream from RBDD. In 2003, an estimated 145 salmon displaying spring-run characteristics passed RBDD. However, because

a greater number than this were estimated to enter Beegum Creek, Clear Creek and Battle Creek, no spring-run Chinook salmon were estimated to have spawned in the mainstem Sacramento River in 2003.

Similarly, Reclamation (2003) reports that redd counts conducted in the Sacramento River during the typical spring-run spawning period (late August and September) have shown low numbers of new redds relative to new redds counted during winter-run spawning timing and fall-run spawning timing. Peaks in redd count numbers are evident during winter-run spawning and fall-run spawning but not during spring-run spawning. During redd surveys the number of new redds has diminished through July and then increased at the end of September before large increase that typically occurs after October 1 when they become classified as fall-run. This suggests that the number of spring-run Chinook salmon spawning in the Sacramento River is low (average of 26 redds counted) relative to the average spring-run escapement estimate of 908 between 1990 and 2001 in the mainstem Sacramento River. The additional fish have not been accounted for in tributaries upstream of the RBDD.

Any spawning of spring-run Chinook salmon that may occur in this reach of the river may be adversely affected by poor water quality (water temperature), adverse flow conditions, physical habitat alteration, hybridization with hatchery stock, and recreational sportfishing and poaching. Each of these potential effects is described below.

PASSAGE IMPEDIMENTS/BARRIERS

Keswick Dam marks the upstream extent of currently accessible anadromous salmonid habitat in the Sacramento River. If any spawning of spring-run Chinook salmon occurs in the upper Sacramento River it would likely be upstream of the RBDD

HARVEST/ANGLING IMPACTS

Sportfishing regulations in the Sacramento River allow for the taking of salmon after August 1 to the end of December. During August, late spawning winter-run and Chinook salmon exhibiting spring-run behavior are present in this reach of the river. Therefore, some take is likely. Beginning in August, early spawning fall-run Chinook salmon begin to arrive and they likely make up the majority of the harvest through the end of the year.

The affect of poaching on spring-run Chinook salmon in this reach of the river is not known but deliberate poaching activity is not likely heavy until later in the year when fall-run have arrived. However, this section of the river is a popular year-round sportfishery and some spring-run may be misidentified by anglers and taken prior to August 1.

WATER TEMPERATURE

Generally, successful spawning for Chinook salmon occurs at water temperatures below 60°F (NMFS 1997). Since 1993 managing water temperatures for winter-run Chinook salmon from May through August have exhausted the cold water pool by September. Therefore, water temperatures routinely exceed the 60°F criteria for spawning required for spring-run Chinook salmon in September and October.

WATER QUALITY

Water quality in this reach of the Sacramento River is generally not at a level to cause direct adverse effects on spawning adult salmonids.

FLOW CONDITIONS

Large flow fluctuations are the main concern regarding adverse flow conditions in the middle and upper Sacramento River. Historically, the largest and most frequent flow reductions have occurred in the late summer and early fall when flashboards at the ACID Dam required adjustment. In years of full water deliveries by the CVP, flows had been reduced from levels of 10,000 to 14,000 cfs to a level of 5,000 cfs (NMFS 1997). Currently, under the CVP/SWP BO, flow reductions are conducted in intervals to prevent the stranding of juveniles and spawning adults likely are not affected by changes in flow. However, eggs in redds and developing embryos may be affected as described below under embryo incubation.

SPAWNING HABITAT AVAILABILITY

Spring-run Chinook salmon are the earliest spawning of anadromous salmonids in the Sacramento River Basin, therefore the few spring-run that may spawn in the mainstem Sacramento River would have first access to available habitat. However, later spawning fall-run Chinook salmon are quite numerous in the upper Sacramento River and may superimpose their redds on existing spring-run redds thus eliminating any advantage to spring-run early spawning.

PHYSICAL HABITAT ALTERATION

Chinook salmon require clean loose gravel from 0.75 to 4.0 inches in diameter for successful spawning (NMFS 1997). The construction of dams in the upper Sacramento River has eliminated the major source of suitable gravel recruitment to reaches of the river below Keswick Dam. Gravel sources from the banks of the river and floodplain have also been substantially reduced by levee and bank protection measures. Levee and bank protection measures restrict the meandering of the river which would normally release gravel into the river through natural erosion and deposition processes. However, because very little spawning occurs in this portion of the river, it is not likely that a lack of suitable spawning gravel in this reach of the river has a significant negative effect on spring-run Chinook salmon spawning.

HATCHERY EFFECTS

The FRFH is the only hatchery in the Central Valley producing spring-run Chinook salmon. Prior to 2004, FRFH hatchery staff differentiated spring-run from fall-run by applying a cut-off date to fish entering the hatchery. Those fish ascending the ladder from September 1 through September 15 were assumed to be spring-run Chinook salmon while those ascending the ladder after September 15 were assumed to be fall-run (Kastner 2003). This practice led to considerable hybridization between spring- and fall-run Chinook salmon (DWR 2004a). Since 2004, the fish ladder remains open during the spring months, closing on June 30, and those fish ascending the ladder are marked with an external tag and returned to the river. This practice allows FRFH staff to identify those previously marked fish as spring-run when they re-enter the ladder in September, reducing potential hybridization with the fall-run (DWR 2004a). There are no observable genetic differences between the FRFH spring and fall runs, however the spring run enters the river in April, May and June as bright (green) fish.

In order to reduce mortality associated with downstream migration subsequent to hatchery releases, fish are often trucked to and released in San Pablo Bay. These practices likely increase

straying rates increasing the potential for Feather River Hatchery produced spring-run Chinook salmon to hybridize with naturally spawning Chinook salmon throughout the Central Valley (Williams 2006).

3.3.7.3 EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The Sacramento River supports a popular year-round recreational fishery. It is possible that anglers could disturb developing embryos in redds while wading.

WATER TEMPERATURE

The embryo incubation life stage of Chinook salmon is the most sensitive to elevated water temperatures. Preferred water temperatures for Chinook salmon egg incubation and embryo development range from 46°F to 56°F (NMFS 1997). A significant reduction in egg viability occurs at water temperatures above 57.5°F and total mortality may occur at 62°F (NMFS 1997).

WATER QUALITY

Water quality issues that may produce adverse effects on spring-run Chinook salmon include both point source and non-point source pollution. The inactive Iron Mountain Mine in the Spring Creek watershed near Keswick Dam creates the largest discharge of toxic material into the Sacramento River. There are three metals of particular concern: copper, cadmium and zinc. The early life stages of salmon are the most sensitive to these metals (NMFS 1997). The acid mine drainage from Iron Mountain Mine is among the most acidic and metal laden anywhere in the world (NMFS 1997). Historically, discharge from the mine has produced massive fish kills.

In 1983 the Iron Mountain Mine site was declared a superfund site by the EPA. Since that time various mitigation measures have been implemented including a neutralization plant that has improved the ability to control metal loadings to the river. NMFS (1997) reported that although significant improvements have been made, basin plan objectives had not yet been achieved in 1997. Since that time, other mitigation measures have been implemented resulting in a 95 percent reduction in historic copper, cadmium and zinc discharges (EPA 2006). At present, acid mine waste still escapes untreated from waste pile and seepage on the north side of Iron Mountain and flows into Boulder Creek, which eventually flows into the Sacramento River (EPA 2006). However, there were no significant exceedances of dissolved metal concentrations in the Sacramento River in 2002 and 2003 (CDFG 2004c). Another point source of pollution in the upper Sacramento River identified in NMFS (1997) is the Simpson Mill near Redding which discharges PCBs into the river.

Non-point source pollution consists of sediments from storm events, stormwater runoff in urban and developing areas and agricultural runoff. Sediments constitute nearly half of the material introduced to the river from non-point sources (NMFS 1997). Excess silt and other suspended solids are mobilized during storm events from plowed fields, construction and logging sites and mines. High sediment loading can interfere with eggs developing in redds by reducing the ability of oxygenated water to percolate down to eggs in the gravel. Stormwater runoff in urban areas can transport oil, trash, heavy metals and toxic organics all of which are potentially harmful to incubating eggs. Agricultural runoff can contain excess nutrients, pesticides and trace metals.

FLOW CONDITIONS

Flow fluctuations are the primary concern related to potential adverse effects on the embryo incubation life stage of spring-run Chinook salmon. For example, if spawning salmon construct redds during periods of high flow, those redds could become dewatered during subsequent periods of low flow. Historically, the largest and most rapid flow reductions have occurred during the irrigation season (normally, early April through October) when adjustments are required at the ACID Dam. To accommodate these adjustments, Sacramento River flows at times have been decreased by one-half or greater, over the course of a few hours (NMFS 1997). Currently, under the CVP/SWP BO, flow reductions are divided into several intervals to prevent the stranding of juveniles. However, reducing the rates of flow reduction does not protect existing redds from becoming dewatered.

3.3.7.4 JUVENILE REARING AND OUTMIGRATION

PASSAGE IMPEDIMENTS

Keswick Dam at RM 302 presents an impassable barrier to upstream migrating adult Chinook salmon hence it represents the upstream extent of spring-run Chinook salmon habitat on the mainstem Sacramento River. The ACID Dam, located about three miles below Keswick Dam, represents the furthest upstream impediment, by potentially causing injury, to juvenile outmigration. The dam is only in place during the irrigation season which typically extends from April through November. During the rest of the year neither upstream adult migration nor downstream juvenile outmigration is hindered. Juveniles outmigrate past the dam by either dropping as much as ten feet over the dam to the river below or moving through the bypass facility.

The RBDD, at the downstream extent of the upper Sacramento River, creates the final passage impediment to downstream outmigration in this reach of the river. When the dam gates are lowered (currently mid-May through mid-September), Lake Red Bluff is formed slowing flows and delaying juvenile outmigration allowing more opportunities for predation. Historically there was both direct and indirect mortality associated with fish using an ineffective juvenile fish bypass facility at the dam. A “Downstream Migrant Fish Facility” was installed as part of the Headworks system in 1990 which appears to have reduced mortality associated with use of the bypass facility.

WATER TEMPERATURE

Following the installation of the TCD at Shasta Dam in 1997 water temperatures in this reach of the river seldom exceed 60°F and are suitable for juvenile salmon rearing year-round.

WATER QUALITY

Point source pollution may occur from both the Iron Mountain Mine and the Simpson Mill as described above. Because the juvenile life stage of Chinook salmon is the most susceptible to adverse effects from pollution and the proximity of these two potential sources of pollution, potential adverse effects are likely more profound in the upper Sacramento River compared to the lower reaches. Effects of non-point source pollution from urban runoff and agricultural drainage are similar to those described above for the middle Sacramento River. However, pollution associated with urban runoff is likely higher due to the proximity of the cities of Redding and Red Bluff.

FLOW CONDITIONS

There is likely very little rearing of juvenile spring-run Chinook salmon that occurs in the upper Sacramento River. Additionally, any spring-run juvenile Chinook salmon juveniles in this reach are likely only there during winter months when flows are not affected by agricultural diversions.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

In certain sections of the Sacramento River from Keswick Dam to Red Bluff Diversion, less than 20 percent of the river bank is built as a levee or used bank protection measures to protect the City of Redding and Red Bluff as well as nearby agricultural land from flooding. The rest of the river has been channelized due to the geological formation and controlled flow regimes in the upper Sacramento River downstream from Keswick Dam and Red Bluff Diversion resulting in channelization and disconnection of the river from its historic floodplain. This has negative effects on riparian habitat due to the river's inability to naturally recruit riparian species seedlings as well as woody debris to deposit elsewhere. Woody debris and SRA habitat provide important escape cover for juvenile salmon. Aquatic and terrestrial insects, a major component of juvenile salmon diet, are dependent on riparian habitat. Aquatic invertebrates are dependent on the organic material provided by a healthy riparian habitat and many terrestrial invertebrates also depend on this habitat. Studies by the CDFG as reported in NMFS (NMFS 1997) demonstrated that a significant portion of juvenile Chinook salmon diet is composed of terrestrial insects, particularly aphids which are dependent on riparian habitat.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Controlled flow regimes and channelization of the upper Sacramento River have resulted in a loss of natural river morphology and function.

LOSS OF FLOODPLAIN HABITAT

Controlled flow regimes and channelization of the upper Sacramento River have resulted in a disconnection of the river with its historic floodplain.

ENTRAINMENT

Adverse effects due to entrainment of outmigrating juvenile spring-run Chinook salmon at unscreened diversions are similar to those described above for the middle Sacramento River. The new downstream migrant fish facility at the RBDD appears to have alleviated entrainment problems at the RBDD.

PREDATION

Significant predators of juvenile spring-run Chinook salmon in the upper Sacramento River include Sacramento pikeminnow and both hatchery and wild steelhead. Striped bass, a significant predator in lower reaches of the river, typically do not utilize the upper Sacramento River; however, they are present immediately below the RBDD.

The most serious adverse effect due to predation occurs in the vicinity of the RBDD. Passage through Lake Red Bluff can delay outmigrating juvenile spring-run Chinook salmon and increases the opportunities for predation by both fish and birds (Vogel and Smith 1986 as cited in NMFS 1997). Chinook salmon juveniles passing under the gates at the RBDD are heavily preyed upon by both striped bass and Sacramento pikeminnow (NMFS 1997). Large

concentrations of Sacramento pikeminnow have been observed accumulating immediately below the RBDD when juvenile Chinook salmon are present (Garcia 1989 *in* NMFS 1997).

HATCHERY EFFECTS

The extent of predation on juvenile Chinook salmon by hatchery-reared steelhead is not known. However, steelhead releases by the CNFH may have a high potential for inducing high levels of predation on naturally produced Chinook salmon (CALFED 2000c). The CNFH has a current production target of releasing approximately 600,000 steelhead in January and February at sizes of 125 to 275 mm (CALFED 2000c).

3.3.8 NORTHERN SIERRA NEVADA DIVERSITY GROUP

The northern Sierra Nevada spring-run Chinook salmon Diversity Group historically was comprised of populations in the Mokelumne, American, Yuba, and Feather rivers and Butte, Big Chico, Deer, Mill, and Antelope creeks (**Figure 3-7**). Currently, spawning populations of Chinook salmon exhibiting spring-run characteristics occur in each of these rivers/creeks except for the Mokelumne and American rivers.

Figure 3-7. Northern Sierra Nevada Spring-run Chinook Salmon Diversity Group

3.3.8.1 FEATHER RIVER

The Feather River watershed is located at the north end of the Sierra Nevada. The watershed is bounded by the volcanic Cascade Range to the north, the Great Basin on the east, the Sacramento Valley on the west, and higher elevation portions of the Sierra Nevada on the south. The Feather River watershed upstream of Oroville Dam is approximately 3,600 square miles and comprises approximately 68 percent of the Feather River Basin. Downstream of Oroville Dam, the basin extends south and includes the drainage of the Yuba and Bear Rivers. The Yuba River joins the Feather River near the City of Marysville, 39 river miles downstream of the City of Oroville, and the confluence of the Bear River and the Feather River is 55 river miles downstream of the City of Oroville. Approximately 67 miles downstream of the City of Oroville, the Feather River flows into the Sacramento River, near the town of Verona, about 21 river miles upstream of Sacramento. The Feather River watershed, upstream of the confluence of the Sacramento and Feather rivers, has an area of about 5,900 square miles.

The Feather River supports runs of both spring- and fall-run Chinook salmon. Historically, spring-run Chinook salmon immigrated to the upper tributaries of the Feather River in the spring and early summer where they would hold and eventually spawn in late summer or early fall. Fall-run Chinook salmon would immigrate to the lower Feather River in the fall and spawn immediately upon arrival. The construction of Oroville Dam presented an impassable migration barrier to upstream migration and today spawning is confined to the lower Feather River, primarily in the eight-mile reach extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet. Currently, the genetic distinctness of the two runs is not clear. DWR (2004a) reports that the FRFH-produced spring-run Chinook salmon as well as naturally spawning spring-run Chinook salmon in the Feather River were more closely related to fall-run than the documented spring-run populations in Butte, Mill and Deer creeks. Given that both spring-run and fall-run Chinook salmon spawn in the same reach of the Feather River and at about the same time, in high densities, it is likely that the population is hybridized. Nevertheless, fish exhibiting the typical life history of the spring-run are found holding at the Thermalito Afterbay Outlet and the Fish Barrier Dam as early as March (DWR 2004a). Annually, 30,000 to 170,000 Chinook salmon spawn in the lower Feather River, however, the proportion of putative spring-run to fall-run is unknown.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The construction of Oroville Dam presented an impassable migration barrier to upstream migration and today spawning is confined to the lower Feather River, primarily in the eight-mile reach extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet. There are no known passage impediments to upstream migrating adult Chinook salmon below the Fish Barrier Dam.

HARVEST/ANGLING IMPACTS

The sportfishery in the lower Feather River currently allows the taking of salmon from January 1 through September 30. From about mid-August through September; only Chinook salmon exhibiting spring-run timing would likely be in the river. Additionally, unusually high densities of fish in the lower Feather River likely create favorable poaching opportunities.

WATER TEMPERATURE

Suitable water temperatures for adult spring-run Chinook salmon migrating upstream to spawning grounds reportedly range from 57°F to 67°F (NMFS 1997). However, spring-run Chinook salmon are immature when upstream migration begins and need to hold in suitable habitat for several months prior to spawning. The maximum suitable water temperature for holding is reported to be about 59°F to 60°F (NMFS 1997). Under a 1983 agreement between CDFG and DWR, water temperatures are generally maintained below 60°F year-round above the Thermalito Afterbay Outlet (DWR 1983), but can exceed 65°F downstream during the summer months.

WATER QUALITY

Water quality in the lower Feather River is not likely to adversely affect immigrating adult anadromous salmonids. However, water quality may affect more sensitive life stages as discussed below under embryo incubation.

FLOW CONDITIONS

Except during flood events, flows in the reach of the lower Feather River extending downstream to the Thermalito Afterbay Outlet (Low Flow Channel) are maintained at a constant 600 cfs. Under the new Settlement Agreement, as part of the FERC relicensing for the Oroville Facilities, flows in the Low Flow Channel will be increased to a constant 800 cfs (FERC 2007). The instream flow requirements below the Thermalito Afterbay Outlet are 1,700 cfs from October through March and 1,000 cfs from April through September. It is likely that flow conditions in the lower Feather River seldom affect this life stage.

SPAWNING

The Feather River supports one of the largest runs of Chinook salmon in the Central Valley (Sommer *et al.* 2001b). Approximately 75 percent of the natural spawning for Chinook salmon occurs between the Fish Barrier Dam at RM 67 and the Thermalito Afterbay Outlet at RM 59, with the remainder occurring in the reach downstream of the Thermalito Afterbay Outlet to Honcut Creek at RM 44 (Sommer *et al.* 2001b).

PASSAGE IMPEDIMENTS/BARRIERS

The construction of Oroville Dam and subsequent blocking of upstream migration has eliminated the spatial separation between spawning fall-run and spring-run Chinook salmon. Reportedly, spring-run Chinook salmon migrated to the upper Feather River and its tributaries from mid-March through the end of July (CDFG 1998). Fall-run Chinook salmon reportedly migrated later and spawned in lower reaches of the Feather River than spring-run Chinook salmon (Yoshiyama *et al.* 2001). Restricted access to historic spawning grounds currently causes spring-run Chinook salmon to spawn in the same lowland reaches that fall-run Chinook salmon use as spawning habitat. The overlap in spawning site locations, combined with an overlap in spawning timing (Moyle 2002) with temporally adjacent runs, may be responsible for inbreeding between spring-run and fall-run Chinook salmon in the lower Feather River (Hedgecock *et al.* 2001).

In the Feather River, spring-run Chinook salmon spawning may occur a few weeks earlier than fall-run spawning, but currently there is no clear distinction between the two, because of the disruption of spatial segregation by Oroville Dam. Thus spawning of spring-run Chinook

salmon occurs during the same months as fall-run. This presents difficulties from a management perspective in determining the proportional contribution of total spawning escapement by the spring- and fall-runs. Because of unnaturally high densities of spawning in the Low Flow Channel, spawning habitat is likely a limiting factor. Intuitively it could be inferred that the slightly earlier spawning Chinook salmon displaying spring-run behavior would have better access to the limited spawning habitat, however, early spawning likely leads to a higher rate of redd superimposition. Redd superimposition occurs when spawning Chinook salmon dig redds on top of existing redds dug by other Chinook salmon. The rate of superimposition is a function of spawning densities and typically occurs in systems where spawning habitat is limited (Fukushima *et al.* 1998). Redd superimposition may disproportionately affect early spawners, and therefore potentially affect Chinook salmon exhibiting spring-run life history characteristics. As part of the Settlement Agreement for FERC relicensing of the Oroville Facilities, one or more weirs will be installed in the upper section of the river to aid in spatially segregating the spring- and fall runs (FERC 2007).

HARVEST/ANGLING IMPACTS

Regulations allow taking of salmon from January 1 through September 30. During this time period, Chinook salmon displaying spring-run behavior likely make up the majority of the spawning population. Unusually high densities of Chinook salmon in the lower Feather River likely create favorable poaching opportunities.

WATER TEMPERATURE

Releases are made from the coldwater pool in Lake Oroville Reservoir and this cold water generally provides suitable water temperatures in the Low Flow Channel (i.e., reach of the river extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet) (DWR 2001). However, downstream of the Thermalito Afterbay Outlet, water temperatures can reach 74°F in the summer (DWR 2001).

WATER QUALITY

Water quality in the lower Feather River is not likely to adversely affect spawning adult salmon. However, water quality may affect more sensitive life stages as discussed below under embryo incubation.

FLOW CONDITIONS

Flows in the Low Flow Channel are regulated to 600 cfs, except during flood events when flows have reached as high as 150,000 cfs (DWR 1983). The instream flow requirements below the Thermalito Afterbay Outlet are 1,700 cfs from October through March and 1,000 cfs from April through September. PHABSIM indicates that at flows of 600 cfs in the Low Flow Channel, approximately 91 percent of potential spawning habitat is available. High Flow Channel approximately 86 percent of the potential spawning habitat is available at 1,000 cfs (DWR 2004e).

SPAWNING HABITAT AVAILABILITY

Spawning habitat for Chinook salmon below Oroville Dam has been affected by changes to the geomorphic processes caused by several factors, including hydraulic mining, land use practices, construction of flood management levees, regulated flow regimes, and operation of Oroville

Dam. The dam blocks sediment recruitment from the upstream areas of the watershed. In the lower reaches of the river, levees and bank armoring prevent gravel recruitment. Periodic flows of sufficient magnitude to mobilize smaller sized gravel from spawning riffles result in armoring of the remaining substrate. DWR (DWR 1996) evaluated the quality of spawning gravels in the lower Feather River based on bulk gravel samples and Wolman surface samples obtained during spring 1996. The study concluded that the worst scoured areas had an armored surface layer too coarse for spawning salmonids. Additionally, much of the streambed substrate in the reach from the Fish Barrier Dam to the Thermalito Afterbay Outlet is composed of large gravel and cobble, which is too large for construction of spawning redds for Chinook salmon. This reach of the lower Feather River is by far the most intensively used spawning habitat of the river for salmon. The settlement agreement as part of the Oroville FERC relicensing process provides provisions for a gravel supplementation and monitoring program (FERC 2007).

PHYSICAL HABITAT ALTERATION

Regulation of the lower Feather River by the Oroville facilities has changed both streamflow and sediment discharge. Attenuation of peak flows, decreased winter flows, increased summer flows, and changes to flow frequencies have led to a general decrease in channel complexity downstream of Oroville Dam. Because several species and races of fish occur in the lower Feather River, a diversity of habitat types is required. Decreases in channel diversity lead to a decrease in habitat diversity and quality.

HATCHERY EFFECTS

The FRFH is the only hatchery in the Central Valley producing spring-run Chinook salmon. Prior to 2004, FRFH staff differentiated spring-run from fall-run by applying a cut-off date to fish ascending the fish ladder. Those fish ascending the ladder from September 1 through September 15 were assumed to be spring-run Chinook salmon while those ascending the ladder after September 15 were assumed to be fall-run (Kastner 2003). This practice led to considerable hybridization between spring- and fall-run Chinook salmon (DWR 2004a). Since 2004, the fish ladder remains open during the spring months and those fish ascending the ladder are marked with an external tag and returned to the river. This practice allows FRFH staff to identify those previously marked fish as spring-run when they re-enter the ladder in September (DWR 2004a). While this practice reduces the potential for hybridization with the fall-run in the hatchery, it is likely that many hatchery produced spring-run hybridize with the fall-run because of the lack of temporal and spatial isolation in the Feather River Low Flow Channel as mentioned above.

EMBRYO INCUBATION

Redd superimposition is likely the most serious factor affecting embryo incubation of spring-run Chinook salmon in the Feather River. Chinook salmon spawning escapements to the lower Feather River are much higher than available spawning habitat can support leading to high rates of redd superimposition. Spring-run Chinook salmon redds would be more affected than fall-run because spring-run spawn earlier in the year. The Settlement Agreement under the FERC relicensing for the Oroville Facilities calls for the installation of one or more weirs in the Low Flow Channel of the Feather River to aid in the spatial segregation of fall and spring-run Chinook salmon which should reduce the adverse effects of redd superimposition on spring-run Chinook salmon redds (FERC 2007).

HARVEST/ANGLING IMPACTS

The lower Feather River supports a popular year-round fishery. It is possible that redds could be disturbed by wading anglers.

WATER TEMPERATURE

Spring-run Chinook salmon embryos incubating in the Low Flow Channel are likely not adversely affected by high water temperatures as water temperatures seldom exceed 60°F. However, embryos from early spawning spring-run Chinook salmon that may have constructed redds downstream of the Thermalito Afterbay Outlet may experience water temperatures lethal to embryos. However, under the Settlement Agreement as part of the FERC relicensing process for the Oroville Facilities, increases in flow through the Low Flow Channel will likely lead to a slight reduction in water temperatures downstream of the Thermalito Afterbay Outlet.

WATER QUALITY

As part of the FERC relicensing process for the Oroville Facilities, six of the relicensing studies specifically address metals contamination in the lower Feather River. As part of these studies, water quality samples were collected at 17 locations within the lower Feather River. Samples exceeding aquatic life water quality criteria occurred for four constituents: total aluminum, iron, copper, and lead. In the reach of the Feather River extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet, 19 percent of the water quality samples exceeded aquatic life water quality criteria. Samples taken from the reach of the Feather River extending from the Thermalito Afterbay Outlet downstream to the confluence with the Sacramento River were variable, but all were higher than the upstream reach and 3 exceeded aquatic life water quality criteria 100 percent of the time. Copper exceeded aquatic life water quality criteria in 5 of 276 samples; two of these occurrences were in the reach of the Feather River extending from the Fish Barrier Dam downstream to the Thermalito Afterbay Outlet. Iron only exceeded aquatic life water quality criteria at three sampling locations; all locations were downstream of the lower Feather River confluence with Honcut Creek. Lead exceeded aquatic life water criteria only once at several stations, but three or four times at the two most downstream stations on the Feather River. Heavy metal contamination could affect embryo survival.

FLOW CONDITIONS

Adverse effects on developing embryos could occur if a flow fluctuation caused redds to become dewatered while eggs were incubating.

Oroville Facilities releases are regulated and subject to regulatory flow criteria. Under an agreement with CDFG, flows in the Low Flow Channel are regulated to 600 cfs, except during flood events when flows have reached as high as 150,000 cfs (DWR 1983). The instream flow requirements below the Thermalito Afterbay Outlet are 1,700 cfs from October through March and 1,000 cfs from April through September.

Results from the PHABSIM indicate that at flows of 600 cfs in the Low Flow Channel, approximately 91 percent of potential spawning habitat is available, and in the reach extending downstream from the Thermalito Afterbay Outlet approximately 86 percent of the potential spawning habitat is available at 1,000 cfs (DWR 2004e).

JUVENILE REARING AND OUTMIGRATION

Juvenile Chinook salmon in the lower Feather River have been reported to emigrate from approximately mid-November through June, with peak emigration occurring from January through March (Cavallo Unpublished Work; DWR 2002a; Painter *et al.* 1977). From 1999 to 2003 DWR conducted snorkel, seine and electrofishing surveys in the lower Feather River. Age-0 Chinook salmon were very abundant in the spring but were nearly absent from summer surveys, suggesting behavior consistent with fall-run (DWR 2004b).

WATER TEMPERATURE

Water temperatures in the Low Flow Channel normally remain below 62°F year-round and are suitable for juvenile Chinook salmon rearing. During the January through March time period, when approximately 96 percent of juvenile Chinook salmon emigrate (DWR 2002a), water temperatures generally remain suitable for emigration throughout the lower Feather River (DWR 2003).

WATER QUALITY

At times, heavy metal concentrations in the lower Feather river are known to exceed EPA guidelines as discussed above under embryo incubation. Exposure of juveniles for extended periods of time could lead to decreased survival.

FLOW CONDITIONS

Flows in the Low Flow Channel of the Feather River, where most juvenile rearing of salmonids occurs, is maintained at a constant 600 cfs year-round except during flood events. Some flow fluctuations may occur downstream of the Thermalito Afterbay Outlet that have the potential to strand juvenile rearing or outmigrating salmonids. Since 2001, DWR has been conducting a juvenile stranding study on Chinook salmon and steelhead in the lower Feather River. Empirical observations and aerial surveys identified over 30 areas that have the potential to strand juveniles with flow decreases. However, sampling of isolated areas indicated relatively little juvenile salmonid stranding. Furthermore the proportion of stranded salmonids represented a very small percentage (<<1 percent) of the estimated number of emigrants (DWR 2004c).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Fixed flows in the lower Feather River have resulted in fewer channel forming or re-shaping events leading to a lack of habitat diversity. This lack of diversity results in unnatural riparian conditions and a lack of recruitment of riparian vegetation.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Channel complexity refers to the diversity of geomorphic features in a particular river reach. Features such as undercut banks, meanders, point bars side channels and backwaters all provide habitat for juvenile salmonids. Regulation of the lower Feather River by the Oroville facilities has changed both streamflow and sediment discharge. Attenuation of peak flows, decreased winter flows, increased summer flows, and changes to flow frequencies have led to a general decrease in channel complexity downstream of Oroville Dam. Because several species and races of fish occur in the lower Feather River, a diversity of habitat types is required. Decreases in channel diversity lead to a decrease in habitat diversity and quality.

The high concentration of spawning salmonids in the Low Flow Channel results in a high concentration of juveniles in the Low Flow Channel. Seesholtz *et al.* (2003) found that most out-migration of juvenile Chinook salmon occurs between January and April and that these fish are relatively small. Based on historic accounts of juvenile salmonid emigration, the current peak in the emigration period is somewhat earlier than pre-dam conditions (Painter *et al.* 1977; Warner 1954). Seesholtz *et al.* (2003) further report that substantial numbers of juveniles remain in the Low Flow Channel through the end of June. Seesholtz *et al.* (2003) speculate that this early emigration may be caused by competition with other juvenile salmonids, including Chinook salmon and steelhead, for rearing habitat.

LOSS OF FLOODPLAIN HABITAT

Regular intermediate flood flushing flows to maintain geomorphic function of the river and replenish fish and riparian habitats are generally rare in the lower Feather River because of flow regulation by the Oroville Facilities. Lack of frequent high flow/flood events has led to a lack of floodplain renewal and connectivity to the channel.

ENTRAINMENT

The main diversion on the lower Feather River downstream of the Thermalito Afterbay occurs at Sunset Pumps at RM 38.6. The pumps divert 65,500 acre-feet of water annually. Although the diversion is screened, the mesh size does not meet NOAA or CDFG criteria, and some entrainment of juvenile salmonids likely occurs.

PREDATION

Known predators of Chinook salmon, including steelhead and pikeminnow, occur throughout the Low Flow Channel, although counts of these predators are reported to be low (Seesholtz *et al.* 2003). There are also a variety of predatory birds within this stretch of the Feather River, which may feed on salmon.

Significant numbers of predators do reportedly exist in the High Flow Channel below the Thermalito Afterbay Outlet. Analysis of CWT recovery data indicates that predation on hatchery-reared Feather River Chinook salmon released in the Feather River is high, however further analysis reveals that most of this predation takes place in the Sacramento River downstream of the Feather River confluence (DWR 2004d).

One aspect of the Oroville Project operations and facilities that may enhance predation in the High Flow Channel is that the high density of juveniles in the Low Flow Channel may cause early emigration of juvenile salmonids. Because juvenile rearing habitat in the Low Flow Channel is limited, juveniles may be forced to emigrate from the area due to competition for resources. Relatively small juvenile salmonids may be less capable of avoiding predators than those that rear to a larger size in the Low Flow Channel prior to beginning their seaward migration.

HATCHERY EFFECTS

The FRFH raises and releases both spring- and fall-run Chinook salmon. It is likely that these hatchery-reared fish compete for limited resources with naturally spawned fish in the lower Feather River. There is speculation that the early outmigration of Chinook salmon observed in

the Feather River is because of competition for limited resources. Additionally, the FRFH produces and releases yearling steelhead into the lower Feather River. These fish are large enough to prey on juvenile Chinook salmon.

3.3.8.2 YUBA RIVER

The lower Yuba River consists of the approximately 24-mile stretch of river extending from Englebright Dam, the first impassible fish barrier along the river, downstream to the confluence with the Feather River near Marysville.

ADULT IMMIGRATION AND HOLDING

Adult spring-run Chinook salmon immigration and holding has previously been reported to primarily occur in the Yuba River from March through October (Vogel and Marine 1991), with upstream migration generally peaking in May (SWRI 2002).

PASSAGE IMPEDIMENTS/BARRIERS

Englebright Dam presents an impassable barrier to upstream migration for anadromous salmonids and marks the upstream extent of currently accessible Chinook salmon habitat. Daguerre Point Dam may also provide a partial barrier to upstream migration. The design of Daguerre Point Dam fish ladders, as currently operated by the U.S. Army Corps of Engineers (USACE), are suboptimal. For example, during high flows across the spillway, the fish ladder is obscured making it difficult for salmonids migrating upstream to find the entrances to the fish ladders. Fall-run Chinook salmon have been observed attempting to leap over the dam, indicating that these fish were unable to navigate the fish ladders (CALFED and YCWA 2005). Both ladders also tend to become loaded with organic material and sediment, which can directly inhibit passage and/or reduce attraction flows at the ladder entrances. The fish ladder exits are close to the spillway, which can result in fish being swept back over the dam while attempting to exit the ladder.

Daguerre Point Dam can delay or prevent upstream migration of adult spring-run Chinook salmon in the lower Yuba River (NMFS 2007c). Daguerre Point Dam includes suboptimal fish ladder design and sheet flow across the dam spillway that reportedly may interfere with attraction to ladder entrances, particularly during high flow periods (January through March) (NMFS 2007c). The location of the ladder entrances also makes it difficult for immigrating adults to find the entrances (NMFS 2007c). Since 2001, wooden flash boards have been periodically affixed to the crest of the dam during low flow periods to aid in directing the flows towards the fish ladder entrances. Fish passage monitoring data from 2006 indicates that the installation of the flash boards resulted in an immediate and dramatic increase in the passage of salmon up the ladders, and is thought to have improved the ability of salmon to locate and enter the ladders (NMFS 2007c). Both ladders, particularly the north ladder, reportedly tend to clog with woody debris during high flow events, however, a log boom was installed at the north ladder in 2003 to reduce woody debris accumulation and an updated inspection and maintenance plan has allowed for more frequent inspection and cleaning of the ladders. Additionally, gravel buildup at the top of both ladders reportedly can block passage or reduce attraction flows at ladders, however, since 2003 the Corps has implemented a program to reduce gravel accumulation in front of the ladders (NMFS 2007c). Options to improve fish passage at Daguerre Point Dam were identified by the USFWS' Anadromous Fish Restoration Program (AFRP).

The Project Modification Report recently completed by the USACE included engineering surveys, hydraulic evaluation, and a preliminary environmental assessment. There is no anticipated date for the implementation or completion of improvements to Daguerre Point Dam.

HARVEST/ANGLING IMPACTS

Poaching of adult Chinook salmon at the Daguerre Point Dam fish ladders has been well documented by CDFG, and is considered a chronic problem. Poaching is exacerbated when fish congregate below Daguerre Point Dam during low and high flows when the ladders are not open. In addition, poachers have tampered with the fish ladders to prevent adult salmon passage and thus increasing the concentration of individual fish below the dam.

Fishing for Chinook salmon on the lower Yuba River is regulated by CDFG. CDFG angling regulations permit fishing for Chinook salmon from the mouth of the Yuba River to Daguerre Point Dam year-round. Harvest of Chinook salmon downstream of Daguerre Point Dam is permitted from January 1 through February 28 and from August 1 through October 15. It is illegal to harvest salmon upstream of Daguerre Point Dam at any time.

WATER TEMPERATURE

Water temperatures in the Yuba River remain fairly cool year-round due to cool water releases from Engle bright Dam. Additionally, deep coldwater pools are available providing summer holding habitat downstream of the Narrows I and Narrows II powerhouses, or further downstream in the Narrows Reach (YCWA *et al.* 2007), where water depths can exceed 40 feet.

WATER QUALITY

Water quality in the lower Yuba River is adequate to support Chinook salmon adult immigration.

FLOW CONDITIONS

The natural hydrograph of the Yuba River is generally characterized by rapid increases and decreases in flows in the late-fall through winter (i.e., November through March) associated with seasonal precipitation events. During the spring months (i.e., April through June) flows exhibit more gradual, sustained increases and decreases. During the summer (i.e., July through October) flows remain relatively stable). Therefore, flow conditions during the spring-run Chinook salmon immigration period are generally relatively stable.

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

From Daguerre Point Dam upstream to Englebright Dam there are no barriers to upstream adult immigration.

HARVEST/ANGLING IMPACTS

Angling impacts on spawning spring-run Chinook salmon are likely minimal because harvest is prohibited above Daguerre Point Dam where most spawning occurs.

WATER TEMPERATURE

Average daily water temperatures recorded at Daguerre Point Dam from 1997 to 2001 ranged from 57.7°F in September to 56.0°F in October.

WATER QUALITY

Water quality in the lower Yuba River is adequate to support Chinook salmon adult spawning.

FLOW CONDITIONS

Flows during the time that spring-run Chinook salmon would be spawning are relatively stable.

SPAWNING HABITAT AVAILABILITY

Most spawning habitat in the lower Yuba River is upstream of Daguerre Point Dam. Although water temperatures below the dam are likely suitable for Chinook salmon spawning, gravel downstream of the dam is embedded with silt (YCWA 2000). Spawning habitat above Daguerre Point Dam is considered marginal as Englebright Dam blocks recruitment of spawning gravel to the lower Yuba River.

PHYSICAL HABITAT ALTERATION

The most extensive habitat alterations in the lower Yuba River have occurred as a result of gold mining operations. The Yuba Goldfields are located along the lower Yuba River near Daguerre Point Dam, approximately 10 miles north of Marysville. The area of the Goldfields is approximately 8,000 acres. The Goldfields have been used for gold mining for about 100 years. As a result thousands of acres of continuous mounds of cobble and rock terrain have been left behind. As a result of the permeability of the substrates composing the Goldfields, several interconnected channels and ponds have formed throughout the area. Surface water in the ponds and canals of the Goldfields are hydraulically connected to the Yuba River. A proportion of flow entering the Goldfields is eventually returned to the Yuba River downstream of Daguerre Point Dam via an outlet canal. Prior to 2003, a fraction of the lower Yuba River Chinook salmon population (e.g., spring-run, fall-run, and late-fall-run) and, presumably, steelhead routinely migrated from the mainstem of the Yuba River into the Yuba Goldfields via the outlet canal. In 2003, a fish barrier was constructed at the outlet canal to prevent fish from entering the Yuba Goldfields. However, fish were still observed passing the barrier during flood or high flow events.

HATCHERY EFFECTS

Hatchery reared spring-run Chinook salmon were planted in the Yuba River during the 1970s. Additionally, adipose fin-clipped Chinook salmon have been observed in the Yuba River during recent carcass surveys indicating that some level of straying into the Yuba watershed is occurring. Monitoring efforts in the Yuba River have confirmed FRFH spring-run occur there (M. Tucker, NMFS, pers. comm.). Hybridization of the FRFH spring-run with the native spring-run population would result in compromising the genetic integrity and lowering the fitness of the latter. The hatchery stock would compete with native spring-run over available holding and spawning habitat, and possibly transfer the Feather River strain of IHNV to the local population.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because the lower Yuba River supports a year-round recreational fishery, it is possible that some level of redd disturbance by wading anglers occurs.

WATER TEMPERATURE

Spring-run Chinook embryo incubation primarily occurs in the lower Yuba River from September through March (YCWA *et al.* 2007). The intragravel residence times of incubating eggs and alevins (yolk-sac fry) are highly dependent upon water temperatures. Maximum Chinook salmon embryo survival reportedly occurs in water temperatures ranging from 41°F to 56°F (USFWS 1995c). The average water temperature in the Yuba River at Daguerre Point Dam ranges from approximately 47°F in January and February to approximately 57°F in September.

WATER QUALITY

Water quality in the lower Yuba River is generally good. There is a concern that a substantial amount of mercury may be in the Yuba Goldfields that could be mobilized by flood events but this would likely be downstream of developing embryos.

FLOW CONDITIONS

Flow reductions from normal maintenance and emergency operations of the Narrows I and II powerhouses below Englebright dam has been associated with cases of redd dewatering. Since 1991, maintenance activities have been scheduled at such times that potential redd dewatering would be minimized. Currently, flows are kept fairly constant during the time period when spring-run Chinook salmon embryos would be developing.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

The average daily mean water temperature downstream of Daguerre Point Dam from May through September ranges between 57.9°F in May to 61.6°F in September at Marysville (SWRI 2002). These temperatures are within the suitable range for juvenile spring-run Chinook salmon rearing and outmigration.

WATER QUALITY

Water quality in the lower Yuba River is generally good. There is a concern that a substantial amount of mercury may be in the Yuba Goldfields that could be mobilized by flood events.

FLOW CONDITIONS

Field observations on the lower Yuba River indicate that both natural and controlled flow reductions can cause some degree of fish stranding (YCWA 1998; YCWA 1999). The magnitude of stranding is site-specific and associated with the specific developmental stage of the fry prior to the onset of flow reductions, channel morphology, and aquatic habitat characteristics.

There are two types of stranding that are associated with flow reductions:

- Stranding associated with the rate of flow reductions (i.e., ramping rates), which determines if the juvenile fish can react quickly enough to avoid being stranded from exposed substrates in side channels and channel margins as flows decrease.

- ❑ Stranding associated with the magnitude of flow reductions, regardless of ramping rate, which determines the extent of stranding within off channel habitats as flows decrease.

The SWRCB requires that YCWA, in consultation with the CDFG, NMFS, and USFWS verify that salmon fry are being protected from dewatering events during controlled flow reductions on the lower Yuba River. However, some level of mortality associated with controlled flow reductions is unavoidable, and therefore should be considered as a factor when assessing threats to juvenile salmonids in the lower Yuba River (YCWA 1999).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The reduction of peak flows in the late winter and spring have resulted in a reduction of riparian vegetation. There is a wide variation throughout the growing season of willow regeneration because each species of willow requires flows at specific periods for reproduction and growth. Cottonwood regeneration is also more prominent under natural flow regimes (YCWA 2000).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Attenuated peak flows and controlled flow regimes have altered the area's geomorphology and have affected the natural meandering of the river downstream of Englebright Dam.

LOSS OF FLOODPLAIN HABITAT

Controlled flows and decreases in peak flows has reduced the frequency of floodplain inundation resulting in a separation of the river channel from its natural floodplain.

ENTRAINMENT

As juvenile salmonids pass Daguerre Point Dam, physical injury may occur as they pass over the dam or through its fish ladders (SWRI 2002). Water diversions in the lower Yuba River generally begin in the early spring and extend through the fall. As a result, potential threats to juvenile steelhead occur at the Hallwood-Cordua and South Yuba Brophy diversions.

Fish screens recently installed at the Hallwood-Cordua diversion are considered to be an improvement over those previously present but, the current pipe design may not allow sufficient flow to completely eliminate juvenile salmonid losses at the diversion.

The South Yuba-Brophy system diverts water through an excavated channel from the south bank of the lower Yuba River to Daguerre Point Dam. The water is then subsequently diverted through a porous rock dike that is intended to exclude fish. The current design of this rock structure does not meet NMFS or CDFG juvenile fish screen criteria (SWRI 2002).

There are also three major screeded diversions on the lower Yuba River located upstream of Daguerre Point Dam: (1) the Browns Valley Pumpline Diversion Facility; (2) the South-Yuba/Brophy Water District Canal; and (3) the Hallwood-Cordua Canal. In addition, there are 16 unscreened water diversion facilities downstream of Daguerre Point Dam (SWRI 2002) which could potentially entrain juvenile salmonids in the lower Yuba River.

PREDATION

The extent of predation on juvenile Chinook salmon in the Yuba River is not well documented, however, several non-native introduced known predators of juvenile salmonids are found in the Yuba River including striped bass, American shad and black bass species. Sacramento pikeminnow, a native predatory species is also found in the lower Yuba River. Manmade

alterations to the lower Yuba River channel (i.e., Daguerre Point Dam) may provide more predation opportunities for pikeminnow than would occur under natural conditions.

HATCHERY EFFECTS

The extent of potential hatchery effects on juvenile Chinook salmon in the lower Yuba River is unknown. It is possible that some hatchery-reared Chinook salmon from the FRFH may move into the lower Yuba River in search of rearing habitat. Some competition for resources with naturally spawned Chinook salmon could occur as a result. Additionally, hatchery-reared steelhead from the FRFH could likewise move into the Yuba River in search of rearing habitat and may prey on juvenile Chinook salmon.

3.3.8.3 BUTTE CREEK

Butte Creek originates in the Jonesville Basin, Lassen National Forest, on the western slope of the Sierra Nevada Mountains, and drains about 150 square miles in the northeast portion of Butte County. Butte Creek enters the Sacramento Valley southeast of Chico and meanders in a southwesterly direction to the initial point of entry into the Sacramento River at Butte Slough. A second point of entry into the Sacramento River is through the Sutter Bypass and Sacramento Slough.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Butte Creek is a highly developed watershed system with multiple diversions as well as water imports from foreign sources. Fish passage through Butte Creek is affected by about 22 major structures and an estimated 60 to 80 minor structures (e.g., pump diversions). Currently, it is estimated that salmonids have access to approximately 53 miles of Butte Creek (DWR 2005a).

There are several fish passage impediments and barriers on Butte Creek upstream of Highway 99, including the Quartz Bowl Falls (natural impediment) and the Centerville Diversion Dam (manmade barrier). CDFG reported that salmon and steelhead are unable to migrate upstream of the Quartz Bowl Falls on an annual basis (DWR 2005a). CDFG biologist report observing salmon in the reach between Quartz Bowl Falls and the Centerville Head Dam on only three occasions in the past 25 years when spring flows were in excess of 2,000 cfs (e.g., 1998 and 2003).

HARVEST/ANGLING IMPACTS

Recreational fishing in Butte Creek is limited to catch-and-release of trout and salmon from November 15 through February 15 with gear restrictions (i.e., artificial lures and barbless hooks only). These restrictions apply to the reach of Butte Creek extending from the Oro-Chico Road Bridge upstream to the Centerville Head Dam. Downstream of this point, recreational fishing is allowed year-round only for species other than trout and salmon.

WATER TEMPERATURE

Water temperatures were monitored from June through October from Cable Bridge (downstream) to Quartz Bowl (upstream) within the spring-run Chinook salmon holding and spawning reach of Butte Creek in 2002. **Table 3-1** depicts water temperature exceedances of

critical values as measured at different locations in Butte Creek during 2002 from June through October.

Table 3-1. Water Temperature Exceedances in Butte Creek in 2002

Location	Number of Days Equal to or Exceeding		
	15.0°C (59°F)	17.5°C (63.5°F)	20.0°C (68°F)
Quartz Bowl Pool	105	57	8
Chimney Rock	113	68	18
Pool 4	121	81	41
Centerville Estates	122	81	44
Cable Bridge	127	99	54

Pre-spawning mortality surveys were conducted in 2002 from the Parrot-Phelan Diversion to the Centerville Head Dam. There were 1,699 pre-spawning mortalities observed from June 26, 2002 to September 19, 2002. Higher than normal water temperatures in conjunction with a large number of adult returns resulted in an outbreak of Columnaris (*Flavobacterium columnare*). Pre-spawning mortalities in Butte Creek prior to this had been reported, however, they have been sporadically recorded, but have never been systematically assessed (CDFG 2000).

There were approximately 17,294 adult spring-run Chinook salmon that migrated to Butte Creek during 2003, of those an estimated 11,231 pre-spawning mortalities occurred. According to CDFG pathologists, the primary cause of these mortalities was an outbreak of two diseases, *Flovobacterium columnare* (Columnaris) and the protozoan *Ichthyophthirius multiphilis* (Ich).

WATER QUALITY

Currently, water quality conditions in Butte Creek meet all EPA water quality constituent requirements.

FLOW CONDITIONS

The present PG&E hydropower facilities divert water from the West Branch of the Feather River at the Hendricks Head Dam near Stirling City, which is then combined with Butte Creek water diverted at the Butte Head Dam. Power is generated at two sites – the DeSabra Powerhouse located above spring-run Chinook salmon holding and spawning areas, and the Centerville Powerhouse located in the middle of the approximately 11-mile holding and spawning reach. Annual diversion from the West Branch of the Feather River average approximately 47,000 acre-feet, and provides approximately 40 percent of the flows in Butte Creek during the months of July through September.

Diversions at the PG&E Centerville Head Dam supply water to the Centerville Powerhouse and reduce flows in Butte Creek to a minimum of 40 cfs from June 1 through September 14. The reach of Butte Creek between the Centerville Head Dam and the Centerville Powerhouse is approximately 5.5 miles long and is considered to be the highest quality and quantity of summer holding habitat in Butte Creek.

Diversions at the Centerville Head Dam which supply water to the Centerville Powerhouse, significantly reduce water temperatures in the reach immediately below the powerhouse due to reduced transit time and shading along the diversion canal. This reduction in water temperatures provides additional summer holding habitat that would potentially not exist.

PG&E determined that maintaining flows through the DeSabra Forebay above 80 cfs to 100 cfs helped to maintain cool water temperatures. While the existing operation of PG&E project facilities seems to provide an overall benefit to salmon holding and spawning, several potential future modifications to PG&E operations which may further improve water temperature conditions are as follows:

- ❑ Provide a flow bypass around DeSabra Forebay.
- ❑ Develop a water temperature model for flows entering Butte Creek from the West Branch of the Feather River.
- ❑ Avoid flow fluctuations during holding and spawning periods.
- ❑ Provide potential alternate conveyance and discharge points along the Centerville Canal which supplies water to the Centerville Powerhouse.

SPAWNING

Spring-run Chinook salmon in Butte Creek primarily spawn in stream reaches between the Parrot-Phelan Diversion Dam and the Centerville Head Dam (USFWS 2003a).

PASSAGE IMPEDIMENTS/BARRIERS

Historically, dams, inefficient fish ladders, and the dewatering of portions of Butte Creek as a result of water diversions created impediments to upstream passage for spawning adult spring-run Chinook salmon. Since the early 1990s, restoration actions in Butte Creek have focused on improving instream flow during the spring critical immigration period, thereby increasing the likelihood that fish will succeed in reaching the upstream holding and spawning areas, even in dry years. Currently, the minimum flow for allowing upstream passage is estimated at 80 cfs (CALFED 2006).

HARVEST/ANGLING IMPACTS

Butte Creek, from the confluence with the Sacramento River upstream to the Oro-Chico Road Bridge crossing south of Chico, is closed to trout and salmon fishing year-round. From the Oro-Chico Road Bridge crossing upstream to the Centerville Head Dam, catch and release fishing for trout and salmon is allowed from November 15 through February 15. However, Butte Creek is open to fishing for other species all year and some inadvertent catch of spring-run Chinook salmon may occur.

WATER TEMPERATURE

Water temperatures between Parrot-Phelan Diversion Dam and the Centerville Head Dam in Butte Creek frequently exceed the reported optimums for spring-run Chinook spawning. Water temperatures frequently exceed 59°F from July through September. In recent years, as escapement in Butte Creek has increased, mortality of pre-spawning adults has also increased due to a combination of high water temperatures and the bacterial disease Columnaris, leading to

speculation that the adult carrying capacity of Butte Creek has been reached (Stillwater Sciences Website 2007). An estimated 17,294 adult spring-run Chinook salmon migrated to Butte Creek during 2003, of which an estimated 11,231 died prior to spawning (Ward *et al.* 2003b). Pre-spawn mortalities were primarily due to high water temperatures, overcrowding of fish in limited holding pools, and disease (e.g., Columnaris and Ich) (Ward *et al.* 2003b).

Subsequent to the 1991 FERC requirement that PG&E maintain a minimum release of 40 cfs from June through September below the Centerville Head Dam, Ward *et al.* (2003b) report that the flow and temperature regime appears to have maximized survival and spawning success.

WATER QUALITY

Available data indicate that overall water quality in Butte Creek ranges from good to excellent in the upper watershed and degrades in quality lower in the system (Butte Creek Watershed Website 2004). Both pH and dissolved oxygen concentrations appear to be below Central Valley Regional Water Quality Control Board (RWQCB) criteria all of the time. Turbidity, mineral concentrations, nutrient loads and heavy metal concentrations (e.g., lead) have at times exceeded Central Valley RWQCB criteria for short periods of time (Butte Creek Watershed Website 2004).

FLOW CONDITIONS

PG&E's minimum instream flow requirement at the Lower Centerville Diversion Dam is 40 cfs from June 1 to September 14. Average monthly flows from June through September (1998-2002) were between 49 cfs and 46 cfs. During the onset of the spawning period in mid-September of 2004, PG&E in consultation with CDFG and NMFS, increased flows to 60 cfs (PG&E 2005).

SPAWNING HABITAT AVAILABILITY

Based upon estimates of spawning habitat, the reach of Butte Creek upstream of the Centerville Powerhouse could support 152 to 1,316 spawners at 40 cfs and 270 to 2,352 spawners at 130 cfs. The reach downstream of the powerhouse could support 1,262 to 10,976 spawners at 130 cfs. Within the 11-mile spring-run Chinook salmon holding and spawning reach, the area with the most deep holding pools is within the upper three miles of the reach while the majority of suitable spawning gravel substrate is within the lower five miles of the reach (Ward *et al.* 2003b).

PHYSICAL HABITAT ALTERATION

Hydropower generation has altered flows in Butte Creek since about 1908. During the key June to September holding period, diversions from the West Branch of the Feather River have increased natural flows in the creek and have generally provided cooler temperatures (Ward *et al.* 2003b).

The reach of Butte Creek from the Centerville Powerhouse downstream to the Parrott-Phelan Dam has undergone and continues to undergo residential development. Channel modification projects designed to repair or prevent flood-related damage to roads and houses have degraded natural processes which serve to recruit gravel, provide instream cover and forage, and provide summer holding pools (Butte Creek Watershed Website 2004).

HATCHERY EFFECTS

The trucking of FRFH spring-run, and their release into San Pablo Bay, facilitates the straying of adult spring-run hatchery returns and threatens the Butte Creek spring-run population. Genetic integrity of the Butte Creek spring-run may be compromised, and their fitness and productivity lowered. The hatchery stock would compete with native spring-run over available holding and spawning habitat, and possibly transfer the Feather River strain of IHNV to the local population. The BRT considers the FRFH spring-run Chinook salmon program to be a major threat to the genetic integrity of wild spring-run Chinook salmon populations in the Central Valley (NMFS 2003).

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because Butte Creek is open to angling year-round, there may be some inadvertent negative impacts to embryo incubation from anglers wading through redds or otherwise disturbing substrates containing redds.

WATER TEMPERATURE

The thermal criteria used to evaluate the suitability of spring-run Chinook salmon water temperatures suggests that water temperatures between 57.2°F and 60.8°F for a duration of approximately 20 days could potentially result embryo mortality rates of up to 25 percent from September 15 to September 30 (Armour 1991; CDFG 1998). However, it has been suggested that given that Butte Creek spring-run Chinook salmon are genetically distinct from the Mill Creek and Deer Creek populations (Lindley *et al.* 2004), it is likely that they have adapted to the warmer environs of the Butte Creek watershed. It could be possible that Butte Creek spring-run Chinook salmon can tolerate water temperatures exceeding 60°F which can occur during the first month of embryo incubation. However, there also may be higher embryo mortality rate for eggs deposited during first month (September) of the spawning period, relative to those deposited later during October when water temperatures decrease below approximately 55°F (**Figure 3-8**).

Figure 3-8. Water Temperatures Recorded in Butte Creek Near Chico During the Spring-run Chinook Salmon Embryo Incubation Period (September through January)

(USGS Gage: 39.7260°N 121.7090°W)

WATER QUALITY

Available data indicate that overall water quality in Butte Creek ranges from good to excellent in the upper watershed and degrades in quality lower in the system (Butte Creek Watershed Website 2004). Both pH and dissolved oxygen concentrations appear to be below Central Valley RWQCB criteria all of the time. Turbidity, mineral concentrations, nutrient loads and heavy metal concentrations (e.g., lead) have at times exceeded Central Valley RWQCB criteria for short periods of time (Butte Creek Watershed Website 2004).

The upper reaches of Butte Creek reportedly have relatively high dissolved oxygen concentrations. Monitoring conducted by DWR between December 1990 and October 1992, recorded dissolved oxygen levels ranging from 9.1 mg/l to 13.1 mg/l. These levels exceed minimum EPA requirements (PG&E 2005).

FLOW CONDITIONS

PG&E's minimum instream flow requirement at the Lower Centerville Diversion Dam is 40 cfs from June 1 to September 14. Average monthly flows from June through September (1998-2002) were between 49 cfs and 46 cfs. During the onset of the spawning period in mid-September of 2004, PG&E in consultation with CDFG and NMFS, increased flows to 60 cfs (PG&E 2005).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures during the period when flows are managed and when juvenile Chinook salmon are present (e.g., October 15 through January), are likely near optimal ranges. However, water temperatures could be a concern during the late spring especially in the lower reaches of Butte Creek. During the 2002-2003 juvenile migration study period in Butte Creek, the majority of Butte Creek juvenile spring-run Chinook salmon emigrated as fry from December through January. As observed during previous study years, some young-of-the-year remained in Butte Creek above the Parrot-Phelan Diversion Dam prior to emigrating in the spring (Ward *et al.* 2004).

WATER QUALITY

Available data indicate that overall water quality in Butte Creek ranges from good to excellent in the upper watershed and degrades in quality lower in the system (Butte Creek Watershed Website 2004). Both pH and dissolved oxygen concentrations appear to be below Central Valley RWQCB criteria all of the time. Turbidity, mineral concentrations, nutrient loads and heavy metal concentrations (e.g., lead) have at times exceeded Central Valley RWQCB criteria for short periods of time (Butte Creek Watershed Website 2004).

FLOW CONDITIONS

Butte Creek is primarily a free-flowing stream lacking large storage dams to control or buffer flows (CDFG 1999a). Flows are highly variable with the majority of out migration of juveniles occurring during high flow events (CDFG 1999a).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The distribution of riparian habitat, particularly in the lower reaches of Butte Creek, has been reduced by anthropogenic changes for flood control, agriculture and urbanization (Butte Creek Watershed Website 2004).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

The reach of Butte Creek from the Centerville Powerhouse downstream to the Parrott-Phelan Dam has undergone, and continues to undergo, residential development. Channel modification projects designed to repair or prevent flood-related damage to roads and houses have degraded natural processes which serve to recruit gravel, provide instream cover and forage, and provide summer holding pools (Butte Creek Watershed Website 2004).

LOSS OF FLOODPLAIN HABITAT

Although Butte Creek is bordered by levees in some areas, it also passes through Butte Slough and the Sutter Bypass where connectivity to the floodplain still exists to some extent (Butte Creek Watershed Website 2004).

ENTRAINMENT

In Butte Creek most water diversion facilities have been screened or modified to prevent juvenile fish entrainment (PG&E 2005). In addition, as part of PG&E's FERC relicensing project, PG&E has proposed to undertake a project assessing potential juvenile entrainment at its project facilities including the Hendricks Canal, Toadtown Canal and Powerhouse, Butte Canal, DeSabra Forebay and Powerhouse, Lower Centerville Canal, and Centerville Powerhouse (PG&E 2005).

PREDATION

Introduced fish species that are known predators in the Butte Creek system include largemouth and smallmouth bass, black and white crappie, channel catfish and potentially, striped bass and American shad. The native Sacramento pikeminnow is also a major predator on juvenile salmonids particularly near manmade structures (Butte Creek Watershed Website 2004).

HATCHERY EFFECTS

Juvenile Chinook salmon in Butte Creek are not likely directly affected by hatchery operations. There is some potential for outmigrating juveniles to be preyed upon by hatchery steelhead as they enter either the Sacramento or Feather rivers.

3.3.8.4 BIG CHICO CREEK

Big Chico Creek originates on Colby Mountain, located in Tehama County, California. The creek flows 45 miles to its confluence with the Sacramento River in Butte County. The creek's elevation ranges from 120 feet at the Sacramento River to 6000 feet at Colby Mountain. A portion of Big Chico Creek flows through the city of Chico, California's Bidwell Park and California State University, Chico. Big Chico Creek currently supports a remnant, non-sustaining population of spring-run Chinook salmon.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Big Chico Creek has no major reservoirs, but has two small dams and three natural barriers that could impede anadromous fish migration.

Five Mile Dam was built by the USACE for the purpose of flood control in 1963. The dam effectively split the Big Chico Creek flows into three separate channels—Big Chico Creek, Sycamore Channel, and Lindo Channel. The design of the flood control structure creates a ponding effect upstream during flood events. This causes gravels to drop out of suspended load upstream of the diversion which creates a gravel bar that blocks the flow to Lindo Channel unless it the gravel bar is mechanically removed. As a result, Lindo Channel frequently lacks sufficient flows to allow upstream migrants to pass, and has the potential to trap adults within the channel during immigration to spawning areas upstream (DWR 2005b).

The Iron Canyon fish ladder was built in the late 1950s to facilitate fish passage through Bidwell Park. This structure has been damaged, and frequently impedes adult salmonid upstream migration. Currently, a project is in planning phase to repair the fish ladder to allow fish passage to an additional 9 miles of spawning habitat over a wider range of flows (CDFG Website 2005). In addition, fish passage through the narrow canyon walls of Bear Hole, located downstream of the Iron Canyon fish ladder, impedes fish passage during low flows. Under high flow conditions, fish have been observed passing major barriers (Iron Canyon). However, under normal and low-flow conditions fish passage is more problematic (DWR 2005b).

HARVEST/ANGLING IMPACTS

Recreational catch-and-release fishing in Big Chico Creek is permitted: (1) one mile downstream of Bidwell Park, is limited to June 16 through October 15 with gear restrictions (i.e., artificial lures and barbless hooks only); and (2) from Bear Hole to the Big Chico Creek Ecological Reserve from November 1 through April 30. Fishing upstream of Big Chico Creek Ecological Reserve is prohibited year-round.

WATER TEMPERATURE

During low flows in the summer, water flows continuously through Big Chico Creek, however, in Lindo Channel, flows become intermittent. It has been suggested that water temperatures from Iron Canyon to Higgins Hole, which may contain holding adult spring-run Chinook salmon, can potentially reach critical levels during the late summer, particularly during dry water years (DWR 2005b).

Higgins Hole is the upstream limit to spring-run Chinook salmon immigration and is reportedly the best summer holding habitat available in Big Chico Creek. However, mean daily water temperatures during the summer months reportedly generally range from 64°F to 68°F (**Figure 3-9**).

Figure 3-9. Average Daily Water Temperatures in Big Chico Creek Near Chico During the Spring-run Chinook Salmon Adult Immigration and Holding Period March through September (2000-2005)

Source: CDEC

WATER QUALITY

Water quality in Big Chico Creek and Lindo Channel has been degraded by cadmium, mercury, and other metals associated with gold mining in the upper watershed. The California State University, Chico reported significant concentrations of fecal coliform bacteria during the summer months due to Sycamore pool, which is heavily used as a swimming hole. However, Big Chico Creek currently meets EPA water quality constituent standards. There is also potential for increased suspended sediment loads during the cleaning of Sycamore Pool which is formed by One-Mile Dam. However, a project was completed in 1997 which constructed a bypass waterway that isolates the cleaning area from the flowing creek. The bypass channel consists of a concrete box culvert installed below the surface of the pool bottom. The channel extends the entire length of the pool exiting beyond the fish ladder. A flash board dam will be installed at the entrance to the pool to provide for the diversion of clean water from the channel during cleaning operations.

FLOW CONDITIONS

Mean monthly flows in Big Chico Creek from 1930 to 1986 during the spring-run Chinook salmon immigration and holding period (i.e., February through August) range from approximately 400 cfs to approximately 40 cfs.

Big Chico Creek flows through the Chico alluvial fan at the Five-Mile Recreation Area. Flows at Five-Mile are regulated for flood control by diversion of high flows from a single stilling basin in Big Chico Creek and two flood bypass channels (Lindo Channel and Sycamore Channel). The invert elevations of Big Chico Creek and the Lindo Channel diversion are similar, thus flows are sustained in both channels during the summer low flow period. However, due to a gravel bar formation below the stilling basin, flows in Lindo Channel become intermittent from May through November each year.

SPAWNING

Spring-run Chinook salmon in Big Chico Creek primarily spawn in stream reaches between the Higgins Hole and Iron Canyon (CDFG 2004a).

PASSAGE IMPEDIMENTS/BARRIERS

The first barrier to upstream migration on Big Chico Creek occurs in Iron Canyon where a jumble of boulders has accumulated in the Creek. These boulders present an impassable barrier at normal flows but allow passage at high flows (Big Chico Creek Watershed Alliance Website 2007). The Iron Canyon fish ladder was built in the late 1950s to facilitate fish passage. This structure has been damaged, and frequently impedes adult salmonid upstream migration. Currently, a project is underway to repair the fish ladder to allow fish passage to an additional nine miles of spawning habitat over a wider range of flows (CDFG Website 2005). The waterfall at Higgins Hole is currently thought to be the uppermost barrier to anadromous fish migrations (CDFG 2001a).

HARVEST/ANGLING IMPACTS

Currently, Big Chico Creek is open to catch and release fishing from the confluence with the Sacramento River to Bear Hole located approximately one mile downstream of Bidwell Park during the June 16 to February 15 time period, however, from October 15 through February 15 only barbless artificial lures may be used. Big Chico Creek, from Bear Hole to the upper boundary of the Big Chico Creek Ecological Reserve is open to catch and release fishing, with barbless artificial lures, from November 1 through April 30. From the upper boundary of the ecological reserve to Higgins Hole Falls, Big Chico Creek is closed to fishing at all times of the year.

WATER TEMPERATURES

Summer water temperatures in Big Chico Creek are marginal for holding spring-run Chinook salmon and are seldom suitable for spawning until mid-October (Big Chico Creek Watershed Alliance Website 2007). **Figure 3-10** depicts stream water temperatures recorded in Big Chico Creek near Chico during the normal spring-run Chinook salmon spawning period of September through October.

Figure 3-10. Average Daily Water Temperature in Big Chico Creek Near Chico During Adult Spring-run Chinook Salmon Spawning Period September through October (2000-2004)

WATER QUALITY

A number of issues and concerns have been raised regarding the water quality in the Big Chico Creek watershed, primarily, increased sediment loads and turbidity, fecal coliform contamination, urban stormwater runoff, groundwater contamination, agricultural runoff, siltation-, pollutant-, and garbage-related contamination from the Minnehaha Mine, sediment-, erosion-, and septic-related contamination from the Boy Scout Camp at Chico Meadows, and the potential threat of petroleum contamination from Highway 32 (CDFG 2001a).

FLOW CONDITIONS

Adult spring-run Chinook salmon enter Big Chico Creek between March and June, although, late arriving individuals often have difficulty in upstream migrations because of low-flow conditions. Early arriving individuals are normally blocked by waterfalls. Spring-run Chinook salmon normally spend summer months in deep pools from Iron Canyon to Higgins Hole and spawn in adjacent riffles when water temperatures become suitable in the fall (Big Chico Creek Watershed Alliance Website 2007).

SPAWNING HABITAT AVAILABILITY

A survey of spawning gravels was conducted by DWR in 1997 to determine the gravel size distribution at various spawning sites in Big Chico Creek. The sites were located along Big Chico Creek at Highway 32; below the Five-Mile Area flood control structure; and at Rose Avenue. The gravel sizes ranged from 20 mm to 100 mm (approximately 1 to 4 inches) in mean diameter. Gravels within these ranges are considered to be suitable for salmonid spawning (Big Chico Creek Watershed Alliance Website 2007).

Gravel recruitment downstream of the Five-Mile Flood Diversion Complex is reduced and gravel also becomes trapped in the One-Mile Pond from which it is customarily removed rather than transported downstream (Big Chico Creek Watershed Alliance Website 2007). Additionally, the

practice of removing large woody debris from urban and floodway stream reaches has reduced habitat and increased streambed scouring (Big Chico Creek Watershed Alliance Website 2007).

PHYSICAL HABITAT ALTERATION

The presence of dams on Big Chico Creek limits the composition and volume of sediments transported which reduces the supply of spawning gravels downstream of the dams. Large volumes of suspended sediment in the bedload are deposited within the stilling pond above the Five-Mile area. As a result, coarse sediments are not transported downstream below the Five-Mile area. At Chico's One-Mile Recreation Area, the flow is again reduced and additional volumes of sediment are deposited on the upstream side of the dam. Low-flow silt transport in the Big Chico Creek has been increased by swimming pool clean out and summer water activities by humans, dogs and horses. Unlike high-flow conditions in which silt only deposits where flow velocity is reduced in backwater and overflow sites, silt carried during low flows settle out in riffles and pools where it degrades habitat for spawning (Big Chico Creek Watershed Alliance Website 2007).

HATCHERY EFFECTS

The trucking of FRFH spring-run, and their release into San Pablo Bay, facilitates the straying of adult spring-run hatchery returns and threatens the Big Chico Creek spring-run population. Genetic integrity of the Big Chico Creek spring-run may be compromised, and their fitness and productivity lowered. The hatchery stock would compete with native spring-run over available holding and spawning habitat, and possibly transfer the Feather River strain of IHNV to the local population.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because Big Chico Creek is open to angling during the spring-run Chinook salmon embryo incubation period, there may be some inadvertent negative impacts to embryo incubation from anglers wading through redds or otherwise disturbing substrates containing redds.

WATER TEMPERATURE

The thermal criteria used to evaluate the suitability of spring-run Chinook salmon water temperatures suggests that water temperatures between 57.2°F and 60.8°F for approximately 20 days could potentially result in embryo mortality rates of up to 25 percent from September 15 to September 30 (USFWS 1996; Armour 1991; and CDFG 1998). However, it is hypothesized that Big Chico Creek spring-run Chinook salmon may be more tolerant of high water temperatures than those in nearby streams (e.g., Mill, Deer and Butte creeks) (Lindley *et al.* 2004). There would likely be higher embryo mortality rate for eggs deposited during the first month (September) of the spawning period, relative to those deposited later during October of some water years when temperatures decrease below approximately 55°F (**Figure 3-11**).

Figure 3-11. Water Temperatures Recorded in Big Chico Creek Near Chico During the Spring-run Chinook Salmon Embryo Incubation Period (September through January)
(39.7680°N 121.7770°W)

WATER QUALITY

A number of issues and concerns have been raised regarding the water quality in the Big Chico Creek watershed, primarily, increased sediment loads and turbidity, fecal coliform contamination, urban stormwater runoff, groundwater contamination, agricultural runoff, siltation-, pollutant-, and garbage-related contamination from the Minnehaha Mine, sediment-, erosion-, and septic-related contamination from the Boy Scout Camp at Chico Meadows, and the potential threat of petroleum contamination from Highway 32 (CDFG 2001a).

FLOW CONDITIONS

Due to flood control management structures (e.g., Lindo Channel and the Sycamore Creek Bypass Channel) Big Chico Creek lacks the flows necessary to maintain the optimal substrate size distributions for the successful incubation of spring-run Chinook salmon embryos. Substrates are often dominated by small gravel, sand, and fine sediments which reduce the interstitial spaces between substrates. Such reductions can result in decreased water flow through redds, leading to low dissolved oxygen concentrations, and poor removal of metabolic wastes. These conditions could reduce embryo growth rates, fitness, and survival.

Fluctuation in flows during the embryo incubation period that could potentially cause redd dewatering events in Big Chico Creek have not been reported to date.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in Big Chico Creek, downstream of Iron Canyon, are not suitable for salmonids during the summer months. Most juvenile rearing of spring-run Chinook salmon occurs in the foothill reaches (Big Chico Creek Watershed Alliance Website 2007).

WATER QUALITY

A number of issues and concerns have been raised regarding the water quality in the Big Chico Creek watershed, primarily, increased sediment loads and turbidity, fecal coliform contamination, urban stormwater runoff, groundwater contamination, agricultural runoff, siltation-, pollutant-, and garbage-related contamination from the Minnehaha Mine, sediment-, erosion-, and septic-related contamination from the Boy Scout Camp at Chico Meadows, and the potential threat of petroleum contamination from Highway 32 (CDFG 2001a).

FLOW CONDITIONS

Flows in Big Chico creek begin to decline in the late-spring and are continuous only in the main channel by summer. The Lindo Channel and Mud Creek channels have only intermittent flow during most years during the summer months (DWR 2005a). As a result of these receding flows there is a potential that juvenile fish emigrating later in the spring may be exposed to sub-optimal water temperatures and stranding due to receding flows in Big Chico Creek and its flood control channels (CDFG 2001a).

Lindo Channel often ceases to flow, sometimes trapping downstream migrants several times during a single season (Ward *et al.* 2004). However, a habitat evaluation of Big Chico Creek, Lindo Channel, and Mud Creek conducted by CDFG in 2001 determined that these waterways provided juvenile Chinook salmon with a variety of habitats with suitable cover, substrates, and water temperatures during the winter and early spring (CDFG 2001a).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Anthropogenic changes in the Big Chico Creek watershed have reduced or degraded riparian habitat. However, some programs are underway to improve riparian habitat by various groups in the area. For example, there has been marked improvement in riparian habitat in Lindo Channel between Manzanita Avenue and Mangrove Avenue (Big Chico Creek Watershed Alliance Website 2007).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Some of the valley reaches in Lindo Channel, Mud and Rock creeks that are maintained for flood control, lack sufficient vegetation to maintain stream structure (Big Chico Creek Watershed Alliance Website 2007).

LOSS OF FLOODPLAIN HABITAT

Flows in Big Chico Creek, as it emerges onto the Chico Fan at the Five-Mile Recreation Area are regulated for flood control by diversion of flows into two bypass channels: Lindo Channel and the Sycamore Creek Bypass Channel. This has resulted in a disconnection of the river to its normal floodplain and likely results in less habitat diversity in the lower reaches of Big Chico Creek (Big Chico Creek Watershed Alliance Website 2007).

ENTRAINMENT

Currently, juvenile salmonids have a potential for being entrained at the Parrot-Phelan Pumping Station. There are currently plans to develop a "fish-friendly" alternative for the M&T Ranches' Parrot-Phelan Pumping Station by relocating the pumping station and providing fish screens on the diversion structures. In addition to providing water supply to agricultural operations in the area, CDFG and USFWS also hold rights to use water to flood wetlands in the Llano Seco Ranch they own and operate. CDFG and USFWS do not use their water rights because of potential

impacts to salmon. Relocation of the pumping station would allow them to exercise their legal rights and also reduce fish entrainment along Big Chico Creek.

Entrainment and/or impingement of juvenile fish at the various flood control structures and diversions in Big Chico Creek could potentially cause physical harm to rearing and emigrating juveniles during high flows in the winter and early spring. As a result these structures constitute a chronic threat to spring-run Chinook juvenile rearing and emigration life stage.

PREDATION

Smallmouth bass are abundant in the valley zone of Big Chico Creek. Smallmouth bass are particularly abundant in dry years while in wet years, high flows typically scour the fish from streams. Therefore, during dry years, smallmouth bass likely present a predation problem for juvenile salmonids in Big Chico Creek (Big Chico Creek Watershed Alliance Website 2007). Big Chico Creek also supports a population of brown trout which are a known piscivorous species (Big Chico Creek Watershed Alliance Website 2007).

HATCHERY EFFECTS

From 1987 to 1992, spring-run Chinook salmon fry were planted in Big Chico Creek during the spring. The plants did not appear to be successful in that very few, if any, of the planted fish returned to spawn (Big Chico Creek Watershed Alliance Website 2007).

3.3.8.5 DEER CREEK

Deer Creek is part of the lower Cascade Mountain Range and drains an area of approximately 229 square miles. Deer Creek meets the Sacramento River near the town of Vina at RM 230. Deer Creek currently supports a small self-sustaining population of spring-run Chinook salmon. The viability of the population in Deer Creek is dependent on the maintenance and protection of what is currently considered to be excellent habitat. Unlike many Central Valley watersheds, headwater stream habitat in the drainages adjacent to Mount Lassen remains relatively undisturbed. Deer Creek has approximately 25 miles of accessible anadromous fish habitat within the Lassen National Forest.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The first natural barrier in Deer Creek is a fall about nine miles upstream of Polk Springs and approximately 40 miles from the mouth. This fall is about 16 feet high, and salmon had never been known to pass beyond it until a fish ladder was constructed in 1943. There is a second fall on Deer Creek about ten miles upstream of the falls near Polk Springs. This fall contains a sheer drop of about 20 feet. A fish ladder also was constructed at this barrier in early 1950s, but is not operated to allow spring-run Chinook salmon to move upstream because the upstream areas are thought to lack holding habitat (Deer Creek Conservancy Website 2007).

Deer Creek has five potential manmade physical impediments to fish passage in the lower watershed; (1) Stanford-Vina Ranch Diversion Dam, which is equipped with marginally functioning fish ladders; (2) Cone-Kimball Diversion Dam; (3) North Main Diversion Canal; (4) Deer Creek Irrigation Company Dam (a collapsible structure that is not a permanent impediment

to fish passage); and (5) an unnamed canal. Historically, these water diversions caused instream flows to decrease to levels which blocked access for late-summer upstream fish migration (DWR 2005a). However, the Stanford Vina Ranch Irrigation Company (SVRIC) has responded to CDFG requests for voluntary system shut downs to provide "transport windows" for migrating anadromous salmonids (Deer Creek Conservancy Website 2007).

The SVRIC has also made fish ladder improvements. The negative impacts of water diversions from Deer Creek may be mitigated by a proposed water exchange project, which would provide replacement water in lieu of water from water diversions during biologically critical periods. Replacement water may be from groundwater wells or other sources. Development of this replacement water requires some funding. All of the diversion structures would contain CDFG-designed and operated fish ladders and screens (Deer Creek Conservancy Website 2007).

HARVEST/ANGLING IMPACTS

The entire Deer Creek fishery is limited to catch and release of spring-run Chinook salmon, which occurs from below upper Deer Creek Falls and fishway downstream to the USGS gaging station from the last Saturday in April to November 15 with gear restrictions (i.e., artificial lures and barbless hooks only), and from the USGS gaging station to the mouth of Deer Creek from June 16 through September 30.

WATER TEMPERATURE

The following water temperature information was obtained from the Deer Creek Watershed Conservancy (Deer Creek Conservancy Website 2007).

DWR maintains a water temperature data logger at the Highway 99 Bridge. Data records exist in a computerized database for the period of July 1993 to present. This station is part of the DWR Water Quantity and Quality Measurement Program for collecting long-term basic data at various stations. Since May of 1997, DWR also has maintained continuous water temperature recorders at eight stations in Deer Creek (i.e., at the mouth, Highway 99, upper diversion dam, Ponderosa Way, A Line Road, the Meadows, Upper Falls, and Apperson Camp). However, permanent funding is needed for these gaging stations to negotiate pulse flows with irrigation districts, as the stations are not currently funded after 2009.

A review of the data from July 1993 to the present for the Highway 99 Bridge station indicates that, during the period of mid-May through mid-September, water temperatures exceeded 80°F on numerous occasions.

The CDFG previously monitored water temperatures via data loggers on Deer Creek at Stanford-Vina Dam, A Line Road Crossing, and Ponderosa Way. Data exist for portions of the years from 1992 to 1996. These units were displaced in the floods of January 1997. The purpose for temperature monitoring was to evaluate spring-run salmon life history patterns (e.g., adult/juvenile migration patterns). CDFG has particular concerns about temperatures greater than 80°F below Stanford-Vina Dam.

Reviews of the CDFG data indicate that maximum water temperatures observed at Stanford-Vina Dam for April, May, and June of 1994 were 77.2°F, 81.1°F, and 86.0°F, respectively. There is

only one year of record for this station. At the next station upstream (Ponderosa Way), the maximum 1992 water temperature occurred on July 17 (76.1°F). Records for Ponderosa Way during 1993, 1994, and 1996 are incomplete. The maximum water temperature for 1995 was 67.6°F on July 18. The uppermost station at A Line Road Crossing had an observed maximum water temperature in 1992 of 69.6°F (July 17). In 1993, the maximum water temperature at this station was 66°F, which occurred on August 2. The maximum observed water temperatures during 1994 and 1995 were 69.8°F (July 20) and 62.2°F (August 5), respectively. No records exist for the summer and fall during 1996 at A Line Road Crossing.

WATER QUALITY

Water quality monitoring in Deer Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy Website 2007; DWR 2005a). Deer Creek currently meets EPA water quality standards.

FLOW CONDITIONS

Water diversions reduce streamflow in Deer Creek which may impede migration of adult spring-run Chinook salmon. There is a proposed water exchange project that may allow adequate flows during periods of fish migration. However, an instream flow assessment is necessary to determine appropriate flow levels in Deer Creek (Deer Creek Conservancy Website 2007).

SPAWNING

The Upper Canyon Reach of Deer Creek extends from the lowermost Highway 32 Bridge crossing downstream approximately 14 miles. The known range for adult spring-run Chinook salmon spawning extends from the Upper Falls downstream to the mouth of the canyon (DWR 2005a). Deer Creek is reported to have excellent spawning and holding habitat throughout the Lower Canyon Reach upstream to the Upper Deer Creek Falls near Highway 32.

PASSAGE IMPEDIMENTS/BARRIERS

Deer Creek has five potential manmade physical impediments to fish passage in the lower watershed; (1) Stanford-Vina Ranch Diversion Dam, which is equipped with marginally functioning fish ladders; (2) Cone-Kimball Diversion Dam; (3) North Main Diversion Canal; (4) Deer Creek Irrigation Company Dam (a collapsible structure that is not a permanent impediment to fish passage – but can be during dry springs when irrigation begins early in the year); and (5) an unnamed canal. Historically, these water diversions caused instream flows to decrease to levels which blocked access for late-summer upstream fish migration (DWR 2005a). However, the SVRIC has responded to CDFG requests for voluntary system shut downs to provide "transport windows" for migrating anadromous salmonids (Deer Creek Conservancy Website 2007).

HARVEST/ANGLING IMPACTS

Regulations in Deer Creek permit catch and release fishing only. From Deer Creek falls, downstream for 31 miles, catch and release fishing with artificial lures and barbless hooks is permitted from the last Saturday in April through November 15. From the USGS gaging station

cable crossing downstream to the mouth of Deer Creek, catch and release fishing is permitted from June 16 through September 30.

WATER TEMPERATURES

Maximum daily water temperatures from the Upper Falls to Ponderosa Way from June through October (1995 through 1998) range between 65.5°F and 72.5°F (Klamath Resource Information System Website 2007). It is likely that suitable water temperatures for spawning spring-run Chinook salmon do not occur until mid- to late-October.

WATER QUALITY

Water quality monitoring in Deer Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy Website 2007; DWR 2005a).

FLOW CONDITIONS

There has been no salmonid flow habitat relationships developed for salmonids in Deer Creek. Because there are no major storage facilities on Deer Creek, late fall and winter flow patterns in the area where spring-run Chinook salmon spawning occurs, mimic natural patterns.

SPAWNING HABITAT AVAILABILITY

Spring-run Chinook salmon habitat in the upper watershed is considered to be excellent, with numerous holding areas and an abundance of spawning gravel (DWR 2005a; USFWS 1999). Flood protection, cattle grazing and water diversions have had a negative effect on habitat in the lower watershed. Stream channelization has reduced the opportunities for gravel deposition. Gravels that might have been deposited are likely to be washed downstream during high flow events because of the increased shear stress produced in these straightened reaches (DWR 2005a; USFWS 1999).

PHYSICAL HABITAT ALTERATION

While habitat in the upper watershed is relatively pristine, channelization has occurred in the lower watershed reducing opportunities for natural deposition of spawning gravel. Additionally, water diversions have led to low-flow conditions which can effect habitat availability (DWR 2005a; USFWS 1999).

HATCHERY EFFECTS

The trucking of FRFH spring-run, and their release into San Pablo Bay, facilitates the straying of adult spring-run hatchery returns and threatens the Deer Creek spring-run population. Genetic integrity of the Deer Creek spring-run may be compromised, and their fitness and productivity lowered. The hatchery stock would compete with native spring-run over available holding and spawning habitat, and possibly transfer the Feather River strain of IHNV to the local population.

EMBRYO INCUBATION

Embryo incubation in Deer Creek reportedly occurs from mid-August through mid-March (Deer Creek Conservancy Website 2007).

HARVEST/ANGLING IMPACTS

Because Deer Creek is open to angling during most of the spring-run Chinook salmon embryo incubation period, there may be some inadvertent negative impacts to embryo incubation from anglers wading through redds or otherwise disturbing substrates containing redds.

WATER TEMPERATURE

Water temperature monitoring efforts on Deer Creek include data collected from 1993 to the present at the Highway 99 Bridge as part of the DWR Water Quantity and Quality Measurement Program. In addition, since May of 1997, DWR also has maintained continuous water temperature recorders at eight stations in Deer Creek (Deer Creek Conservancy Website 2007): (1) at the mouth of Deer Creek; (2) Highway 99; (3) upper diversion dam; (4) Ponderosa Way; (5) A Line Road; (6) the Meadows; (7) Upper Falls; (8) and Apperson Camp. However, permanent funding is needed for these gaging stations to negotiate pulse flows with irrigation districts, as the stations are not currently funded after 2009. In addition, data collected at these locations is not representative of conditions within primary spring-run Chinook salmon spawning areas located farther upstream (i.e., the Highway 32 Bridge upstream to the Upper Falls).

Based on recent relatively high natural production estimates for Deer Creek, it is likely that water temperatures in the upstream reaches of Deer Creek are suitable for all juvenile spring-run life stages, including embryo incubation.

WATER QUALITY

Water quality monitoring in Deer Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy Website 2007; DWR 2005a).

FLOW CONDITIONS

There are no significant water diversions in the upstream reaches (i.e., primary spawning habitat) of Deer Creek that could result in unnatural flow fluctuations that could cause redd dewatering events.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Deer Creek reportedly provides relatively good habitat for juvenile salmonids (DWR 2005a). Water temperatures recorded in Deer Creek during the 1997-98 brood year (CDFG 1999b) were within the reported optimal ranges for the juvenile rearing and emigration period (January through March).

WATER QUALITY

Water quality monitoring in Deer Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (Deer Creek Conservancy Website 2007; DWR 2005a). Concentrations of aluminum have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (Deer Creek Conservancy Website 2007; DWR 2005a).

FLOW CONDITIONS

Deer Creek flow average about 320 cfs over the course of a year, however, the stream experiences a high snowmelt flow almost every year and high flows resulting from rain on snow events. These high flows have been known to reach over 21,000 cfs breaching the levee system (MacWilliams *et al.* 2004). The downstream migration of juvenile spring-run Chinook salmon occurs concurrently with peak flows from January through March. The extent to which flow fluctuations from water diversions in Deer Creek may cause juvenile stranding is currently unknown.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Recent studies have concluded that aquatic habitat in Deer Creek is limited by the current flood control project in the valley floor of the watershed. Effects of the flood control project include lack of habitat diversity and riparian vegetation due to channel maintenance and clearing (MacWilliams *et al.* 2004)

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Flood control activities such as stream channelization, levee construction, and clearing have led to a lack of habitat diversity by constraining high flow and flood events between the levees (MacWilliams *et al.* 2004).

LOSS OF FLOODPLAIN HABITAT

The Deer Creek Flood Control Project was completed by the USACE in 1953. About 16 km of levees were built along lower Deer Creek to control flooding and the channel was straightened and cleared. As a result of this work, natural geomorphic processes were disrupted and the riparian zone was limited to a small band within the constructed levees effectively severing the connection between Deer Creek and the floodplain (MacWilliams *et al.* 2004).

ENTRAINMENT

In Deer Creek, fish screens have been in place at all diversions, although some mortality is still reported to occur (Klamath Resource Information System Website 2007).

PREDATION

Green sunfish, largemouth and smallmouth bass, striped bass and American shad are all piscivorous species that have been introduced to the Sacramento watershed. It is likely that sunfish and bass species both occur in Deer Creek and the loss of natural stream function associated with flood control measures likely enhances predation opportunities.

HATCHERY EFFECTS

Juvenile Chinook salmon in Deer Creek are not likely directly affected by hatchery operations. There is some potential for outmigrating juveniles to be preyed upon by hatchery steelhead as they enter either the Sacramento River.

3.3.8.6 MILL CREEK

Mill Creek is an eastside tributary to the Sacramento River that flows in a southwesterly direction for approximately 60 miles and drains 134 square miles. The creek originates near a thermal spring area in Lassen Volcanic National Park at an elevation of approximately 8,200

feet. It initially flows through meadows and dense forests and then descends rapidly through a steep rock canyon into the Sacramento Valley. Upon emerging from the canyon, the creek flows 8 miles across the Sacramento Valley floor, entering the Sacramento River about 1 mile north of the town of Tehama, near Los Molinos, at an elevation of approximately 200 feet.

The Revised Draft Anadromous Fish Restoration Plan identifies Mill Creek as one of the high priority tributaries to the upper Sacramento River, particularly for its populations of spring-run Chinook salmon and steelhead.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

There are no major reservoirs on Mill Creek. However, two diversions, Ward Dam and Upper Diversion Dam, have historically diverted most of the natural flow during the summer months. Clough Dam, a private diversion serving the properties of two local land owners, was partially washed out in the 1997 flood. The remnants of the dam were removed in 2002.

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Mill Creek. For purposes of fishing regulations, the creek is divided into two reaches. From the Lassen National Park boundary downstream to the USGS gaging station at the mouth of Mill Creek Canyon, fishing with barbless hooks and artificial lures is allowed from the last Saturday in April through November 15. From that point downstream to the mouth, fishing is allowed from June 16 through September 30.

WATER TEMPERATURE

Average daily mean water temperatures from May through September (i.e., during the adult spring-run Chinook salmon holding period) in upper Mill Creek during 1997 ranged from approximately 50°F to approximately 70°F. During this period average daily water temperatures generally remained between 60°F and 65°F (Harvey-Arrison 1999).

WATER QUALITY

Water quality in Mill Creek is adequate to support spring-run Chinook salmon adult immigration and holding.

FLOW CONDITIONS

Mill Creek supports three water diversions. During the irrigation season, instream flows may drop low enough to prevent late migrating adults from moving upstream (DWR 2005a). In dry years when natural flows are low and diversions are operating, increased water temperatures occurring from May through June in the lower reaches of Mill Creek can create a thermal barrier, preventing or delaying adult spring-run Chinook salmon upstream migration (DWR 2005a).

SPAWNING

In Mill Creek, spring-run Chinook salmon hold and spawn from approximately the Lassen National Park boundary downstream to the Little Mill Creek confluence (CDFG 1999b).

PASSAGE IMPEDIMENTS/BARRIERS

Prior to 1997, Clough Dam created a partial barrier to upstream migration in Mill Creek and was utilized as a counting station. In 1997, a flood breached Clough Dam allowing unimpaired access to lower Mill Creek (CDFG 1999b).

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Mill Creek. For purposes of fishing regulations, the creek is divided into two reaches. From the Lassen National Park boundary downstream to the USGS gaging station at the mouth of Mill Creek Canyon, fishing with barbless hooks and artificial lures is allowed from the last Saturday in April through November 15. From that point downstream to the mouth, fishing is allowed from June 16 through September 30.

WATER TEMPERATURES

Maximum daily water temperatures in Mill Creek at various locations recorded from April through November ranged from 62.7°F to 73.0°F. In most locations in Mill Creek, water temperatures suitable for spawning occur generally in about the beginning of September. Water temperatures near Little Mill Creek are generally not suitable for spawning until about the beginning of October (CDFG 1999b).

WATER QUALITY

Water quality monitoring in Mill Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (DWR 2005a). Concentrations of aluminum and copper have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (DWR 2005a). Erosion from recent volcanic deposits in and near Lassen Volcanic National Park, in the headwaters of Mill Creek, contributes turbidity to the stream nearly year-round (CDFG 1999b). These water quality conditions likely have no adverse effects on immigrating Chinook salmon.

FLOW CONDITIONS

There have been no flow habitat relationships developed for Mill Creek. There are no major water storage facilities on Mill Creek and water diversions are not occurring during the time and in the area where spring-run Chinook salmon are spawning. Therefore, flows during the spring-run Chinook salmon spawning period tend to mimic historic conditions that occurred under natural flow regimes.

SPAWNING HABITAT AVAILABILITY

The upper reaches of Mill Creek located above diversion dams reportedly provide excellent spring-run spawning habitat (DWR 2005a). Approximately 48 miles of currently accessible spawning habitat exists from the confluence of Little Mill Creek upstream to Morgan Hot Springs (Klamath Resources Information Website 2007). Spawning habitat availability in the upper reaches of Mill Creek is reportedly not easily identifiable due to the variable size range of available substrates. However, individuals appear to be capable of accessing suitable size gravels located beneath the armored surfaces of the river bed (Klamath Resource Information System Website 2007).

SPAWNING SUBSTRATE AVAILABILITY

High gravel embeddedness has been reported in some spawning areas (Klamath Resource Information System Website 2007).

PHYSICAL HABITAT ALTERATION

The Mill Creek watershed is relatively long and narrow, with steep slopes. Steep slopes adjacent to the main channel have served as barriers to activity and land use allocations have protected these areas such that the mainstem of the stream is essentially undisturbed (CDFG 1999b).

HATCHERY EFFECTS

The trucking of FRFH spring-run, and their release into San Pablo Bay, facilitates the straying of adult spring-run hatchery returns and threatens the Mill Creek spring-run population. Genetic integrity of the Mill Creek spring-run may be compromised, and their fitness and productivity lowered. The hatchery stock would compete with native spring-run over available holding and spawning habitat, and possibly transfer the Feather River strain of IHNV to the local population.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Mill Creek during a portion of the embryo incubation period for spring-run Chinook salmon. Therefore, redds may be exposed to inadvertent disturbance by wading anglers.

WATER TEMPERATURE

Spring-run Chinook salmon redds are located in the upstream reaches of Mill Creek which are generally characterized as having favorable water temperatures during the majority of the embryo incubation period (September through January).

WATER QUALITY

Water quality monitoring in Mill Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (DWR 2005a). Concentrations of aluminum and copper have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (DWR 2005a). Erosion from recent volcanic deposits in and near Lassen Volcanic National Park, in the headwaters of Mill Creek, contributes turbidity to the stream nearly year-round (CDFG 1999b). Increased turbidity could adversely affect developing Chinook salmon embryos.

FLOW CONDITIONS

Flow conditions in the upstream reaches of Mill Creek are not affected by water diversions. As a result, any changes in flow that could potentially result in decreased oxygen flow, or redd dewatering events, would be due to natural fluctuations in streamflow.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Mill Creek reportedly provides relatively good habitat for juvenile salmonids (DWR 2005a). Water temperatures recorded in Mill Creek during the 1997-1998 brood year (CDFG 1999b)

were within the reported optimal ranges for the juvenile rearing and emigration period (January through March).

WATER QUALITY

Water quality monitoring in Mill Creek has shown levels of coliform bacteria, minerals and nutrients to be low and not restrictive to beneficial use (DWR 2005a). Concentrations of aluminum and copper have at times exceeded the California Toxic Rule and the EPA chronic criteria for the protection of freshwater organisms (DWR 2005a). Erosion from recent volcanic deposits in and near Lassen Volcanic National Park, in the headwaters of Mill Creek, contributes turbidity to the stream nearly year-round (CDFG 1999b).

FLOW CONDITIONS

The downstream migration of juvenile spring-run Chinook salmon occurs concurrently with peak flows from January through March. The extent to which flow fluctuations from water diversions in Mill Creek may affect juvenile salmonid habitat availability and cause juvenile stranding is currently unknown.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The Mill Creek watershed is relatively long and narrow, with steep slopes. Steep slopes adjacent to the main channel have served as barriers to activity and land use allocations have protected these areas such that the mainstem of the stream is essentially undisturbed (Klamath Resource Information System Website 2007).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

The Mill Creek watershed is relatively long and narrow with steep slopes. Steep slopes adjacent to the main channel have served as a barrier to human activity and the environment is essentially undisturbed (Klamath Resource Information System Website 2007)

LOSS OF FLOODPLAIN HABITAT

Because Mill Creek is a relatively narrow watershed with steep slopes, there is little natural connection with the floodplain in the upper reaches.

ENTRAINMENT

In Mill Creek, fish screens have been in place at all diversions, although some mortality is still reported to occur (Klamath Resource Information System Website 2007).

PREDATION

Smallmouth bass, brown trout and green sunfish are all non-native predators known to exist in Mill Creek. The extent of predation that occurs on juvenile spring-run Chinook salmon is unknown.

HATCHERY EFFECTS

Juvenile Chinook salmon in Mill Creek are not likely directly affected by hatchery operations. There is some potential for outmigrating juveniles to be preyed upon by hatchery steelhead as they enter the Sacramento River.

3.3.8.7 ANTELOPE CREEK

Antelope Creek flows southwest from the foothills of the Cascade Range entering the Sacramento River nine miles southeast of the town of Red Bluff. The drainage is approximately 123 square miles and the average stream discharge is 107,200 acre-feet per year.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Though there are diversion structures in the valley sections of Antelope Creek, there are no major impoundments. A fish ladder at Edwards Irrigation Dam was constructed in 2007 and is reported to be adequate for fish passage. Currently, Paynes Crossing (Middle Slab) is a passage impediment during springs when there is low flow (Brenda Olson, USFWS, personal communication). Anadromous fish (spring- and fall-run Chinook salmon and steelhead) have been able to maintain passage to the upper watershed (Klamath Resource Information System Website 2007). During low-flow conditions, the number of adult spring-run Chinook salmon entering upstream habitat can be reduced due to decreases in water velocities and depths.

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Antelope Creek. For purposes of fishing regulations, the creek is divided into two reaches. From the confluence with the north fork downstream to the USGS gaging station at the mouth of Antelope Creek Canyon, fishing with barbless hooks and artificial lures is allowed from the last Saturday in April through November 15. From that point downstream to the mouth, fishing is allowed from June 16 through September 30. Therefore, the recreational fishery is open for most of the spring-run Chinook salmon adult immigration life stage, although harvest is not allowed.

WATER TEMPERATURE

Maximum water temperatures recorded during July and August from 1992 to 1995 ranged from 67°F to 70°F. Water temperatures are likely to warm to support Chinook salmon holding unless cool water refugia are found in deep pools.

WATER QUALITY

As reported in the Eastside Watershed Assessment, there are some water quality concerns in the lower section of Antelope Creek with the agriculture return ditch.

FLOW CONDITIONS

The degree to which water diversions and structures can impact spring-run Chinook salmon in Antelope Creek varies between years. In some years, some or all of the natural streamflow may be diverted by water-rights holders from mid-spring into the fall (Klamath Resource Information System Website 2007).

SPAWNING

Based on reported observations of spring-run Chinook salmon, the range of their distribution is equal to approximately 9 miles, and extends from approximately 1.6 miles downstream of the Paynes Creek crossing upstream to near McClure Place on the North Fork, and to Bucks Flat on the South Fork (Klamath Resource Information System Website 2007). A total of eight spring-

run Chinook salmon were counted during the annual spawning snorkel survey in 2001. This was a total reduction from 154 counted during a 1998 survey (CDFG 2002).

PASSAGE IMPEDIMENTS/BARRIERS

Local landowners and CDFG are pursuing a partnership with the Service to implement a fish passage improvement program for Antelope Dam. A fish ladder has been operating at the dam since 1981. Floodwaters damaged the ladder, and a new, more technologically advanced ladder needs to be installed, and improvements need to be made to the face of the dam to promote use of the ladder. If funding is available, the project will be completed in 2007. Other than occasional low-flow conditions and beaver dams, there are no other manmade impediments to salmonid upstream migration in Antelope Creek (NMFS Website 2007).

HARVEST/ANGLING IMPACTS

Catch and release fishing is allowed in Antelope Creek. For proposes of fishing regulations, the creek is divided into two reaches. From the confluence with the north fork downstream to the USGS gaging station at the mouth of Antelope Creek Canyon, fishing with barbless hooks and artificial lures is allowed from the last Saturday in April through November 15. From that point downstream to the mouth, fishing is allowed from June 16 through September 30.

WATER TEMPERATURE

Maximum daily water temperatures in Antelope Creek at various locations recorded from April through November (1996, 1997, and 1998) ranged from 60.6°F to 68.9°F (Klamath Resource Information System Website 2007).

WATER QUALITY

Water quality in Antelope Creek likely does not cause any adverse effects to spring-run Chinook salmon spawning.

FLOW CONDITIONS

Antelope Creek fish habitat is relatively unaltered above the valley floor but lack of adequate migratory attraction flows into the Sacramento River to this habitat prevents optimum use by anadromous fish (DWR Website 2007b). In wettest years, average flows in winter months range from 200 to 1,200 cfs. In the driest years, flows in winter average 50 cfs. In all but the wettest years, summer and early fall flows average from 20 to 50 cfs. The natural flow pattern is altered by diversions in the lower creek from spring through fall. Flows are typically diverted from April 1 through October 31 (County of Butte Website 2007).

SPAWNING HABITAT AVAILABILITY

Vanicek (1993) rated spawning habitat as fair to poor in Antelope Creek. There have been no flow habitat relationships developed for Antelope Creek.

SPAWNING SUBSTRATE AVAILABILITY

Vanicek (1993) reported that substrate in Antelope Creek is primarily sand and silt. The effects of fine sediment on spawning areas in Antelope Creek are unknown (Klamath Resource Information System Website 2007).

PHYSICAL HABITAT ALTERATION

The Antelope Creek watershed is relatively long and narrow with steep slopes. Steep slopes adjacent to the main channel have served as a barrier to human activity and the environment is essentially undisturbed (Klamath Resource Information System Website 2007).

HATCHERY EFFECTS

The trucking of FRFH spring-run, and their release into San Pablo Bay, facilitates the straying of adult spring-run hatchery returns and may threaten the Antelope Creek spring-run population. Genetic integrity of the Antelope Creek spring-run could be compromised, and their fitness and productivity lowered. The hatchery stock would compete with native spring-run over available holding and spawning habitat, and possibly transfer the Feather River strain of IHNV to the local population.

EMBRYO INCUBATION**HARVEST/ANGLING IMPACTS**

Catch and release fishing is allowed in Antelope Creek during a portion of the embryo incubation period for spring-run Chinook salmon. Therefore, redds may be exposed to inadvertent disturbance by wading anglers.

WATER TEMPERATURE

Water temperatures on the Middle Fork, North Fork, and South Fork of Antelope Creek during the warmest water temperature conditions occurring during (e.g., September, October, and November) are listed in **Table 3-2** below. These water temperatures are above the reported optimum for the embryo incubation life stage, however the magnitude to which these water temperatures would decrease by the onset of the embryo incubation period in September is unknown.

Table 3-2. Seven Day Maximum Water Temperature Recorded in the Middle Fork, South Fork, and North Fork of Antelope Creek During the First Portion of the Spring-run Chinook Salmon Embryo Incubation Life Stage in 1996, 1997, and 1998

Location	Date	Seven Day Maximum Water Temperature (°F)
Middle Fork Antelope Creek	7/21/97	67.8 ¹
South Fork Antelope Creek	8/18/96	73.7 ²
North Fork Antelope Creek	7/21/97	62.2 ³

1996: MF Antelope Creek data collected from July 1 through October 15; SF Antelope Creek² data collected from April 9 through November 1; NF Antelope Creek data collected from July 1 through October 15

1997: MF Antelope Creek¹ data collected from April 9 through November 1; SF Antelope Creek data collected from April 9 through November 1; NF Antelope Creek³ data collected from April 9 through November 1

Source: (Klamath Resource Information System Website 2007)

WATER QUALITY

Because Antelope Creek habitat in the upstream watershed is basically undisturbed, water quality in areas where redds are established likely has no adverse effects on developing embryos.

FLOW CONDITIONS

Antelope Creek fish habitat is relatively unaltered above the valley floor, however, flow conditions on Antelope Creek during the spring-run Chinook salmon embryo incubation period are not known at this time.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures during the spring-run Chinook salmon juvenile rearing and outmigration period have not been reported to the public, although real-time water temperature and flow monitoring data recorders were recently installed at various locations in Antelope Creek as part of an AFRP monitoring project.

WATER QUALITY

Although little water quality information on Antelope Creek is available, because Antelope Creek habitat in the upstream watershed is basically undisturbed, water quality in the upstream reaches likely have no adverse effects on juvenile salmonids.

FLOW CONDITIONS

The downstream migration of juvenile spring-run Chinook salmon occurs concurrently with peak flows from January through April. The extent to which flow fluctuations from water diversions in Antelope Creek may affect juvenile salmonid habitat availability and cause juvenile stranding is currently unknown. However, there are two diversions in Antelope Creek at the canyon mouth. One is operated by the Edwards Ranch, which has water rights of 50 cfs, and the other by the Los Molinos Water Company which has a water right of 70 cfs. Flows are diverted between April 1 and October 31. The stream is usually dewatered when both diversions operate (Klamath Resource Information System Website 2007). In 2007 and 2008, rescues of spring Chinook salmon juveniles and steelhead have been necessary due to an early irrigation season. Permanent funding is needed for these gaging stations to negotiate pulse flows with irrigation districts (Brenda Olson, USFWS, personal communication).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The Antelope Creek watershed is relatively long and narrow with steep slopes. Steep slopes adjacent to the main channel have served as a barrier to human activity and the environment is essentially undisturbed (Klamath Resource Information System Website 2007).

LOSS OF FLOODPLAIN HABITAT

Because Antelope Creek is a relatively narrow watershed with steep slopes, there is little natural connection with the floodplain (Klamath Resource Information System Website 2007).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

The Antelope Creek watershed is relatively long and narrow with steep slopes. Steep slopes adjacent to the main channel have served as a barrier to human activity and the environment is

essentially undisturbed. Therefore, above the valley floor, the creek has essentially retained its natural functions.

ENTRAINMENT

The Antelope Main canal could potentially cause entrainment or impingement of juvenile spring-run Chinook salmon. The diversions associated with this canal are equipped with fish screens, but there are no bypasses. In addition, entrainment has been observed at Paynes Crossing (Brenda Olson, USFWS, personal communication).

PREDATION

Smallmouth bass, brown trout and green sunfish are all non-native predators known to exist in Antelope Creek. The extent of predation that occurs on juvenile Chinook salmon is unknown.

HATCHERY EFFECTS

Juvenile Chinook salmon in Antelope Creek are not likely directly affected by hatchery operations. There is some potential for outmigrating juveniles to be preyed upon by hatchery steelhead as they enter either the Sacramento River.

3.3.9 BASALT AND POROUS LAVA DIVERSITY GROUP

The basalt and porous lava spring-run Chinook salmon Diversity Group historically was comprised of populations in Battle Creek, the upper Sacramento River (upstream of where Keswick and Shasta dams now reside), the McCloud River, and the Pit River (**Figure 3-12**). Currently, within this diversity group, spawning populations of Chinook salmon exhibiting spring-run characteristics occur in Battle Creek and the mainstem Sacramento River immediately downstream of Keswick Dam.

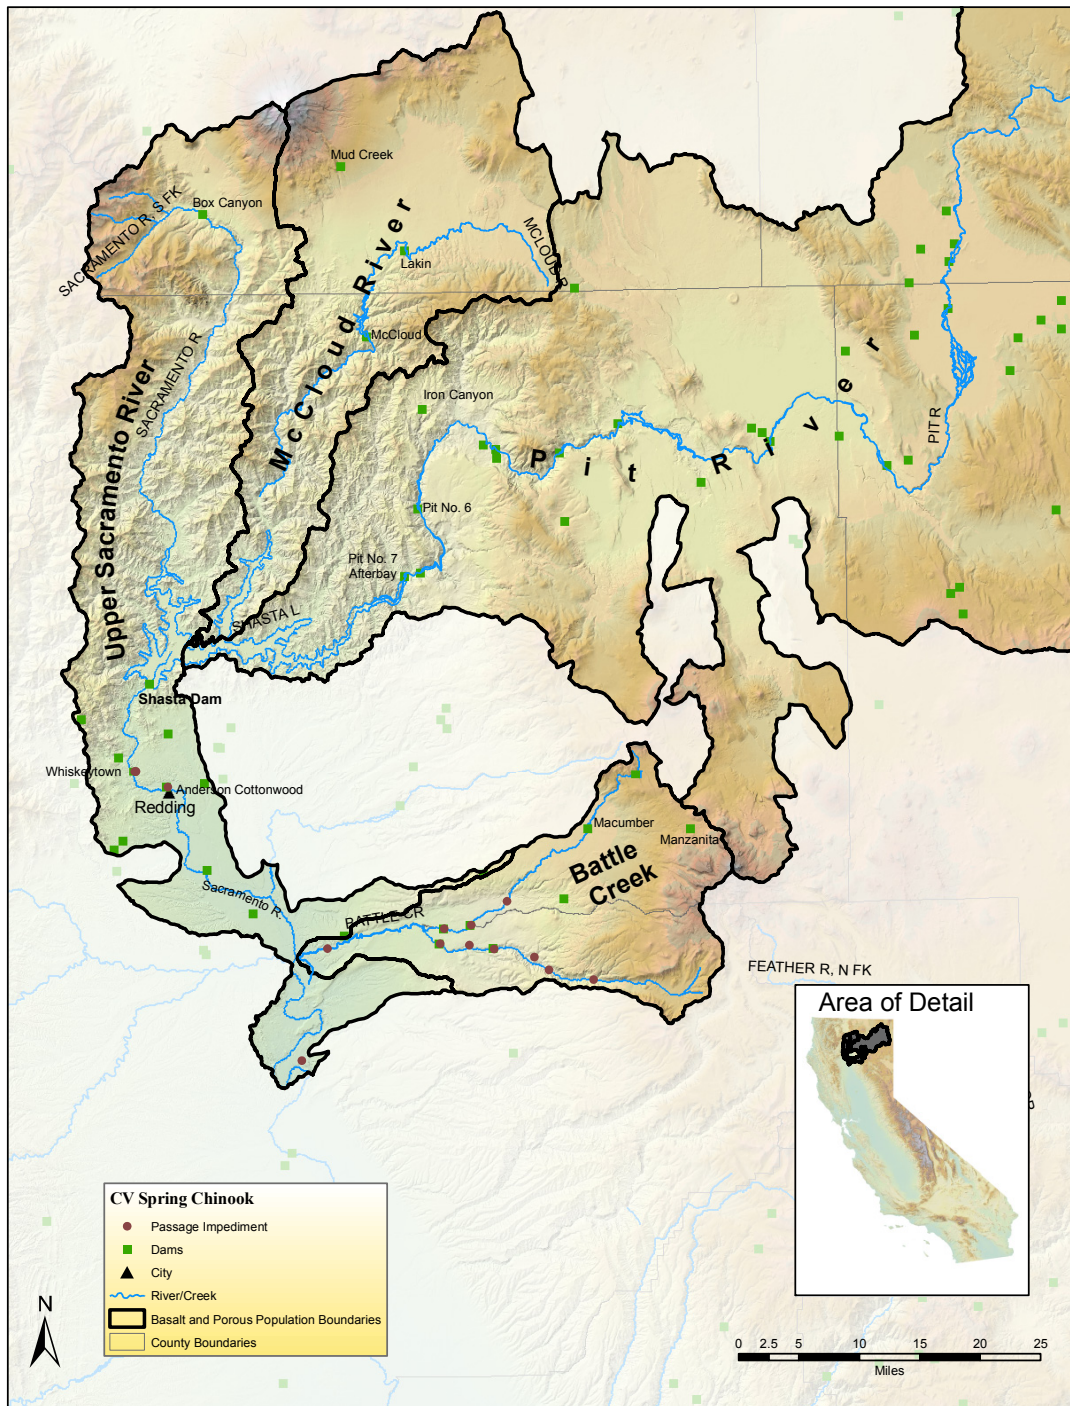

Figure 3-12. Basalt and Porous Lava Spring-run Chinook Salmon Diversity Group

3.3.9.1 BATTLE CREEK

Battle Creek enters the Sacramento River approximately five miles southeast of the Shasta County town of Cottonwood. It flows into the Sacramento Valley from the east, draining a watershed of approximately 360 square miles.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

The main stem of Battle Creek has had three structures that act as potential impediments to adult anadromous fish migration: (1) the CNFH barrier weir that diverts returning hatchery fish into the hatchery for brood stock collection each year from September through early March; (2) the Orwick seasonal gravel diversion dam; and (3) the tailrace from PG&E's Coleman Powerhouse, which had been known to attract anadromous salmonids into an area with little spawning habitat, but has currently been improved by the construction of a fish exclusion weir in 2004.

HARVEST/ANGLING IMPACTS

Battle Creek supports a popular recreational fishery. As a result, some level of poaching likely occurs. Current fishing regulations do not allow any fishing from the mouth of Battle Creek to 250 feet upstream of the weir at the CNFH. Upstream of that point, catch and release fishing with artificial lures and barbless hooks is allowed from the last Saturday in April to November 15.

WATER TEMPERATURE

Battle Creek water temperatures is generally cool because of the many cold springs that feed into it and because it receives significant snowmelt during the spring and summer. However, operation of hydroelectric facilities also influences water temperatures in Battle Creek. Reduced streamflow resulting from diversions may cause the water temperatures in the stream to warm. Shunting water between the power facilities also may cause stream warming if the water flows in open canals for some distance (KRIS Website 2007).

The North Fork Battle Creek contains excellent habitat for spring-run Chinook, even at the lowest (i.e., elevation) sections because cold springs feed the creek. The South Fork is also influenced by springs and would maintain at least acceptable habitat in its lower sections under a restored flow regime. The observed water temperatures in Battle Creek also indicate that the mainstem might provide some acceptable habitat for spring Chinook holding in wet years (USFWS 2008). Average daily water temperatures for various locations in the mainstem and north and south forks of Battle Creek are shown below in **Table 3-3**.

Table 3-3. Average Daily Water Temperatures (°F) in Battle Creek From 1 June through 30 September (Adult Holding Period), 1998 through 2007.

Average Daily Water Temperature (°F) from 1 June through 30 September (adult holding period)										
Location	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007
Battle Creek at Mouth	—	64.0	67.0	67.7	67.2	65.4	66.3	65.4	64.4	66.8

Source: (USFWS 2008)

WATER QUALITY

Little information on water quality in Battle Creek is available. However, it is assumed to be quite good as Battle Creek also provides water to the CNFH.

FLOW CONDITIONS

Two studies were conducted to determine the flows necessary to facilitate fish passage within the Battle Creek watershed (Kier Associates 1999). The results of these two studies were used to develop instream flow alternatives for the Battle Creek Salmon and Steelhead Restoration Project (Reclamation and SWRCB 2005). These new recommended minimum instream flows range from 35 to 88 cfs.

SPAWNING

Prime quality spawning, holding, and rearing habitat for steelhead, and winter-run and spring-run Chinook occurs upstream of Wildcat and Coleman dams on the north and south forks of Battle Creek, respectively. The habitat and water temperatures in these upper stream reaches are excellent for all life stages of salmonids. Battle Creek has complex channel features that create relatively good habitat for Central Valley salmonids including, an abundance of coldwater springs, high natural flows, and continuous flows during the summer months. High quality spawning habitat for spring-run Chinook salmon is primarily located upstream of Wildcat and Coleman dams on the north and south forks of Battle Creek (DWR 2005a).

PASSAGE IMPEDIMENTS/BARRIERS

The mainstem of Battle Creek has had three structures that act as potential impediments to adult anadromous fish migration: (1) the CNFH barrier weir that diverts returning hatchery fish into the hatchery for brood stock collection each year from September through early March; (2) the Orwick seasonal gravel diversion dam; and (3) the tailrace from PG&E's Coleman Powerhouse, which had been known to attract adult Chinook salmon and steelhead into an area with little spawning habitat, but has currently been improved by the construction of a fish exclusion weir in 2004 (DWR 2005a).

In the mid-1990s, the fish ladders at Eagle Canyon on North Fork Battle Creek and PG&E's Colman Dam on South Fork Battle Creek were intentionally closed primarily to manage populations of spring-run Chinook salmon. Closing the ladders limited the amount of stream available for spring-run Chinook salmon that passed the CNFH barrier weir. It was assumed that this would increase the rate at which fish encounter each other during the spawning season, and would reduce entrainment by unscreened diversions.

The North Fork Battle Creek has three dams: (1) Wildcat Dam; (2) Eagle Canyon Dam; and (3) North Battle Creek Dam. All of these structures are located downstream of natural barriers to upstream fish migration. These structures divert water for hydroelectric power production.

The South Fork of Battle Creek also has three hydroelectric diversion dams downstream of natural barriers: (1) South Diversion Dam; (2) Inskip Dam; and (3) Coleman Dam.

HARVEST/ANGLING IMPACTS

Battle Creek supports a popular recreational fishery. As a result, some level of poaching likely occurs. Current fishing regulations do not allow any fishing from the mouth of Battle Creek to 250 feet upstream of the weir at the CNFH. Upstream of that point, catch and release fishing with artificial lures and barbless hooks is allowed from the last Saturday in April to November 15.

WATER TEMPERATURE

DWR has 22 water temperature monitoring locations within the Battle Creek watershed. Field parameters such as dissolved oxygen, electrical conductivity, turbidity, and water temperature have been collected since 1998 (DWR 2005a).

Average daily water temperatures in 1988 and 1989 in Battle Creek above the CNFH approached or exceeded lethal water temperatures for holding and spawning spring-run Chinook salmon during summer months. During the period July 1 to September 14, average water temperature exceeded 66.2°F in all four years, indicating that spring-run Chinook salmon adults holding at the site would be unable to successfully spawn.

Water temperatures in Battle Creek warm at lower elevations due to higher air temperatures. The North Fork above its confluence with the South Fork is the warmest location while those reaches upstream are cooler. Water temperatures generally do not rise significantly between Wildcat Diversion Dam and Eagle Canyon Dam because large amounts of cold spring water enter the creek at Eagle Canyon, located between these two locations. High water temperatures that may occur at these locations are partially a result of low flows related to hydropower operation. Water temperatures become cool enough (i.e., < 66°F) for adult spring-run Chinook holding at Eagle Canyon Diversion Dam and the North Battle Feeder Dam.

During the period July 1 to September 14, 2001, average water temperatures exceeded 66.2°F below the Wildcat Diversion Dam and the Eagle Canyon Diversion Dam, indicating that spring-run Chinook adults at the site would be unable to successfully spawn. During the period September 15 through 30, average water temperatures did not exceed 62°F, indicating that all sites were suitable for spring-run Chinook salmon spawning (Armour 1991), (USFWS 1995d), and (CDFG 1998).

WATER QUALITY

Water quality in Battle Creek is suitable for salmonid spawning.

FLOW CONDITIONS

Monthly average flows in Coleman Canal above the Coleman Forebay (USGS Gage 11376450) from August through October were greater than 250 cfs (1979 to 2001). Results of an IFIM study conducted by the Battle Creek Working Group (Kier Associates 1999), determined that flows necessary to provide 95 percent of the maximum weighted usable area (WUA) for the upper reaches of North Fork Battle Creek would be approximately 60 cfs from August through September. The monthly average flow in North Fork Battle Creek below the diversion to Eagle Canyon power canal (USGS Gage 11376150) from August through November (1995 to 2001) was approximately 30 cfs. The average monthly average flow in North Fork Battle Creek below

the diversion to the Wildcat Channel (USGS Gage 11376160) from August through November (1995 to 2001) was approximately 35 cfs.

Results of the IFIM study conducted by the Battle Creek Working Group (Kier Associates 1999), determined that flows necessary to provide flows that would provide 95 percent of the maximum WUA for the upper reaches of South Fork Battle Creek would be approximately 65 cfs from August through September. The monthly average flow in South Fork Battle Creek at the South Powerhouse power canal (USGS Gage 11376410) from August through November (1980 to 2001) were greater than approximately 150 cfs (KRIS Website 2007).

SPAWNING HABITAT AVAILABILITY

Stream channel conditions in Battle Creek are considered suitable for salmonid production (Battle Creek Watershed Conservancy 2004). Reclamation (2003) cited *in* Battle Creek Watershed Conservancy 2004, assumed that key stream habitat conditions were of sufficient quality that the abundance of threatened or endangered salmonid populations could be substantially increased by increasing instream flows and constructing fish passage facilities at the Battle Creek Hydroelectric Project diversion dams.

SPAWNING SUBSTRATE AVAILABILITY

Brown and Kimmerer (2004) report that areas suitable for salmonid spawning, based on substrate particle size, are relatively scarce. However, they also report that in-river conditions are likely not a limiting factor due to the current low population numbers of targeted species.

PHYSICAL HABITAT ALTERATION

Stream channel conditions in Battle Creek during the late 20th century have been considered suitable for salmonid production. Key stream habitat conditions appear to be of sufficient quality such that the abundance of threatened or endangered salmonid populations could be increased by increasing instream flows and constructing fish passage facilities at the Battle Creek Hydroelectric Project diversion dams. Land management activities currently occurring in the watershed appear to have little impact on the potential to restore anadromous salmonids to this watershed (Battle Creek Watershed Conservancy 2004)

HATCHERY EFFECTS

The CNFH is located on lower Battle Creek and operations of the hatchery may have negative effects on habitat in lower Battle Creek. For example: (1) operations of the fish ladder at the CNFH may deny access to upstream habitat for spring-run Chinook salmon; (2) broodstock selection at the CNFH may have led to hybridization of fall- and spring-run stocks; and (3) excess production of fall-run Chinook salmon may be overwhelming the carrying capacity of habitat in lower Battle Creek (Ward and Kier 1999b).

Stakeholders and agencies interested in the restoration of Battle Creek fisheries have been working to modify facilities at the CNFH with the goal of isolating CNFH operations from Battle Creek. For example, an ozone treatment plant was installed to keep pathogens out of the hatchery water supply, preventing the release of diseased fish to the system. Additionally, proposals had been made (Ward and Kier 1999b), and construction since began in 2008, to

modify the CNFH barrier dam to keep hatchery produced fish out of the main portion of the Battle Creek watershed.

A technical review panel determined that the probability of hybridization between spring-run and fall-run Chinook salmon is unknown (CALFED Bay-Delta Program 2004). While the probability of hybridization is unknown, the potential loss of genetic information through such occurrences could be extremely counter productive to recovery efforts. The review panel recommended that the potential for hybridization be minimized by abandoning restoration of fall and late-fall-run Chinook salmon in Battle Creek, or to reserve those efforts until spring-run Chinook salmon populations have become fully restored (i.e., removed ESA protection). It was recommended by the review panel that passage of fall and late-fall Chinook salmon above the dam, via ladder or jumping, be prevented or reduced to the lowest possible level during the initial stages of recovery. This could be achieved by closing the fish ladder to block fall and late-fall-run Chinook salmon migration.

In order to protect spring-run Chinook salmon from introgressing with fall-run in upper Battle Creek, CNFH changed the timing for closing the barrier weir from September 1 to August 1, i.e., the barrier is now closed the last day of July. Most, if not all, of the spring-run Chinook salmon are believed to have moved above the weir by this time; any spring-run Chinook holding below the weir at its closing could potentially spawn below the weir or enter CNFH and possibly be utilized as broodstock for the fall-run program.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Battle Creek supports a popular recreational fishery. As a result, some level of disturbance of redds by wading anglers likely occurs.

WATER TEMPERATURE

Water temperature problems may occur during some years due to the diversion of coldwater springs into canals away from adjacent stream channels on the North Fork and South Fork of Battle Creek. However, it is unknown the degree to which these operations currently affect the spring-run Chinook salmon juvenile rearing and emigration life stage (Reclamation et al. 2004).

WATER QUALITY

Water quality factors in Battle Creek are not expected to have adverse effects on developing Chinook salmon embryos.

FLOW CONDITIONS

The operations of the Battle Creek Hydroelectric Project causes water level changes in some reaches of Battle Creek that are more frequent and rapid than those which occur naturally. The effects of these flow changes have not been the direct focus of any study to date. However, the Battle Creek Working Group has identified potential rates of flow fluctuation of less than 0.10 feet per hour based on previous studies conducted in the Pacific Northwest (Ward and Kier 1999a).

As part of the Battle Creek Salmon and Steelhead Restoration Project, PG&E, in cooperation with the resource agencies, has agreed to adaptively manage instream flows in Battle Creek by adjusting flows at diversion dams to maintain habitat and prevent redd dewatering events (KRIS Website 2007).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperature problems may occur during some years due to the diversion of coldwater springs into canals away from adjacent stream channels on the North Fork and South Fork of Battle Creek. However, it is unknown the degree to which these operations currently affect the spring-run Chinook salmon juvenile rearing and emigration life stage (KRIS Website 2007).

WATER QUALITY

Water quality factors in Battle Creek are not likely to adversely affect juvenile Chinook salmon.

FLOW CONDITIONS

Powerhouse operations cause flow fluctuations of up to 200 cfs in some reaches of the Battle Creek watershed which could potentially lead to juvenile stranding events. It has been estimated that powerhouse diversions on the North Fork and South Fork of Battle Creek divert up to 97 percent of the natural unimpaired flow (Reclamation et al. 2004).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Land management activities currently occurring in the watershed appear to have little impact on the potential to restore anadromous salmonids to this watershed (Battle Creek Watershed Conservancy 2004). Restoration of riparian corridors in lower Battle Creek are currently underway (Battle Creek Working Group 1999).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Stream channel conditions (e.g., gravel distribution and abundance, sedimentation, channel morphology) in Battle Creek are considered to be suitable for salmonid production (Battle Creek Watershed Conservancy 2004). Similarly, land management activities in the watershed are assumed to have little impact on the potential to restore anadromous salmonids to the system (Battle Creek Watershed Conservancy 2004).

LOSS OF FLOODPLAIN HABITAT

There is little to no flood control capacity in the Battle Creek watershed.

ENTRAINMENT

The high volume of surface water diverted from unscreened agricultural and hydroelectric diversions in Battle Creek constitutes a substantial threat to rearing and emigrating juvenile salmonids. However, it is anticipated the installation of positive fish barrier screens in the near future as part of the proposed water management strategy for the Battle Creek watershed will reduce the amount of juvenile entrainment at water diversions (KRIS Website 2007).

PREDATION

The USFWS has identified predation as one of the ways that juvenile salmonids released from the CNFH may affect natural populations of salmonids (Battle Creek Working Group 1999). However, the actual extent of predation on natural populations by steelhead and Chinook salmon on natural populations is not known (Battle Creek Working Group 1999).

HATCHERY EFFECTS

The USFWS has expressed concern that predation, disease transmission and competition/displacement are ways in which juvenile salmonids released from the CNFH may affect natural salmonid populations (Battle Creek Working Group 1999). The actual extent of these potential impacts is not known, although there is speculation that these factors are minimal or non-existent (Battle Creek Working Group 1999). However, these conclusions were not based on completed investigations. Furthermore, these conclusions that suggest minimal impact were derived during a period when Chinook salmon and steelhead populations were depressed. As restoration of Battle Creek salmonid populations proceed, increased interactions between hatchery operations and natural fish populations are expected, suggesting that more investigations of possible impacts are required (Battle Creek Working Group 1999).

3.3.9.2 UPPER SACRAMENTO RIVER

See Section 3.3.7 for a discussion of potential spring-run Chinook salmon in the upper Sacramento River.

3.3.10 NORTHWESTERN CALIFORNIA DIVERSITY GROUP

The northwestern California spring-run Chinook salmon Diversity Group historically was comprised of populations in Stony, Thomes, Beegum, and Clear creeks (**Figure 3-13**). Spring-run Chinook salmon have likely been extirpated from Stony Creek and only small populations of spring-run Chinook salmon occur in Thomes, Beegum, and Clear creeks.

3.3.10.1 THOMES CREEK

Thomes Creek enters the Sacramento River four miles north of the town of Corning. It flows into the Sacramento Valley from the west, draining a watershed of approximately 188 square miles.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

There are no significant dams on Thomes Creek other than two seasonal diversion dams, one near Paskenta and the other near Henleyville. Several small pump diversions are seasonally operated in the stream (DWR Website 2007b). These dams would be in place during the time when spring-run Chinook salmon would be immigrating to upstream areas and likely present obstacles to upstream immigration. Additionally, gravel mining downstream of the Tehama-Colusa Canal siphon crossing has reportedly resulted in a partial barrier to salmonids returning to Thomes Creek to spawn (Vestra Resources, Inc. 2006).

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Thomes Creek is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only.

WATER TEMPERATURE

During most years, water temperatures during the summer months are likely too warm to support adult spring-run Chinook salmon holding. Chinook salmon utilizing Thomes Creek for spawning likely hold in the mainstem Sacramento River.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life. However, water quality is not likely to cause direct harm to adult salmonids utilizing Thomes Creek as a migration corridor.

FLOW CONDITIONS

Thomes Creek is usually dry or intermittent below the USGS stream gage near Paskenta until the first heavy fall rains occur (DWR Website 2007b). Therefore spring-run Chinook salmon utilization of Thomes Creek would likely only occur during wet years.

Figure 3-13. Northwestern California Spring-run Chinook Salmon Diversity Group

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

There are no significant dams on Thames Creek other than two seasonal diversion dams, one near Paskenta and the other near Henleyville. Several small pump diversions are seasonally operated in the stream (DWR Website 2007b). These dams would be in place during the time when spring-run Chinook salmon would be immigrating to upstream areas and likely present obstacles to upstream immigration.

HARVEST/ANGLING IMPACT

Legal harvest of salmonids in Thames Creek is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only.

WATER TEMPERATURE

Water temperatures in Thames Creek are likely too warm to support spring-run Chinook salmon spawning until at least mid-October.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life. Total phosphorus concentrations are at stimulatory levels for algae (DWR Website 2007b).

FLOW CONDITIONS

Flows in the Thames Creek watershed fluctuate seasonally. Summer low flows are frequently measured at less than 4 cfs, while winter flows often exceed 4,500 cfs. Flows recorded at Paskenta range from zero in 1977 to 37,800 cfs during December 1964. The December 1964 runoff event was triggered by a major rain-on-snow storm. Periodic large floods like the 1964 event can result in tremendous bedload movement (DWR Website 2007b).

Thames Creek is usually dry or intermittent below the USGS stream gage near Paskenta until the first heavy fall rains occur (DWR Website 2007b). Therefore, spring-run Chinook salmon spawning in Thames Creek would likely only occur during wet years.

SPAWNING HABITAT AVAILABILITY

Historically, there was about 30 river miles of potential Chinook salmon habitat available in Thames Creek, of which only the lower 4 miles are currently available (NMFS Website 2005). A small spring-run Chinook salmon run was known to utilize habitat about 8 miles upstream of the town of Paskenta when streamflow was adequate (NMFS Website 2005).

PHYSICAL HABITAT ALTERATION

Little data on habitat alteration within the Thomes Creek Watershed is available. However, Gauthier and Hoover (2005) report that Thomes Creek is one of the largest sediment producers in the western United States. Excessive sediment loading is likely caused by land use practices and road building in the upper watershed.

HATCHERY EFFECTS

The FRFH produces spring-run Chinook salmon and the current hatchery practice of releasing juveniles into San Pablo Bay increases potential straying rates. Hatchery effects are likely minimal because Thomes Creek does not support a consistent or sustaining population of spring-run Chinook salmon.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because angling is permitted in Thomes Creek, it is possible that anglers could disturb redds by wading through the stream.

WATER TEMPERATURE

Water temperatures in anadromous salmonid accessible reaches of Thomes Creek likely are not suitable for Chinook salmon embryo incubation until at least mid-October.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life. Total phosphorus concentrations are at stimulatory levels for algae (DWR Website 2007b). These water quality factors would likely decrease survival of Chinook salmon embryos incubating in Thomes Creek.

FLOW CONDITIONS

Thomes Creek has an unimpaired natural pattern of flashy winter and spring flows and very low summer and fall flows creating an environment of fairly inconsistent habitat (CALFED 2000d). Inconsistent flows, particularly during the fall and early winter months, promote an increased potential for redd dewatering. For example, if salmon construct a redd and spawn in shallow water during a period of high flows, a subsequent period of lower flows could result in the redd becoming exposed to dry conditions.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in Thomes Creek likely become unsuitable for rearing Chinook salmon by late spring.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life. Total phosphorus concentrations are at stimulatory levels for algae (DWR Website 2007b).

FLOW CONDITIONS

Thomes Creek has an unimpaired natural pattern of flashy winter and spring flows and very low summer and fall flows creating an environment of fairly inconsistent habitat (CALFED 2000d). These conditions are not conducive to supporting a persistent population of Chinook salmon. However, during wet years some Chinook salmon spawning may occur and lower Thomes Creek could be utilized for some juvenile rearing or, during wet years, some non-natal juvenile rearing may occur.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

The lower reach of Thomes Creek has been significantly altered by the construction of flood control levees and bank protection measures (i.e., riprapping) (CALFED 2000d). These measures have resulted in reduced habitat for juvenile Chinook salmon.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Channel modification projects designed to prevent flood-related damage (e.g., levee construction and bank riprapping) have degraded natural processes which serve to recruit gravel, provide instream cover and forage, and provide habitat diversity in lower Thomes Creek.

LOSS OF FLOODPLAIN HABITAT

The construction of levees and bank riprapping of lower Thomes Creek have disconnected the channel from its historic floodplain, thereby preventing the recruitment of large woody debris and natural processes associated with periodic floodplain inundation.

ENTRAINMENT

Agricultural diversions on Thomes Creek are unscreened and any outmigrating salmonids likely are susceptible to entrainment in the diversions.

PREDATION

Sacramento pikeminnow is likely the most important predator of juvenile salmonids in Thomes Creek. While the pikeminnow is native to these waters, habitat alteration may have changed the predator-prey dynamics in the system conferring an advantage to pikeminnow.

HATCHERY EFFECTS

The trucking of FRFH spring-run Chinook salmon, and their release into San Pablo Bay, facilitates the straying of adult spring-run hatchery returns and could potentially threaten any native spring-run in Thomes Creek.

3.3.10.2 COTTONWOOD/BEEGUM CREEK

Cottonwood Creek drains the west side of the Central Valley and enters the Sacramento River a short distance downstream from the Redding-Anderson area. Beegum Creek is a tributary to Cottonwood Creek and supports most spring-run Chinook salmon habitat in the Cottonwood Creek watershed. Cottonwood Creek is likely used only as a migration corridor.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

There are no storage reservoirs or irrigation diversions in Cottonwood creek, however, the ACID siphon goes under the creek and can be a passage impediment during fall and spring flows.

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Cottonwood Creek and its tributaries is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only.

WATER TEMPERATURE

Clark (1929) reported that Cottonwood Creek formerly supported spring-run Chinook salmon. Currently, other than Beegum Creek, spring-run Chinook salmon likely do not utilize Cottonwood Creek except as a migration corridor to Beegum Creek.

High water temperatures in Cottonwood Creek likely present a thermal barrier to migrating spring-run Chinook salmon beginning in May. This population has been observed to arrive earlier than most spring-run due to high water temperatures at the mouth of Cottonwood Creek (CDFG 2004b).

WATER QUALITY

Water quality in Cottonwood Creek does not likely adversely affect immigrating adult salmonids. However, more sensitive life stages may be affected as discussed below.

FLOW CONDITIONS

During spring of drier years, low flows in Cottonwood Creek may impede or prevent the upstream migration of spring-run Chinook salmon to over-summer holding areas (CALFED 2000d).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Spawning surveys have confirmed that spring-run Chinook salmon are both spatially and temporally isolated from fall-run in Beegum Creek (CDFG 2004b). Potential spawning of Chinook salmon exhibiting spring-run characteristics in Cottonwood Creek is not known but if it does occur, both spatial and temporal overlap in spawning likely occurs due to upstream passage impediments/barriers (such as instream gravel mining operations).

HARVEST/ANGLING IMPACT

Legal harvest of salmonids in Cottonwood Creek and its tributaries is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only.

WATER TEMPERATURE

Spawning in Beegum Creek by spring-run Chinook salmon is delayed until mid- to late-October, which is later than timing observed for other Central Valley spring-run populations. This delay in spawning timing is likely due to high water temperatures extending through September in Beegum Creek (CDFG 2004b).

WATER QUALITY

Water quality in Cottonwood or Beegum Creeks likely has no direct adverse effects on spawning salmonids. However, more sensitive life stages may be affected as discussed below.

FLOW CONDITIONS

Flows in Beegum Creek, where most spring-run Chinook salmon spawning occurs likely mimics historic patterns.

SPAWNING HABITAT AVAILABILITY

Currently, approximately 8 river miles of habitat are available in Beegum Creek for spring-run Chinook salmon (NMFS Website 2005). Recent spawning escapements to Beegum Creek are depicted in **Figure 3-14**.

Figure 3-14. Beegum Creek Spawning Escapement Estimates (1993 - 2007)

Source: (CDFG 2009)

SPAWNING SUBSTRATE AVAILABILITY

Coarse sediment supply in Cottonwood Creek is adversely affected by gravel mining. Mining reduces the natural gravel recruitment to potential spawning areas potentially resulting in channel armoring.

PHYSICAL HABITAT ALTERATION

There are no large water development projects or comprehensive flood control measures in the Cottonwood Creek drainage. Habitat alteration has arisen from timber harvest in the upper watershed, grazing in the middle watershed and extensive gravel mining in the lower watershed.

HATCHERY EFFECTS

The trucking of FRFH spring-run, and their release into San Pablo Bay, facilitates the straying of adult spring-run hatchery returns and may threaten the Cottonwood/Beegum Creek spring-run population. Genetic integrity of the Cottonwood/Beegum Creek spring-run may be compromised, and their fitness and productivity lowered. The hatchery stock would compete with native spring-run over available holding and spawning habitat, with the possibility of transferring the Feather River strain of IHNV to the local population.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because angling is permitted in Cottonwood Creek and its tributaries, it is possible that anglers could disturb redds by wading through the stream.

WATER TEMPERATURE

Spawning in Beegum Creek by spring-run Chinook salmon is delayed until mid- to late-October, which is later than timing observed for other Central Valley spring-run populations. This delay in spawning timing is likely due to high water temperatures extending through September in Beegum Creek (CDFG 2004b). Because spawning is delayed, it is likely that water temperatures for embryo incubation are suitable in Beegum Creek.

WATER QUALITY

The surface water quality of streams draining eastward from the Coast Range is generally poor. These streams generally have very high suspended sediment loads due to the metavolcanic bedrock and schist formations which produce clays that stay in suspension during turbulent flow conditions. Soil disturbance within these watersheds can accelerate erosion and sedimentation processes and lead to increased metal and nutrient concentrations. High concentrations of metals and nutrients are commonly present during both low flow and storm runoff events. These concentrations frequently exceed water quality criteria established for the protection of beneficial use or the maintenance of aquatic life. Total phosphorus concentrations are at stimulatory levels for algae (DWR Website 2007b).

FLOW CONDITIONS

Flows in Beegum Creek, where Chinook salmon embryos would be incubating are not controlled and mimic historic conditions.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures in Beegum Creek are likely cool enough to support Chinook salmon juvenile rearing, however, water temperatures downstream in Cottonwood Creek likely become too warm by early summer such that Cottonwood Creek likely only serves as a migration corridor.

WATER QUALITY

Two major instream gravel extraction projects operate in Cottonwood Creek below the Interstate 5 bridge (CALFED 2000d) which likely degrade water quality for a short distance downstream.

FLOW CONDITIONS

There are no water development projects on Cottonwood Creek therefore, flows are unregulated. Runoff from the watershed is flashy: high in the rainy season and low in the dry season. The baseflow component of the runoff is small.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Extensive gravel mining occurs in lower Cottonwood Creek, which has resulted in a loss of riparian habitat. The remaining portion of the watershed is primarily rural which has helped avoid adverse impacts to the riparian areas.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

There has been little development in the Cottonwood Creek watershed. This has resulted in Cottonwood Creek maintaining most of its historic characteristics and function.

LOSS OF FLOODPLAIN HABITAT

No comprehensive flood control measures have occurred in the Cottonwood Creek drainage resulting in the creek retaining its connection to the floodplain. However, extensive gravel mining occurs in lower Cottonwood Creek, which has resulted in a loss of riparian habitat and floodplain. The remaining portion of the watershed is primarily rural which has helped avoid adverse impacts to the riparian areas.

ENTRAINMENT

There are irrigation diversions but no storage reservoirs on the Cottonwood Creek. Outmigrating juvenile spring-run Chinook salmon could potentially be entrained at unscreened diversions.

PREDATION

Sacramento pikeminnow is likely the most important predator of juvenile salmonids in Cottonwood/Beegum Creek system. While the pikeminnow is native to these waters, habitat alteration may have changed the predator prey dynamics in the system conferring an advantage to pikeminnow.

HATCHERY EFFECTS

3.3.10.3 CLEAR CREEK

Clear Creek is a westside tributary of the upper Sacramento River and enters the river at RM 289 just south of Redding.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Whiskeytown Dam at RM 18.1 is an impassable barrier to adult anadromous salmonids and marks the upstream extent of potential Spring-run Chinook salmon habitat. Prior to 2000, the McCormick-Saeltzer Dam presented a barrier to upstream migration for anadromous salmonids. Following removal of the Dam in 2000, access to approximately 12 miles of coldwater habitat upstream to Whiskeytown Dam was restored.

HARVEST/ANGLING IMPACTS

Legal harvest of salmonids in Clear Creek and its tributaries is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only.

WATER TEMPERATURE

Water temperature targets in Clear Creek are to maintain water temperatures under 60°F during the spring-run Chinook salmon adult immigration and holding life stage period. These water temperatures are maintained by controlling flows from Whiskeytown Dam. However, under the

current flow schedule (see below) it may not be possible to maintain water temperatures under 60°F during particularly hot time periods (USFWS 2003b).

WATER QUALITY

The impact of significant accumulations of mercury is an issue in Clear Creek. Mercury contamination is the result of historic gold mining practices in the watershed (CDFG 2004b).

FLOW CONDITIONS

Prior to 1999, streamflows below Whiskeytown Dam were reduced annually to approximately 50 cfs during the summer and increased in early October to provide suitable water temperatures for fall-run Chinook salmon spawning. A flow schedule for Clear Creek has been incorporated into the CVPIA AFRP that is designed to maintain flows in Clear Creek that will allow water temperatures conducive to all spring-run Chinook salmon life stages. Currently the release schedule call for maintenance of 200 cfs flows from October 1 to June 1 and 150 cfs, or less, from July through September in order to maintain water temperatures below 60°F (USFWS 2003b). However, a flow experiment in August 1998 demonstrated that during hot periods, flows higher than 150 cfs may be required to meet temperature targets (USFWS 2003b).

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

Historically, there were approximately 25 river miles of Chinook salmon habitat available for use in Clear Creek of which only 18.1 are currently accessible (NMFS Website 2005). Presumably this allowed for some spatial segregation between the spring and fall runs. Now there is likely some overlap in spawning habitat creating a potential for hybridization between spring-run and early spawning fall-run Chinook salmon.

Since 2003, a temporary picket weir has been installed from approximately mid August to mid November to spatially segregate spring-run from fall-run. Surveys conducted annually since 2003, during the period that the weir is installed has documented a range of 37 to 81 redds upstream of the weir (USFWS).

HARVEST/ANGLING IMPACT

Legal harvest of salmonids in Clear Creek and its tributaries is not permitted. Angling is permitted but restricted to barbless hooks and artificial flies and lures only.

WATER TEMPERATURE

Water temperature targets in Clear Creek are to maintain water temperatures under 56°F during the spring-run Chinook salmon spawning life stage period. These water temperatures are maintained by controlling flows from Whiskeytown Dam. However, under the current flow schedule (see below) it may not be possible to maintain water temperatures under 56°F during September to allow for early spawning spring-run Chinook salmon (USFWS 2003b). Currently, the 60°F to 56°F transition date is set at September 15 (USFWS 2003b).

WATER QUALITY

The impact of significant accumulations of mercury is an issue in Clear Creek. Mercury contamination is the result of historic gold mining practices in the watershed (CDFG 2004b)

FLOW CONDITIONS

Prior to 1999, streamflows below Whiskeytown Dam were reduced annually to approximately 50 cfs during the summer and increased in early October to provide suitable water temperatures for fall-run Chinook salmon spawning. A flow schedule for Clear Creek has been incorporated into the CVPIA Anadromous Fisheries Restoration Program Plan that is designed to maintain flows in Clear Creek that will allow water temperatures conducive to all spring-run Chinook salmon life stages. Currently the release schedule call for maintenance of 200 cfs flows from October 1 to June 1 and 150 cfs, or less, from July through September in order to maintain water temperatures below 60°F (USFWS 2003b).

SPAWNING HABITAT AVAILABILITY

Currently, approximately 18.1 river miles are available for Chinook salmon spawning in Clear Creek (NMFS Website 2005). Recent spring-run Chinook salmon escapement estimates are depicted in **Figure 3-15**.

Figure 3-15. Index of Clear Creek Spring-Run Chinook Salmon Escapement (1999 – 2008).

Source: (CDFG 2009)

SPAWNING SUBSTRATE AVAILABILITY

The construction of Whiskeytown Dam, gold mining, and significant gravel mining in the Clear Creek watershed has diminished suitable spawning gravel substrate. Currently, gravel replacement projects are being conducted in the watershed (CDFG 2004b).

PHYSICAL HABITAT ALTERATION

The Clear Creek watershed has undergone extensive modification because of Whiskeytown Dam. Currently, Whiskeytown Dam diverts most of the Clear Creek natural streamflow to Spring Creek. However, extensive rehabilitation efforts are currently underway in the watershed.

HATCHERY EFFECTS

In order to reduce mortality associated with downstream migration subsequent to hatchery releases, Central Valley hatchery production is often trucked to San Pablo Bay for release. This practice likely increases straying rates with the potential for returning hatchery adults to hybridize with naturally spawning Chinook salmon throughout the Central Valley (Williams 2006). Due to the proximity of the Feather River to Clear Creek, there is a potential risk of introgression of Clear Creek spring-run with Feather River Hatchery spring-run and fall-run Chinook salmon escapement.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Because angling is permitted in Clear Creek and its tributaries, it is possible that anglers could disturb redds by wading through the stream.

WATER TEMPERATURE

Water temperature targets in Clear Creek are to maintain water temperatures under 56°F during the spring-run Chinook salmon embryo incubation life stage period. These water temperatures are maintained by controlling flows from Whiskeytown Dam. However, under the current flow schedule (see below) it may not be possible to maintain water temperatures under 56°F during the first part of September to accommodate early spawners (USFWS 2003b). Currently, the 60°F to 56°F transition date is set at September 15 (USFWS 2003b).

WATER QUALITY

The impact of significant accumulations of mercury is an issue in Clear Creek. Mercury contamination is the result of historic gold mining practices in the watershed (CDFG 2004b). Mercury is particularly detrimental to developing embryos.

FLOW CONDITIONS

Prior to 1999, streamflows below Whiskeytown Dam were reduced annually to approximately 50 cfs during the summer and increased in early October to provide suitable water temperatures for fall-run Chinook salmon spawning. A flow schedule for Clear Creek has been incorporated into the CVPIA AFRP that is designed to maintain flows in Clear Creek that will allow water temperatures conducive to all spring-run Chinook salmon life stages. Currently the release schedule call for maintenance of 200 cfs flows from October 1 to June 1 and 150 cfs, or less, from July through September in order to maintain water temperatures below 60°F (USFWS 2003b).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperature targets in Clear Creek are to maintain water temperatures under 60°F during the spring-run Chinook salmon juvenile rearing and downstream movement life stage period. These water temperatures are maintained by controlling flows from Whiskeytown Dam. However, under the current flow schedule (see below) it may not be possible to maintain water temperatures under 60°F during particularly hot time periods (USFWS 2003b).

WATER QUALITY

The impact of significant accumulations of mercury is an issue in Clear Creek. Mercury contamination is the result of historic gold mining practices in the watershed (CDFG 2004b).

FLOW CONDITIONS

Prior to 1999, streamflows below Whiskeytown Dam were reduced annually to approximately 50 cfs during the summer and increased in early October to provide suitable water temperatures for fall-run Chinook salmon spawning. A flow schedule for Clear Creek has been incorporated into the CVPIA Anadromous Fisheries Restoration Program Plan that is designed to maintain flows in Clear Creek that will allow water temperatures conducive to all spring-run Chinook salmon life stages. Currently the release schedule call for maintenance of 200 cfs flows from October 1 to June 1 and 150 cfs, or less, from July through September in order to maintain water temperatures below 60°F (USFWS 2003b).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Over 30 years of gravel mining in Clear Creek has led to a reduction in riparian habitat along the lower sections (CDFG 2004b). Riparian habitat provides cover for rearing juveniles as well as insect habitat that serves as an important food source.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Whiskeytown Dam diverts most of the historic flow from Clear Creek into Spring Creek and also regulates flows in Clear Creek such that natural flow regimes no longer occur.

LOSS OF FLOODPLAIN HABITAT

Because Clear Creek flows are regulated, the channel has become incised and some connection to the historic flood plain has been lost.

ENTRAINMENT

The level of potential entrainment that may occur in Clear Creek has not been investigated.

PREDATION

Sacramento pikeminnow is likely the most important predator of juvenile salmonids in Clear Creek. While the pikeminnow is native to these waters, habitat alteration may have changed the predator prey dynamics in the system conferring an advantage to pikeminnow.

HATCHERY EFFECTS

The CNFH on Battle Creek produces and releases both fall-run Chinook salmon and steelhead. Current hatchery production targets are the release of 12 million fall-run Chinook salmon smolts and 500,000 steelhead yearlings annually (DWR 2004a). The fish are released on station. The Chinook release has the potential for creating competition for habitat and food resources for

juvenile spring-run Chinook salmon and the steelhead are of sufficient size to be a significant predator on juvenile Chinook salmon once they have moved out into the Sacramento River.

3.3.11 SUB-ADULT AND ADULT OCEAN RESIDENCE

3.3.11.1 HARVEST

The majority of ocean harvest of Central Valley Chinook salmon stocks occur in the recreational and commercial hook-and-line fisheries off the coasts of California and Oregon (Allen and Hassler 1986). Ocean harvest rate of Central Valley spring-run Chinook salmon is a function of the Central Valley Index, which is defined as the ratio of ocean catch of all Central Valley Chinook salmon south of Point Arena, California to the sum of this catch and the escapement of Chinook salmon to Central Valley streams and hatcheries. The CVI ranged from 0.55 to 0.80 from 1970 to 1995. In the mid 1990s harvest restrictions designed to protect winter-run Chinook salmon reduced the CVI. For example, in 2001 the CVI was 0.27.

Direct estimates of spring-run Chinook salmon ocean harvest are available due to a life history investigation that has coded-wire tagged wild Butte Creek spring-run Chinook salmon juveniles for roughly a decade. Analysis using these CWT'd cohorts has provided evidence that ocean harvest of Butte Creek spring-run Chinook salmon has ranged from 36 percent to 59 percent (Grover *et al.* 2004; McReynolds *et al.* 2007). Although CDFG conducts intensive carcass surveys in Butte Creek to recover and examine a high number of carcasses (and that all spring-run Chinook salmon cwt recoveries are expanded for effort), it should be noted that these estimates (on ocean harvest) could be over-estimates if CWT'd fish that survive and return to Butte Creek as adults are not detected. It also should be noted that ocean harvest rates of fall-run Chinook salmon from the Klamath River system, which have an ocean distribution similar to that of Central Valley spring-run Chinook salmon, are considerably lower than the Butte Creek spring-run Chinook salmon rate (pcouncil.org).

Another approach to understanding the ocean harvest rate of Central Valley spring-run Chinook salmon is to look at the ocean harvest of winter-run Chinook salmon. A biological opinion on the winter-run Chinook salmon ocean harvest suggests that for brood years 1998, 1999, and 2000, the spawner reduction rates associated with winter-run ocean harvest were 0.26, 0.23, and 0.24, respectively. The spawner reduction rate is the observed fishery mortality in terms of adult-equivalents (fish that are expected to survive natural mortality and spawn) divided by the predicted number of spawners that would survive natural mortality in the absence of fishery mortality (NMFS 200b).

Spring-run Chinook salmon ocean harvest is expected be similar to that of winter-run Chinook salmon, if not higher. A spring-run Chinook salmon ocean harvest level of at least approximately 25 percent represents a substantial stressor to the ESU.

3.3.11.2 OCEAN CONDITIONS

The general diets of salmonids in coastal waters are fairly well known for all salmon species in much of the continental shelf region off the West Coast and Alaska. Quantitative studies of the diet of juvenile salmonids in the California Current include those by MacFarlane and Norton (2002) for California, which are most relevant to the Central Valley spring-run Chinook salmon

ESU. This study found intra-specific differences in the type and size of prey consumed, with coho salmon, Chinook salmon, and cutthroat trout tending to be mainly piscivorous. However, ontological shifts to larger more evasive occurring during later life-stages (Brodeur *et al.* 2003). In addition, inter-annual and intra-annual differences in prey availability can lead to major differences in the diet composition of salmonids in the marine environment. The studies conducted to date have found that juvenile salmonids are highly opportunistic in their feeding habits and tend to select the most visually obvious prey within the preferred size range.

Brodeur and Pearcy (1992b) found that juvenile Chinook and coho salmon have the potential to easily exhaust prey resources during years when ocean productivity is low (e.g., El Niño), but during most years they consume less than 1 percent of the total prey production.

In recent years scientific evidence supports hypotheses about the direct and indirect effects of climate change on ocean productivity, and thereby its effects on salmon. Most of this research has focused on the effects of oceanic climate change on the growth and abundance of salmonids (Hollowed *et al.* 2001; Kruse 1998; Myers *et al.* 2000; Pearcy 1997). Two of the most researched phenomena are the ENSO and the PDO. ENSO is a short-term (8 to 15 months) climate change event that occurs at irregular intervals (approximately every 3 to 7 years) and alternates between two phases, the El Niño (warm) and the La Nina (cool).

The PDO is a multi-decadal (20 to 30 year) ENSO-like pattern of North Pacific climate change. The PDO seems to be associated with an inverse relationship between salmon abundance in the Alaska and the U.S. Pacific Coast regions. During a positive PDO phase, the abundance of Alaska salmon is high, and the abundance of U.S. West Coast salmon is low. An abrupt change between positive and negative PDO phases is referred to as a *regime shift*.

ENSO has been shown to produce dramatic effects on marine communities. Alterations in the physical oceanographic properties of the marine environment can be observed as far north as Alaska. Less known is the phenomenon of La Nina, the cool phase of ENSO events that follows El Niño. During the 1982-1983 El Niño event, there were observable alternations in oceanic plankton distributions, fish community structure, and reduced ocean catches off the coastal waters of southern California. Along central California coast, the 1992-1993 El Niño corresponded to delayed phytoplankton blooms, changes in the abundance and distribution of invertebrates, and an increase in the productivity of southern fish species. However, there was a dramatic decline in the northerly rockfish species. More recently, the largest decline in macrozooplankton abundance off central southern California occurred during the 1997-1998 El Niño (Pearcy 1997).

Changes in the physiology and behavior of salmonid populations have been recorded during ENSO events. Reduced condition and growth of sockeye salmon in the Gulf of Alaska during the 1997-1998 El Niño event was related to alterations in the primary prey base. Lower survival rates of juvenile coho salmon upon entering the ocean, higher mortality of adult coho, and reduced size in both coho and Chinook salmon occurred off the coast of Oregon during the 1982-1983 El Niño (Pearcy 1997).

In a study conducted by MacFarlane and Norton (2002) during the 1997-1998 El Niño event on juvenile Chinook salmon in the Gulf of the Farallones, an embayment on the central California coast. The Gulf of the Farallones is a large section of the continental shelf extending from Pt. Reyes, north of San Francisco Bay to the Farallon Islands. It receives freshwater outflow from the Sacramento and San Joaquin rivers. It is the point of ocean entry for an estimated 60 million Chinook salmon smolts spawned from four runs; fall, late-fall, winter, and spring in streams and hatcheries of the Central Valley.

Relative growth rates of juvenile Chinook salmon were estimated from daily otolith increment width of individuals captured via trawl at locations in the Gulf of the Farallones. Plankton samples were also collected at 5 meters and 15 to 25 meters below the surface to estimate secondary productivity and zooplankton composition. The mean otolith increment widths were used as an index of somatic growth during the first 100 days after leaving the Bay-Delta. Growth rate indices for juvenile salmonids caught during the 1998 El Niño period were significantly greater ($P < 0.0001$) than for fish collected in 1999. Juvenile salmon in the Gulf of the Farallones not only grew faster and had greater lipid concentrations during the El Niño period, their condition (Fulton's K-factor) was better as well. In 1998, mean K increased to approximately 1.42 for gulf salmon from approximately 1.03 at ocean entry, compared with a change from 1.04 at ocean entry to 1.32 in the gulf during 1999.

Primary productivity, indexed by chlorophyll *a* concentrations, was similar between the two years, however, the distribution of phytoplankton differed. In 1998, phytoplankton were distributed within the gulf on the continental shelf to the west. Greater nutrient freshwater influx coupled with higher sea surface temperatures in 1998 may have accounted for the higher productivity in the gulf during the El Niño event. These data indicate that the 1997-1998 El Niño event was not detrimental to juvenile Chinook salmon growth during the earliest stages their life cycle in the marine environment.

A dramatic increasing trend in the abundance of Alaska salmon that began in the late 1970s has been correlated with relatively warmer sea surface temperatures in the North Pacific. Hare and Matura (2001) hypothesized that a sharp negative shift in the PDO climate index in the fall of 1998 may signify a climate change event that will reverse salmon production trends that began in the 1970s. Since the 1990s Western Alaska has observed extremely low Chinook salmon and chum salmon returns, but returns of salmon in the south-central and southeast of Alaska have at times reached historical highs (ADFG 2002). In general, escapement data indicate that salmon returns in many U.S. Pacific Northwest rivers have improved since the late 1990s.

3.4 STRESSOR PRIORITIZATION

3.4.1 STRESSOR MATRIX DEVELOPMENT

3.4.1.1 STRESSOR MATRIX OVERVIEW

Stressor matrices, in the form of Microsoft Excel spreadsheets, were developed to structure the spring-run Chinook salmon diversity group, population, life stage, and stressor information into hierarchically related tiers so that stressors within each diversity group and population in the ESU could be prioritized. The individual tiers within the matrices, from highest to lowest, are:

(1) diversity group; (2) population; (3) life stage; (4) primary stressor category; and (5) specific stressor. These individual tiers were related hierarchically so that each variable within a tier had several associated variables at the next lower tier, except at the lowest tier. The three diversity groups were equally weighted in order to be consistent with the recovery criteria described in this recovery plan, which were, in-part, based on the “representation and redundancy” rule described in Lindley *et al.* (2007). This rule reflects the importance of having multiple diversity groups comprised of multiple independent populations in order to recover the ESU (Lindley *et al.* 2007).

The general steps required to develop and utilize the spring-run stressor matrices are described as follows:

1. Each population within a diversity group was weighted so that all population weights in the diversity group summed to one;
2. Each life stage within the population was weighted so that all life stage weights in the population summed to one;
3. Each primary stressor category within a life stage was weighted so that all primary stressor category weights in a life stage summed to one;
4. Each specific stressor within a primary stressor category was weighted so that all specific stressor weights in a primary stressor category summed to one;
5. A composite weight for each specific stressor was obtained by multiplying the product of the population weight, the life stage weight, the primary stressor weight, and the specific stressor weight by 100;
6. A normalized weight for each specific stressor was obtained by multiplying the composite weight by the number of specific stressors within a particular primary stressor group; and
7. The stressor matrix was sorted by the normalized weight of the specific stressors in descending order.

The completed stressor matrix sorted by normalized weight is a prioritized list of the life stage-specific stressors affecting the ESU. For spring-run Chinook salmon, threats were prioritized within each diversity group as well as within each population. Specific information explaining the individual steps taken to generate these prioritized lists is provided in the following sections.

3.4.1.2 POPULATION IDENTIFICATION AND RANKING

The threats assessment for the Central Valley spring-run Chinook salmon ESU included rivers that both historically supported and currently support spring-run Chinook salmon populations. Lindley *et al.* (2004), which describes the population structure of threatened and endangered Chinook salmon ESUs in California's Central Valley Basin was used to identify 12 individual rivers that historically supported and currently support spring-run Chinook salmon populations. These 12 spring-run Chinook salmon populations were categorized into three diversity groups as described by Lindley *et al.* (2007) (**Table 3-4**).

Table 3-4. Extant Central Valley Spring-run Chinook Salmon Populations Included in the Threats Assessment Categorized by Diversity Group

-------------------------------------------------------------------------------------------------------------	----------------------------------------	--------------------------------------------------------

Source: (Lindley *et al.* 2007)

Several steps were taken to obtain a population weight. First, for a given population, each of the weighting characteristics listed below received a whole number score of one through four. For example, a population with high abundance and low genetic integrity received a population abundance score of four and a genetic integrity score of one. After scores were identified for the weighting characteristics for each population, the sum of the weighting characteristic scores for one population was divided by the total sum of the scores for all populations within the diversity group. The resultant quotient is the population weight, thus the population weights within a diversity group sum to one. The weighting characteristic scores and population weights for each spring-run Chinook salmon population in each of the three diversity groups are presented in **Tables 3-5, 3-6, and 3-7**.

Within each of the three diversity groups, populations were weighted relative to one another by scoring the weighting characteristics described below.

- ❑ Population abundance
 - A population with relatively low returning adult abundance estimates would receive a low score; highly abundant populations would receive a high score
- ❑ Genetic integrity
 - A population supported primarily by hatchery-produced fish would receive a low score, whereas a population with little to no influence of hatchery-produced fish would receive a high score
- ❑ Population spatial structure
 - A population that is geographically isolated from other populations in the ESU enhances the ESU's spatial structure and would thus receive a high score; populations in close geographic proximity to one another would receive a low score
- ❑ The extent to which the current population is genetically and behaviorally representative of the natural historic population
 - A population that was once extirpated and has been re-established would receive a low score
 - A population supported by hatchery production would receive a low score (i.e., 1 or 2 depending on the degree of hatchery influence)
 - A historically dependent population would receive a low score
 - A population characterized by a consistent and relatively stable returning adult population comprised of naturally-produced fish would receive a high score

Population Weight (Sum to 1)	0.38	0.38	0.25

- Whether the population primarily functions as a source or sink
 - A population with consistently high abundance may serve as a source of individuals to other populations and would receive a high score
 - Populations primarily dependent on fish straying from other populations would receive a low score

- The general habitat quantity and quality available in the population's natal stream

- Several variables were considered when evaluating salmonid habitat availability including, but not limited to flow, water temperature, instream cover, riparian habitat, substrate, and the presence of passage impediments/barriers
- The restoration potential of the population's natal stream
 - Populations on rivers/streams that can be relatively easily restored to increase or improve the amount of habitat available to the fish would receive a high score, whereas populations on rivers with limited habitat and large impassable dams would receive a low score
- Whether the population exhibits a distinctive life history
 - Rivers with habitat conditions amenable to a stream-type life history and/or rivers with fish exhibiting a distinctive stream-type life history would receive a high score; populations exhibiting an ocean-type life history would receive a low score

These eight population characteristics were identified to reflect the VSP framework (McElhany *et al.* 2000) in an attempt to best weight populations according to their relative importance to the viability of the diversity group they belong to. Although some redundancy exists in the specific factors considered among the eight population characteristics, each characteristic uniquely reflects the VSP framework.

3.4.1.3 LIFE STAGE IDENTIFICATION AND RANKING

The life stage identification and ranking procedures for spring-run Chinook salmon were identical to that of winter-run Chinook salmon. Please see Section 2.4.1.3 for a description of those procedures. The life stage weightings for each spring-run Chinook salmon population are presented in Attachment B.

3.4.1.4 STRESSOR IDENTIFICATION AND RANKING

The stressor identification and ranking procedures for spring-run Chinook salmon were identical to that of winter-run Chinook salmon. Please see Section 2.4.1.4 for a description of those procedures.

3.4.2 STRESSOR MATRIX RESULTS

3.4.2.1 NORTHERN SIERRA NEVADA DIVERSITY GROUP

The northern Sierra Nevada spring-run Chinook salmon diversity group is comprised of the Feather and Yuba rivers, and Butte, Big Chico, Deer, Mill, and Antelope creeks. Stressors of very high importance were identified for all populations and life stages in this diversity group including:

- Passage impediments and/or barriers affecting adult immigration in all of the rivers and creeks;
- High water temperatures during the adult immigration and holding life stage in Butte, Big Chico, Deer, Mill, and Antelope creeks;
- The Fish Barrier Dam and Oroville Dam on the Feather River, and Englebright Dam on the Yuba River as barriers blocking access to historic holding and spawning habitats, a

critical factor in the hybridization with fall-run Chinook salmon, and as limiting the instream supply of spawning gravels;

- ❑ Entrainment in the Delta, in the lower and middle sections of the Sacramento River, in Antelope Creek, and in the Yuba River;
- ❑ Sedimentation impacts on the embryo incubation life stage in Butte, Deer, Mill, and Antelope creeks; and
- ❑ Numerous factors affecting the juvenile rearing and outmigration life stage in the Delta and lower Sacramento River such as loss of floodplain habitat, loss of natural river morphology and function, loss of riparian habitat and instream cover, and predation.

Many additional stressors were identified as having a very high importance to the northern Sierra Nevada spring-run Chinook salmon diversity group. The complete prioritized list of life-stage specific stressors to this diversity group is displayed in Attachment B.

3.4.2.2 BASALT AND POROUS LAVA DIVERSITY GROUP

The basalt and porous lava spring-run Chinook salmon diversity group is comprised of the Battle Creek and the mainstem Upper Sacramento River. Stressors of very high importance were identified for both populations and life stages in this diversity group including:

- ❑ RBDD on the Sacramento River and the dams on the North and South forks of Battle Creek as passage impediments to the adult immigration and holding life stage;
- ❑ Keswick Dam as a barrier blocking access to historic holding and spawning habitats, a critical factor in the hybridization with fall-run Chinook salmon, and as limiting the instream supply of spawning gravels;
- ❑ Releases of yearling steelhead produced at CNFH competing with, and more importantly, preying on naturally spawned juvenile Chinook salmon in Battle Creek;
- ❑ Low-flow conditions in Battle Creek during the adult immigration and holding life stage;
- ❑ Entrainment at individual diversions in the Delta, lower and middle Sacramento River, and in Battle Creek;
- ❑ Numerous factors affecting the juvenile rearing and outmigration life stage in the Delta, and lower, middle, and upper Sacramento River such as loss of floodplain habitat, loss of natural river morphology and function, loss of riparian habitat and instream cover, and predation.

Additional stressors were identified as having a very high importance to the basalt and porous lava spring-run Chinook salmon diversity group. The complete prioritized list of life-stage specific stressors to this diversity group is displayed in Attachment B.

3.4.2.3 NORTHWESTERN CALIFORNIA DIVERSITY GROUP

The northwestern California spring-run Chinook salmon diversity group is comprised of the Thomes, Cottonwood/Beegum, and Clear creeks. Stressors of very high importance were identified for all populations and life stages in this diversity group including:

- ❑ High water temperatures in Thomes, Cottonwood/Beegum, and Clear creeks during the adult immigration and holding and spawning life stages;
- ❑ Agricultural diversion dams and excessive channel braiding impeding adult immigration in Thomes Creek;

- ❑ Whiskeytown Dam on Clear Creek as a barrier and as limiting the instream supply of spawning gravels;
- ❑ Sedimentation affecting the embryo incubation life stage in Clear and Cottonwood/Beegum creeks;
- ❑ Loss of riparian habitat and instream cover in Cottonwood/Beegum and Clear creeks;
- ❑ Loss of natural river morphology and function in Cottonwood/Beegum and Clear creeks; and
- ❑ Numerous factors affecting the juvenile rearing and outmigration life stage in the Delta and lower Sacramento River such as loss of floodplain habitat, loss of natural river morphology and function, loss of riparian habitat and instream cover, and predation.

Additional stressors were identified as having a very high importance to the northwestern California spring-run Chinook salmon diversity group. The complete prioritized list of life-stage specific stressors to this diversity group is displayed in Attachment B.

4.0 CENTRAL VALLEY STEELHEAD

4.1 BACKGROUND

4.1.1 LISTING HISTORY

NMFS proposed to list the Central Valley steelhead as endangered on August 9, 1996 (61 FR 41541 (August 1996)). NMFS concluded that the Central Valley steelhead ESU was in danger of extinction because of habitat degradation and destruction, blockage of freshwater habitats, water allocation problems, the pervasive opportunity for genetic introgression resulting from widespread production of hatchery steelhead and the potential ecological interaction between introduced stocks and native stocks. Moreover, NMFS proposed to list steelhead as endangered because steelhead had been extirpated from most of their historical range (61 FR 41541 (August 1996)).

On March 19, 1998, NMFS published a final determination listing the Central Valley steelhead as a threatened species (63 FR 13347 (March 19, 1998)). NMFS concluded that the risks to Central Valley steelhead had diminished since the completion of the 1996 status review based on a review of existing and recently implemented state conservation efforts and federal management programs (e.g., CVPIA AFRP, CALFED) that address key factors for the decline of this species. In addition, NMFS asserted that additional actions benefiting Central Valley steelhead included efforts to enhance fisheries monitoring and conservation actions to address artificial propagation (63 FR 13347 (March 19, 1998)).

On September 8, 2000, pursuant to a July 10, 2000, rule issued by NMFS under Section 4(d) of the ESA (16 USC § 1533(d)), the take restrictions that apply statutorily to endangered species began to apply to Central Valley steelhead (65 FR 42421 (July 10, 2000)).

On January 5, 2006, NMFS departed from their previous practice of applying the ESU policy to steelhead. NMFS concluded that the within a discrete group of steelhead populations, the resident and anadromous life forms of steelhead remain “markedly separated” as a consequence of physical, ecological and behavioral factors, and may therefore warrant delineation as a separate DPS. In addition, on January 5, 2006, NMFS reaffirmed the listing of threatened status of the Central Valley Steelhead DPS (71 FR 834 (January 5, 2006)). NMFS based its conclusion on conservation and protective efforts that, “*mitigate the immediacy of extinction risk facing the Central Valley steelhead DPS.*”

This Central Valley Steelhead DPS includes all naturally spawned populations of steelhead in the Sacramento and San Joaquin rivers and their tributaries, excluding steelhead from San Francisco and San Pablo bays and their tributaries (63 FR 13347 *in* NMFS 2007). This decision also included the CNFH and FRFH steelhead populations (NMFS 2007).

4.1.2 CRITICAL HABITAT DESIGNATION

NMFS proposed critical habitat for Central Valley steelhead on February 5, 1999, in compliance with Section 4(a)(3)(A) of the ESA, which requires that, to the maximum extent prudent and

determinable, NMFS designates critical habitat concurrently with a determination that a species is endangered or threatened (NMFS 1999). On February 16, 2000, NMFS published a final rule designating critical habitat for Central Valley steelhead which became effective on March 17, 2000. Critical habitat was designated to include all river reaches accessible to listed steelhead in the Sacramento and San Joaquin Rivers and their tributaries in California. Also included were river reaches and estuarine areas of the Delta, all waters from Chipps Island westward to Carquinez Bridge, including Honker Bay, Grizzly Bay, Suisun Bay, and Carquinez Strait, all waters of San Pablo Bay westward of the Carquinez Bridge, and all waters of San Francisco Bay (north of the San Francisco/Oakland Bay Bridge) from San Pablo Bay to the Golden Gate Bridge (NMFS 2000).

In response to litigation brought by NAHB on the grounds that the agency did not adequately consider economic impacts of the critical habitat designations (NAHB v. Evans, 2002 WL 1205743 No. 00–Central Valley–2799 (D.D.C.)), NMFS sought judicial approval of a consent decree withdrawing critical habitat designations for 19 Pacific salmon and *O. mykiss* ESUs. The District Court in Washington DC approved the consent decree and vacated the critical habitat designations by Court order on April 30, 2002 (NAHB v. Evans, 2002 WL 1205743 (D.D.C. 2002)).

NMFS proposed new critical habitat for Central Valley steelhead on December 10, 2004, and published a final rule designating critical habitat for this species on September 2, 2005 which became effective on January 2, 2006. The designated critical habitat encompasses 2,308 miles of stream habitat in the Central Valley and an additional 254 square miles of estuary habitat in the San Francisco-San Pablo-Suisun Bay complex. For a list of designated critical habitat units, see the September 2, 2005 Federal Register Notice (70 FR 52488 (September 2, 2005)).

4.1.3 UNIQUE SPECIES CHARACTERISTICS

4.1.3.1 LIFE HISTORY STRATEGY

Steelhead may exhibit anadromous behavior or remain in fresh water for their entire life. Resident forms are usually referred to as “rainbow” trout, while anadromous life forms are termed “steelhead.” Steelhead typically migrate to marine waters after spending 1 to 3 years in fresh water. They reside in marine waters for typically 1 to 4 years prior to returning to their natal stream to spawn as 2- to 5-year-olds. Unlike Pacific salmon, steelhead are capable of spawning more than once before they die. However, it is rare for steelhead to spawn more than twice before dying; and most that do so are females (Moyle 2002).

Currently, Central Valley steelhead are considered “ocean-maturing” (also known as winter steelhead, although summer steelhead may have been present prior to construction of large dams (Moyle 2002). Ocean maturing steelhead enter fresh water with well-developed gonads and spawn shortly after river entry. Central Valley steelhead begin entering fresh water in August, with peak in late September through October. They hold until flows are high enough in tributaries to enter for spawning (Moyle 2002). Steelhead adults typically spawn from December through April with peaks from January through March in small streams and tributaries where cool, well-oxygenated water is available year-round (McEwan and Jackson 1996b and Hallock *et al.* 1961). Depending on water temperature, steelhead eggs may incubate in redds for 1.5 to 4

weeks before hatching as alevins. Following yolk sac absorption, alevins emerge from the gravel as young juveniles or fry and begin actively feeding (Moyle 2002).

Regardless of life history strategy, for the first year or two, steelhead are found in cool, clear, fast-flowing permanent streams and rivers where riffles predominate over pools, where ample cover from riparian vegetation or undercut banks, and where invertebrate life is diverse and abundant. In streams, strong shifts in habitat occur with size and season. The smallest fish are most often found in riffles; intermediate size fish in runs; and large size fish in pools. Steelhead are found where daytime water temperatures range from nearly 32°F in winter to 81°F in the summer (Moyle 2002).

When water temperatures become stressful in streams, juvenile steelhead are faced with the increased energetic costs of living at high water temperatures. Hence, juvenile steelhead will move into fast riffles to feed because of increased abundance of food, even though there are additional costs associated with maintaining position in fast water. At high water temperatures, steelhead also are more vulnerable to unusual stress, and likely to die as a consequence. When water temperatures are high for steelhead but optimal for a coexisting fish species, interactions may reduce steelhead growth (Moyle 2002).

Predators also have a strong effect on microhabitats selected by steelhead. Small steelhead select places to live based largely on proximity to cover in order to hide from avian predators (Moyle 2002).

Optimal water temperatures for growth of steelhead have been reported around 59°F to 64.4°F (Moyle 2002). Many factors affect choice of water temperatures by steelhead, including the availability of food. As steelhead grow, they establish individual feeding territories; juveniles typically rear for one to two years (and up to four years) in streams before emigration as “smolts” (juvenile fish which can survive the transition from fresh water to salt water) (61 FR 41541 (August 1996)). Some may use tidal marsh areas, non-tidal freshwater marshes, and other shallow water areas in the Delta as rearing areas for short periods prior to their final emigration to the sea. In the Sacramento River, juvenile steelhead migrate to the ocean in spring and early summer at 1 to 3 years of age and 10 to 25 cm FL, with peak migration through the Delta in March and April (Reynolds *et al.* 1993). Hallock *et al.* (1961) found that juvenile steelhead in the Sacramento River basin migrate downstream during most months of the year, but the peak emigration period occurred in the spring, with a much smaller peak in the fall.

Growth of steelhead in fresh water is highly variable, but sizes of 10 to 12 cm FL at the end of year one and 16 to 17 cm at the end of year two are fairly typical. An additional spurt of growth may occur in spring, just prior to smolting, giving smolts age one and above an additional size advantage. Steelhead are primarily drift feeders and may forage in open water of estuarine subtidal and riverine tidal wetland habitats. The diet of juvenile steelhead includes emergent aquatic insects, aquatic insect larvae, snails, amphipods, opossum shrimp, and small fish (Moyle 2002).

Steelhead may remain in the ocean from one to four years, growing rapidly as they feed in the highly productive currents along the continental shelf (Barnhart 1986). The age composition of

high seas steelhead is dominated by one-year (61.9 percent) and two-year (31.4 percent) ocean fish, with a maximum of six years at sea (Burgner *et al.* 1992). Steelhead experience most of their marine phase mortality soon after they enter the Pacific Ocean (Percy 1992). Ocean mortality is poorly understood. Possible causes of juvenile steelhead mortality are predation, starvation, osmotic stress, disease, and advective losses (Wooster 1983; Hunter 1983, both cited in Percy 1992). Marine mortality of adult steelhead may occur from unauthorized high seas driftnet fisheries, predation, competition, and environmental conditions in the ocean (Cooper and Johnson 1992). Competition between steelhead and other species for limited food resources in the Pacific Ocean may be a contributing factor to declines in steelhead populations, particularly during years of low productivity (Cooper and Johnson 1992).

Oceanic and climate conditions such as sea surface temperatures, air temperatures, strength of upwelling, El Niño events, salinity, ocean currents, wind speed, and primary and secondary productivity affect all facets of the physical, biological and chemical processes in the marine environment. Some of the conditions associated with El Niño events include warmer water temperatures, weak upwelling, low primary productivity (which leads to decreased zooplankton biomass), decreased southward transport of sub-arctic water, and increased sea levels (Percy 1992). For juvenile steelhead, warmer water and weakened upwellings are possibly the most important of the ocean conditions associated with El Niño. Because of the weakened upwelling during an El Niño year, juvenile California steelhead would need to more actively migrate offshore through possibly stressful warm waters with numerous inshore predators. Strong upwelling is probably beneficial because of the greater transport of smolts offshore, beyond major concentrations of inshore predators (Percy 1992).

Steelhead have well-developed homing abilities and usually spawn in the same stream and area in which they had lived as fry. These fish also are capable of spawning in tributaries that dry up during summer, because fry emigrate soon after hatching (Moyle 2002). Steelhead usually do not eat when migrating upstream and often lose body weight.

Central Valley steelhead spawn below dams on every major tributary within the Sacramento and San Joaquin River systems. The female steelhead selects a site with good intergravel flow, digs a redd with her tail, usually in the coarse gravel of the tail of a pool or in a riffle, and deposits eggs while an attendant male fertilizes them. Water velocities over redds are typically 20 to 155 cm/sec, and in depths are 10 to 150 cm. Mating behavior between a pair of large adult fish is similar to that of other salmonids but complicated by the presence of other males, which sneak into spawn along with the mated pair (Moyle 2002). The sneaker males can range from small par that have probably never been to sea, to jacks, to slightly smaller subordinate sea-run males, kept at bay by the aggressive attacks of the dominant male (Moyle 2002).

Eggs in the redd are covered with gravel dislodged just upstream by similar redd building actions. The number of eggs laid per female depends on size and origin but ranges from 200 to 12,000 eggs. The eggs hatch in three to four weeks at 50 to 59°F, and fry emerge from the gravel two to three weeks later (Moyle 2002). However, factors such as redd depth, gravel size, siltation, and water temperature can speed or retard the time to emergence (Shapovalov and Taft 1954). The fry initially live in quiet waters close to shore and exhibit little aggressive behavior for several weeks (Moyle 2002).

4.1.3.2 HISTORIC SPAWNING HABITAT UTILIZATION

Central Valley steelhead historically were well-distributed throughout the Sacramento and San Joaquin rivers prior to dam construction, water development, and watershed perturbations of the 19th and 20th centuries (NMFS 1996, Busby *et al.* 1996 in NMFS 2007). They were found from the upper Sacramento and Pit River systems (now inaccessible due to Shasta and Keswick Dams) south to the Kings and possibly the Kern River systems, and in both east- and west-side Sacramento River tributaries (Yoshiyama *et al.* 1996). Lindley *et al.* (2006) estimated that historically there were at least 81 independent Central Valley steelhead populations distributed primarily throughout the eastern tributaries of the Sacramento and San Joaquin Rivers. Presently, impassable dams block access to 80 percent of historically available habitat, and block access to all historical spawning habitat for about 38 percent of historical populations (Lindley *et al.* 2006). Existing wild steelhead stocks in the Central Valley are mostly confined to the upper Sacramento River and its tributaries, including Antelope, Deer, and Mill creeks and the Yuba River. Populations may exist in Big Chico and Butte Creeks, and a few wild steelhead are produced in the American and Feather rivers (CDFG 1996b).

4.1.4 STATUS OF CENTRAL VALLEY STEELHEAD

4.1.4.1 HISTORIC POPULATION TRENDS

Historic Central Valley steelhead run sizes are difficult to estimate given the paucity of data, but may have approached one to two million adults annually (McEwan 2001). By the early 1960s, the steelhead run size had declined to about 40,000 adults (McEwan 2001). Over the past 30 years, the naturally-spawned steelhead populations in the upper Sacramento River have declined substantially (**Figure 4-1**) (NMFS 2007).

4.1.4.2 CURRENT STATUS

Until recently, Central Valley steelhead were thought to be extirpated from the San Joaquin River system. Recent monitoring has detected small self-sustaining populations of steelhead in the Stanislaus, Mokelumne, and Calaveras rivers, and other streams previously thought to be devoid of steelhead (McEwan 2001). Incidental catches and observations of steelhead juveniles also have occurred on the Tuolumne and Merced rivers during fall-run Chinook salmon monitoring activities, indicating that steelhead are widespread, throughout accessible streams and rivers in the Central Valley (Good *et al.* 2005).

Figure 4-1. Estimated Natural Steelhead Run Size on the Upper Sacramento River, 1967 Through 1993

4.1.4.3 EXTINCTION RISK ASSESSMENT

The majority of BRT votes were for “in danger of extinction,” and the remainder was for “likely to become endangered” Abundance, productivity, and spatial structure were of highest concern (4.2–4.4), although diversity considerations were of significant concern (3.6). All categories received a 5 from at least one BRT member. The BRT was highly concerned that what little new information was available indicated that the monotonic decline in total abundance and in the proportion of wild fish in the Central Valley steelhead DPS was continuing. Other major concerns included the loss of the vast majority of historical spawning areas above impassable dams, the lack of any steelhead-specific status monitoring, and the significant production of out-of-DPS steelhead by the Nimbus and Mokelumne river fish hatcheries. The BRT viewed the anadromous life history form as a critical component of diversity within the DPS and did not place much importance on sparse information suggesting widespread and abundant steelhead populations in areas above impassable dams. Dams both reduce the scope for expression of the anadromous life history form, thereby greatly reducing the abundance of anadromous steelhead and prevent exchange of migrants among resident populations, a process presumably mediated by anadromous fish.

As previously discussed, NMFS determined that Central Valley steelhead should not be listed as “endangered” but as threatened because conservation and protective efforts “mitigate the immediacy of extinction risk facing the Central Valley steelhead DPS.”

4.2 LIFE HISTORY AND BIOLOGICAL REQUIREMENTS

4.2.1 ADULT IMMIGRATION AND HOLDING

4.2.1.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Steelhead are predominantly winter steelhead; therefore, the following information describes the life history of winter steelhead. Adult steelhead generally immigrate from the ocean to the Sacramento River from August through March (McEwan 2001). The general life stage timing for each individual steelhead population is displayed in **Figures 4-2, 4-3, 4-4, and 4-5**.

4.2.1.2 BIOLOGICAL REQUIREMENTS

Adult steelhead immigration into the Delta and the lower Sacramento River occurs from August through March (McEwan 2001; NMFS 2004a), and peaks during January and February (Moyle 2002). Suitable water temperatures for adult steelhead migrating upstream to spawning grounds range from 46°F to 52°F (NMFS 2000; NMFS 2002; SWRCB 2003). Prolonged exposure to water temperatures above 73°F is reported to be lethal to adult steelhead (Moyle 2002).

Adult steelhead hold in deep pools with cool water, normally in the mainstem rivers, until flows are high enough in tributaries to allow entrance for spawning (Moyle 2002). The minimum depth requirement for passage of adults is reported to be 7 inches (Thompson 1972) although the distance fish must travel through shallow water areas is also a critical factor. Additionally, water velocities exceeding 10 to 13 ft/sec likely present barriers to upstream migration (Reiser and Bjornn 1979).

4.2.2 ADULT SPAWNING

4.2.2.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Central Valley adult steelhead generally begin spawning in late December and extend through to March, but also can range from November through April (CDFG 1986). The general life stage timing for each individual steelhead population is displayed in Figures 4-2, 4-3, 4-4 and 4-5.

4.2.2.2 BIOLOGICAL REQUIREMENTS

Steelhead adults typically spawn from December through April with peaks from January through March in small streams and tributaries where cool, well oxygenated water is available year-round (Hallock *et al.* 1961; McEwan 2001). Steelhead spawn in areas with a gravel substrate and water velocities ranging from 1 to 3.6 ft/sec but prefer velocities of about 2 ft/sec (30–110 cm/sec) at depths of 6 to 28 inches (Bovee 1978). Likewise, the USFWS (1995c) reported a water velocity range for steelhead spawning of 0.5–3.6 ft/sec (15.2–109 cm/sec) at similar depths. The preferred gravel particle size for steelhead spawning ranges from 0.25 to 3.0 inches in diameter, with a sand and silt component of less than 5 percent (USFWS 1995c).

A review of the literature suggests optimal conditions for steelhead spawning occur at water temperatures $\leq 52^\circ\text{F}$ (NMFS 2001; NMFS 2002; Reclamation 1997; SWRCB 2003; USFWS 1995c). The literature also reports high survival and normal development (Kamler and Kato 1983; Redding and Schreck 1979; Rombough 1988) at temperatures below 54°F, however, some evidence suggests that symptoms of thermal stress arise at or near 54.0°F (Humpesch 1985; Timoshina 1972).

4.2.3 EMBRYO INCUBATION

4.2.3.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

California Central Valley adult steelhead eggs incubate within the gravel and hatch from approximately 19 to 80 days at water temperatures ranging from 60°F to 40°F, respectively. After hatching, the young fish (alevins) remain in the gravel for an extra two to six weeks before emerging from the gravel and taking up residence in the shallow margins of the stream. Steelhead generally initiate their embryo incubation period from late-December to June (CDFG 1996b). The general life stage timing for each individual steelhead population is displayed in Figures 4-2, 4-3, 4-4 and 4-5.

4.2.3.2 BIOLOGICAL REQUIREMENTS

Steelhead embryo incubation generally occurs from December through June in the Central Valley. Following deposition of fertilized eggs in the redd, they are covered with loose gravel. Central Valley steelhead eggs can reportedly survive at water temperature ranges of 35.6°F to 59°F (Myrick and Cech 2001). However, steelhead eggs reportedly have the highest survival rates at water temperature ranges of 44.6°F to 50.0°F (Myrick and Cech 2001). The eggs hatch in three to four weeks at 50°F to 59°F, and fry emerge from the gravel four to six weeks later (Shapovalov and Taft 1954).

Steelhead embryo development requires a constant supply of well oxygenated water. This implies a loose gravel substrate allowing high permeability with little silt or sand deposition during the development time period.

4.2.4 JUVENILE REARING AND OUTMIGRATION

4.2.4.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Most juvenile steelhead spend one to three years in fresh water before emigrating to the ocean as smolts (Shapovalov and Taft 1954). The primary period of steelhead smolt outmigration from rivers and creeks to the ocean generally occurs from January to June. The general life stage timing for each individual steelhead population is displayed in Figures 4-2, 4-3, 4-4 and 4-5.

BIOLOGICAL REQUIREMENTS

Regardless of life history strategy, for the first year or two of life rainbow trout and steelhead are found in cool, clear, fast-flowing permanent streams and rivers where riffles predominate over pools, there is ample cover from riparian vegetation or undercut banks, and invertebrate life is diverse and abundant (Moyle 2002). The smallest fish are most often found in riffles; intermediate size fish in runs; and larger fish in pools. Steelhead can be found where daytime water temperatures range from nearly 32°F to 81°F in the summer (Moyle 2002). However, an upper water temperature limit of 65°F is preferred for growth and development of Sacramento River and American River juvenile steelhead (NMFS 2002a).

Studies indicate that the majority of returning adult steelhead in the Central Valley spend two years in freshwater before emigrating to the ocean (McEwan 2001). For juvenile steelhead to

survive the winter, they must avoid predation and high flows by finding cover and velocity refuge in the interstitial spaces between cobbles and boulders (Bjornn 1971; Everest *et al.* 1986). Age 0+ steelhead can use shallower habitats and can find interstitial cover in gravel-sized substrates, while age 1+ or 2+ steelhead need a coarser cobble/boulder substrate for cover (Bisson *et al.* 1988).

4.2.5 SMOLT OUTMIGRATION

4.2.5.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

In the Sacramento River, juvenile steelhead migrate to the ocean in spring and early summer at 1 to 3 years of age and 10 to 25 cm FL with peak migration through the Delta in March and April (Reynolds *et al.* 1993). Hallock *et al.* (1961) found that juvenile steelhead in the Sacramento River basin migrate downstream during most months of the year, but the peak emigration period occurred in the spring, with a much smaller peak in the fall.

4.2.5.2 BIOLOGICAL REQUIREMENTS

Steelhead successfully smolt at water temperatures in the 43.7°F to 52.3°F range (Myrick and Cech 2001). Optimum water temperature range for successful smoltification in young steelhead is 44.0°F to 52.3°F (Rich 1987). Wagner (1974) reported smolting ceased rather abruptly when water temperatures increased to 57°F-64°F.

In the Sacramento River, juvenile steelhead migrate to the ocean in spring and early summer at 1 to 3 years of age and 10 to 25 cm FL, with peak migration through the Delta in March and April (Reynolds *et al.* 1993). Hallock *et al.* (1961) found that juvenile steelhead in the Sacramento River basin migrate downstream during most months of the year, but the peak emigration period occurred in the spring, with a much smaller peak in the fall.

4.2.6 SUB-ADULT AND ADULT OCEAN RESIDENCE

4.2.6.1 GEOGRAPHIC AND TEMPORAL DISTRIBUTION

Steelhead may remain in the ocean from one to four years, growing rapidly as they feed in the highly productive currents along the continental shelf (Barnhart 1986). Compared to Chinook salmon, relatively little is known about the geographic distribution of steelhead in the ocean.

4.2.6.2 BIOLOGICAL REQUIREMENTS

Oceanic and climate conditions such as sea surface temperatures, air temperatures, strength of upwelling, El Niño events, salinity, ocean currents, wind speed, and primary and secondary productivity affect all facets of the physical, biological and chemical processes in the marine environment. Some of the conditions associated with El Niño events include warmer water temperatures, weak upwelling, low primary productivity (which leads to decreased zooplankton biomass), decreased southward transport of sub-arctic water, and increased sea levels (Percy 1997). For juvenile steelhead, warmer water and weakened upwellings are possibly the most important of the ocean conditions associated with El Niño. Because of the weakened upwelling during an El Niño year, juvenile California steelhead would need to more actively migrate offshore through possibly stressful warm waters with numerous inshore predators. Strong

upwelling is probably beneficial because of the greater transport of smolts offshore, beyond major concentrations of inshore predators (Pearcy 1997).

4.3 THREATS AND STRESSORS

4.3.1 SUMMARY OF ESA LISTING FACTORS

Central Valley steelhead have been extirpated from most of their historical range. At the time of listing, NMFS was concerned with widespread degradation, destruction and blockage of freshwater habitats within this region, and the potential results of continuing habitat destruction and water allocation problems, the pervasive opportunity for genetic introgression resulting from widespread production of hatchery steelhead and the potential ecological interaction between introduced stocks and native stocks.

In 1996, NMFS estimated that Central Valley total run size based on dam counts, hatchery returns, and past spawning surveys was probably less than 10,000 fish. Both natural and hatchery runs have declined since the 1960s. Counts at RBDD averaged 1,400 fish from 1991 to 1996, compared with runs in excess of 10,000 fish in the late 1960s. Run-size estimates for the hatchery produced American River stock averaged less than 1,000 fish, compared to 12,000 to 19,000 in the early 1970s (CDFG 1996b).

Historically, steelhead occurred naturally throughout the Sacramento and San Joaquin River basins; however, stocks have been extirpated from large areas of the Sacramento River Basin and of the San Joaquin River Basin. The California Advisory Committee on Salmon and Steelhead (1988) reported a reduction in Central Valley steelhead habitat from 6,000 miles historically to 300 miles at present. Reynolds *et al.* (1993) reported that 95 percent of salmonid habitat in California's Central Valley has been lost, largely due to mining and water development activities. They also noted that declines in Central Valley steelhead stocks are "*due mostly to water development, inadequate instream flows, rapid flow fluctuations, high summer water temperatures in streams immediately below reservoirs, diversion dams which block access, and entrainment of juveniles into unscreened or poorly screened diversions.*" Other problems related to land use practices (agriculture and forestry) and urbanization also have certainly contributed to stock declines.

The major threat to genetic integrity for Central Valley steelhead comes from past and present hatchery practices. Sufficient overlap of spawning hatchery and natural fish within this DPS probably exists for some genetic introgression to occur. Also a substantial problem with straying of hatchery fish exists within this DPS (Hallock 1989). Habitat fragmentation and population declines resulting in small, isolated populations also pose genetic risk from inbreeding, loss of rare alleles, and genetic drift.

In 1998, NMFS continued to identify long-term declines in abundance, small population sizes in the Sacramento River, and the high risk of interbreeding between hatchery and naturally spawned steelhead as major concerns for Central Valley steelhead. The significant loss of historic habitat, degradation of remaining habitat from water diversions, reduction in water quality and other factors, harvest impacts, and the lack of monitoring data on abundance as other important risk factors for this DPS. Nevertheless, NMFS concluded that the risks to Central

Valley steelhead had diminished based on a review of existing and recently implemented state conservation efforts and federal management programs (e.g., CVPIA AFRP, CALFED) that address key factors for the decline of this species. NMFS stated that Central Valley steelhead were benefiting from two major conservation initiatives, being simultaneously implemented: (1) the CVPIA, which was passed by Congress in 1992; and (2) the CALFED Program, a joint state/federal effort implemented in 1995.

The CVPIA is specifically intended to remedy habitat and other problems associated with the construction and operation of the CVP. The CVPIA has two key features related to steelhead. First, it directs the Secretary of the Interior to develop and implement a program that makes all reasonable efforts to double natural production of anadromous fish in Central Valley streams (Section 3406(b)(1)) by the year 2002. The AFRP was initially drafted in 1995 and subsequently revised in 1997. Funding has been appropriated since 1995 to implement restoration projects identified in the AFRP planning process. Second, the CVPIA dedicates up to 800,000 acre-feet of water annually for fish, wildlife, and habitat restoration purposes (Section 3406(b)(2)) and provides for the acquisition of additional water to supplement the 800,000 acre-feet (Section 3406(b)(3)). USFWS, in consultation with other federal and state agencies, has directed the use of this dedicated water yield since 1993.

The CALFED Program, which began in June 1995, was charged with the responsibility of developing a long-term Bay-Delta solution. A major element of the CALFED Program is the ERP, which was intended to provide the foundation for long-term ecosystem and water quality restoration and protection throughout the region. Among the non-flow factors for decline that have been targeted by the Program are unscreened diversions, waste discharges and water pollution prevention, impacts due to poaching, land derived salts, exotic species, fish barriers, channel alterations, loss of riparian wetlands, and other causes of estuarine habitat degradation.

The level of risk faced by the Central Valley steelhead DPS may have diminished since the 1996 listing proposal as a result of habitat restoration and other measures that have recently been implemented through the CALFED and CVPIA programs. Although most restoration measures designed to recover Chinook salmon stocks do benefit steelhead or are benign in that regard, focusing restoration solely on Chinook salmon leads to inadequate measures to restore steelhead because of their different life histories and resource requirements, particularly that of rearing juveniles (McEwan 2001). Additional actions that benefit Central Valley steelhead include efforts to enhance fisheries monitoring, like the Central Valley Steelhead Monitoring Plan, and conservation actions to address artificial propagation.

In 2005 and 2006, NMFS affirmed that risk factors for Central Valley steelhead include extirpation from most of the historical range, a monotonic decline in abundance, declining proportion of wild fish in spawning runs, substantial opportunity for deleterious interactions with hatchery fish (including out-of-basin-origin stocks).

4.3.1.1 DESTRUCTION, MODIFICATION, OR CURTAILMENT OF HABITAT OR RANGE

The spawning habitat for Central Valley steelhead has been greatly reduced from its historical range. The vast majority of historical spawning habitat for Central Valley steelhead has been

eliminated by fish passage impediments associated with water storage, withdrawal, conveyance, and diversions for agriculture, flood control, and domestic and hydropower purposes. Modification of natural flow regimes has resulted in increased water temperatures, changes in fish community structures, depleted flow necessary for migration, spawning, rearing, and flushing of sediments from spawning gravels. These changes in flow regimes may be driving a shift in the frequencies of various life history strategies, especially a decline in the proportion of the population migrating to the ocean. Land use activities, such as those associated with agriculture and urban development, have altered steelhead habitat quantity and quality.

Although many historically harmful practices have been halted, much of the historical damage to habitats limiting steelhead remains to be addressed, and the necessary restoration activities will likely require decades.

4.3.1.2 OVERUTILIZATION FOR COMMERCIAL, RECREATIONAL, SCIENTIFIC, OR EDUCATION PURPOSES

Steelhead have been, and continue to be, an important recreational fishery throughout their range. Although there are no commercial fisheries for steelhead in the ocean, inland steelhead fisheries include tribal and recreational fisheries. In the Central Valley, recreational fishing for steelhead is popular, yet harvest is restricted to only the visibly marked hatchery-origin fish, which reduces the likelihood of retaining naturally spawned wild fish.

The permits NMFS issues for scientific or educational purposes stipulate specific conditions to minimize take of steelhead individuals during permitted activities. There are currently 11 active permits in the Central Valley that may affect steelhead. These permitted studies provide information about Central Valley steelhead that is useful to the management and conservation of the DPS.

4.3.1.3 DISEASE OR PREDATION

Steelhead are exposed to bacterial, protozoan, viral, and parasitic organisms in spawning and rearing areas, hatcheries, migratory routes, and the marine environment. Very little current or historical information exists to quantify changes in infection levels and mortality rates attributable to these diseases for steelhead. Naturally spawned fish tend to be less susceptible to pathogens than hatchery-reared fish.

Introduction of non-native species and modification of habitat have resulted in increased predatory populations and salmonid predation in river systems. In general, predation rates on steelhead are considered to be an insignificant contribution to the large declines observed in West Coast steelhead populations. In some local populations, however, predation may significantly influence salmonid abundance when other prey species are not present and habitat conditions lead to the concentration of adults and/or juveniles.

4.3.1.4 INADEQUACY OF EXISTING REGULATORY MECHANISMS

FEDERAL EFFORTS

There have been several federal actions attempting to reduce threats to the Central Valley steelhead DPS. The BOs for the CVP and SWP and other federal projects involving irrigation

and water diversion and fish passage, for example, have improved or minimized adverse impacts to steelhead in the Central Valley. There have also been several habitat restoration efforts implemented under CVPIA and CALFED programs that have led to several projects involving fish passage improvements, fish screens, floodplain management, habitat restoration, watershed planning, and other projects that have contributed to improvement of steelhead habitat.

However, despite federal actions to reduce threats to the Central Valley steelhead DPS, the existing protective efforts are inadequate to ensure the DPS is no longer in danger of extinction. There remain high risks to the abundance, productivity, and spatial structure of the steelhead DPS.

NON-FEDERAL EFFORTS

Measures to protect steelhead throughout the State of California have been in place since 1998. The state's Natural Communities Conservation Planning (NCCP) program involves long-term planning with several stakeholders. A wide range of measures have been implemented, including 100 percent marking of all hatchery steelhead, zero bag limits for unmarked steelhead, gear restrictions, closures, and size limits designed to protect smolts. NMFS and CDFG are working to improve inland fishing regulations to better protect both anadromous and resident forms of *O. mykiss* populations. A proposal to develop a comprehensive status and trends monitoring plan for Central Valley steelhead was submitted for funding consideration to the CALFED ERP in 2005. The proposal, drafted by CDFG and the interagency Central Valley Steelhead Project Work Team, was selected by the ERP Implementing Agency Managers, and is to receive funding as a directed action. Long-term funding for implementation of the monitoring plan, once it is developed, still needs to be secured. There are many sub-watershed groups, landowners, environmental groups, and non-profit organizations that are conducting habitat restoration and planning efforts that may contribute to the conservation of steelhead.

However, despite federal and non-federal efforts to promote the conservation of the Central Valley steelhead DPS, few efforts address conservation needs at scales sufficient to protect the entire steelhead DPS. The lack of status and trend monitoring and research is one of the critical limiting factors to this DPS.

4.3.1.5 OTHER NATURAL AND MANMADE FACTORS AFFECTING ITS CONTINUED EXISTENCE

NMFS and the BRT is concerned that the proportion of naturally produced fish is declining. Two artificial propagation programs for steelhead in the Central Valley – CNFH and FRFH – may decrease risk to the DPS to some degree by contributing increased abundance to the DPS. Potential threats to natural steelhead posed by hatchery programs include: (1) mortality of natural steelhead in fisheries targeting hatchery-origin steelhead; (2) competition for prey and habitat; (3) predation by hatchery-origin fish on younger natural fish; (4) genetic introgression by hatchery-origin fish that spawn naturally and interbreed with local natural populations; and (5) disease transmission.

Changes in climatic events and global climate, such as El Niño ocean conditions and prolonged drought conditions, can threaten the survival of steelhead populations already reduced to low abundance levels as the result of the loss and degradation of freshwater and estuarine habitats.

Floods and persistent drought conditions have reduced already limited spawning, rearing, and migration habitats.

Unscreened water diversions entrain outmigrating juvenile steelhead and fry. Unscreened water diversions and CVP and SWP pumping plants entrain juvenile steelhead, leading to fish mortality.

4.3.2 NON-LIFE STAGE-SPECIFIC THREATS AND STRESSORS FOR THE DPS

Potential threats to the California Central Valley steelhead population that are not specific to a particular life stage include the potential negative impacts of the current artificial propagation program utilizing several hatcheries in the Sacramento-San Joaquin drainage, the small wild population size, the genetic integrity of the population due to both hatchery influence and small population size, and the potential effects of long-term climate change. Each of these potential threats is discussed in the following sections.

4.3.2.1 ARTIFICIAL PROPAGATION PROGRAM

Currently, four hatcheries in the Central Valley produce steelhead to supplement the Central Valley wild steelhead population. The hatcheries and their current production targets are listed in **Table 4-1**.

Table 4-1. Hatcheries Producing Steelhead in the Central Valley

Hatchery	Production Target
Coleman National Fish Hatchery	600,000
Feather River Fish Hatchery	450,000
Nimbus Fish Hatchery	430,000
Mokelumne Fish Hatchery	100,000

Potential adverse effects to wild steelhead populations associated with hatchery production are similar to those described in Section 2.3.2.1 for winter-run Chinook salmon. However, recent research has indicated that approximately 63 to 92 percent of steelhead smolt production is of hatchery-origin (NMFS 2003), which is a higher percentage than winter-run Chinook salmon estimates. More importantly, these data suggest that the relative proportion of wild to hatchery smolt production is decreasing (NMFS 2003). All California hatchery steelhead programs began 100 percent adipose fin-clipping in 1998 to differentiate between hatchery steelhead from natural steelhead.

Propagation of steelhead at the CNFH has been occurring for over 50 years. Hatchery-origin and natural-origin steelhead have been managed as a single stock; mixing of hatchery and natural origin population components occurred through spawning at the hatchery and intermingling of natural spawners in Battle Creek. Niemela *et al.* (2008) used genetic pedigree analysis to evaluate relative reproductive success and fitness among hatchery-origin and natural origin population components based on multilocus DNA microsatellite genotypes. Preliminary results suggest that hatchery origin spawners experienced low relative reproductive success, producing significantly fewer adult offspring in comparison to natural origin spawners. Additionally, repeat spawning was more prevalent in the natural origin component of the population.

4.3.2.2 SMALL POPULATION SIZE

Potential adverse effects of a small population size for steelhead would be similar to those described above in Section 2.3.2.2 for winter-run Chinook salmon. The California Central Valley steelhead DPS mean annual escapement was estimated at 1,952 based on a 5-year period ending in 1993 (Good *et al.* 2005). During that time period a minimum escapement of 1,425 and a maximum escapement of 12,320 were observed (Good *et al.* 2005). A long-term trend analysis indicated that the population was declining (Good *et al.* 2005). In the 2005 Updated Status of Central Valley Steelhead, NMFS suggests that there has been no significant status change since the 1993 data and the population continues to decline (Good *et al.* 2005). The steelhead run in the Feather River has been increasing over the past several years; however, over 99 percent of the run is of direct hatchery-origin (DWR 2002b).

4.3.2.3 GENETIC INTEGRITY

There is still significant local genetic structure to Central Valley steelhead populations, although fish from the San Joaquin and Sacramento basins cannot be distinguished genetically (Nielsen *et al.* 2003). Hatchery effects appear to be localized – for example, Feather River and Feather River Hatchery steelhead are closely related as are American River and Nimbus Hatchery fish (DWR 2002b). Leary *et al.* (1995) report that hatchery straying has increased gene flow among steelhead populations in the Central Valley and that a smaller amount of genetic divergence is observed among Central Valley populations compared to wild British Columbia populations largely uninfluenced by hatcheries. Currently, natural annual production of steelhead smolts in the Central Valley is estimated at 181,000 and hatchery production is 1,340,000 for a ratio of 0.148 (Good *et al.* 2005). Current monitoring by hydroacoustic tracking has revealed that Mokelumne River/Hatchery steelhead (FRFH source stock) are straying into the American River (J. Smith, EBMUD, pers. comm.).

There has also been significant transfer of genetic material among hatcheries within the Central Valley as well as some transfer from systems outside the Central Valley. There have also been transfers of steelhead from the Feather River Hatchery to the Mokelumne Hatchery. For example, eyed eggs from the Nimbus hatchery were transferred to the FRFH several times in the late 1960s and early 1970s (DWR 2002b). Also, Nimbus Hatchery steelhead eggs have often been transferred to the Mokelumne Hatchery. Additionally, an Eel River strain of steelhead was used as the founding broodstock for the Nimbus Hatchery (CDFG 1991c). In the late 1970s, a strain of steelhead was brought in from Washington State for the Feather River Hatchery (DWR 2002b).

4.3.2.4 LONG-TERM CLIMATE CHANGE

The potential effects of long-term climate change on Central Valley steelhead would be similar to those described above in Section 2.3.2.4 for winter-run Chinook salmon. However, because steelhead normally spend a longer time in freshwater as juveniles than other anadromous salmonids, any negative effects of climate change may be more profound on steelhead populations.

4.3.3 SAN FRANCISCO, SAN PABLO AND SUISUN BAYS

4.3.3.1 ADULT IMMIGRATION AND HOLDING

Steelhead adult immigration and holding in California's Central Valley Basin occurs from August through March. Threats to steelhead that potentially may occur in the bays are similar to those described above in Section 2.3.3.1 for winter-run Chinook salmon.

4.3.3.2 JUVENILE REARING AND OUTMIGRATION

Threats to steelhead juvenile rearing and outmigration that potentially occurs in the Bays are similar to those described above in Section 2.3.3.2 for winter-run Chinook salmon.

4.3.4 SACRAMENTO-SAN JOAQUIN DELTA

4.3.4.1 ADULT IMMIGRATION AND HOLDING

Threats to steelhead adult immigration and holding that potentially occur in the Delta are similar to those described above in Section 2.3.4.1 for winter-run Chinook salmon. Because water temperatures in the Delta are normally too warm for this life stage from August through mid-October, it is likely that most steelhead have passed through the Delta into the mainstem Sacramento River and beyond by this time. Water temperatures in the Delta would not be suitable for this life stage during August and September.

4.3.4.2 JUVENILE REARING AND OUTMIGRATION

In the Sacramento River, juvenile steelhead migrate to the ocean in winter and spring, with peak migration through the Delta in March and April (Reynolds et al. 1993). According to juvenile steelhead catch data in the Delta from 1995 to 2006, peak juvenile steelhead catch occurred during March and April at Mossdale, and during January through May at Chipps Island (IEP Website 2007).

Factors creating threats to the juvenile rearing and outmigration life stage of steelhead would be similar to those described above in Section 2.3.4.2 for winter-run Chinook salmon. Water temperatures in the Delta begin rising in April and are likely unsuitable after May.

As discussed in Section 2.3.4.2 predation is considered a major source of fish loss in the Clifton Court Forebay. Past predation studies and fisheries management at Clifton Court Forebay have focused on loss of entrained fish due to predatory fish. Mayfield (2008) suggests that predatory birds may also play a role in predation losses at the forebay and that double-crested cormorants (*Phalacrocorax auritus*) are a likely predator on entrained juvenile steelhead and even more so on other smaller salmonid juveniles.

4.3.5 LOWER SACRAMENTO RIVER (PRINCETON [RM 163] TO THE DELTA)

4.3.5.1 ADULT IMMIGRATION AND HOLDING

Adult steelhead immigration into the Delta and the lower Sacramento River occurs from August through March (McEwan 2001; NMFS 2004a), and peaks during January and February (Moyle 2002). See Section 4.2.1 for a more complete description of the biological requirements and

description of this life stage. Factors that may adversely affect steelhead adult immigration and holding in the lower Sacramento River include passage impediments, adverse flow conditions, harvest in the sportfishery, poaching, and potential water quality problems, particularly adverse water temperatures.

PASSAGE IMPEDIMENTS/BARRIERS

In the lower Sacramento River, flows are diverted into the SDWSC. Adult salmon have been caught close to the locks at the upstream end of the channel and have also been observed to be blocked from migrating upstream by the locks (NMFS 1997). It is likely that some steelhead also enter the channel and may be delayed in their upstream migration.

HARVEST/ANGLING IMPACTS

There is no commercial fishery for steelhead in the Sacramento River. The in-river sportfishery generally allows the taking of hatchery steelhead (identified by adipose fin-clip) during the adult immigration and holding period. The Valley district regulations and special regulations prohibit the harvest of any non-clipped rainbow trout/steelhead in anadromous waters above the Deschutes Road Bridge.

The extent of poaching of steelhead in this reach of the river is unknown. There are no man-made structures that would unnaturally increase densities allowing for easy poaching however, some level of poaching likely occurs due to snagging by anglers or inadvertent misidentification of caught fish.

WATER QUALITY

Suitable water temperatures for adult steelhead migrating upstream to spawning grounds range from 46°F to 52°F (CDFG 1991c). Because water temperatures in the lower Sacramento River generally exceed these temperatures, this reach of the river likely serves only as a migration corridor.

Additionally, NMFS (NMFS 1997) reports that recent research has indicated that water temperatures in the lower Sacramento River may have risen by as much as 4°F to 7°F since the late 1970s. Potentially the cumulative losses of shade along the river may have influenced water temperatures in this reach.

FLOW CONDITIONS

During high flow or flood events, water is diverted into the Sutter and Yolo bypasses upstream of the City of Sacramento. Adult steelhead migrating upstream may enter these bypasses, where their migration may be delayed or blocked by control structures. To date, there have not been any measures implemented to protect adult salmonids from entrainment into the flood control bypasses (NMFS 1997).

4.3.5.2 JUVENILE REARING AND OUTMIGRATION

Because of relatively warm waters in the lower Sacramento River, juvenile steelhead likely only use this section of the river for a migration corridor. The primary period for steelhead smolt emigration occurs from March through June (Castleberry *et al.* 1991).

WATER TEMPERATURE

Water temperature in the lower Sacramento River likely does not adversely affect juvenile steelhead as it is used primarily as a migration corridor. However, outmigrating or rearing juvenile steelhead may also be exposed to warmwater releases from the Colusa Drain at Knights Landing. Warm water is released from the drain to the river mainly from April through June. Releases from the drain can exceed 2,000 cfs and 80°F. Although steelhead would likely show an avoidance reaction to the warmwater, it may present a partial thermal barrier to downstream migration.

WATER QUALITY

The major point source threat of pollution in the Sacramento River is the Iron Mountain Mine as described above for spring-run Chinook salmon. However, because the Iron Mountain Mine is so far north of the lower Sacramento River, most heavy metal contaminants from the mine have likely either settled out or have been diluted to acceptable EPA standards by the time water reaches this reach of the river. Within the lower Sacramento River and Bay-Delta there are three large municipal water treatment plants which can be an important point source of pollution: the West Sacramento WWTP, the Sacramento Regional WWTP, and the Stockton Sewage Treatment Plant. Pre-treatment, primary treatment and secondary treatments in place since the 1950s have all reduced pollutant loading to the system however, heavy metal loadings and toxic organic pollutants remain a major concern (NMFS 1997).

The main non-point sources of pollution in the lower Sacramento River are urban runoff and agricultural drainage. Stormwater runoff from the city of Sacramento has been shown to be acutely toxic to aquatic invertebrates (NMFS 1997). Significant urban runoff also occurs during the dry season and is created from domestic/commercial landscape irrigation, groundwater infiltration, pumped groundwater discharges and construction projects (NMFS 1997). The Colusa Basin Drain is the largest source of agricultural return flow in the Sacramento River. It drains agricultural areas serviced by the Tehama-Colusa and Glenn-Colusa Irrigation districts and discharges to the Sacramento River below Knights Landing. The drain has been identified as a major source of warm water, pesticides, turbidity, suspended sediments, dissolved solids, nutrients and trace metals (NMFS 1997).

FLOW CONDITIONS

Flood control structures in the lower Sacramento River are designed to divert water from the river during a major flood event into the Butte Creek basin and the Sutter and Yolo bypasses. The diversions can be significant. For example, the flood control system can divert as much as four to five times more flow down the bypasses than remains in the river (NMFS 1997). Juvenile steelhead migrating down the river may enter the diversions during storm events. Studies conducted on the Sutter Bypass show that the highest proportion of flows are diverted from December through March with a peak occurring in February (NMFS 1997). Juveniles diverted into the bypasses may experience migration delays, potential stranding as flood flows recede and increased rates of predation.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Bank stabilization for flood control purposes has resulted in extensive areas of streambank riprapping. Rip-rapping the river bank involves removing vegetation along the bank and upper levees which removes most instream and overhead cover in nearshore areas. Overhanging

vegetation is referred to as SRA habitat. Woody debris and overhanging vegetation within SRA habitat provide escape cover for juvenile salmonids from predators. Aquatic and terrestrial insects are an important component of juvenile salmonid diet. These insects are dependent on a healthy riparian habitat.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Flood control measures, regulated flow regimes and river bank protection measures have all had a profound effect on riparian and instream habitat in the lower Sacramento River. Levees constructed in this reach are built close to the river in order to increase streamflow, channelize the river to prevent natural meandering, and maximize the sediment carrying capacity of the river (NMFS 1997). Channelization of the river requires bank protection measures such as riprapping to reduce the effects of streambank erosion. Additionally, nearshore aquatic areas are deepened and sloped to a uniform gradient, such that variations in water depth, velocity and direction of flow are replaced by consistent moderate to high velocities. Juvenile steelhead utilize slow and slack water velocities for rearing and the channelization of the river has removed most of this habitat type.

LOSS OF FLOODPLAIN HABITAT

The process of channelizing the lower Sacramento River has resulted in a loss of connectivity with the floodplain which serves as an important source of woody debris and gravels that aid in establishing a diverse riverine habitat, as well as increasing primary and secondary productivity and exporting nutrients.

ENTRAINMENT

Entrainment is defined as the redirection of fish from their natural migratory pathway into areas or pathways not normally used. Entrainment also includes the take, or removal, of juvenile fish from their habitat through the operation of water diversion devices and structures such as siphons, pumps and gravity diversions (NMFS 1997). A primary source of entrainment is unscreened or inadequately screened diversions. A survey by CDFG identified 350 unscreened diversions along the Sacramento River downstream of Hamilton City.

Entrainment of juvenile winter-run Chinook salmon has been identified as one of the most significant causes of mortality in the Delta (NMFS 1997) and is likely also true for steelhead. In addition, a program to flood rice field stubble during the winter has been implemented extending the period for potential entrainment (NMFS 1997).

Outmigrating juvenile steelhead may also be diverted into the Yolo or Sutter bypasses during high flow or flood events and stranded as flood waters recede. The entrance to the Yolo Bypass is the Fremont Weir upstream of Sacramento near the confluence with the Feather River. During high flows weir gates are open and because the weir is not screened, juveniles enter the Yolo Bypass, where they may rear and eventually leave through the lower end upstream of Chipps Island in the Delta, or be trapped in isolated ponds as waters recede. Additionally, Sacramento River water is diverted into the SDWSC, and outmigrating juvenile steelhead may enter the channel where water quality, flow levels and rearing conditions are extremely poor (NMFS 1997).

PREDATION

Only limited information on predation of steelhead juveniles is available. Native species that are known to prey on juvenile steelhead include Sacramento pikeminnow and potentially other steelhead. Predation by pikeminnow can be significant when juvenile salmonids occur in high densities such as below dams or near diversions. Although Sacramento pikeminnow are a native species and predation on juvenile steelhead is a natural phenomenon, loss of SRA habitat and artificial instream structures tend to favor predators and may change the natural predator-prey dynamics in the system favoring predatory species (CALFED 2000c). Non-native striped bass may also be a significant predator on juvenile steelhead. Although no recent studies of striped bass predation on juvenile salmonids have been completed, Thomas (1967 *in* NMFS 1997) found that in the lower Sacramento River, salmon accounted for 22 percent of striped bass diet.

HATCHERY EFFECTS

Hatchery steelhead may prey on juvenile wild steelhead. In the lower Sacramento River, hatchery steelhead from the FRFH are planted in the Feather River below Yuba City at a large enough size and at a time when they could intercept other rearing wild steelhead.

4.3.6 MIDDLE SACRAMENTO RIVER (RED BLUFF DIVERSION DAM [RM 243] TO PRINCETON [RM 163])

4.3.6.1 ADULT IMMIGRATION AND HOLDING

In this reach of the river, the potential threats to the adult immigration and holding life stage of steelhead arise from a potential passage impediment at the GCID HCPP, potential water quality problems, particularly adverse water temperatures, harvest in the sportfishery and poaching.

PASSAGE IMPEDIMENTS/BARRIERS

Although the GCID HCPP (~RM 205) and associated water diversions present problems for emigrating juvenile salmonids, adults are not likely affected.

HARVEST/ANGLING IMPACTS

Current sportfishing regulations in the Sacramento River allow for the taking of hatchery steelhead during the adult immigration and holding period. The Valley district regulations and special regulations prohibit the harvest of any non-clipped rainbow trout/steelhead in anadromous waters above the Deschutes Road Bridge. It is possible that some wild steelhead could be holding in the mainstem river below the RBDD prior to spawning in late December to March.

The extent of poaching of steelhead in this reach of the river is unknown. Some level of poaching likely occurs due to snagging by anglers or inadvertent misidentification of caught fish. Additionally, when passage at the RBDD is hindered there may be unusually high densities of salmonids downstream of the dam that present poaching opportunities.

WATER TEMPERATURE

Water Temperatures in this reach of the river are similar to those occurring in the lower Sacramento River. However, some holding of adult steelhead may occur downstream of the RBDD in deep coldwater pools. With the installation of the TCD at Shasta Dam in 1997, water

temperatures have cooled slightly and suitable water temperatures for adult holding likely extend downstream of the RBDD for a short distance during the winter months.

WATER QUALITY

Water quality in the middle Sacramento River is not likely to adversely affect adult steelhead.

4.3.6.2 JUVENILE REARING AND OUTMIGRATION

Factors that may adversely affect juvenile steelhead in the middle Sacramento River are similar to those that occur in the lower river as described above. However, in addition to those factors there is a potential downstream passage impediment at the GCID's HCPP at RM 205.

WATER TEMPERATURE

Water temperature issues in the middle Sacramento River are similar to those described above in the lower Sacramento River. Water temperatures normally exceed 60°F from July through September and in dry years can often exceed 66°F (NMFS 1997).

WATER QUALITY

The only point source pollution that has been identified and may potentially affect this reach of the river is the Iron Mountain Mine described in Section 3.5.1.2. Non-point source pollution sources include both urban and agricultural runoff similar to that described above for the lower Sacramento River. Urban runoff is likely not as great in this reach of the river as that occurring in the lower Sacramento River but agricultural runoff is likely similar or greater.

FLOW CONDITIONS

Flow conditions, under current regulated flow regimes, in the middle Sacramento River likely have little effect on outmigrating juvenile steelhead.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Loss of riparian habitat that has occurred in the middle Sacramento River is similar to that described above for the lower Sacramento River.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Physical habitat alteration that has occurred in the middle Sacramento River is similar to that described above for the lower Sacramento River. The river is not quite as confined in this reach as levees are constructed further from the channel than those occurring in the lower river.

LOSS OF FLOODPLAIN HABITAT

Although the river is not quite as confined in this reach as levees are constructed further from the channel than those occurring in the lower river, the river is disconnected from its historic floodplain by flood control measures including regulated flows and levees.

ENTRAINMENT

The exact number of unscreened diversions in this reach of the river is not known. A study by the California Advisory Committee on Salmon and Steelhead Trout completed in 1987 reported that over 300 unscreened irrigation, industrial, and municipal water supply diversions occur on the Sacramento River between Redding and Sacramento (NMFS 1997). Although most of these

diversions are small, cumulatively they likely entrain a large number of outmigrating juvenile salmonids.

Studies are currently underway to determine the effectiveness of new fish screens at the GCID HCPP to determine the effectiveness of new fish screens installed in 2001 (Reclamation 2007). However, juvenile emigration data suggest that peak steelhead movement past the GCID facility occurs in spring and early summer months, when pumping volume may be high (CUWA and SWC 2004).

Historically, the GCID HCPP at RM 205 has created downstream migration problems for juvenile salmonids. The GCID pumping plant may divert up to 20 percent of the Sacramento River. Rotary drum fish screens were installed in 1972 to help protect juvenile salmon but they were largely ineffective and never met NMFS or CDFG screen design criteria. Flat plate screens were installed in front of the rotary screens in 1993 to help alleviate the problem until a more permanent solution could be found. Juvenile steelhead are exposed to the GCID pumping plant facilities as early as mid-July extending into late November when the diversion season ends.

The interim flat-plate screens were an improvement over the rotary drum screens but were still likely to subject juvenile salmonids to impingement due to high approach velocities along the screens, inadequate sweeping to approach velocities, and long exposure time at the screen (USFWS 1995 *in* NMFS 1997). Construction of a new screening facility was completed in 2001 and the testing and monitoring program for the facility are now underway (Reclamation 2007). The testing and monitoring of the new facility is scheduled to be completed in 2007 (Reclamation 2007).

PREDATION

Predation on juvenile steelhead in the middle Sacramento River is likely occurring from native Sacramento pikeminnow, native and hatchery-reared steelhead and striped bass. Although the extent of predation is unknown, predation from Sacramento Pikeminnow and striped bass is likely similar to that occurring in the lower Sacramento River as described above. Predation from hatchery steelhead is likely somewhat less than that occurring in the lower Sacramento River because the Feather River hatchery fish enter the Sacramento River downstream of this reach. Additionally, steelhead released from the CNFH are likely more evenly distributed throughout the river by the time they reach this section.

Opportunities for high predation rates also may be present at the GCID HCPP. The plant is described below as a passage impediment. Studies have indicated that Sacramento pikeminnow are the primary predator at the pumping plant, although striped bass were also found with salmonids in their stomachs (CALFED 2000c). Vogel and Marine (1995) report that predation is likely in the vicinity of the fish screens associated with the diversion.

HATCHERY EFFECTS

Direct adverse effects of hatchery operations are likely minimal in the middle reach of the Sacramento River primarily because steelhead released from the FRFH enter the river downstream and steelhead released by the CNFH are likely more evenly distributed throughout the system by the time they reach the middle reach.

4.3.7 UPPER SACRAMENTO RIVER (KESWICK DAM TO RED BLUFF DIVERSION DAM)

4.3.7.1 ADULT IMMIGRATION AND HOLDING

In this reach of the river, the potential threats to the adult immigration and holding life stage of steelhead arise from potential passage impediments at the RBDD, harvest in the sportfishery and poaching. Keswick Dam, at the upstream terminus of this reach of the river presents an impassable barrier to upstream migration.

PASSAGE IMPEDIMENTS/BARRIERS

Keswick Dam (~RM 302) presents an impassable barrier to all upstream migration of steelhead and represents the upstream extent of anadromous salmonid habitat in the mainstem Sacramento River. The ACID Dam (RM 298.5) was constructed in 1917 about three river miles downstream of the current Keswick Dam. Originally the dam was a barrier to upstream fish migration until 1927 when a poorly designed fish ladder was installed (NMFS 1997). The dam is a 450-foot long flashboard structure which has the capability of raising the backwater level 10 feet. The dam is only installed during the irrigation season which typically runs from early April to October or early November. As mentioned above, the fish ladder providing passage around the dam was poorly designed and although steelhead were able to negotiate the ladder, it did present a partial impediment to upstream migration. In 2001, a new fish ladder was installed. Post-project monitoring indicates that the new fish ladder is operating effectively (CDFG 2004c). Another potential problem associated with the facility is that high volume releases from the ACID's canal downstream of the dam may create false attraction flows for migrating adult salmon or steelhead leading them into the canal where they could be stranded (NMFS 1997). Regardless of potential problems associated with the ACID Dam, the facility likely affects only a small portion of the run. The reach from the ACID Dam to Keswick Dam is three miles; representing only a small portion of the potential spawning area.

The RBDD at RM 243 is a concrete structure 52 feet high and 740 feet long. The dam has 11 gates which are raised or lowered to control the level of Lake Red Bluff enabling gravity diversion into the TCC. Permanent fish ladders are located on each abutment of the dam. The fish ladders are inefficient in allowing upstream migration of adult salmonids (NMFS 1997). In several radio tagging studies of adult winter-run Chinook salmon, 43-44 percent of tagged fish were blocked by the dam (Vogel *et al.* 1988, Hallock *et al.* 1982 in NMFS 1997). Tagged winter-run Chinook salmon that eventually passed the dam were delayed by an average of 125 hours in one study (Vogel *et al.* 1988 in NMFS 1997) and 437 hours in a previous study (Hallock *et al.* 1982 in NMFS 1997). At present, the dam gates are kept in the raised position from September 15 through May 14, which should allow for the free passage of immigrating steelhead.

HARVEST/ANGLING IMPACTS

The take of wild trout is allowed from April 1 through the end of August (1 per day) above the Deschutes River Bridge. Wild trout are defined as not having an adipose fin-clip and being less than 16 inches in length. Wild trout greater than 16 inches in length are considered steelhead and take is not allowed. High densities of salmonids near Keswick Dam could create poaching opportunities.

WATER TEMPERATURE

Water temperatures in the upper Sacramento River during the fall and winter months when adult steelhead would be immigrating are suitable for this life stage.

WATER QUALITY

Water quality in the upper Sacramento River likely does not adversely affect adult steelhead.

FLOW CONDITIONS

Flow fluctuations in the upper Sacramento River are not of a magnitude to adversely affect adult steelhead.

4.3.7.2 SPAWNING

Specific information regarding steelhead spawning within the mainstem Sacramento River is limited due to lack of monitoring. Currently, the number of steelhead spawning in the Sacramento River is unknown because redds cannot be distinguished from a large resident rainbow trout population that has developed as a result of managing the upper Sacramento River for coldwater species.

Spawning in this reach of the Sacramento River may be affected by adverse flow conditions, physical habitat alteration, recreational sportfishing and poaching, and poor water quality (water temperature). Each of these potential effects is described below.

PASSAGE IMPEDIMENTS/BARRIERS

Keswick Dam presents an impassable barrier to upstream salmonid migration and, therefore, marks the upstream extent of currently accessible spawning habitat in this reach of the Sacramento River.

HARVEST/ANGLING IMPACTS

Harvest of steelhead in this reach of the river is likely similar to that in the middle reach. High densities of salmonids near Keswick Dam could create poaching opportunities.

WATER TEMPERATURE

Because of suitable water temperatures in this reach of the river and only marginal water temperature conditions downstream of the RBDD, almost all spawning activity likely occurs in the upper Sacramento River.

WATER QUALITY

Water quality in the upper Sacramento River is similar to that described in the middle reach described above. Because of the proximity of the Iron Mountain Mine, point source pollutants may be more concentrated in this reach of the river but effects on spawning are likely negligible.

FLOW CONDITIONS

Large flow fluctuations are the main concern regarding adverse flow conditions in the middle and upper Sacramento River. The largest and most frequent flow reductions have occurred in the late summer and early fall when flashboards at the ACID Dam require adjustment. However, because the largest flow reductions normally occur before spawning takes place, it is not likely

that adverse flow conditions in this reach of the river have a significant negative effect on steelhead.

SPAWNING HABITAT AVAILABILITY

As stated above, the level of steelhead spawning in the upper Sacramento River is unknown; however, it is generally thought that available spawning habitat in the upper Sacramento River is sufficient to support the winter-run Chinook salmon population at its currently low level (NMFS 1997). However, as the population recovers, spawning gravel availability could become a limiting factor (NMFS 1997). These same factors likely apply to steelhead.

PHYSICAL HABITAT ALTERATION

The construction of dams in the upper Sacramento River has eliminated the major source of suitable gravel recruitment to reaches of the river below Keswick Dam. Gravel sources from the banks of the river and floodplain have also been substantially reduced by levee and bank protection measures. Levee and bank protection measures restrict the meandering of the river which would normally release gravel into the river through natural erosion and deposition processes.

HATCHERY EFFECTS

Hatchery influence on spawning steelhead has not been evaluated. However, because a large proportion of steelhead stocks in the Central Valley are of hatchery origin, it is likely that significant inter-breeding between hatchery and wild fish occurs.

4.3.7.3 EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The Sacramento River supports a popular year-round recreational fishery. It is possible that anglers could disturb developing embryos in redds while wading.

WATER TEMPERATURE

The embryo incubation life stage of steelhead is the most sensitive to elevated water temperatures. Because embryo incubation of steelhead in the upper Sacramento River generally would occur from January through June, water temperatures are likely suitable for embryo incubation.

WATER QUALITY

Water quality issues that may produce adverse effects on steelhead include both point source and non-point source pollution. The inactive Iron Mountain Mine in the Spring Creek watershed near Keswick Dam creates the largest discharge of toxic material into the Sacramento River. There are three metals of particular concern: copper, cadmium and zinc. The early life stages of salmon are the most sensitive to these metals (NMFS 1997). The acid mine drainage from Iron Mountain Mine is among the most acidic and metal laden anywhere in the world (NMFS 1997). Historically, discharge from the mine has produced massive fish kills.

In 1983 the Iron Mountain Mine site was declared a superfund site by the EPA. Since that time various mitigation measures have been implemented including a neutralization plant that has improved the ability to control metal loadings to the river. NMFS (1997) reported that although

significant improvements have been made, basin plan objectives had not yet been achieved in 1997. Since that time, other mitigation measures have been implemented resulting in a 95 percent reduction in historic copper, cadmium and zinc discharges (EPA 2006). At present, acid mine waste still escapes untreated from waste pile and seepage on the north side of Iron Mountain and flows into Boulder Creek, which eventually flows into the Sacramento River (EPA 2006). However, there were no significant exceedances of dissolved metal concentrations in the Sacramento River in 2002 and 2003 (CDFG 2004c). Another point source of pollution in the upper Sacramento River identified in NMFS (1997) is the Simpson Mill near Redding which discharges PCBs into the river.

Non-point source pollution consists of sediments from storm events, stormwater runoff in urban and developing areas and agricultural runoff. Sediments constitute nearly half of the material introduced to the river from non-point sources (NMFS 1997). Excess silt and other suspended solids are mobilized during storm events from plowed fields, construction and logging sites and mines. High sediment loading can interfere with eggs developing in redds by reducing the ability of oxygenated water to percolate down to eggs in the gravel. Stormwater runoff in urban areas can transport oil, trash, heavy metals and toxic organics all of which are potentially harmful to incubating eggs. Agricultural runoff can contain excess nutrients, pesticides and trace metals.

FLOW CONDITIONS

Flow fluctuations are the primary concern related to potential adverse effects on the embryo incubation life stage of steelhead. For example, if spawning steelhead construct redds during periods of high flow, those redds could become dewatered during subsequent periods of low flow. Historically, the largest and most rapid flow reductions have occurred during the irrigation season (normally, early April through October) when adjustments are required at the ACID Dam. To accommodate these adjustments, Sacramento River flows at times have been decreased by one-half or greater, over the course of a few hours (NMFS 1997). Currently, under the CVP/SWP BO, flow reductions are divided into several intervals to prevent the stranding of juveniles. However, reducing the rates of flow reduction does not protect existing redds from becoming dewatered.

4.3.7.4 JUVENILE REARING AND OUTMIGRATION

Factors that may adversely affect juvenile steelhead in the upper Sacramento River are similar to those described above in the middle Sacramento River and include physical habitat alteration, water quality, predation, passage impediments, and entrainment.

PASSAGE IMPEDIMENTS

Keswick Dam at RM 302 presents an impassable barrier to upstream migrating adult steelhead hence it represents the upstream extent of steelhead habitat on the mainstem Sacramento River. The ACID Dam, located about three miles below Keswick Dam, represents the furthest upstream impediment, due to injury, to juvenile outmigration. The dam is only in place during the irrigation season which typically extends from April through November. During the rest of the year neither upstream adult migration nor downstream juvenile outmigration is hindered. Juveniles migrate past the dam by either dropping as much as ten feet over the dam to the river

below or moving through the bypass facility. In either case, juveniles may become disoriented and more susceptible to predation.

The RBDD, at the downstream extent of the upper Sacramento River, creates the final passage impediment to downstream outmigration in this reach of the river. The dam is described in Section 3.3.3.1. When the dam gates are lowered, Lake Red Bluff is formed slowing flows and delaying juvenile outmigration, allowing more opportunities for predation as described above in Section 3.6.5.3. Predation is also facilitated below the dam as described in Section 3.6.5.3. Historically, there was both direct and indirect mortality associated with fish using an ineffective juvenile fish bypass facility at the dam. A Downstream Migrant Fish Facility was installed in 1992, which appears to have reduced mortality associated with use of the bypass facility.

WATER TEMPERATURE

Following the installation of the TCD at Shasta Dam in 1997 water temperatures in this reach of the river seldom exceed 60°F and are suitable for juvenile steelhead rearing year-round.

WATER QUALITY

Point source pollution may occur from both the Iron Mountain Mine and the Simpson Mill as described in Section 3.5.1.2. Because the juvenile life stage of steelhead is the most susceptible to adverse effects from pollution and the proximity of these two potential sources of pollution, potential adverse effects are likely more profound in the upper Sacramento River compared to the lower reaches. Effects of non-point source pollution from urban runoff and agricultural drainage are similar to those described above for the middle Sacramento River. However, pollution associated with urban runoff is likely higher due to the proximity of the cities of Redding and Red Bluff.

FLOW CONDITIONS

Although flow fluctuations do occur in the upper Sacramento River for maintenance activities at the ACID or other water project control measures, flow reductions are governed by ramping rates which likely negate adverse effects due to flow fluctuations on juvenile steelhead.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Levee building, bank protection measures and the disconnection of the river from its historic floodplain have all had negative effects on riparian habitat. Woody debris and SRA habitat provide important escape cover for juvenile salmon. Aquatic and terrestrial insects, a major component of juvenile salmon diet, are dependent on riparian habitat. Aquatic invertebrates are dependent on the organic material provided by a healthy riparian habitat and many terrestrial invertebrates also depend on this habitat. Studies by the CDFG as reported in NMFS (NMFS 1997) demonstrated that a significant portion of juvenile Chinook salmon diet is composed of terrestrial insects, particularly aphids, which are dependent on riparian habitat.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Controlled flow regimes and channelization of the upper Sacramento River have resulted in a loss of natural river morphology and function.

LOSS OF FLOODPLAIN HABITAT

The construction of levees and streambank protection measures have resulted in a disconnection of the river with its historic floodplain.

ENTRAINMENT

Adverse effects due to entrainment of outmigrating juvenile steelhead at unscreened diversions are similar to those described above for the middle Sacramento River. The new downstream migrant fish facility at the RBDD has reduced entrainment problems at the RBDD.

PREDATION

Significant predators of juvenile steelhead in the upper Sacramento River include Sacramento pikeminnow and both hatchery and wild steelhead. Striped bass, a significant predator in lower reaches of the river, typically do not utilize the upper Sacramento River; however, they are present immediately below the RBDD.

The most serious adverse effect due to predation occurs in the vicinity of the RBDD. Passage through Lake Red Bluff can delay outmigrating juvenile steelhead and increases the opportunities for predation by both fish and birds (Vogel and Smith 1986 as cited *in* NMFS 1997). Salmonid juveniles passing under the gates at the RBDD are heavily preyed upon by both striped bass and Sacramento pikeminnow (NMFS 1997). Large concentrations of Sacramento pikeminnow have been observed accumulating immediately below the RBDD when juvenile salmonids are present (Garcia 1989 *in* NMFS 1997).

HATCHERY EFFECTS

The extent of predation on juvenile wild steelhead by hatchery-reared steelhead is not known. However, steelhead releases by the CNFH may have a high potential for inducing high levels of predation on naturally produced wild salmonids (CALFED 2000c). The CNFH has a current production target of releasing approximately 600,000 steelhead in January and February at sizes of 125 to 275 mm (CALFED 2000c). Juvenile steelhead released by the CNFH may also compete for resources with naturally produced juvenile steelhead.

4.3.8 NORTHERN SIERRA NEVADA DIVERSITY GROUP

4.3.8.1 AMERICAN RIVER

The American River drains a watershed of approximately 1,895 square miles (Reclamation 1996), and is a major tributary to the Sacramento River. The American River has historically provided over 125 miles of riverine habitat to anadromous and resident fishes. Presently, use of the American River by anadromous fish is limited to the 23 miles of river below Nimbus Dam (the lower American River).

The Nimbus Fish Hatchery steelhead program mitigates for steelhead spawning habitat eliminated by construction of Nimbus Dam, with an annual goal of releasing 430,000 yearling steelhead. Specific information on the number and status of indigenous American River steelhead is lacking but early reports suggested that steelhead entered the river during most months of the year and included a spring run. Early Nimbus Fish Hatchery broodstock included naturally produced fish from the American River and stocks from the Mad, Eel, Sacramento and

Russian rivers. Based on the ESA listing, the indigenous American River steelhead are presumed to be phenotypically similar to Central Valley steelhead. However, American River steelhead may not have been phenotypically or genotypically similar to the Central Valley stock based on anecdotal run timing information and Nimbus Fish Hatchery records that suggest some American River steelhead were physically larger than typical Sacramento or Feather River winter-run steelhead. The present run of American River winter steelhead are physically larger and demonstrate a freshwater entry timing more similar to winter run Eel River steelhead than the Central Valley stock (Lee 2008).

The American River winter steelhead run appears to be a predominately hatchery supported run and since the 2001-2002 trapping season, 97.8% of the steelhead trapped are of hatchery origin. Surveys also suggest that the number of steelhead actually spawning in the river is small. During the last 10 years, most adult steelhead trapped appear to be three years of age and the number of smaller fish (16 in.) during the same period averaged less than two percent (Lee 2008).

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

In 1955, Folsom and Nimbus dams were constructed on the mainstem of the American River approximately 28 and 23 miles, respectively, upstream from the confluence with the Sacramento River. Fish passage facilities were not built at Folsom or Nimbus dams blocking all anadromous salmonid upstream migration at Nimbus Dam. Anadromous salmonids are now restricted to the lower 23 miles of the American River extending from Nimbus Dam downstream to the confluence with the Sacramento River.

HARVEST/ANGLING IMPACTS

Current fishing regulations allow for the harvest of hatchery-reared steelhead (identified by an adipose fin clip) in the American River. The harvesting of wild steelhead is not allowed. However, heavy angling pressure in the river likely leads to some wild steelhead mortality even for those fish that are caught and released. The number of hatchery-reared steelhead harvested in the American River is estimated to have been 116 in 1998 (April through December), 567 in 1999 (January through December), 499 in 2000 (January through December) and 469 in 2001 (January and March through June) (CDFG 1999c, 2000b, 2001d and 2002b).

WATER TEMPERATURE

Water temperatures in the American River during the steelhead adult immigration and holding period (November through April) are generally below 55°F, which is suitable for this life stage (SWRI 2004).

WATER QUALITY

Water quality in the American River is generally good and meets applicable regulatory standards for both aquatic life and human health, with few exceptions. Therefore, water quality conditions in the lower American River are not expected to affect adult steelhead immigration.

FLOW CONDITIONS

Operation of Folsom and Nimbus dams has resulted in higher flows during the fall and summer and significantly lower flows during winter and spring. However, flow standards in the American River are adequate to support steelhead adult immigration.

SPAWNING

Steelhead spawning in the lower American River occurs from December through April. In 2003, 2004 and 2005, between 40 and 48 percent of steelhead redds were found in the upper three miles of the American River (Hannon and Deason 2005). From 2002 through 2005, 95 percent of all steelhead redds in the American River were found upstream of the Watt Avenue Bridge (Hannon and Deason 2005).

PASSAGE IMPEDIMENTS/BARRIERS

Anadromous salmonids are now restricted to the lower 23 miles of the American River extending from Nimbus Dam downstream to the confluence with the Sacramento River.

HARVEST/ANGLING IMPACTS

Current fishing regulations allow for the harvest of hatchery-reared steelhead (identified by an adipose fin clip) in the American River. The harvesting of wild steelhead is not allowed.

WATER TEMPERATURE

In the American River, steelhead spawning generally occurs from January through April. Water temperatures during this time period are generally below 55°F and suitable for steelhead spawning (SWRI 2004).

WATER QUALITY

The Ambient Monitoring Program (AMP) was established under the Sacramento Coordinated Monitoring Program (CMP) to characterize ambient water quality conditions in the Sacramento and American rivers. As reported by the AMP, based on data from 1992 through 1998, monitored ambient water quality constituents meet applicable regulatory standards for both aquatic life and human health, with few exceptions. Therefore, water quality in the lower American River is adequate to support successful steelhead spawning.

FLOW CONDITIONS

The construction and operation of Folsom Dam has altered the historic flow regime of the lower American River. Historically, fluctuations during the fall and winter were caused by natural rainfall patterns, but the dry season flows were low and fairly constant. Varying water demands of the CVP have shifted the timing of flow fluctuations to late spring and summer (CDFG 1991c). This shift in the timing of flow fluctuations likely does not affect steelhead spawning. However, flow fluctuations can have an effect on steelhead spawning habitat. For example, reductions from 2,500 cfs to 1,500 cfs would result in a loss of over 60 percent of viable spawning habitat and dewater up to 40 acres of potential spawning habitat (CDFG 2001b).

SPAWNING HABITAT AVAILABILITY

Observations of lower American River spawning gravel indicate that substrate particle sizes are relatively large compared to those typically used by steelhead in other streams. A lack of

suitable spawning gravel may be related to the lack of recruitment of smaller gravel from upstream of Nimbus and Folsom dams (CDFG 1991c).

PHYSICAL HABITAT ALTERATION

The lower American River currently provides a diversity of aquatic habitats, including shallow riffles, glides, runs, pools and of channel backwater habitats. From Nimbus Dam downstream to Goethe Park (approximately nine river miles), the river is relatively unrestricted by levees. From Goethe Park downstream to the confluence with the Sacramento River, the river is constrained by levees which have resulted in a corresponding decrease in habitat diversity (SWRI 2004).

HATCHERY EFFECTS

The source stock of the Nimbus Hatchery steelhead program is from the Eel River, with one-time genetic infusions of CNFH and Warm Springs Hatchery stocks (SWFSC 2003). The run-timing of Nimbus Hatchery steelhead indicates Eel River derivation, and recent genetic analysis (Nielsen *et al.* 2003) links the hatchery stock to the natural spawning population in the American River. The Nimbus Hatchery stock is not part of the Central Valley steelhead DPS, and its impacts to the American River population include genetic introgression, altered life history, and competition over spawning and rearing habitat in the lower American River. Nimbus Hatchery spawns steelhead and re-releases them back into the American River. This may diversify age structure of steelhead in the hatchery stock (advantage) and river (genetic disadvantage), as kelts have higher fecundity and larger eggs. However, as kelts have the potential to spawn again, they compound the effects from annual number of hatchery stock releases. Hatchery returns increase the abundance of the run overall, but dominate or displace natural steelhead numbers.

The steelhead spawning population of the American River ranges between 200 and 400 adults (Reclamation 2005), and includes an unknown percentage of Nimbus Hatchery steelhead. The Hatchery may affect water quality and aquatic life in the American River from its effluent discharge, with unknown implications of disease transmission.

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

The lower American River is open to recreational fishing year-round. Therefore, there is a potential for wading anglers to disturb redds.

WATER TEMPERATURE

Embryo incubation of steelhead in the lower American River generally occurs from January through May. During this period, water temperatures are normally below 55°F until about the beginning of May and remain below 60°F for the remainder of May, which is suitable for steelhead embryo incubation (SWRI 2001).

WATER QUALITY

The AMP was established under the Sacramento CMP to characterize ambient water quality conditions in the Sacramento and American rivers. As reported by the AMP, based on data from 1992 through 1998, monitored ambient water quality constituents meet applicable regulatory standards for both aquatic life and human health, with few exceptions. For aquatic life, four

metals exceeded the California Toxics Rule for EPA criteria. At Nimbus Dam, lead and zinc exceed applicable criteria less than once every three years, and cadmium, more than once every three years. At Discovery Park, cadmium would exceed applicable criteria more than once every three years, and copper, lead and zinc would exceed applicable criteria less than once every three years (SWRI 2004). Heavy metal concentrations that exceed EPA criteria may adversely affect developing steelhead embryos.

AMP pesticide monitoring conducted on the lower American River has occasionally detected diazinon, diuron, and simazine. The concentrations of diuron and simazine are well below concentrations identified as slightly toxic to fish; diazinon, however, was detected seven times over four years at concentrations above CDFG's recommended maximum values for fish (SWRI 2004). Pesticide concentrations above CDFG recommended values could adversely affect developing steelhead embryos.

FLOW CONDITIONS

CDFG aerial redd surveys conducted in the early 1990s have produced evidence that Chinook salmon redds are dewatered as a result of flow reductions during the fall and winter months. The same is likely true for steelhead (Water Forum 1996). The potential for significant losses to steelhead is greatest when flows are low and redds are concentrated (Water Forum 1996). CDFG conducted a four-year flow fluctuation study during 1997 to 2000. Results of the study indicate that (1) flow fluctuations are regular occurrences in the lower American River; (2) flow fluctuations are more common during the October to June time period and (3) flow fluctuations can significantly change steelhead spawning habitat viability (CDFG 2001c). The need to meet water supply requirements south of the Delta and Delta water quality standards has resulted in fluctuating flow patterns that can dewater spawning areas and associated redds (SWRI 2004).

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

Water temperatures during the summer months can become unsuitable for juvenile steelhead rearing and potentially high water temperatures is believed to be one of the limiting factors for steelhead production (SWRI 2001).

WATER QUALITY

The AMP was established under the Sacramento CMP to characterize ambient water quality conditions in the Sacramento and American rivers. As reported by the AMP, based on data from 1992 through 1998, monitored ambient water quality constituents meet applicable regulatory standards for both aquatic life and human health, with few exceptions. For aquatic life, four metals exceeded the California Toxics Rule for EPA criteria. At Nimbus Dam, lead and zinc exceed applicable criteria less than once every three years, and cadmium, more than once every three years. At Discovery Park, cadmium would exceed applicable criteria more than once every three years, and copper, lead and zinc would exceed applicable criteria less than once every three years (SWRI 2004).

AMP pesticide monitoring conducted on the lower American River has occasionally detected diazinon, diuron, and simazine. The concentrations of diuron and simazine are well below

concentrations identified as slightly toxic to fish; diazinon, however, was detected seven times over four years at concentrations above CDFG's recommended maximum values for fish (SWRI 2004).

FLOW CONDITIONS

Stranding of juvenile steelhead because of rapid flow fluctuations is frequently observed in the lower American River (SWRI 2001). During a four-year study of isolation events from 1997 to 2000, a total of 22 separate events were observed (CDFG 2001c). Mortality of young salmonids that become stranded is near 100 percent. Sources of mortality in such cases include predation by fish, avian predators and thermal stress (SWRI 2001). Fluctuating flows are believed to result in considerable stranding and loss of steelhead fry in the lower American River (Water Forum 1996).

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

Riparian habitat along the American River is in relatively good condition from Nimbus Dam downstream to the Howe Avenue Bridge, however, revetted banks become common and riparian cover becomes limited downstream from that point (Water Forum 1996).

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

The lower American River currently provides a diversity of aquatic habitats, including shallow fast-water riffles, glides, runs, pools, and off-channel backwater habitats. The reach of the river extending from Nimbus Dam (RM 23) downstream to Goethe Park (RM 14), is primarily unrestricted by levees, but is bordered by some developed areas. This reach of the river is contained by natural bluffs and terraces cut into the side of the channel. The river reach from Goethe Park downstream to the confluence with the Sacramento River is bordered by levees. The construction of levees changed the geomorphology and has resulted in a reduction in river meanders and an increase in depth (SWRI 2001).

LOSS OF FLOODPLAIN HABITAT

High floodplains produced by the deposition of sandy sediments from upstream hydraulic mining during the Gold Rush are disconnected from the river except during extremely high flow events. Without a regular cycle of floodplain inundation, species favoring infrequent inundation and many non-native species have taken advantage of the altered system and reduced the ecological integrity of the floodplain (USACE *et al.* 2001).

ENTRAINMENT

The City of Sacramento's Fairbairn WTP, located about seven miles upstream of the confluence with the Sacramento River, is the only major diversion on the lower American River. Although the diversion is screened, it reportedly does not meet NMFS/CDFG standards. There is a possibility that juvenile salmonids, including steelhead can become entrained (Water Forum 1996).

PREDATION

American shad, striped bass and species of black bass are all known to inhabit the lower American River and likely prey on juvenile salmonids. Additionally, manmade structures and

channel confinement in the lower section of the river may have altered habitat conditions favoring native predators such as Sacramento pikeminnow.

HATCHERY EFFECTS

The Nimbus Hatchery raises and releases yearling steelhead into the American River. It is possible that some portion of these fish do not immediately begin a downstream migration and may prey on smaller naturally produced steelhead juveniles in the river.

4.3.8.2 AUBURN/COON CREEK

Auburn Ravine originates north of Auburn in Placer County and drains an area of approximately 70 square miles. Auburn Ravine flows westward out of the Sierra foothills into the East Side Canal, and is hydraulically connected to the Sacramento River via the East Side Canal and the Natomas Cross Canal near the town of Verona.

It is unlikely that Auburn Ravine historically harbored a persistent native population of salmonids. Low elevation streams in the Sierra foothills, such as Auburn Ravine, may have been essentially dry in the summer and fall. Because of their intermittent nature, these streams were not conducive to significant or consistent steelhead populations. However, anecdotal information suggests that adult steelhead have been captured and released by anglers in the Ophir area, approximately 10 miles upstream of the city of Lincoln. Additionally, long-time residents report that steelhead routinely spawned near Auburn (JSA 1999b).

Adult steelhead immigration into the Delta and the lower Sacramento River occurs from August through March (McEwan 2001; NMFS 2004a), and peaks during January and February (Moyle 2002). To reach Auburn Ravine, steelhead would migrate up the Sacramento River and enter the Natomas Cross Canal near the town of Verona. Traveling upstream in the Natomas Cross Canal, fish would then enter the East Canal and migrate slightly over 1 mile upstream to the Auburn Ravine confluence.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS/BARRIERS

Currently, there are numerous water diversions within Auburn Ravine. Most of these are seasonal agricultural diversions supplied by temporary flashboard dams that are normally in place from April 15 to October 15 having little if any effect on upstream migrating adult steelhead. There are two temporary dams located near the city of Lincoln that may remain in place until as late as mid-November, Lincoln Ranch Duck Club Dam and the Hemphill Dam, both of which are barriers to upstream migration at low to moderate flows and could present obstacles to the early part of the steelhead run (Sierra Business Council 2003).

There are several permanent structures within Auburn Ravine that present obstacles to upstream migration at all but high flows. The first of these structures is the Nevada Irrigation District gaging station located about one-quarter mile downstream of State Route 65 in Lincoln. The structure is a full channel width concrete section forming a broad plume with vertical sides and an upward sloping approach. The structure is likely a significant impediment to adult steelhead upstream migration at all but the highest flows (Sierra Business Council 2003). The next

permanent manmade structure in Auburn Ravine is the Nevada Irrigation District Auburn Ravine 1 Dam located off Chili Hill Road near Ophir. This is a gravity arch dam with a crest about 8 feet above the tailwater during normal flows. The dam is an impediment to upstream migration at all but high flows. There is also a natural waterfall just upstream of Ophir that is impassable at low flows.

HARVEST/ANGLING IMPACTS

Catch and release fishing for trout is allowed from the fourth Saturday in May through October 14. This is outside of the time period when steelhead would be expected to be migrating upstream in Auburn Ravine.

WATER TEMPERATURE

Water temperatures in Auburn Ravine typically cool rapidly from mid-October through November and begin warming in March. During this time period, water temperatures generally fall below 60°F in October, and remain below 55°F from November through the beginning of March (Sierra Business Council 2003). These water temperatures should not adversely affect the adult steelhead immigration and holding life stage.

WATER QUALITY

Water quality in Auburn Ravine is generally good. In terms of heavy metal concentrations, copper is the only metal found in Auburn Ravine that occasionally exceeds California's Toxic Rule (Sierra Business Council 2003) and is not likely to adversely affect steelhead adult immigration.

FLOW CONDITIONS

Flow conditions in Auburn Ravine are significantly different under current management practices than those that occur naturally. Jones & Stokes Associates (1999) estimated flows under natural conditions and current management conditions. The results of this comparison are depicted in **Figure 4-6**. These flow conditions are not likely to adversely affect steelhead adult immigration and may provide some benefit when compared to historic conditions.

Figure 4-6. Estimated Flows in Auburn Ravine Under Natural and Current Conditions

Source: (JSA 1999b)

SPAWNING

PASSAGE IMPEDIMENTS/BARRIERS

The same passage impediments as described above for adult immigration apply to the spawning life stage.

HARVEST/ANGLING IMPACTS

Catch and release fishing for trout is allowed from the fourth Saturday in May through October 14. This is outside of the time period when steelhead would be expected to be spawning.

WATER TEMPERATURE

Water temperatures in Auburn Ravine typically cool rapidly from mid-October through November and begin warming in March. During this period, water temperatures generally fall below 60°F in October, and remain below 55°F from November through the beginning of March (Sierra Business Council 2003). These water temperatures should not adversely affect the steelhead spawning life stage.

WATER QUALITY

Water quality in Auburn Ravine is fairly good and is not expected to adversely affect steelhead spawning.

FLOW CONDITIONS

Currently, winter flows are dominated by discharges from the Lincoln Wastewater Treatment and Reclamation Facility downstream of the town of Lincoln and runoff caused by rainfall events upstream of that point where most spawning is likely to occur.

SPAWNING HABITAT AVAILABILITY

The results of a stream survey by Jones & Stokes Associates downstream of the Lincoln Wastewater Treatment and Reclamation Facility (RM 10.5) indicated relatively poor spawning habitat in this reach of Auburn Ravine (JSA 1999a). The habitat was found to be of low quality because of the lack of gravel for spawning and a shifting sand substrate that could potentially smother redds.

There appears to be good spawning habitat near Ophir, particularly in the vicinity of the Nevada Irrigation District Auburn Ravine 1 Dam. There is also reportedly good spawning habitat in Dutch Ravine, a tributary of Auburn Ravine near Ophir. However, it is not known if impediments to fish passage in Auburn Ravine prevent utilization of this reach.

PHYSICAL HABITAT ALTERATION

Auburn Ravine is a relatively small watercourse, and little of the instream flow is from natural runoff. Most of the instream flow is water imported from the Yuba River, Bear River, and American River watersheds through various means, to meet domestic and agricultural needs in western Placer County and southeastern Sutter County (Sierra Business Council 2003). Related to the distribution of these water supplies, there are approximately 10 small seasonal diversion dams installed throughout Auburn Ravine. Each dam is usually less than 10 feet high and ponds water for diversion into agricultural areas. Larger dams also divert water into major canals.

HATCHERY EFFECTS

Stocking records do not indicate that steelhead have been planted in Auburn Ravine. Historically, rainbow trout were planted in Auburn Ravine until 1965, and rainbow trout continue to be planted in water bodies connected to Auburn Ravine (e.g., the Bear River and associated reservoirs).

EMBRYO INCUBATION

HARVEST/ANGLING IMPACTS

Catch and release fishing for trout is allowed from the fourth Saturday in May through October 14. This is outside of the time period when wading anglers may disrupt steelhead embryos developing in redds.

WATER TEMPERATURE

Discharges from the Lincoln Wastewater Treatment and Reclamation Facility and the Auburn Wastewater Treatment Plant (RM 24.9) increase water temperatures downstream from their respective points of discharge. However, the Basin Plan requires that discharges shall not increase water temperatures more than 5°F above the receiving water temperature (RWQCB 2005). Based on very limited water temperature data collected in 2003 and 2004, water temperatures within and upstream of the area near Ophir provide suitable water temperatures for

embryo incubation, however; water temperatures increase rapidly further downstream to the next measurement point, about four miles downstream of Ophir, and are likely not suitable after about mid-March (Sierra Business Council 2003).

WATER QUALITY

Water quality in Auburn Ravine is fairly good. In terms of heavy metal concentrations, copper is the only metal found in Auburn Ravine that occasionally exceeds California's Toxic Rule (Sierra Business Council 2003).

FLOW CONDITIONS

Flow conditions upstream of the Lincoln Wastewater Treatment facilities, where most steelhead embryos would likely be developing, are likely similar to historic conditions in that they are dominated by rainfall events and irrigation diversions are minimal.

JUVENILE REARING AND OUTMIGRATION

WATER TEMPERATURE

The lack of shading provided by loss of riparian buffers in the downstream reaches of Auburn Ravine contributes to elevated summer water temperatures. CDFG conducted electrofishing on seven reaches of Auburn Ravine in the fall/winter of 2004 and the spring of 2005 (CDFG unpublished data). The CDFG survey results suggest that Auburn Ravine contains a fairly strong steelhead/rainbow trout population with almost all juvenile rearing occurring upstream of the Lincoln Wastewater Treatment and Reclamation Facility.

Water temperatures in the vicinity of Ophir are generally cool year-round with the warmest temperatures being recorded in September at 61°F. Water temperatures cool quickly to below 55°F by November and remain below 53°F until the following July (City of Auburn 1997).

WATER QUALITY

Water quality in Auburn Ravine is generally good. Occasionally concentrations of copper may exceed California's Toxic Rule (Sierra Business Council 2003), but this is not expected to adversely affect juvenile steelhead.

FLOW CONDITIONS

As described above, flows in Auburn Ravine are significantly different under current management practices compared to natural conditions. Because summer flows are typically higher than would be expected from a Central Valley Sierra foothill stream and winter flows are also higher under existing conditions because of the introduction of water from other sources, flows are likely not a limiting factor in Auburn Ravine. However, there is a two to four week window in late October, when the Wise Powerhouse ceases operations, and prior to the onset of winter rains, which may limit available habitat but likely not more than would have occurred under historic conditions.

LOSS OF RIPARIAN HABITAT AND INSTREAM COVER

There has been significant urban development in Auburn Ravine which has resulted in a degraded riparian habitat.

LOSS OF NATURAL RIVER MORPHOLOGY AND FUNCTION

Historically, instream flows in Auburn Ravine were ephemeral (Sierra Business Council 2003). Under natural instream flow conditions, flows gradually declined through the spring, summer, and early fall until the first seasonal storm events occurred. Estimated monthly mean flows in Auburn Ravine under natural conditions range from no flow during mid- to late-summer to approximately 26 cfs during the winter (City of Auburn 1997). Under current management practices, flows in Auburn Ravine are much more consistent from spring through mid-fall. Currently, winter flows are dominated by discharges from wastewater treatment facilities and runoff caused by rainfall events. Summer flows are dominated by irrigation water deliveries. Summer flows have been reported to range from 30 to 175 cfs (Nevada Irrigation District, daily flow in Auburn Ravine below State Route 65, 1976 through 1998). In September and October, flows are substantially decreased as irrigation demands diminish or cease. Flows during this period often are less than three cfs (JSA 1999a). Water management practices in Auburn Ravine have altered the natural temporal variation in instream flows, and as a result, have altered the natural temporal variation in water temperatures.

LOSS OF FLOODPLAIN HABITAT

Regulated flows and flood protection have eliminated much of the connectivity of Auburn Ravine with the historic floodplain.

ENTRAINMENT

During the irrigation season, there are temporary diversion dams throughout Auburn Ravine. All of these diversions are unscreened or poorly screened creating a high risk of entrainment for outmigrating juvenile salmonids. Although most of these dams are not operational during peak juvenile steelhead outmigration, the Sierra Business Council has rated five of them as having a moderate need for screening (Sierra Business Council 2003). Additionally, two permanent diversions, Hemphill Dam and the Nevada Irrigation District Auburn Ravine 1 Dam, are rated as high in priority for screen installations (Sierra Business Council 2003). The Nevada Irrigation District Auburn Ravine 1 Dam is particularly important as spawning and rearing habitat upstream of the dam are rated as excellent (Sierra Business Council 2003).

PREDATION

Several exotic species have been introduced to Auburn Ravine including bluegill and black bullhead, both of which prey on small salmonids. Additionally, black bass species may have been introduced to the area. Manmade structures and alteration of the natural flow regime may have created conditions favoring native predators including Sacramento pikeminnow.

HATCHERY EFFECTS

Most steelhead entering Auburn Ravine are likely of hatchery-origin. It is doubtful that conditions in Auburn Ravine are sufficient to support a self-sustaining population.

4.3.8.3 DRY CREEK

Dry Creek originates in the Sierra Nevada Foothills, drains approximately 101 square miles (ECORP Consulting 2003) and is hydraulically connected to the Sacramento River *via* the Natomas East Main Drainage Canal. Below Elverta Road, Dry Creek diverges into two channels (i.e., the Main Fork and the North Fork). The Main Fork lies to the south and contains flow

year-round. The North Fork is several feet higher than the Main Fork and functions as an overflow channel (Foothill Associates 2003). Tributaries to Dry Creek include Secret Ravine, Miners Ravine, Strap Ravine, Antelope Creek, Clover Valley Creek, and Linda Creek.

According to information presented in the *Dry Creek Watershed Coordinated Resource Management Plan* (ECORP Consulting 2003), the mainstem of Dry Creek is not suitable spawning habitat, but is considered only as a migration corridor to upstream areas containing spawning habitat for anadromous salmonids.

ADULT IMMIGRATION AND HOLDING

PASSAGE IMPEDIMENTS
