ACKNOWLEDGMENT

Valuable cooperation and assistance were provided by water users and by public and private agencies in the field work and preparation of data for this report on Sacramento Valley water use.

The U. S. Department of Interior, Bureau of Reclamation, furnished data on reservoir operation, streamflow, diversions, and Delta salinity.

The U. S. Geological Survey provided streamflow and ground water level data, and the National Weather Service furnished streamflow and precipitation records.

The Pacific Gas and Electric Company and the Sacramento Municipal Utility District made available records of power consumption for diversions computations.

The State Water Resources Control Board, Division of Water Rights, furnished information on water rights and water use on Sacramento Valley streams and participated in land-use surveys and field inspections in the Delta.

Mr. William O. Pruitt, Irrigation Engineer, University of California at Davis, furnished data and information concerning climatic conditions and evapotranspiration factors.

FOREWORD

The combined effect of substantially below-normal precipitation during 1976 and record low precipitation in 1977 imposed an unusual burden on the operation of both the State Water Project and the Central Valley Project in meeting their water delivery objectives.

This is the second report on the Sacramento Valley Water Use Survey that began in 1976 to (1) learn more about dry-year hydrology, and (2) obtain information that would help manage our limited water supplies. This report presents the findings of that survey for 1977.

The report contains data and analyses of precipitation, runoff, streamflow, diversions, accretions, land and water use, water rights, Delta salinity, and other information necessary for determining the effect of the drought on the Sacramento and Feather Rivers and in the Sacramento-San Joaquin Delta. It also shows graphically the changes that occurred in ground water levels within the Sacramento Valley between 1975 and 1977.

Federal and other public agencies, as well as private agencies, have assisted in the survey by providing a portion of the data presented.

The California Water Commission serves as a policy advisory body to the Director of Water Resources on all California water resources matters. The nine-member citizen Commission provides a water resources forum for the people of the State, acts as liaison between the legislative and executive branches of State Government, and coordinates Federal, State, and local water resources efforts.

Chapter I. INTRODUCTION

Water supplies markedly affect the lives of California citizens and the State's economy. Nonirrigated farmlands, such as pasture and grain, depend on direct rainfall. Irrigated areas depend not only on direct rainfall but also on water stored in surface and ground water reservoirs. Snow, which is "stored" in the higher elevations during winter, is a major source of runoff in the late spring and early summer. Both rainfall and snowmelt runoff are stored in foothill reservoirs and later released for irrigation and many other uses.

During the 1976-77 season, California experienced below-normal precipitation throughout the State. In the Sacramento Valley, precipitation from October 1, 1976, through August 31, 1977, ranged from 30 to 50 percent of normal. A moderate-sized storm occurred in September 1977, but it did not produce significant runoff because most of the precipitation was absorbed by dry watersheds. The snowpack in Northern and Central California was close to the lowest of record. Unimpaired runoff in the Sacramento Valley ranged from about 14 percent of normal in the southern portions to about 43 percent at Red Bluff. The annual unimpaired runoff for the Sacramento and San Joaquin Rivers to the Delta was only 27 percent of normal.

Sacramento Valley Water Use Survey

During the early part of the 1976 irrigation season, water supply inventories showed that reservoirs were being depleted at a greater rate than had been estimated. A substantial part of the increased use was directly related to the below-normal precipitation. Less apparent, however, was the reason for higher-than-estimated losses of water between the upstream reservoirs and the Delta.

The Sacramento Valley Water Use Survey program was developed cooperatively by the Department of Water Resources (Department), the U. S. Bureau of Reclamation (USBR), and the State Water Resources Control Board (SWRCB), to determine why increased releases were necessary to meet water demands and to provide supplemental information that would help managers make decisions to equitably distribute the limited water supplies. The program was oriented primarily toward measurement of water quantities. The only water quality problem considered was salinity in the Delta.

Scope of Survey

The Survey, which began in July 1976 and continued in 1977, covered the area from Shasta Dam on the north (Plate 1) to Vernalis on the south (Plate 2). The survey included the service area of the Sacramento-San Joaquin Delta as shown on Plate 2.

Records of monthly flows at streamflow gaging stations operated by State and Federal agencies along the major streams and tributaries in the Sacramento Valley and around the periphery of the Delta are included in the survey. Also included are estimates and measurements of monthly diversions and return flow along major streams. The location of stream-gaging stations, return flows, and precipitation stations, and of major diversions and places of use are shown on Plate 3.

Records of inflow, storage, and release for Shasta, Folsom, and Oroville Lakes and exports from the Delta were obtained from project operators. The scope of the survey also included compilation of records of salinity in the western Delta derived from continuous electrical conductivity recorders, and data on climatic and runoff conditions.

Scope of Report

This report contains a summary of hydrologic data collected during the 1977 irrigation season. The basic data presented were compiled from information currently being collected under ongoing programs and from additional field work undertaken specifically for this survey.

Some of the basic data presented herein are preliminary and subject to revision. Final data will be included in periodic published reports of the Department and other cooperating agencies.

Dry Year Program of the State Water Resources Control Board (SWRCB)

The SWRCB has responsibilities for administration of programs dealing with water rights and water quality. During the drought, many interests were concerned that water users would inadvertently interfere with water rights of others if not forewarned about the availability of water. To reduce this possibility, the Dry Year Program was established as a function within the Division of Water Rights. This program was designed to protect and enforce priorities of surface water users. Activities conducted under this program were closely allied with the activities conducted under the Sacramento Valley Water Use Survey. Therefore, a free interchange of information was made between the two programs.

The program elements directly related to the Sacramento Valley Water Use Survey program were as follows:

1. Estimates were made of the water available to satisfy water rights. Over 3,800 notices were sent to water users in the central and northern parts of the State requesting them to conserve water and to divert only water to which they were entitled.
2. Additional staff was assigned to respond to an unprecedented increase in water rights complaints.
3. An interagency agreement was entered into between the SWRCB and the Department. Under the agreement, the Department supplied personnel to investigate uses of water under appropriative and assumed riparian rights on the Sacramento River and its main tributaries and appropriative diverters in the Delta. The Department also conducted a crop survey of the Delta lowlands.

Information collected under the Dry Year Program has been considered and information concerning land and water use in the Delta has been incorporated into this report.

Summary

The 1976-77 unimpaired runoff of the Sacramento-San Joaquin Rivers to the Delta was only 27 percent of normal, the lowest since records have been maintained. Reservoir storage on December 1, 1977, was only 30 percent of normal. During 1976 and 1977 irrigation seasons, stored water was depleted at rates in excess of planned project operations.

Although water conservation measures had been initiated in 1976, increased emphasis was given to reductions in water use during 1977. The USBR announced that only 75 percent of the normal contract quantities would be delivered to water users along the Sacramento River. The Department limited deliveries to contractors on the Feather River to only 50 percent of normal entitlements. The SWRCB implemented a Dry Year Program and mailed notices to water right holders announcing the forecast of limited water supplies and requesting their cooperation in diverting only water to

which they were entitled. The SWRCB also made field investigations of water right complaints in an effort to enforce water right entitlements.

Diversions from the main river channels above Sacramento during 1977 were about 75 percent of the diversions during the 1976 irrigation season. Reductions in river diversions were attributed to: (1) water contract restrictions placed on water diverters by the USBR and the Department, (2) compliance with notices sent to water users by the SWRCB, and (3) new wells drilled to supplement surface diversions.

Over 95 percent of the appropriative rights along the main stem of the Sacramento and Feather Rivers were contractually augmented by stored water. Water diverted without proper rights from these channels was estimated to be less than 1 percent of the total water diverted.

Ground water levels declined as much as 18 metres (60 feet) between the spring of 1975 and the spring of 1977 in the southern portion of the Sacramento Valley west of Knights Landing. Data and information were insufficient to estimate the amount of ground water recharge from river channels and the amount of pumping from the ground water basin. However, most of the decline in water levels upstream from Colusa was attributed to lack of water supply for recharge. In the reach downstream from Colusa, drawdown in excess of about 1.5 metres (5 feet) was attributed to increased pumping. The greatest losses in both ground and surface water occurred in the reach from Colusa to Sacramento.

Land use in the Delta during 1977 did not change substantially from 1976. In 1976, the total irrigated area and the double-cropped land was 203 900 hectares (503,800 acres) and 6 176 hectares (15,300 acres) respectively, as compared with 207 500 hectares (512,800 acres) and 3 747 hectares (9,260 acres), respectively, for 1977. Changes in crop patterns did not result in any substantial reduction in water use. The total water use during the 1976 season was computed to be 2 156 cubic hectometres (1,748,000 acre-feet), as compared with 2 125 cubic hectometres (1,722,000 acre-feet) for 1977.

Water was computed to be available until the first part of July to satisfy riparian uses. On a mean monthly flow basis, during 1977, shortages of water to satisfy riparian rights and Delta outflow prevailed during the months of July and August. Assumed riparian use of water within the Sacramento Valley and in the Delta service area exceeded the nonproject runoff by approximately 360 cubic hectometres (290,000 acre-feet) during these months. Estimated project water used by appropriators in the Delta uplands during June, July and August was about 165 cubic hectometres (135,000 acre-feet).

Salinity was allowed to move into the Delta channels in compliance with emergency regulations of the SWRCB. The daily maximum 1 000 mg/l chloride concentration level moved in as far as the vicinity of Rio Vista on the Sacramento River and Jersey Point on the San Joaquin River.

Conclusions

1. The restriction imposed by contracts for water from the Central Valley Project and the State Water Project was the principal reason for reductions in diversions from the Sacramento and Feather Rivers during the 1977 irrigation season.

2. Minimal reductions from the 1976 level in the amount of water used by agricultural crops in the Delta service area were achieved. However, some impairments in water quality occurred, particularly in the western Delta, from the relaxation in water quality criteria.

3. Stored water from the Central Valley Project and the State Water Project was used to provide acceptable quality of water within the Delta. The Delta service area benefited from this use of stored water. Impairments in water quality resulted in minimal reduction in crop yields.

4. Stored water was used to supplement riparian water supplies for assumed riparian land in the Delta service area during July and August, and was used by Delta uplands appropriators during the latter part of June and during July and August.

5. Additional data are needed to quantify ground water and its movement. Ground water data collection should be continued to monitor ground water level trends and to inventory and classify wells to create a data base for future ground water investigations.

Sacramento River at Hood. The major inflow tributary to the Delta.

Chapter II. WATER SUPPLY

During the 1977 irrigation season, very low flows of the Sacramento River were caused by diversions from the river for irrigation, low accretions to the river by ground water seepage, and minimum releases of water from Shasta, Trinity, Oroville, Folsom, and other reservoirs.

Water in the Delta service area is supplied from (1) direct precipitation, (2) tributary inflows, and (3) ground water contributions to the Delta uplands. Water is removed from the Delta by (1) evaporation and transpiration (agriculture, water surfaces, riparian vegetation, etc.), (2) exportation to areas outside of the Delta, (3) urban uses within the Delta, and (4) outflows into Suisun Bay.

Precipitation

In the Sacramento Valley, direct precipitation is generally a source of water for growing crops during early spring. In normal years, rainstorms during March and April substantially reduce the demand for irrigation diversions during those months and affect the demand in the same month from year to year. During 1977, rainfall in the Valley was well below normal for January through April, and temperatures during March and April were warmer than normal, resulting in increased diversions as compared with a year of normal precipitation and temperature.

Table 1 presents the monthly precipitation for January through October 1977 at stations throughout the Sacramento Valley and Delta areas. The corresponding normal monthly precipitation is also shown. (The precipitation stations are shown on Plates 2 and 3.) At the bottom of Table 1, the average monthly precipitation for the Delta service area is shown. Also, the total monthly acre-feet based on the average precipitation for both the lowlands and uplands areas are shown.

Runoff Comparisons

To compare runoff conditions on a particular stream, the average or normal runoff for that stream over a period of years must be computed. Deviations from the normal are expressed as a percentage for each year considered. Runoff comparisons are based on percentages of average determined for the 50-years October 1920 through September 1970.

Since runoff conditions are affected by man-made impairments, an equitable comparison throughout the water year requires that all runoff quantities be adjusted to unimpaired runoff. Unimpaired runoff is determined from measured (actual) runoff by adjusting for the quantitative effect of storage development, diversions or importations above the point where the flow is measured.

Table 2 compares unimpaired runoff for the major streams tributary to the Sacramento Valley and Delta for 1923-24, 1930-31 and 1933-34 through 1976-77.

Table 3 presents a monthly comparison of runoff for October 1976 through October 1977, for the major streams tributary to the Sacramento Valley and Delta. The water year totals shown at the bottom of the table do not include October 1977.

Reservoir Storage

The dry period from January 1976 to November 1977, resulted in drastically reduced inflow to the storage reservoirs in the Sacramento River drainage basin. This lack of inflow, plus the heavy demands for irrigation water and for Delta salinity control flows, resulted in extremely low reservoir levels in October 1977. On December 1, 1977, the storage was about 30 percent of the normal for that date.

Storms in December 1977 and January 1978, changed the water picture. Based on February 1, 1978, forecasts, the Department and the USBR announced plans to provide full entitlements to water contractors during 1978. Above normal rainfall conditions during February, March and April of 1978 made water available to make up deficiencies sustained by water contractors during 1977 and also to provide surplus water.

Table 4 shows the water in storage for major reservoirs on tributaries to the Sacramento Basin as of December 1, 1977, compared to the same time in the previous 2 years. To summarize this data, water storage in all reservoirs in a given stream system has been combined (as if there were only one reservoir for each stream), and shown on Plate 4.

Reservoir Operations

Most of the winter runoff made available for summer use in the Sacramento Valley basin is regulated by Shasta Lake on the Sacramento River, Folsom Lake on the American River, and Lake Oroville on the Feather River.

Table 5 presents monthly reservoir operations for Shasta Lake, Keswick Reservoir, Oroville-Thermalito Reservoir complex, Folsom Lake, and Lake Natoma for March through October 1977.

Inflow to Keswick Reservoir included releases from Shasta Lake and water imported from the Trinity River Division of the Central Valley Project, which enters Keswick Reservoir via Spring Creek Power Plant.

The computed inflows shown for Lake Oroville in Table 5 do not include amounts pumped back into the reservoir during May and June. The release figures shown are the amounts of water passing through the dam via the Hyatt Power Plant minus the quantities pumped back, to indicate the net amount of inflow into the Thermalito Complex from Lake Oroville. (Flows from Lake Oroville to Palermo Canal are not included in the release figures, since these flows do not enter the Thermalito Complex.) Water also enters the Thermalito Complex below Oroville Dam through the Kelley Ridge Power Plant and is shown in Table 16.

Under the heading, "Thermalito Diversion Dam Release to River", Table 5 gives the amounts released through the diversion dam, over the Fish Barrier Dam, and through the Feather River Fish Hatchery, which are located between the diversion dam and the Thermalito Afterbay release facilities. Quantities shown for Thermalito Afterbay release are the regulated amounts of water released into the Feather River from Thermalito Afterbay. These releases, plus releases from the diversion dam (assuming no accretions or losses en route) make up the total flow in the Feather River below the Thermalito Complex.

Inflows to Lake Natoma shown in Table 5 are equivalent to the releases through Folsom Dam except for some minor accretions or losses. Releases to the American River below Nimbus Dam include releases made for the fish hatchery, but do not include diversions to Folsom South Canal.

The inflows shown in Table 5 for Shasta, Oroville, and Folsom Lakes are "computed inflows" developed from measured data on storage, release, precipitation, and evaporation. The computed inflows are an estimate of the flows that would have passed the site of the respective dams if the dams were nonexistent.

Streamflow

The main streams of the Sacramento Valley are the Sacramento, Feather, Yuba, and American Rivers. Major tributary streams entering the Sacramento River above Red Bluff are Cottonwood, Battle, and Cow Creeks. Below Red

U. S. Geological Survey measuring the flow of the Sacramento River.

Bluff, Mill, Deer, and Big Chico Creeks enter the river from the east and Elder, Thomes, and Stony Creeks enter from the west. Considerable flow is lost by percolation or used by diverters between the foothills (where these creeks are measured) and the river, a distance of 15 to 30 kilometres (10 to 20 miles).

In July 1977, the minor streams were observed from the air. Each creek bed was dry at the point where it entered the river. The contributions from these and other creeks were adjusted to account for water lost below the foothill measurement site in Table 15.

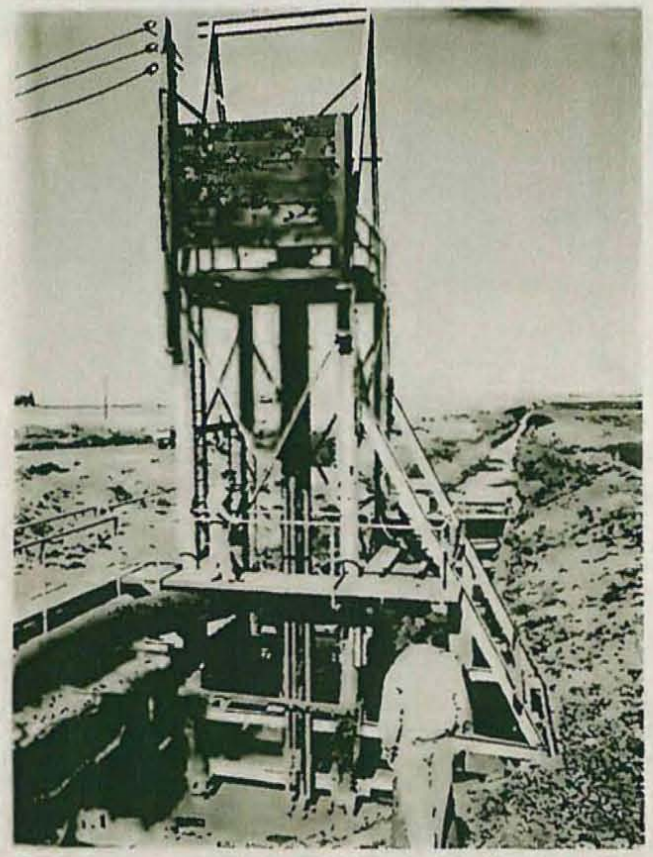
Gaging Stations

Gaging stations record water levels at various points on rivers and drains and through large drainage and canal pumping plants upstream from Sacramento. Flow measurements at each station determine a relationship between gage height and flow. From this relationship and a record of gage heights, daily and monthly flows were computed.

Table 6 shows quantities of water passing the principal gaging stations on the Sacramento, Feather, and American Rivers; on various streams tributary to the Sacramento and Feather Rivers; and on streams tributary to the Delta. Many of the flows presented in Table 6 were measured by the U. S. Geological Survey (USGS).

Table 6 also shows irrigation return flows (insofar as these were obtainable) and exports from the Delta. In many instances, these records of flow were obtained by methods other than those described for regular gaging stations. For example, for pumped drainage, records are obtained by rating the pump.

The locations of the surface water measurement stations are shown on Plate 2 and Plate 3.



Drainage pump in the Delta lowlands.

Accretions to Streamflow

Accretions consist of surface and ground water inflows to the stream from any source and include tributary inflows, surface and subsurface return flow from irrigation, precipitation, and percolation from adjacent ground water. These accretions are of major importance as additional irrigation supplies.

Accretions can be either measured or unmeasured. Measured accretions are surface accretions that can be measured by gaging stations or other means. These are shown in Table 6 as minor tributaries and irrigation return flow stations. Unmeasured accretions are computed quantities and make up the balance between measured inflows and outflows along a particular stream reach. Tables 15 and 16 summarize measured monthly flows and diversions, along with computed monthly accretions (or losses, as shown by a negative figure) occurring along each reach of each stream between gaging stations.

The term "return flow" is used to indicate that portion of diverted water that is not used and that finds its way by surface drainage or by percolation to the original source. It is then available for reuse by other diverters. The computed accretions within a stream reach may include substantial amounts of return flow, as well as accretions from other sources.

Irrigation Return Flow

Irrigation practices in the Sacramento Valley have historically provided considerable return flow to the river. Prior to 1976 and 1977 irrigation seasons, the return flow amounted to approximately 30 percent of the applied irrigation water. Much of the return flow consisted of carriage water - water that is excess to the entitlements but necessary to force adequate water to the last diverter on the conveyance canal. The carriage water was not reused by the diverter, but became available for use by downstream diverters.

Water project operations have, in prior years, benefited by a considerable quantity of return flow to meet the needs of downstream diverters and Delta requirements. During the extremely dry year of 1977, it was estimated that less than 15 percent of the diverted water returned to the river.

Ground Water Conditions and Changes

During this drought, a large number of wells in the Sacramento Valley were put into production and ground water was used in large quantities. This, along with the lack of normal recharge of the ground water basin, resulted in a drop in ground water levels. Many wells have shown the lowest levels of record.

The following sections document the extent of these changes in ground water conditions. Possible effects of these ground water conditions are discussed in Chapter IV under "Interrelationship between Surface and Ground Water". Ground water data used in this survey were collected by the Department's cooperative ground water level measurement program and by the USGS. Between July 1977 and January 1978, the USGS measured wells located within about 3 kilometres (2 miles) of the Sacramento River at major bridge crossings every 2 or 3 weeks.

Ground water level contour maps of the Sacramento Valley between Red Bluff and Sacramento were prepared for springtime water level measurements of 1975 and 1977 (see Plates 5 and 6). A contour map also was drawn showing changes in water level measurements between the above 2 years (see Plate 7). An additional reference point was a map showing water level contours for spring 1968, the last time prior to 1975 that such a map was prepared. With these contour maps as a base, water level profiles transverse to the Sacramento River

were drawn at each gaging station between Red Bluff and Sacramento (see Figures 1 and 2). The USGS, using its recently collected data, also plotted water level profiles transverse to the river at a number of locations, some of which were at river gages, showing ground water levels. This information has been considered in this report.

The amount of ground water depleted from the basin between Sacramento and Red Bluff (within the area covered by contours) from spring 1975 to spring 1977, was estimated to be about 2 100 cubic hectometres (1,700,000 acre-feet). This estimate was derived from area and water levels shown on the contour maps, using an average specific yield factor of 7 percent, and assuming that all water level contours represent zones of free ground water. Actually, many well measurements represent pressure levels in confined zones, which if excluded would result in a change in storage less than 2 100 cubic hectometres (1,700,000 acre-feet).

At the end of the 1977 irrigation season, the ground water levels were measured. No contour map was prepared; however, an estimate was made of the depletion of ground water from the basin during the period from spring 1977 to fall 1977 by taking the average change in ground water level for each quarter of each township (9 square miles) and multiplying that by the specific yield for that area. The estimated total depletion north of Sacramento was approximately 1 200 cubic hectometres (1,000,000 acre-feet). Of this total depletion, about 700 cubic hectometres (600,000 acre-feet) occurred south of Colusa and about 500 cubic hectometres (400,000 acre-feet) occurred north of Colusa.

Areal Summary of Changes

The following paragraphs describe spring 1977 ground water conditions and changes in water levels since spring 1975 in several areas of the Sacramento Valley. Also described are some findings of the USGS well measurement program conducted in July and August 1977. The spring 1968 water levels did not vary greatly from those of spring 1975, which indicates that the major declines began in 1975. Table 7 presents a summary, by county, of the average change per measured well in ground water levels between the spring measurements of 1975 and 1977. Data for Yolo and Sacramento Counties pertain only to wells located in the area north of the latitude of Sacramento (north of township 8 north).

North of Hamilton City. In the area north of Hamilton City, spring 1977 ground water contours, as in the past, showed a general slope of the ground water table toward the Sacramento River and southward down the valley (Plate 6). These contours, when compared with those of spring 1975, showed declines in ground water levels generally from 3 to 6 metres (10 to 20 feet)(see Figure 1 and Plate 7).

Since agricultural development in this area is not extensive, increased pumping for irrigation probably was not the major factor in the decline of ground water levels. Ground water would tend to move southward to lower elevations in the basin and into the river, where hydraulically possible. The lack of normal recharge would result in a net depletion of ground water in storage.

Ground water levels at the Tehama-Los Molinos bridge crossing, the most northerly measurement location, were about 1 to 1.5 metres (3 to 5 feet) higher than the river stage in summer 1977. Ground water, therefore, could flow toward the river at that point. Farther downstream, ground water levels dropped below the river stage, about 1.8 metres (6 feet) at Vina Bridge and 2.5 to 4 metres (8 to 13 feet) at Hamilton City. These differences in head between surface and ground water indicate that water could flow from the river toward the ground water basin.

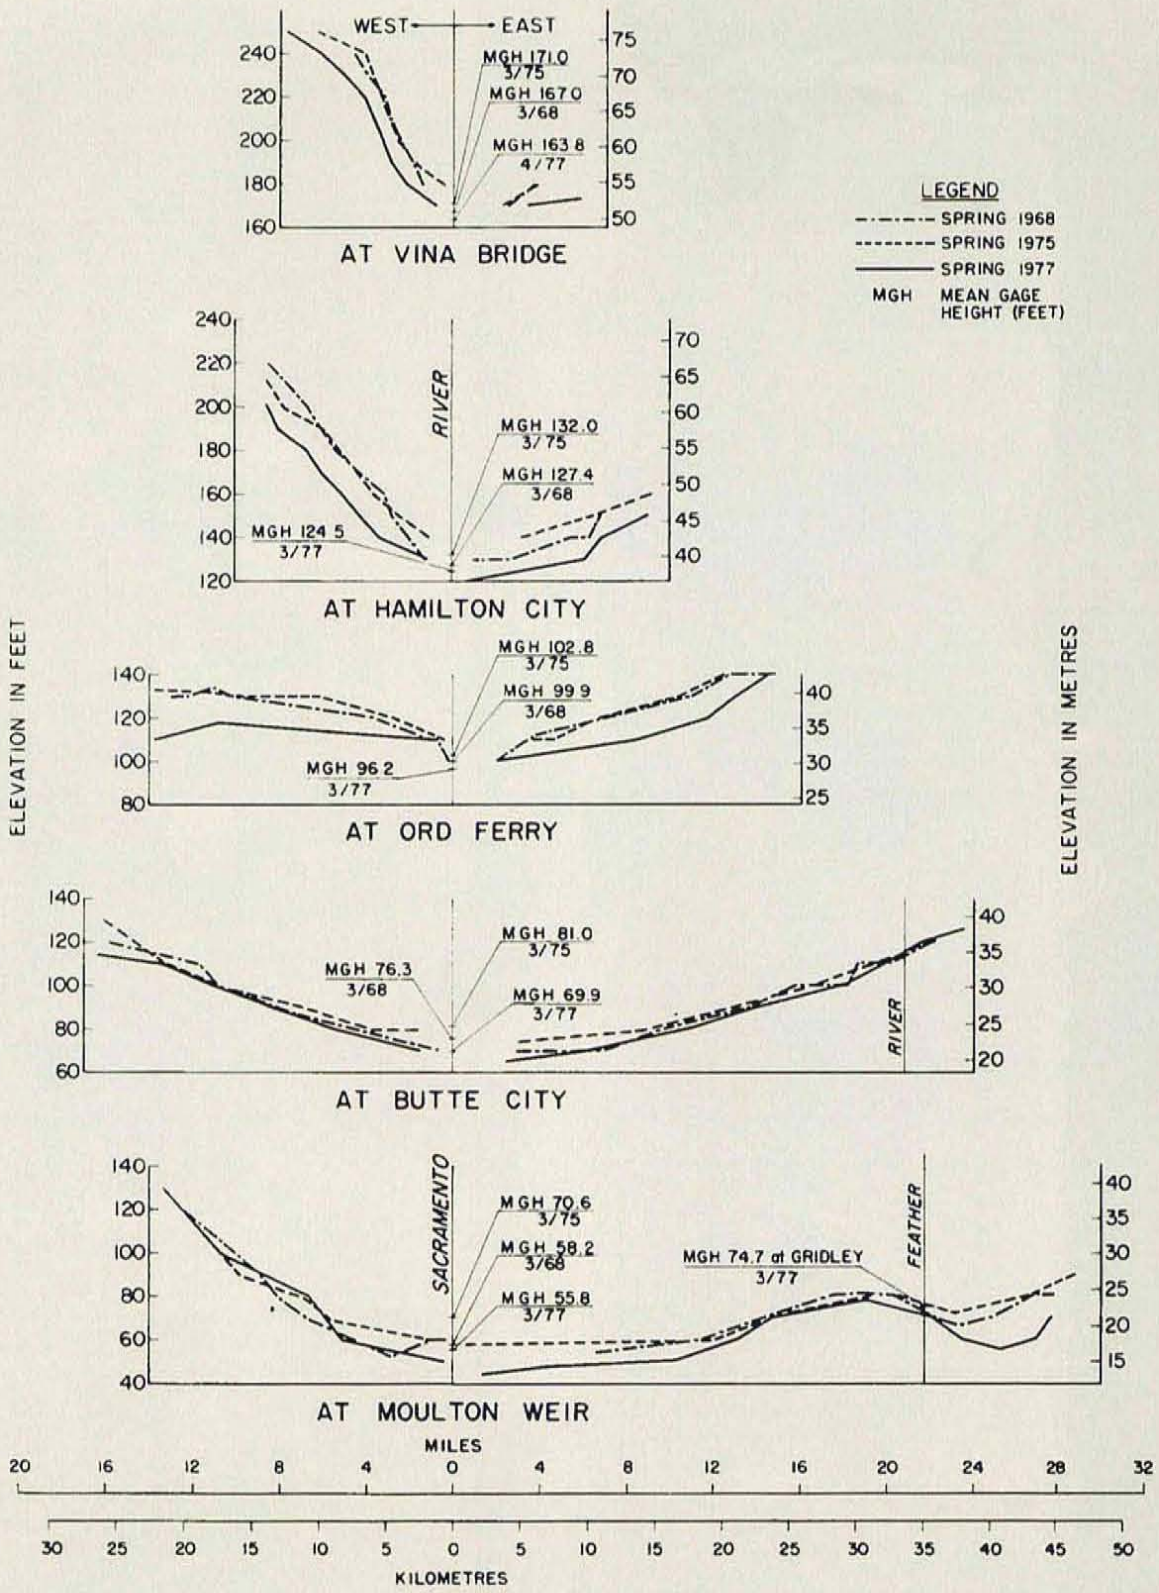


Figure 1. GROUND WATER LEVEL PROFILES UPSTREAM FROM COLUSA

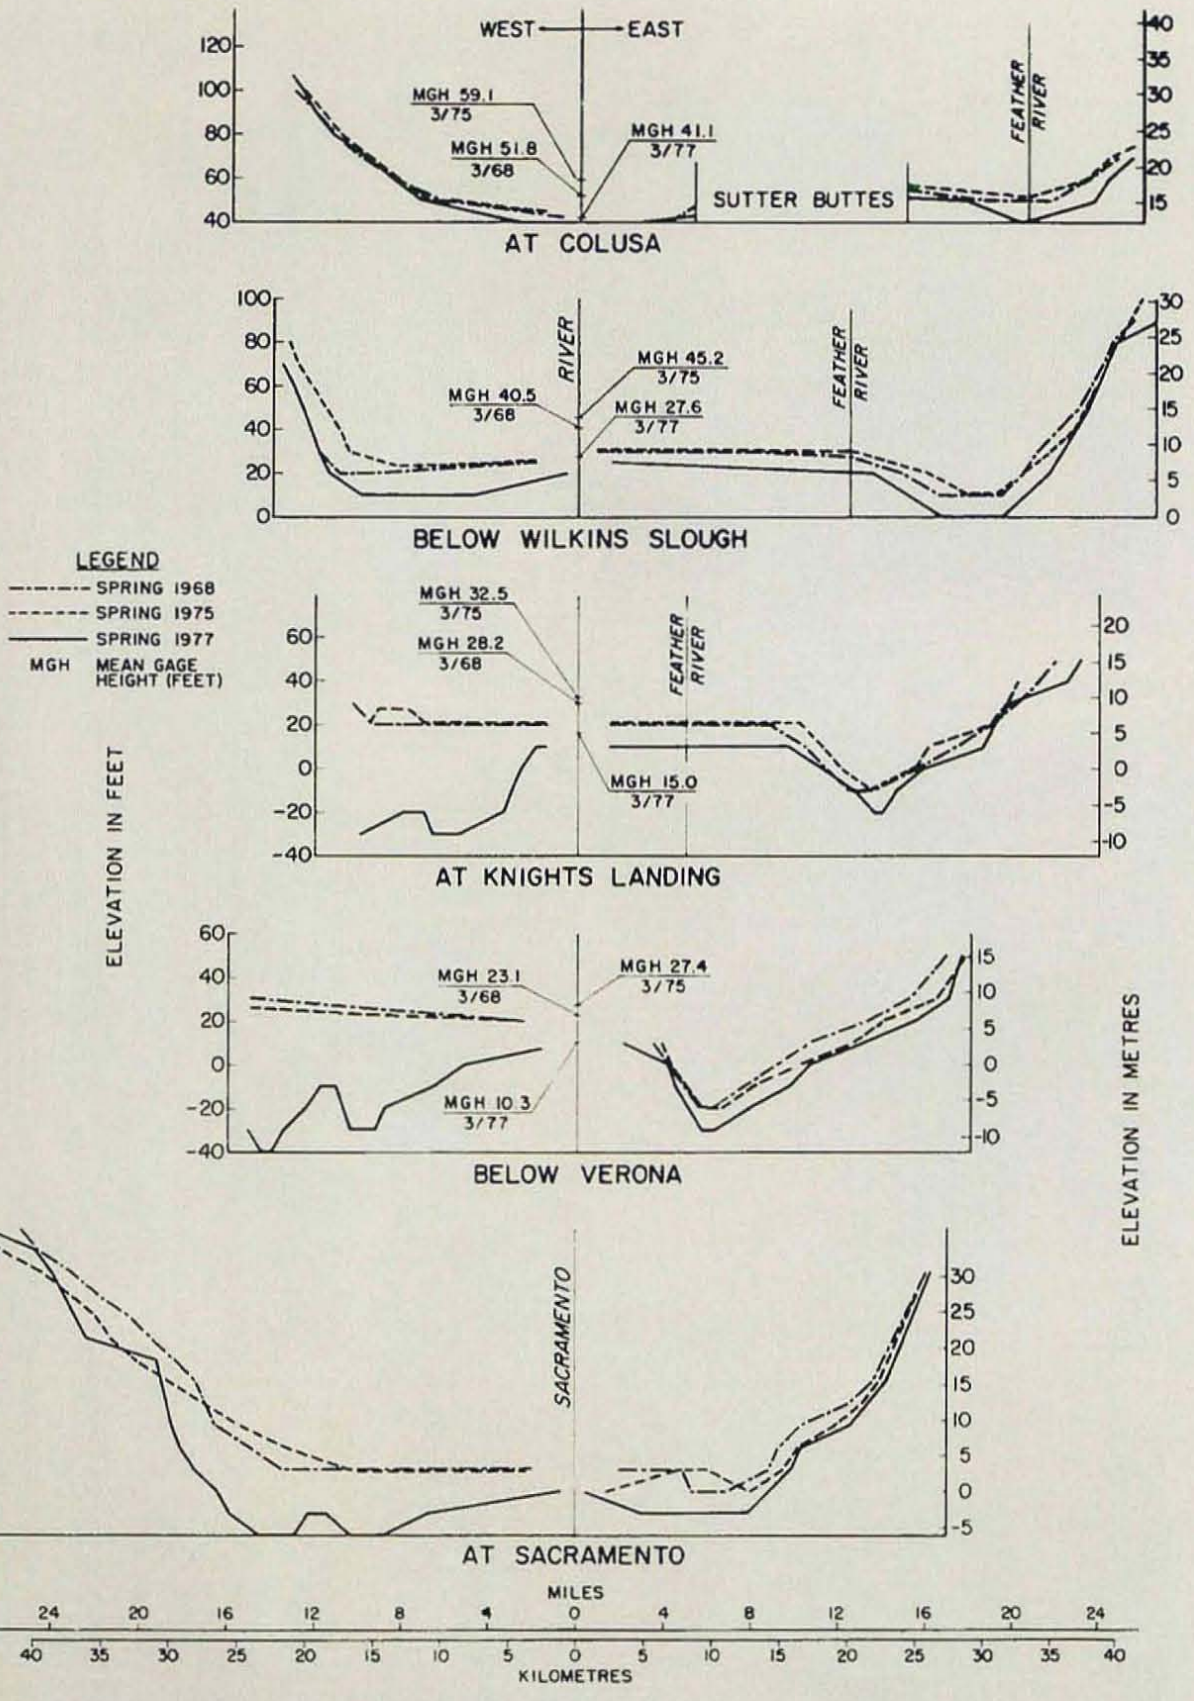

Figure 2. GROUND WATER LEVEL PROFILES DOWNSTREAM FROM COLUSA

Hamilton City to Colusa. From Hamilton City southward to about Butte City, where considerable ground water is used. water levels for the most part declined about 3 to 4.5 metres (10 to 15 feet) on both sides of the river between the spring measurements of 1975 and 1977. From Butte City southward to Colusa, declines were generally in the order of 1 to 2 metres (3 to 6 feet). In general, the water table continued to slope toward the river and down the valley (see Figure 1 and Plates 6 and 7).

USGS profiles showed ground water levels near the river remaining below the river stage, varying up to 4 metres (13 feet) at Colusa. Water in the river, therefore, would tend to seep into the adjacent ground water basin.

South of Colusa. In the Colusa County area south of Colusa, the spring 1977 water levels generally were 3 to 6 metres (10 to 20 feet) below those of spring 1975. The largest drops in the water table occurred in Yolo County, particularly south and west of Knights Landing. Deep pumping depressions have developed in some areas 6 to 20 kilometres (4 to 12 miles) west of the Sacramento River. Depressions in the vicinity of Woodland, for example, were more than 15 metres (50 feet) below the spring 1975 water levels (Plate 7).

In Sutter and Sacramento Counties, water levels for the most part declined less than 2 metres (6 feet). In Placer County, the decline was about 1.5 to 4.5 metres (5 to 15 feet)(see Plates 7 and 8).

In the area south of Knights Landing, the water table in spring 1975 was only slightly below the river stage. In the spring of 1977 the water table generally sloped steeply toward the large pumping depressions about 3 kilometres (2 miles) west of the river. However, USGS profiles show the water level in wells near the river to be only slightly below the river stage, indicating that the water table is being maintained by recharge from the river (see Figure 2).

Feather River. Ground water levels on the east side of the Feather River in Butte County declined as much as 4.5 metres (15 feet) between the spring measurements of 1975 and 1977. On the west side, declines generally were less than 2 metres (6 feet). In Sutter and Yuba Counties, declines were generally 2 to 3 metres (6 to 10 feet) on both sides of the river, except in an area south of the Bear River, where the decline was about 6 metres (20 feet). The water table generally sloped away from the river, indicating a possible loss of river-flow to the adjacent ground water basin (see Figure 2 and Plates 6 and 7).

Overall Ground Water Conditions

Ground water levels in the Sacramento Valley fluctuate considerably during the year. Normally, the peak levels occur in March or April after fall and winter precipitation and runoff have recharged the ground water basin. The low levels generally occur in July or August, after ground water has been withdrawn to help meet irrigation requirements.

During the past two drought years, peak water levels have occurred earlier in the water year and at much lower elevations. These two conditions reflect the lack of normal recharge of the ground water basin after it has been drawn down for irrigation. Plate 8 shows fluctuations in water levels for selected wells that typify seasonal changes in water levels for the basin since 1968. The wide fluctuations shown for Well No. 9N/2E-16N1, in Yolo County, are typical for wells withdrawing water from confined zones.

From the limited data available, it was impossible to accurately estimate the rates of loss from the rivers to the ground water basin.

Chapter III. WATER USE

Water utilization includes uses of water by nature or by people, either consumptive or nonconsumptive, and losses of water incidental to those uses. The term "diversions" means the gross amounts of water taken from the river channel as measured at the point of diversion.

In the Delta, water is served to the islands through innumerable siphons, culverts, and pumping plants, or by percolation from adjacent channels that cannot be accurately measured. Therefore, consumption of water in the Delta service area was computed by multiplying land-use acreages by appropriate unit evapotranspiration (ET) factors, as discussed in the appendix.

The procedures for computing water use in 1977 were essentially the same as the procedures used in 1976. Minor modifications were made as a result of changing conditions and new information developed in the 1977 survey.

Diversions Upstream from Sacramento

Surface diversions from the Sacramento, Feather, and Yuba Rivers are shown in Tables 8, 9 and 10. The smaller unmeasured diversions were computed from electric power records obtained from the power companies. The larger diversions along the Sacramento River, which amounted to 88 percent of the total water diverted, were measured by the USBR. The Department measured the major diversions from the Feather River.

Early in 1977, the USBR requested each water contractor along the Sacramento River to reduce river diversions by 25 percent of their total contract quantities. In May, on the basis of the February 1, 1977, forecast of water supply, the SWRCB notified riparian water users that unless they had a

Water diversion pump on the Sacramento River

contract with some water agency to provide them with water, they should restrict their water use to 60 percent of the amount normally diverted in June, 45 percent in July, and 50 percent in August.

As a result of these notices and the drought, many river diverters drilled wells to supplement the deficient river supply. Some wells are believed to receive a significant amount of replenishment from the surface streams. However, insufficient data were available to quantify the relative amounts drawn from the river and the ground water body.

During 1976 a field survey was made to identify the unmeasured smaller pumping plants along the Sacramento River between Shasta Dam and Sacramento, the Feather River below Oroville Dam, the Yuba River below the gaging station near Marysville, the Bear River below Wheatland, and the American River below "H" Street Bridge. No diversions were found along the latter two reaches. Since most small pumps are operated by electric motors, power consumption records provided the basis for estimates of diversions.

Monthly amounts of water diverted at the individual points are presented in Tables 8, 9 and 10. Diversions for the Sacramento and Feather Rivers have been segregated into stream reaches, defined by gaging stations at each end of the reach. Total monthly diversions in acre-feet within each reach are shown in Tables 8 and 9, and summarized in Tables 15 and 16. Table 10 is presented only for determining the net tributary inflow to the Feather River from the Yuba River.

Land Uses in Sacramento-San Joaquin Delta

Land-use surveys of the Sacramento-San Joaquin Delta service area were made in 1976 and 1977. Colored 35mm slides were taken from the air and viewed on a screen. The field boundaries and other land configurations were then delineated on USGS base maps. The types of crops and field boundaries were interpreted by specialists and noted by symbols on the maps. Field checks verified the photo interpretations.

The surveys covered the entire Delta service area, both "lowlands" and "uplands". The lowlands are those lands generally below the 1.5 metre (5-foot) elevation above mean sea level. The uplands lie outside of the lowlands and are served by irrigation water for the most part diverted from Delta channels. Lands that lie outside of the Delta lowlands and that are served by diversions from below the lowest gaging stations on streams flowing to the Delta are also considered as Delta uplands. The boundary of the Delta service area is shown on Plate 2. Areas of the various types of irrigated and nonirrigated crops, native and riparian vegetation, water surfaces, and other nonagricultural areas are shown in Table 12.

Consumptive Use of Water

Unit consumptive use factors for agriculture are determined by experimental investigations and by measurements of water in irrigated areas. Unit values of consumptive use are generally used for long-range water resource planning, and are therefore those that would occur under average conditions of water supply and climate. Values that have previously been used would not necessarily be applicable to a dry year such as 1977. Unit values given in the 1976 Sacramento Valley Water Use Survey report were reviewed and modified to reflect 1977 conditions. Although the monthly consumptive use varied significantly from the 10-year average, the annual values were not significantly different. Regardless of this similarity, it should be noted that irrigation demands from streamflows are substantially higher during the drought, because irrigation water must be substituted for rainfall normally contributing to the soil moisture.

Table 11 presents the modified monthly unit consumptive use factors for crops, nonagricultural vegetation, urban areas, and evaporation from water surfaces in the Delta service area. These unit factors, when applied in corresponding areas of land use in the Delta, provide an estimate of the water consumed. A more detailed explanation of the work done in developing the unit use factor is given in the appendix of this report.

"Consumptive use" as used herein is synonymous with "Evapotranspiration". The total volume of water derived from rainfall is considered as having been available for use in the Delta as one of the sources of water supply (see Tables 12 and 17). The total rainfall in a particular month was assumed to be fully used during

that same month, either by the crop or as a contribution to soil moisture. This rainfall, being low, did not contribute to surface runoff. Table 12 presents total monthly consumptive use for the March through October period.

Leaching and Preirrigation

In the Delta it is common practice to periodically leach and preirrigate the land by flooding after the crops have been harvested. On August 25, 1977, an aerial survey showed that about 1 000 hectares (2,400 acres) were flooded. A field check on September 15 showed only about 400 hectares (1,000 acres) flooded. On November 23 an aerial survey showed about 14 000 hectares (35,000 acres) flooded.

Exports from Delta

Normally, exports are made from the Delta by the Department for the State Water Project, by the USBR for the Central Valley Project, and by the City of Vallejo. During 1977, additional exports were made to East Bay Municipal Utility District (EBMUD), the City of San Francisco, and Marin County.

The State Water Project diverts water from Old River via Clifton Court Forebay and the Delta Pumping Plant to the California Aqueduct. The Central Valley Project diverts water from Old River via the Tracy Pumping Plant to the Delta-Mendota Canal and from Rock Slough via a pumping plant to the Contra Costa Canal. The City of Vallejo pumps water from Cache Slough. These diversion locations are shown on Plate 2.

During 1977 a pumping plant was installed on Middle River to provide an emergency supply of water for the Bay area. Water was pumped into the existing Mokelumne River Aqueduct of EBMUD for use in a portion of the EBMUD service area and also for use by the Contra Costa County Water District. Additional information is given in the Department's report, "The Continuing California Drought", under the heading, "Water Exchanges", beginning on page 85. The location of the emergency facilities is shown on Figure 4 of that report.

Salinity Control

The extent of salinity intrusion into the Delta is related to the rate and time of occurrence of Delta outflow and can therefore be controlled by freshwater outflow in sufficient quantities to counteract salinity intrusion.

Historically, outflow from the Delta has often been insufficient to prevent harmful salinity intrusion in the western Delta. Since the construction of the Central Valley Project and the State Water Project, releases of stored water have effectively restrained such intrusion.

In 1975, ocean salinity was almost completely repelled from entering the Delta. As shown on Plate 9, the maximum intrusion of 1 000 milligrams per litre chloride concentration was almost 5 kilometres (3 miles) downstream from Antioch. The monthly average computed Delta outflow to repel ocean salinity during the irrigation season ranged from 1 900 cubic metres per second (66,000 cubic feet per second) in March down to 270 cubic metres per second (9,500 cubic feet per second) in August (see Table 13). During the summer (June through September), the average computed Delta outflow was 400 cubic metres per second (14,200 cubic feet per second). This amounts to 4 400 cubic hectometres (3,500,000 acre-feet). The quality of the water in the Delta was better than required by water quality objectives established by the SWRCB.

In 1976 the maximum intrusion of the 1 000 milligrams per litre chloride concentration during the irrigation

season moved upstream about 15 kilometres (9 miles) to approximately Emmaton on the Sacramento River and Blind Point on the San Joaquin River (see Plate 9). The quality was essentially in compliance with objectives established for a dry year by the SWRCB. The computed Delta outflow ranged from a maximum of 266 cubic metres per second (9,400 cubic feet per second) in January, to 93 cubic metres per second (3,300 cubic feet per second) in September. The average outflow for the four summer months was 103 cubic metres per second (3,650 cubic feet per second). This amounts to 1 080 cubic hectometres (876,000 acre-feet).

On December 1, 1976, Sacramento Valley reservoirs were at relatively low levels. Carryover storage, which a year earlier had been 11 600 cubic hectometres (9.4 million acre-feet) was at 6 500 cubic hectometres (5.3 million acre-feet).

With precipitation substantially less than normal, it was apparent that large quantities of stored water would be required to control salinity intrusion. However, this same water was needed for other uses in other areas.

Prompted by the severity of the water shortage, the SWRCB held a special hearing on January 20 and 21, 1977, to consider a relaxation of quality objectives for the Delta. As a result of these hearings, an interim water quality control plan for 1977 was developed to conserve the limited water supplies and to help spread the burden of the critically dry year. Details of the plan were published in an SWRCB report, "Interim Water Quality Control Plan for 1977, Sacramento-San Joaquin Delta and Suisun Marsh", dated February 1977.

With the increased severity of the drought, stored water was being depleted at an alarming rate to satisfy even the interim water quality objectives. As a result, the SWRCB adopted emergency regulations on June 2, 1977, further relaxing the water quality objectives and allowing further reductions in Delta outflow. The resultant intrusion of ocean salinity moved the maximum 1 000 milligrams per litre chloride concentration to a point near Rio Vista on the Sacramento River and Jersey Point on the San Joaquin River, as shown on Plate 9. The computed Delta outflow (Table 13) ranged from 140 cubic metres per second (4,900 cubic feet per second) in February, to 59 cubic metres per second (2,100 cubic feet per second) in June. The average for the summer months was 74 cubic metres per second (2,600 cubic feet per second) or 784 cubic hectometres (635,000 acre-feet).

Water supply conditions to provide for Delta outflow greatly improved with storms in December 1977 and January 1978. Following these storms, a special hearing was held by SWRCB on February 2, 1978, and the emergency regulations were repealed.

Monthly maximum and same-day minimum chloride concentrations are listed in Table 14 for nine western Delta salinity observation stations.

Chapter IV. INVENTORY AND ANALYSIS

Data on water supply, water utilization, and water rights have been condensed into summary tables and charts for study and analyses in Tables 15 through 22.

Inventory of Water Supply and Use - 1977

An inventory of the source and disposition of the water supply of the major streams in the Sacramento Valley and of the Delta were compiled for 1977 conditions. Some elements of the inventory, such as surface stream and return flows and diversions were directly measured. Other elements, such as ground water and Delta consumptive use, were estimated.

Sacramento River

Table 15 summarizes monthly streamflow, diversions, and unmeasured accretions along the Sacramento River between Shasta Lake and Sacramento, along with computed inflow to Shasta Lake and the change in storage. The items, "Computed Inflow" and "Change in Storage", were taken from Table 5. Computed inflow was developed by the USBR from data on storage, release, precipitation, and evaporation.

Releases from Shasta Lake enter Keswick Reservoir for reregulation and are augmented by imports from the Trinity River Division of the Central Valley Project, which enter Keswick Reservoir through Spring Creek Power Plant. Flows from the Feather and American Rivers are considered as tributary inflows in the last two reaches near Sacramento. Diversions from the Feather River below Nicolaus were included in the diversions for the reach, Knights Landing to Verona. Total diversions and accretions for the entire river from Keswick to Sacramento are shown at the end of Table 15.

Feather River

Table 16 summarizes monthly streamflow, diversions, and accretions along the Feather River from Lake Oroville to Nicolaus and the computed inflow and change in storage for Lake Oroville. Items relative to operation of Oroville-Thermalito complex were taken from Table 5.

The complex of Thermalito Forebay, Afterbay, and Diversion Dam, together with their release and diversion facilities between Oroville Dam and the Thermalito Afterbay Release, was considered to be the first reach along this river system. Flows from Kelley Ridge power plant enter this reach below Oroville Dam. Several large diversions, including Sutter Butte and Western Canals, divert water from Thermalito Afterbay. The release to the Feather River from Thermalito Diversion Dam is considered to be an outflow from this reach and an inflow to the following reach. Flows from the Yuba and Bear Rivers are considered as tributary inflows in the last two reaches.

Sacramento-San Joaquin Delta

Table 17 summarizes water supply and water use of the Delta service area during March through October 1977. The Delta tributary inflow was obtained from Table 6, and the volume of precipitation was obtained from Table 1. The amounts shown under the heading, "Urban Requirement Imported or from Wells" were assumed to be supplied from sources other than Delta channels.

Under the heading "Water Use", monthly quantities of consumptive use in the Delta service area, exportations from Delta channels, and change in soil moisture are presented. The total

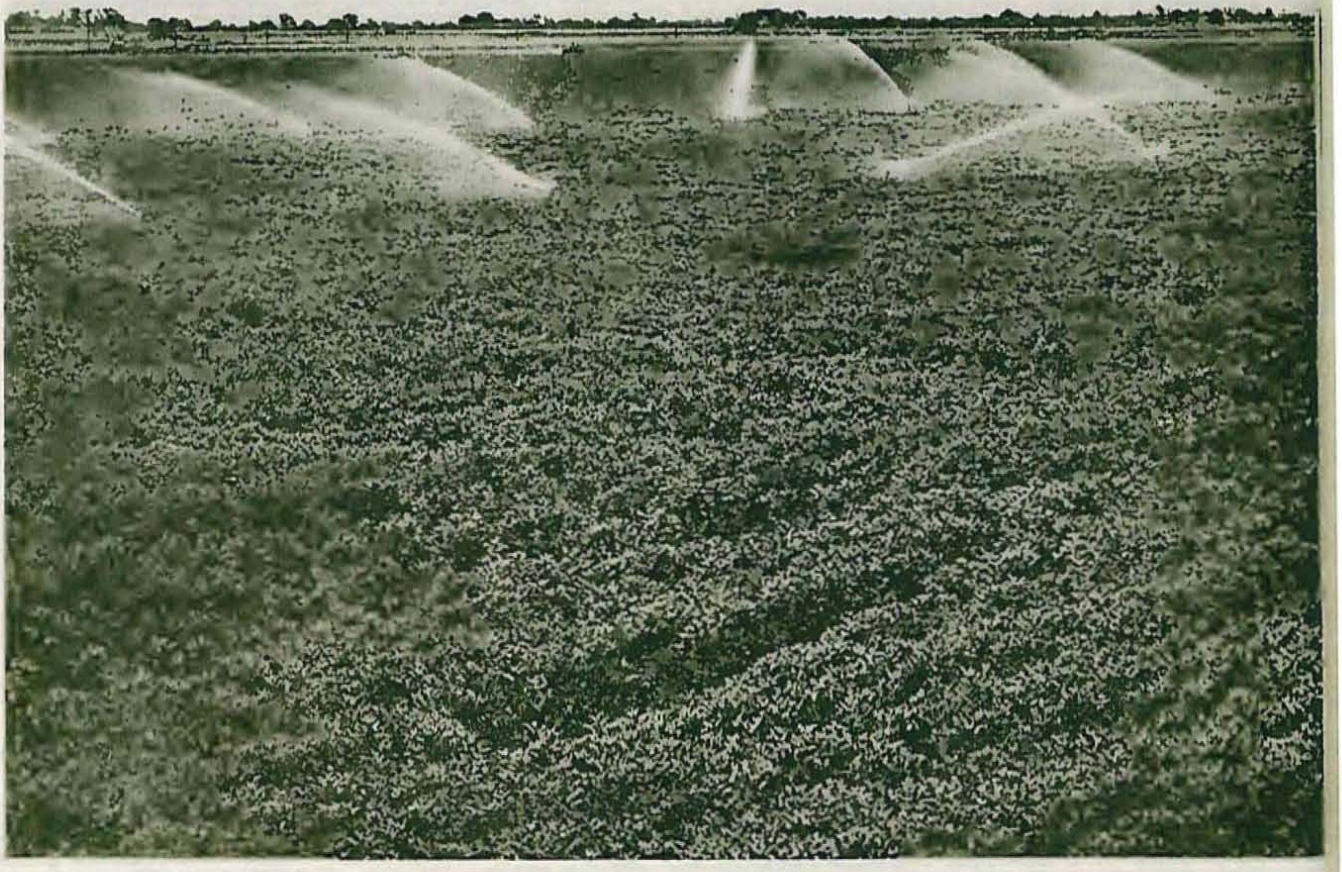
consumptive use was obtained from Table 12. Total exports were obtained from Table 6.

The 1977 monthly soil moisture gains and losses in the Delta were estimated from past studies by the Department, modified by the land and water use analysts to reflect, in their judgment, the 1977 conditions. The maximum soil moisture in the Delta lowlands was considered to be 250 millimetres of water per metre (3 inches per foot) of rooting depth. Maximum soil moisture in the Delta uplands is one-half that of the lowlands. The minimum soil moisture was nearly zero. This minimum limit of soil moisture was considered to occur when lands were either non-cropped or were in dry farmed crops. In general, water from precipitation and channel seepage supply soil moisture during spring, and crops deplete the soil moisture during summer.

Channel seepage is assumed to be 25 millimetres of water per metre (0.3 inches per foot) of rooting depth for the Delta lowlands only. While channe seepage cannot be measured, this is believed to be a reasonable assumption

Under the heading "Computed Surface Outflow" are the monthly quantities obtained by subtracting water use from water supply. These residual flows are estimates of the net amounts of fresh-water outflow from the Delta at its western extremity. The computed average monthly rate of flow is also presented.

Total consumptive use in the Delta service area (Table 12) for the period March through October 1977, amounted to 2 125 cubic hectometres (1,722,000 acre-feet). This figure is 1 percent lower than the total use for the same period during 1976.



Irrigation of Safflower

Monthly Diversions and Accretions

Table 18 and Plate 10 compare 1977 diversions above Sacramento with diversions for the 5-year period 1972-1976, thus enabling a comparison of diversion quantities and diversion patterns in recent years. The monthly diversions in percentage of total seasonal diversion are also shown in Table 18 to compare diversion patterns with those of prior years.

The percentage of normal runoff at Sacramento River at Sacramento is shown for comparison with the diversions for the season.

The diversions in April are higher in the drier years than in the normal or above normal years. Also, March would probably show higher diversions if comparative data were available. The reasons for the high March and April diversions in the dry years are to increase the soil moisture that was not supplied by rainfall and to irrigate crops planted earlier than normal. Table 18 shows that maximum monthly diversion occurred in May and June, while the irrigation pattern for earlier years presented in the Bulletin 23 series, "Surface Water Flow", shows July to be the maximum month of irrigation. With the exception of 1977, when deficiencies had to be taken, increased diversions are attributable in part to increased diversions via Corning Canal since 1961, and Tehama-Colusa Canal since 1966. Diversions to Tehama-Colusa Canal during March through October of 1977 amounted to 152 cubic hectometres (123,000 acre-feet).

Plate 10 shows a substantial reduction in the 1977 diversions, particularly during May, when rainfall was above normal and temperatures were below normal, resulting in a considerably reduced water demand. The seasonal total diversion was 74 percent of the 1976 diversion quantity.

Table 19 compares unmeasured accretions for the last 31 years of record. (Sufficient data were not available for 1970 and 1971 to enable reliable estimates of diversions and accretions.) These figures represent the total net unmeasured accretions between Sacramento and Keswick Dam and were computed as described in the first part of this chapter. The diversion quantities measured by the USBR for the years since 1963, the last year when all the diversions were measured, were revised to include an estimate of the unmeasured diversions. The increase was approximately 8 percent in most of the years; however, in some years, the increase was less than 5 percent of the measured diversions.

The total of the unmeasured accretions is the net result of all the computed gains or losses within the various river reaches. This quantity of water can be attributed to ground water movement to or from the river, since all surface flows have been measured or estimated. Also shown for purposes of analyses are: (1) runoff in percentage of normal for Sacramento River at Sacramento, and (2) total accretions for April through October and July through September. The July through September period is probably more indicative of the loss or gain between surface flow and ground water.

Plate 11 is a graphical analysis of the monthly data taken from Table 19. The graph shows that the average unmeasured accretions for 1976 and 1977 are below the 10-year averages of both dry and wet years.

Plate 12 is a graphical presentation of the decrease in total seasonal (April through October and July through September in Table 10) unmeasured accretions of the Sacramento River above Sacramento for all years except 1970 and 1971 since 1947.

Diversions during 1977 from the Feather River from Oroville Dam to the mouth amounted to a total of 762 cubic hectometres (617,900 acre-feet) for March through October. These diversions were 62 percent of the 1976 quantities. This quantity of water was diverted by a total of 76 individual points of diversion. Of the 76 points of diversion, there are 13 major diversion points that are measured each year by the Department. These 13 accounted for about 95 percent of the water diverted. Four points of diversion, which take water from Thermalito Afterbay, accounted for 83 percent of the total Feather River diversions.

The unmeasured accretions along the Feather River below Oroville Reservoir are presented in Table 16. The unmeasured accretion between Oroville Dam and Nicolaus for March through October 1976 was a gain of about 205 cubic hectometres (165,700 acre-feet) compared with a loss of 9 cubic hectometres (7,100 acre-feet) in 1977.

Interrelationship between Surface and Ground Waters

Efforts were made to analyze the direct relationship between the decline in unmeasured accretions and the decline in ground water levels. This interrelationship could not be quantified, but is discussed in general terms.

The large declines in ground water levels in the Sacramento Valley between 1975 and 1977 have resulted from two main factors: (1) decreased recharge because of low precipitation and surface flows and (2) increased extractions from the ground water supply to satisfy water demands normally met by surface supplies. In the spring of 1975, the ground water basin was essentially filled to its normal storage capacity. By spring 1977, stored ground water had been depleted by about 2 100 cubic hectometres (1,700,000 acre-feet).

In a sense, the increased use of ground water could be considered incidental conjunctive use of surface and ground water. Ground water served as a reserve supply in many areas to make up the difference between available surface water and the increased irrigation water required to sustain agricultural production during the drought.

The declines in ground water levels during 1976 and 1977 increase the possibility for percolation of streamflow to the ground water basin. Factors having the greatest influence on percolation would be the slope of the hydraulic gradient away from the river, the length of time the hydraulic gradient is sustained, and the permeability of the soils in the area.

Hydraulic Gradient and Duration

In March 1977, the slope of the hydraulic gradient from surface water to ground water immediately adjacent to the Sacramento River was not significantly different than in March 1975, because the river stage dropped along with the water table. The major change in hydraulic gradient was in the water table itself, which changed from an approximately flat slope in 1975 to a rather steep slope toward the pumping depressions in 1977 (see Figures 1 and 2).

Well hydrographs (Plate 8) showed that ground water levels continued to drop through the irrigation season, thereby increasing the slope of the hydraulic gradient away from the river. Decreases in unmeasured accretions to streamflow (see Plate 11) during the irrigation season, therefore, are attributable in part to percolation of streamflow.

With the progressive declines in water levels since 1975, a hydraulic gradient away from the river probably has been maintained for a much longer time than

it would be during normal years. This, along with the steeper hydraulic gradient toward the pumping depressions, would tend to increase the rate of ground water movement away from the river. The steepest landward hydraulic gradients occurred near Knights Landing, where losses in streamflow, as indicated by negative unmeasured accretions, were the greatest. A portion of these losses is due to percolation.

Some irrigation wells, if located in the highly permeable stream deposits near the river, may withdraw more water directly from the river than from the ground water basin. A detailed investigation is required to document the amount and time of travel of water from the river to wells and other movements between surface and ground water resulting from changing hydraulic gradients. Of particular importance is the collection of data that could be used in estimating the quantity of ground water recharged directly from the river.

Recharge of the Ground Water Basin

From a water supply standpoint, percolation of flow from the Sacramento River does not constitute a loss of water. The recharge to the ground water basin becomes available for beneficial use through wells or return flow to the system. Other major sources of recharge are precipitation and applied water. During 1976 and 1977 recharge from precipitation on the valley floor area was negligible.

The ground water basin generally receives variable quantities of recharge through percolation of applied irrigation water. Under normal conditions, about 65 percent of all irrigation water is consumptively used by plants for vegetative growth. The remaining 35 percent percolates, evaporates, or runs off. Depending on the soil, about 10 to 25 percent of the irrigation water percolates into the ground water basin.

When water supplies are deficient, farmers undoubtedly irrigate more efficiently, and less than the normal portions of applied water percolate into the ground water basin. Much less excess water was probably applied intentionally to meet leaching requirements of irrigated crops.

Water Entitlements

In the spring of 1977, the SWRCB, in cooperation with the Department and the USBR, made forecasts of the extent to which water would be available to satisfy existing water rights. Notices were sent to Sacramento and San Joaquin Valley water users who did not have contracts with the USBR or the State requesting their cooperation in limiting water use to the anticipated water supply.

Because of storms in May, the actual runoff of valley streams for May and June was higher than had been forecast. Table 20 compares the percentages of water available to satisfy normal demands under various forecasts and actual measurements and the percentages of normal demand of water used by crops. As indicated in the table, the assumed riparian use based on 1977 conditions was lower than the water supply available to satisfy riparian rights through June, but exceeded the supply in July and August. An overview study was made to quantify the amounts of water diverted for assumed riparian use in excess of the estimated nonproject runoff. The results of the study are summarized in Table 21.

Many assumptions were necessary in making the study. Three of the most significant were: (1) the nonproject runoff was used to satisfy riparian rights before water was made available for other rights, (2) all Delta lowlands and 12 500 hectares (31,000 acres) of the uplands were assumed to have riparian water rights, and (3) for various calculations in this survey, Delta outflow required to

* *"Evaluation of Ground Water Resources: Sacramento County", DWR Bulletin 118-3, July 1974.*

satisfy the 1977 emergency conditions was considered to have rights analogous to riparian rights.

Nonproject Water Supply

The actual recorded outflows of foothill reservoirs were modified by eliminating the effect of projects. Estimated contributions and losses occurring between the foothill reservoirs and the Delta were added to or subtracted from the modified reservoir outflows. The resulting figures are the estimated nonproject runoff available to satisfy riparian rights. They include the flows of Sacramento River at Keswick, the Feather River at Oroville, the Yuba River at Englebright Dam, and the American River at Fair Oaks. A cursory review of the unimpaired runoff and riparian use of the San Joaquin River system was also made. The actual recorded flow at Vernalis was used in the table because significant unimpaired runoff to the Delta occurs only through June.

Assumed Riparian Land and Water Use

The assumed riparian land along the Sacramento River was determined from information provided by USBR. Water diverted by assumed riparian users was computed in two categories; those users who have contracts for water from USBR, and the remaining diverters. According to USBR, practically all of the water users along the Sacramento River who do not have a contract for project water claim riparian rights. The water diverted by these users was estimated from electric power records and assumed to be riparian. Added to this assumed riparian use was an amount of water estimated from information furnished by USBR for use on assumed riparian lands by users who have USBR contracts. An estimate of the riparian use on the Feather, Yuba, and American Rivers was made from information provided by the SWRCB. Actual data from assumed riparian use on these rivers were not available. In the Delta, the extent of riparian rights was based on reports prepared by the USBR entitled "Central Valley Project - Delta Lowlands Service Area Investigation", dated January 1964, and "Central Valley Project - Delta Uplands Service Area Investigation", dated January 1963.

All of the Delta lowlands and 12 500 hectares (31,000 acres) of the Delta uplands were assumed to have riparian rights. However, questions have been raised on whether or not the south Delta has riparian rights to water from the Sacramento River system during July and August of a critical dry year such as 1977, because only a limited amount of water would have flowed across the Delta under natural conditions. The south Delta is generally assumed to have been riparian to the San Joaquin River at least under natural conditions. No special investigations into the status of assumed riparian rights were made under the Sacramento Valley Water Use Survey.

The water use shown for Delta agriculture and Delta water surface, riparian and native vegetation, and urban development was obtained from a computer program operated by the Division of Planning. The use was computed by multiplying crop data collected in 1977 and a unit water use figure adjusted for assumed soil moisture contribution.

Since 1944 project water has been used to repel salinity in the Delta during the summer months. Delta outflow, along with many other Delta water uses, is considered to have riparian rights. Many assumptions can be made in computing the amount of water that has been released to limit salinity intrusion. Table 13 shows the monthly computed amounts of Delta outflow for each year from 1965 through 1977. The table is included to show the magnitude of Delta outflow in the various years.

As indicated in Table 21, the nonproject runoff to satisfy assumed riparian rights was deficient during July and

August. The water deficiencies in nonproject runoff within the Sacramento Valley and the Delta within these months was estimated to be approximately 360 cubic hectometres (290,000 acre-feet). The deficiencies were assumed to be supplied from stored water from the State Water Project and the Central Valley Project. The water was used for Delta outflow and for Delta agriculture. More detailed studies and information on specific water rights would be required to identify the extent of excess use by assumed riparian users on an individual basis.

Table 22 is similar to Table 21, except for different assumptions. In Table 22, Delta outflow and consumptive uses in the Delta other than for agricultural (evaporation from water surfaces, water uses by riparian and native vegetation) were considered to be losses that must be satisfied before other riparian rights. Also, Table 22 is based on a full supply (1976) for assumed riparian rights and, using Table 17, Delta outflow quantities for salinity control. Based on these assumptions, the percent of normal water supply for crops on assumed riparian land during 1977 would have been 95, 29, 30 and 100 for the months June through September, respectively.

Tables 21 and 22 show that all of the nonproject runoff was needed by assumed riparian rights during the months of July and August. Assumed riparian water users diverting from the Sacramento River upstream from Sacramento reduced their diversions about 25 percent of their full demand during June, July, and August. Because of these reductions, sufficient nonproject runoff was available to satisfy actual diversions under assumed riparian rights during June. Only a small amount of water was available for appropriative rights during June, and none was available during July and August. Those appropriators who had contracts for water from the Central Valley Project and the State Water Project were assumed to be diverting stored water in accordance with their contracts during these summer months.

Unauthorized Diversions

From the information collected under the Sacramento Valley Water Use Survey, it was concluded that unauthorized diversions from the main stem of the Sacramento River upstream from Sacramento and from the Feather River was less than 1 percent of the total diversions because contracts were in force for the use of project water to supplement riparian and appropriative water rights. Detailed studies were not made of diversions from the Colusa Basin Drain and other channels tributary to the Sacramento River system. The Sutter Bypass was investigated by the SWRCB and its findings were reported in a report titled "Sutter Bypass, Report on Use of Water During the 1977 Irrigation Season", by Mike Golden, Associate W.R.C. Engineer, under the direction of David Sabiston, Supervising Engineer.

The USBR claims a right to Central Valley Project return flows and alleged that much of the water diverted from the Colusa Basin Drain and some other tributary channels during June, July, and August was return flow from project water and was being diverted without authorization.

In the Delta, except for an interim agreement between the Department and the North Delta Water Agency, uses of project water were not authorized. Based on studies made to develop Table 21, the diversions of project water amounted to about 360 cubic hectometres (290,000 acre-feet) by the assumed riparian water users during July and August primarily in the Delta lowlands, and about 165 cubic hectometres (135,000 acre-feet) by appropriators in the Delta uplands during June, July, and August. It should be recognized that no measurements of diversions were made in the Delta. Estimates of unauthorized diversions were made from estimates of water use based on the crops grown during 1977.

DEFINITIONS

Accretion - Surface and ground water inflows to a reach of a stream.

Appropriative Water Right - A water right which is not derived from the ownership of land abutting a water source but which derives from applying the water to beneficial use.

Assumed Riparian Water Use - A use of water under a claim of a riparian water right that has not been verified by title search or by court decision.

Chloride Concentration - See "Salinity Intrusion".

Confined Ground Water - A body of ground water overlain by material sufficiently impervious to sever free hydraulic connection with all overlying ground water except at the upper edge of the confining stratum where the confined water connects with free ground water. Confined ground water moves in strata, conduits or arteries under the control of the difference in head between the intake and discharge areas of the confined water body.

Consumptive Use - See "Evapotranspiration".

Diversion - Taking water from a stream or other body of water into a canal, pipeline, or other conduit.

Drainage - Removal of surface or ground water from a given area by gravity or by pumping.

Evapotranspiration (ET) - The quantity of water transpired by plants, retained in plant tissues, and evaporated from adjacent soil surfaces in a specified time period. Usually expressed in depth of water per unit area.

Exports - Water diverted from Delta channels and conveyed to areas outside of the Delta service area.

DEFINITIONS

Free Ground Water - Water moving through an interconnected body of pervious material unhampered by impervious confining material, and moving under control of the water table slope.

Impairments - Man-made adjustments to the natural flow.

Leach Water - Water used to flood land for the maintenance of soil salinity.

Lysimeter (Evapotranspirometer) - A device used to measure the evapotranspiration of a crop.

Native Vegetation - Lands that have not been cultivated during the past 3 years; i.e., roadways, levees, barren lands, etc.

Nonproject Runoff - Water quantities that flowed in the Survey Area stream channels that were not provided by the State Water Project, Federal Central Valley Project, or other significant storage, import or export projects.

Percolation - Flow of ground water in streamline flow in any direction through the ground.

Potential Evapotranspiration (PET) - The amount of water that can be transpired by low growing green crop of about the same color as grass, which completely covers the ground, has an unlimited supply of water and an extensive area of similar ground cover.

Precipitation - Total measurable water supply from all forms of falling moisture during a specified time.

Return Flow - Diverted water which is not taken by consumptive use and finds its way back to the original source by surface drainage or percolation.

Riparian Vegetation - Vegetation growing along back of streams and sloughs, and in marsh and meadowland naturally occupied by phreatophites as the dominant vegetation; i.e., tules, willows, and water lilies.

DEFINITIONS

Riparian Water Right - Legal right which assures to the owner of land abutting a stream or other natural body of water the use of a share of such water.

Salinity Intrusion - Relative concentration of chlorides in water expressed in milligrams per litre (mg/l), caused by tidal action mixing the more salty water of the bays or ocean with fresh water flowing toward the ocean.

Seepage - Slow movement of water through small cracks or pores of unsaturated material into or out of a body of water.

Unimpaired Runoff - The runoff that would occur if there were no storage or diversions along a stream.

Water Balance - Balancing the flow in a reach of a channel by equating the inflow and return flow to the outflow, diversions, and unmeasured accretions.

Water Contractors - Water users who have contracts for a supplemental water supply from either the Federal Central Valley Project or the State Water Project.

Water Entitlement - Water that a person is entitled to use on a parcel of land as the result of the exercise of the various types of water rights.

Water Utilization - Uses of water by nature or man, either consumptive or nonconsumptive, including water losses incidental to that use.

Wetness Index - Percent of average annual unimpaired runoff.

BASIN TOTALS			14,547,933	9,376,800	5,271,532	3,241,603

1/ Does not include power regulation reservoirs, afterbay regulation reservoirs, reservoirs less than 5,000 AF capacity, or reservoirs outside the basin which export some water into the basin.
2/ Evaporation loss, no draft in 1976.
3/ Dewatered for fish eradication.
4/ Includes six reservoirs in upper Yuba watershed: Jackson Meadows, French Lake, Faucherie, Bowman Lake, Sawmill, Catfish.
5/ Breached by PG&E.

Metric Conversion: Acre-feet times 1233.5 equals cubic metres.

1/ Delta Service Area as shown on Plate 2.
2/ Excludes 9,260 acres of irrigated grain on double cropped land (see Footnote 4).
3/ Lands normally irrigated, left fallow.
4/ An additional 9,260 acres of grain were grown as a first crop.
5/ Includes 62,353 acres of native vegetation, 1,057 acres idle land, and 3,474 acres of semiagricultural.
6/ Adjusted to conform with 1976 acreages.
7/ Includes 31,162 acres urban, 734 acres recreational, and 634 acres lawn areas.

Metric Conversion: Thousands of acre-feet times 1.2335 equals cubic hectometres.
Acres times 0.40469 equals hectares.

Metric Conversion: Cubic feet per second times 0.028317 equals cubic metres per second.

1/ Computed by the Delta Branch from measured Delta inflow reduced by the exportations, the average evapotranspiration and changes in soil moisture in the Delta Service Area, which were developed by Delta Studies in the early 1960s. Outflows are adjusted for precipitation recorded at Stockton Fire Station No. 4. Outflows for March through October of 1977, were computed using 1977 data of evapotranspiration and soil moisture and as shown on Table 17.

1/ All chloride values are derived from correlation to electrical conductivity measurements. Quantities are high reading for the month and corresponding low reading for the same day.

2/ Electrical conductivity exceeded maximum capacity of instrument (20,000 microsiemens).

1/ Observed zero flow at mouth July 20, 1977. Other months adjusted accordingly for computing accretions. Flow at gage listed in Table 6.
2/ 100 percent of flow intercepted by Tehama-Colusa Canal. Flow at gage listed in Table 6.
3/ 100 percent of flow intercepted by Glenn-Colusa Canal. Flow at gage listed in Table 6.

Metric Conversion: Acre-feet times 1233.5 equals cubic metres.
Miles times 1.6093 equals kilometres.

1/ Net release - does not include amounts pumped back.
2/ All major diversions from Thermalito Afterbay.
3/ Releases from Thermalito Afterbay and Thermalito Diversion Dam.
4/ Includes diversions along Yuba River between its mouth and gaging station, Yuba River near Marysville.
5/ These streams are listed as zero for the computation of unmeasured accretions since most of their flow did not reach the Feather River. Values at these stations are listed in Table 6.
6/ Diversions below Nicolaus included in Table 15.

Metric Conversion: Acre-feet times 1233.5 equals cubic metres.
Miles times 1.6093 equals kilometres.

TABLE 17

SUMMARY OF MONTHLY WATER SUPPLY AND WATER USE - 1977

DELTA SERVICE AREA

Item	Thousands of Acre-Feet							
	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.
Water Supply

Forecast of Supply for Full Riparian Needs (SWRCB) 3/	60	40	55	85
Actual Supply to Meet Full Riparian Needs (DWR) 4/	97	60	69	100
Supply for Crops After Riparian Channel Losses & Delta Outflow Have Been Satisfied 5/	95	29	30	100
Water Use By Crops				
Sacramento River System Above Sacramento 6/	70	67	77	75
Delta Agriculture 7/	83	105	104	109

1/ Based on the forecasted natural runoff by "California Cooperative Snow Survey", Bulletin 120-77, Report No. 2, March 1, 1977. Monthly riparian demand was from 1976 data in the "Sacramento Valley Water Use Survey Report", June 1977.

2/ Not originally forecast, but computed for this report.

3/ Based on the forecasted natural runoff by "California Cooperative Snow Survey", Bulletin 120-77, Report No. 4, May 1, 1977. Monthly normal riparian demand was from 1976 data in the "Sacramento Valley Water Use Survey Report", June 1977.

4/ Actual water supply determined by eliminating project effects from the recorded measurements of flow. Assumed full riparian demand from Table 22.

5/ Assumes evaporation from water surfaces and uses by riparian vegetation cannot take a shortage of water supply and Delta salinity should not be allowed to intrude into the Delta beyond the limits allowed during 1977 (see Table 22).

6/ These percentages were determined by dividing the Assumed Riparian Water Use Total for the Sacramento, Feather, Yuba, and American Rivers in Table 21 by the Sacramento River System Crops in Table 22.

7/ Determined by dividing the computed assumed riparian water use for Delta Agriculture, Total in Table 21 by the comparable figures shown in Table 22.

APPENDIX

ESTIMATE OF EVAPOTRANSPIRATION (ET) FOR THE DELTA - 1976-1977

Climatic conditions affecting evapotranspiration in the Delta area were reviewed for the period, October 1976 to October 1977. Evaporation was substantially higher during the months of March and April and lower in May in comparison to a normal year's evaporation, as illustrated by Figure A-1. Although the pattern of evaporation of the Class A pans for the months of March and April in the Delta area were unusual, in checking evaporation for many stations in the Central Valley from Red Bluff to Bakersfield, the same pattern consistently prevailed. Similar evaporation patterns were observed for other stations along the coast and in Southern California as well. This phenomenon is illustrated by Figure A-2, showing the similarity in the pattern of evaporation among the Davis Hydromet, Gerber 1SW, Shafter Cotton Station, and DWR Wasco 8SW Class A pans. Their similarity substantiates that the pattern of evaporation reflects the actual climatic conditions in the Delta.

Even though the 1976-1977 pattern of the monthly pan evaporation varied from that of the normal years, the annual rate was only slightly higher. This and other climatic factors that influence water consumption were analyzed to determine the evapotranspiration rates of various crops and other land-use categories.

The measurements of the evapotranspiration rates for grass (PET) by a lysimeter method at UC-Davis, the basis for establishing the 1975-76 evapotranspiration of various crops (ET), were terminated in September 1976. Furthermore, measurements at the Davis Weather Station (2WSW) for the current year lacked 2 months of pan evaporation and the validity of several months' were also in question. Therefore, it was not possible to evaluate the current year's water use of the Delta precisely on the same basis that the 1975-76 water use was determined. The method finally adopted, after investigating various alternatives, involved the calculation of coefficients (Kp) for three Class A pans by taking into account the ground cover, mean relative humidity, and 24-hour wind movement. The procedures used are prescribed in the FAO Irrigation and Drainage Paper 24, "Crop Water Requirements", Food and Agriculture Organization (FAO) of the United Nations, by J. Doorenbos, W. O. Pruitt, et al.

The three above mentioned Class A pans have been maintained for several years. These pans, located at Lodi, Brannan Island, and Antioch Pumping Plant, are each exposed to varying environmental conditions that influence the evaporation rates.

FIGURE A-1

DRY LAND ENVIRONMENT
1976 - 1977 EVAPORATION
CLASS A PAN

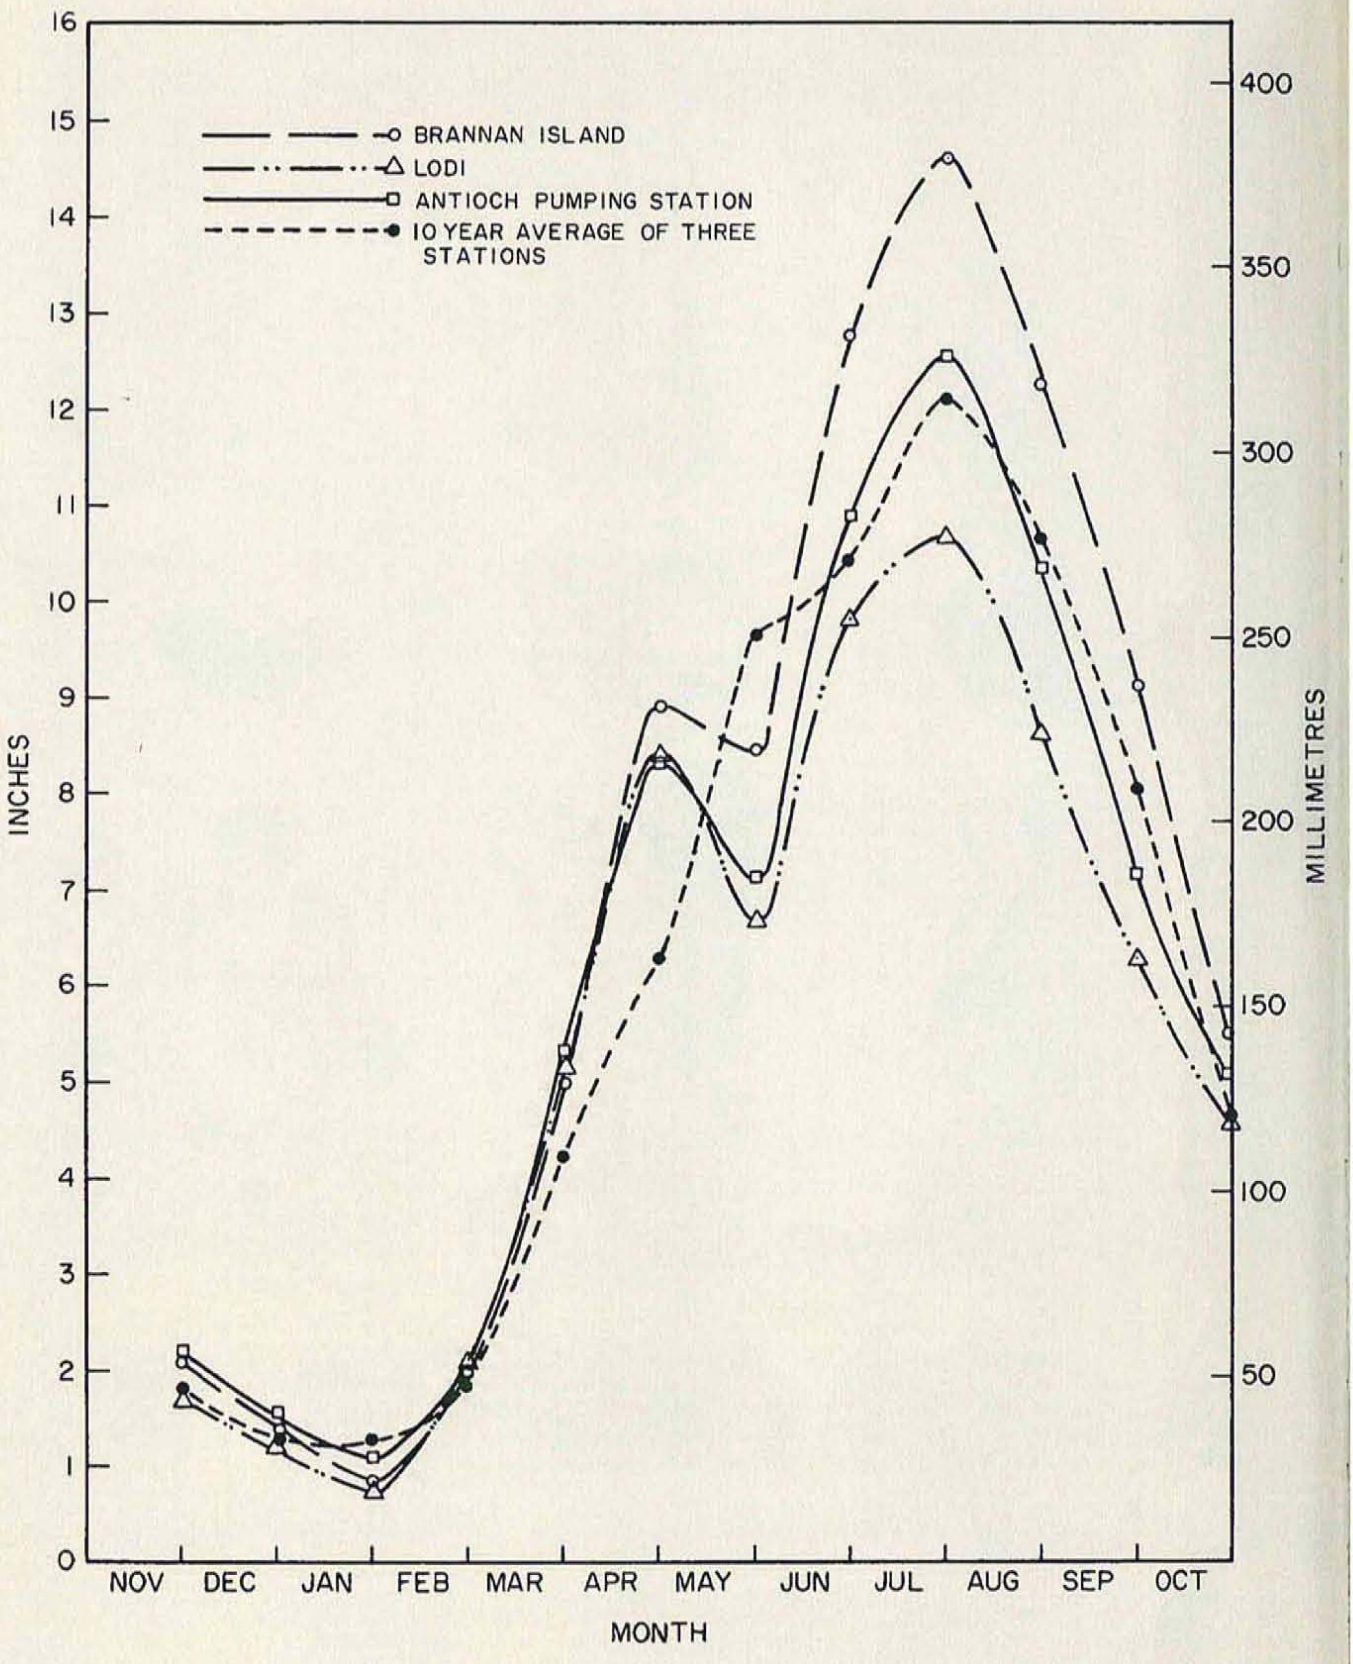

FIGURE A-2

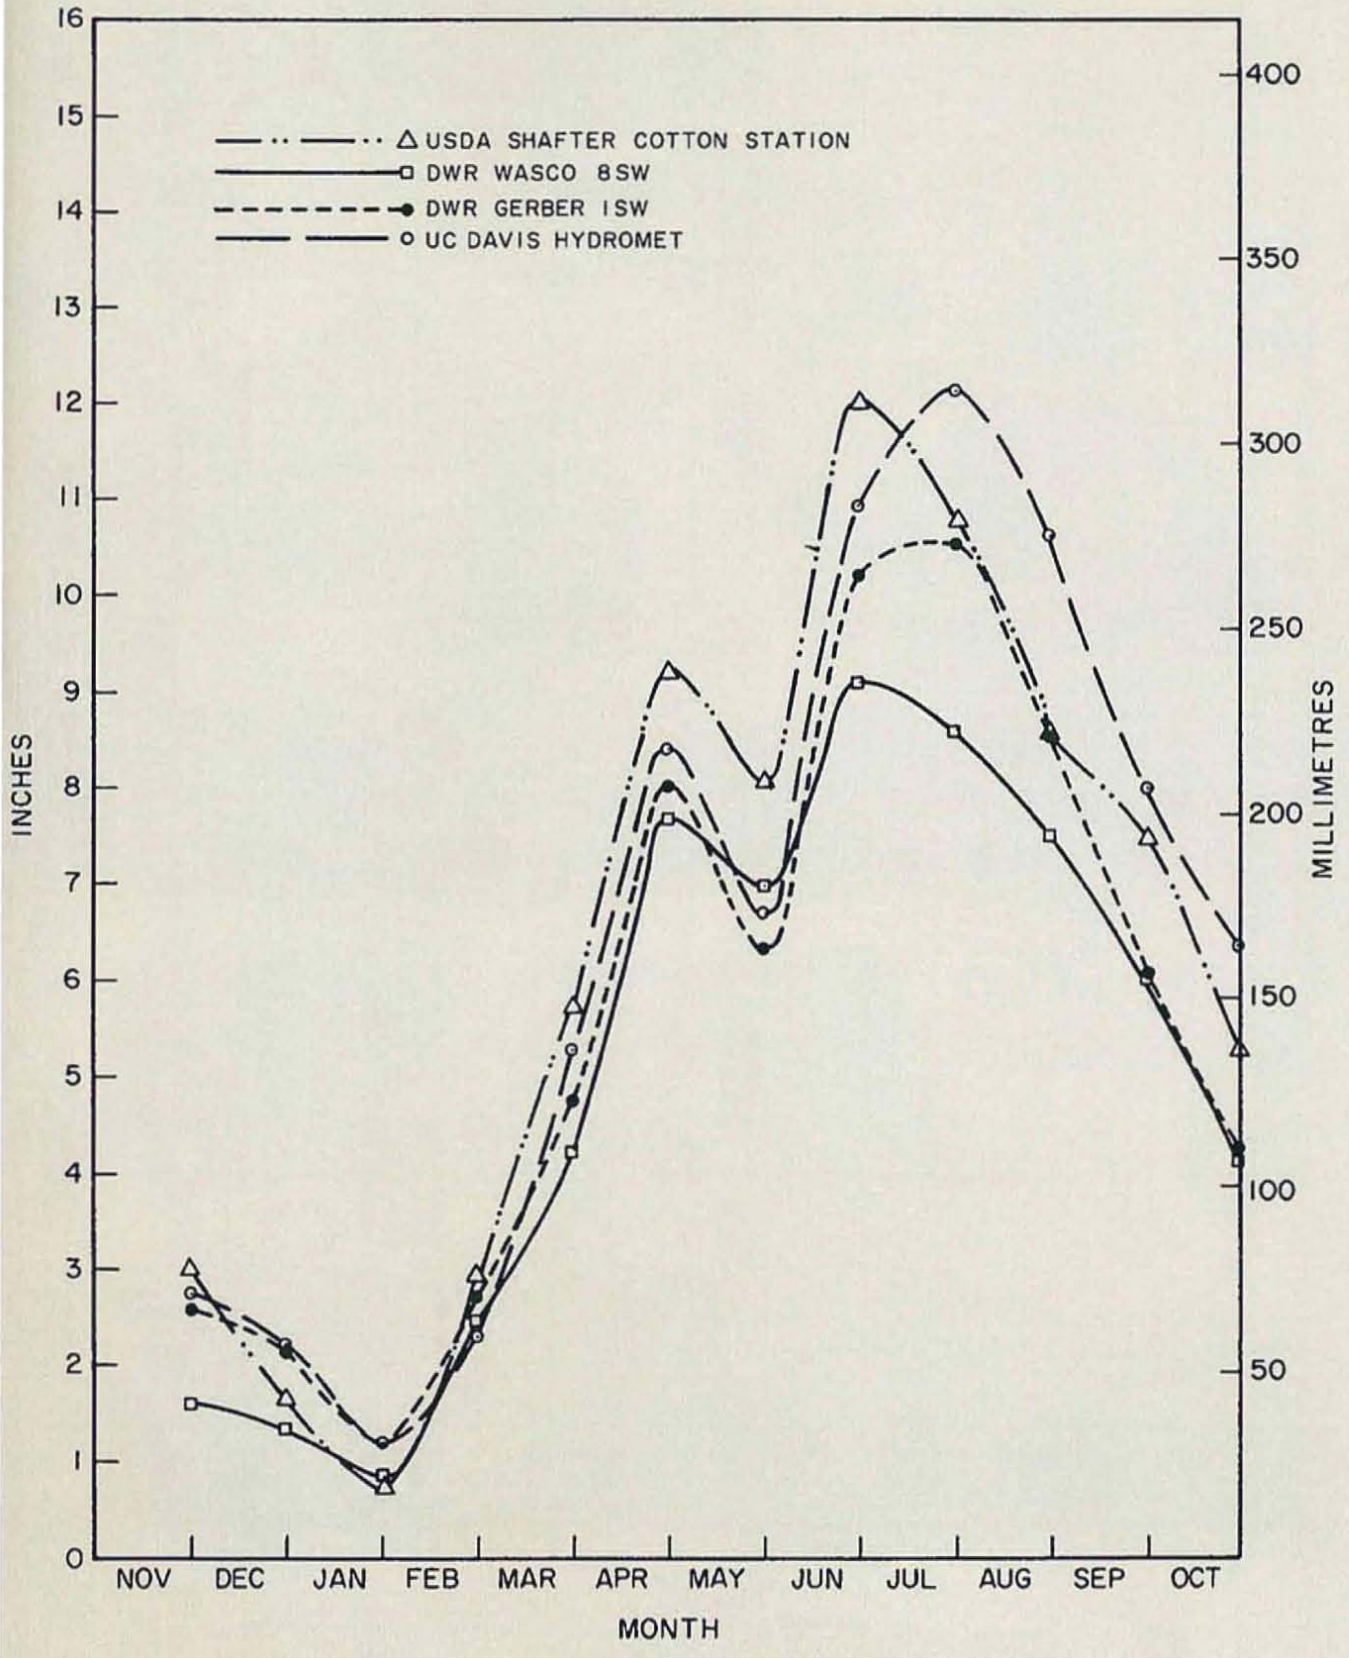
1976 - 1977 EVAPORATION
CLASS A PAN



These variations largely account for the differences in the evaporation rates among them. The monthly evaporation rates from these pans as well as at Davis Hydromet and Davis Weather Station 2WSW are presented in Table A-1. It shows the comparison of the 1975-76, 1976-77, and the 10-year average evaporation rates.

As of May 1, 1977, the pan at Lodi was relocated. The new location of the pan is adjacent to a large irrigated park from which the wind generally prevails. For this reason, Lodi has the lowest evaporation rate of the three pans, during the 1976-77 year.

The level of relative humidity for the three Class A pans in the Delta was based on measurements made at Stockton Airport. The temperature records show little differences among the pan locations, so it was assumed that the relative humidity would likewise be similar.

Wind movements were measured at Lodi and Brannan Island. The Class A pan at Antioch Pumping Plant is located within an almond orchard and it was assumed that wind movement at this station would be much less than that of Brannan Island. The records of wind movement at the Dow Chemical Company at Pittsburg during 1956-65, indicate the prevailing wind is usually from the west and west-northwest directions. This is illustrated by Table A-2, which shows the prevailing wind direction as well as the mean speed at Stockton, Travis AFB, and Sacramento.

Table A-3 shows the factors and values used in deriving the pan coefficients (Kp) and the resulting PET's for each of the three pan locations and for the Delta as a whole. The PET's are the result of taking the product of Ep and Kp values. The noted distance of fetch is the extent of dry land surrounding the pan which is measured toward the prevailing wind from the pan to a green crop, water surface, irrigated land area, or naturally wet area.

Table A-4 shows the comparison of the 1976-77 PET's to those reported in the 1975-76 "Sacramento Valley Water Use Survey" report. The latter PET values were based on more than 10 years of data. The table also shows the percentage differences between the two, which provided the basis for computing the 1976-77 crop unit ET values shown in Table A-5. The ET values shown are the result of adjusting the corresponding long-term ET by the indicated percentage changes.

The growing season for the same annual crops may vary according to the planting and harvesting dates. Therefore, the monthly evapotranspiration for those crops is an integration of the different planting and harvesting dates. This is illustrated in Table A-6. It shows the normal ET of the same crops planted and harvested at various dates along with the composite 1976-77 monthly values. The latter includes the ET rates for the nonirrigation season as well. These are the same values shown for the corresponding crops in Table A-5.

The 1976-77 estimated crop ET rates determined as described in the foregoing and the results are shown in Table A-5 provided the basis for determining the total water consumption occurring in the Delta in that same year. Its findings are reported in the main text of this report.

As mentioned earlier, other methods of determining ET rates were investigated. The other methods were not used because either the basic data essential in completing the analysis were incomplete, or the resulting analysis appeared unreasonable. The PET determined as prescribed by Food and Agriculture Organization of the United Nation and used as a basis determining the ET rates of various crops grown in the Delta was found to be the simplest approach which also gave credence to the evaporation pattern.

CONVERSION FACTORS

English to Metric System of Measurement

Quantity	English unit	Multiply by	To get metric equivalent
Length	inches (in)	25.4	millimetres (mm)
		.0254	metres (m)
	feet (ft)	.3048	metres (m)
	miles (mi)	1.6093	kilometres (km)
Area	square inches (in^2)	6.4516×10^{-4}	square metres (m^2)
	square feet (ft^2)	.092903	square metres (m^2)
	acres	4046.9	square metres (m^2)
		.40469	hectares (ha)
		.40469	square hectometres (hm^2)
		.0040469	square kilometres (km^2)
	square miles (mi^2)	2.590	square kilometres (km^2)
Volume	gallons (gal)	3.7854	litres (l)
		.0037854	cubic metres (m^3)
	million gallons (10^6 gal)	3785.4	cubic metres (m^3)
	cubic feet (ft^3)	.028317	cubic metres (m^3)
	cubic yards (yd^3)	.76455	cubic metres (m^3)
	acre-feet (ac-ft)	1233.5	cubic metres (m^3)
		.0012335	cubic hectometres (hm^3)
		1.233×10^{-6}	cubic kilometres (km^3)
Volume/Time (Flow)	cubic feet per second (ft^3/s)	28.317	litres per second (l/s)
		.028317	cubic metres per second (m^3/s)
	gallons per minute (gal/min)	.06309	litres per second (l/s)
		6.309×10^{-5}	cubic metres per second (m^3/s)
	million gallons per day (mgd)	.043813	cubic metres per second (m^3/s)
Mass	pounds (lb)	.45359	kilograms (kg)
	tons (short, 2,000 lb)	.90718	tonne (t)
		907.18	kilograms (kg)
Power	horsepower (hp)	0.7460	kilowatts (kW)
Pressure	pounds per square inch (psi)	6894.8	pascal (Pa)
Temperature	Degrees Fahrenheit (°F)	$\frac{tF - 32}{1.8} = tC$	Degrees Celsius (°C)
